Just like Taguchi did, six sigma picks up the tools it finds more useful. Among these are the tools used in the Taguchi method (e.g., design of experiment (DoE), analysis of variance (ANOVA), S/N), but many others as well, such as SPC and lean analysis. When lean thinking is added, it is often denoted as the lean six-sigma approach. As it incorporates both operational and process improvements, it is a proper approach to achieve manufacturing excellence in an organized and systematic manner.

Critics contest its novelty, as almost everything it uses existed before, and so are the aspects of its implementation. For someone experienced in the Taguchi method, it also seems to be overcomplex, and could lead to the deployment of different approaches that yield the same end result, with no particular benefit in the redundancy.

It is common to summarize the overall approach with acronyms: a project to achieve optimum consistency in an existing process applies a series of steps known broadly as DMAIC (define, measure, analyze, improve, and control), while a project geared at developing a new process or product is composed of a series of steps represented by DMADV (define, measure, analyze, design and validate, or verify). The latter is also known as DFSS, from design for six sigma, that is, design the new process or product so that it will deliver a six-sigma consistency, which is therefore the same as QbD.

Safety Analysis and Risk Assessment

N Hyatt, Dyadem International Ltd, Toronto, ON, Canada

Importance of Plant Safety in the Dairy Industry

Safety is important in both milk production and dairy processing facilities. Both people and animals can be exposed to a diverse range of hazards. These need to be identified and managed. As an example, people who handle chemicals, antibiotics, vaccines, and veterinary drugs need to be familiar not only with their benefits but also with their potentially hazardous properties. To ensure that these substances are handled safely, the use and distribution of Material Safety Data Sheets (MSDSs) to all involved personnel are a prerequisite.

Chemicals, fertilizers, and pesticides can cause environmental damage and possible contamination problems if improperly used or incorrectly handled. Contamination and pollution can also be caused by incorrect handling and storage of manure and dairy wastes. In some instances, asbestos insulation may be present in older farm buildings, which carries the risk of mesothelioma and necessitates a careful and organized program for removal of such insulation by qualified asbestos removal contractors. Dust can also become a health hazard and, if combustible, could lead to fire and/or explosion.

Typical job safety hazards are also posed by effluent ponds where drowning can occur and with electrical equipment, often of a temporary and makeshift nature, where electrocution through use of ungrounded electrical equipment, in an aqueous environment, can occur. The use of unguarded prime movers, the temporary removal of guards, and the failure to isolate machinery during maintenance are all sources of hazard and risk: the use of lockout/tagout procedures is essential if maintenance of equipment with moving parts is involved. Also, personnel who work at heights may risk falling and those who engage in manual lifting may sustain injuries.

The dairy industry, when compared with many other industries, is not normally associated with high-risk activities. However, large dairy facilities may use a number of hazardous materials that can still pose high risks to both plant personnel and the neighboring communities. As an example, the following substances can present significant risk:

1. Anhydrous ammonia which may be used in refrigeration systems. Release of anhydrous ammonia to the environment, which is normally stored as a liquid under pressure, can result in a highly toxic subcooled aerosol mist that can hug the ground until it heats up and disperses. Such releases can have quite devastating effects in the path of release.
2. Liquid chlorine which may be stored under pressure and normally used for sanitization purposes. Chlorine gas is heavier than air and is highly toxic: it can cause death even in relatively small amounts.
3. Propane which is stored as a liquefied gas in bullets under pressure. Propane may be used as a heating medium for boilers and heating systems. A number of dangerous incidents have arisen as a result of propane bullets becoming overheated, due to external fires impinging on them and causing Boiling Liquid Expanding Vapor Explosions (BLEVEs).

Overall, many different types of hazards are often present at a dairy facility and the failure to be aware of these can lead to accidents and injuries. It therefore follows that potential hazards, in the first instance, need to be formally identified in order for them to be managed.

The key steps in safety analysis are (1) the systematic identification of hazards that are present, whether obvious or latent, (2) the prioritization of hazards using a risk matrix approach, and (3) the management of hazards through the introduction of risk control or risk mitigation measures. Usually, these three steps are adequate for the majority of in-plant safety issues.

Where greater issues that could pose significant risks not only to in-plant personnel but also to the neighboring communities exist, it may be necessary, in addition, to perform a Quantitative Risk Assessment (QRA).

Formal Safety Analysis

A formal safety analysis can be performed using a number of alternative methodologies. These are known collectively as Process Hazards Analysis (PHA). Typically, they proceed as shown in the following six steps:

Step 1: Collect engineering drawings such as Process Flow Diagrams (PFDs), Piping and Instrument Diagrams (P&IDs), and documents that specify the nature and operation of the facility in question. In addition, MSDS for all hazardous substances stored or used at the facility should be available for the analysis.

Step 2: Break down the facility into definable and specific subunits that provide a common function. This is a form of itemizing and is sometimes known as creating 'nodes'.
Step 3: List questions for each subunit or node that can explore and investigate design or operational deviations that might reveal undesirable or possibly hazardous conditions outside the normal range.
Step 4: For each question listed in Step 3, record the causes for the deviations and the consequences that might occur or result from such deviations. In addition, the safeguards that may already be in place to either prevent the cause of the deviation or to protect or mitigate the consequences should be recorded. Furthermore, any recommendations should be considered to reduce the risk by providing additional safeguards that are not currently available.
Step 5: Proceed throughout the facility so that all subunits or nodes are covered.
Step 6: Prepare a detailed report that includes both documentation on the facility as well as details of the PHA.

When this stage is reached, it is possible to create a risk management plan to determine what needs to be done to reduce the risk in order to make the facility safer. Also, when the PHA is being undertaken, it is often best to assemble a team of personnel responsible for the design and operation of the facility so that all possible concerns are systematically investigated.

There are four different types of PHA that are typically used:

1. Hazard and Operability (HAZOP) analysis, where deviations are created by applying guidewords such as High, Low, Reverse, As Well As, Part Of, and Other Than to properties such as Flow, Level, Pressure, Temperature, Concentration, and pH. This is a popular methodology within the process industries but is really applicable only where the systems involve flowing fluids, often on a continuous basis. HAZOP may also be applied to batch operations where the guidewords also include Sooner and Later to account for time aspects.
2. 'What if. . .' analysis, where deviations are created by listing questions that pose design and/or operational problems. This is a relatively simple technique that, although less structured than HAZOP, is applicable to almost any facility or part of any facility regardless of design, function, or operation. Furthermore, it is easy to learn and apply.
3. Failure Mode and Effects Analysis (FMEA), where items of equipment are broken down into components. For each component, the deviations are different possible failure modes for that component. The consequences are the effects of the various types of failure that are identified. FMEA is normally recommended for analyzing equipment failures as opposed to fluid system failures. It can typically be applied to prime movers, instrumentation, and control equipment, and, in addition, is a useful method for improving reliability through the identification of possible failure modes.
4. Checklist analysis, where a list of questions and concerns is created from either preexisting data or information or based upon previous experience. This technique is less structured than the other three methods described above but is useful prior to commissioning a new system where there are concerns over any residual issues that might have been created or overlooked by construction teams.

In addition to these above four methodologies, 'What if . . .' analysis and Checklist analysis are often combined as 'What if/Checklist'. This ensures that an adequate list of questions (i.e., possible deviations) is created. Furthermore, when applying these types of methodologies to occupational safety, the form of analysis used is Job Safety Analysis (JSA) where people's jobs are specifically analyzed for hazards.

All of the above methods are oriented toward the identification of potential hazards and hazardous situations, whether obvious or latent. These analyses normally identify single jeopardy hazards as opposed to double or multiple jeopardy situations. From the standpoint of likelihood, single jeopardy is the most likely and double or multiple jeopardy is far more unlikely.

Definition of Risk

While the identification of hazards, including potential hazards, is of paramount importance, the quantification of risk can, in some instances, be desirable. Risk is a measure of the importance of hazards posed and is a function of both the severity of the hazard and the likelihood, or frequency, of the hazard occurring. The technical definition of risk is the product of the consequence, that is, the severity of the hazard and the frequency, that is, the likelihood of the hazard ever occurring. In other words

$$\text{Risk }(R) = \text{Consequence }(C) \times \text{Frequency }(F)$$

The consequence may be expressed as the chance of mortality, as financial damage that may be incurred or the loss of revenue that may result from an incident. Typically, when consequence is expressed in terms of mortality or, more specifically, in terms of the probability of fatality, the values provided in **Table 1** can be useful.

The frequency is often expressed as the number of times per annum that the incident may occur. Hence, for example, if the incident were likely to occur once every year or so, this would be deemed as 'very likely' but if it occurred only once in a 1000 years it would be deemed as 'very unlikely'. It can seem difficult to envision individual risk levels without comparison to known risks experienced on a day-to-day basis. **Table 2** provides this comparison.

Table 1 Value of fatality probability and associated effects

Value of fatality probability	*Associated effects*
1.0	Effects would be fatal for any individual exposed to the hazard
0.1	With 10 persons exposed to the hazard there would be one fatality
0.01	With 100 persons exposed to the hazard there would be one fatality
0.001	With 1000 persons exposed to the hazard there would be one fatality

Table 2 Example of comparative mortality statistics

Hazard	*Total number of deaths*	*Individual chance of death per year*
Heart disease	757 075	3.4×10^{-3}
Cancer	351 055	1.6×10^{-3}
Work accidents	13 400	1.5×10^{-4}
All accidents	105 000	4.8×10^{-4}
Motor vehicles	46 200	2.1×10^{-4}
Homicides	20 465	9.3×10^{-5}
Falls	16 300	7.4×10^{-5}
Drowning	8100	3.7×10^{-5}
Fires, burns	6500	3.0×10^{-5}
Poisoning by solids or liquids	3800	1.7×10^{-5}
Suffocation, ingested objects	2900	1.3×10^{-5}
Firearms, sporting	2400	1.1×10^{-5}
Railroads	1989	9.0×10^{-6}
Civil aviation	1757	8.0×10^{-6}
Water transport	1725	7.8×10^{-6}
Poisoning by gases	1700	7.7×10^{-6}
Pleasure boating	1446	6.6×10^{-6}
Lightning	124	5.6×10^{-7}
Hurricanes	93	4.1×10^{-7}
Tornadoes	91	4.1×10^{-7}
Bites and stings	48	2.2×10^{-7}

Data on Mortality Statistics for USA, 1974, and revised, 2000: Chemical Manufacturer's Association.

In Figure 1, an example of a risk matrix is shown that can be used in conjunction with a PHA to enable members of a risk analysis team to assess first-order estimates of risk associated with an activity or item of plant. When values are in excess of 10^{-3} deaths per annum then some additional risk control measures or additional risk mitigation should be considered.

Every activity normally carries some level of risk, however small it may be, and most people accept this as part of the day-to-day reality of life. Zero risk for an activity is not usually possible unless the activity ceases altogether.

Risk Assessment

When incidents involving hazardous materials could cause significant in-plant damage and also threaten neighboring communities, it may be in order to consider performing a QRA for the facility. The following steps are usually undertaken:

Step 1: From the PHA already performed and by applying the risk matrix methodology, determine which incidents are high-enough risk to warrant full risk quantification and assessment.

Step 2: Model the consequence of the incident as a function of distance from the hazard source. This is done using mathematical models as typically listed in Table 3.

Step 3: Model the frequency of the potential incidents. A variety of methods can be used as shown in Table 4.

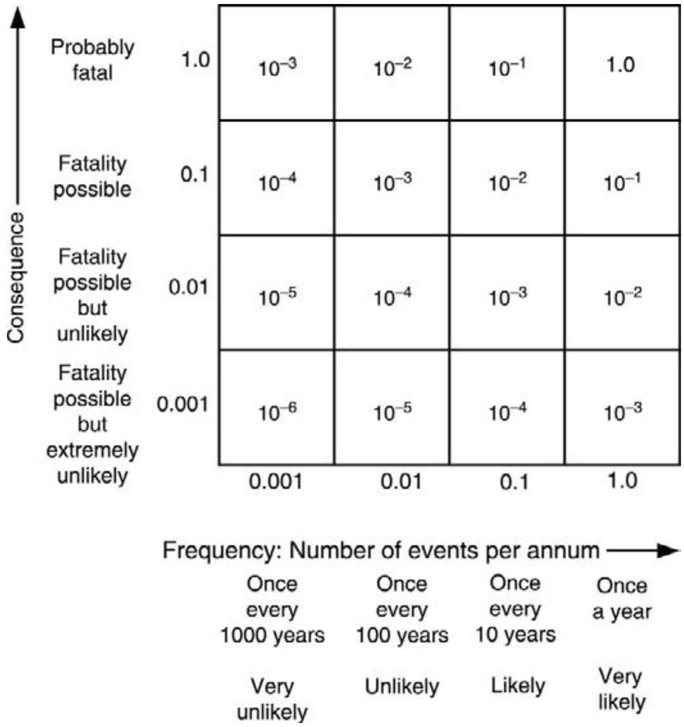
Step 4: Having numerically determined both the consequences, in terms of probability of death per occurrence and frequency of occurrence in times per annum per event, individual risk can be computed as

$$R_i = C_i \times F_i$$

where R_i = individual risk, in deaths per annum for a single event, *i*; C_i = probability of death, dimensionless from the consequence of event, *i*; and F_i = frequency of single event, expressed in events per annum.

The idea behind individual risk is the risk that might be posed to an individual who is in the vicinity and exposed to the hazard in question.

Individual risk is also a function of distance from the hazard, which, although not affecting the frequency,



Consequence		0.001	0.01	0.1	1.0
Probably fatal	1.0	10^{-3}	10^{-2}	10^{-1}	1.0
Fatality possible	0.1	10^{-4}	10^{-3}	10^{-2}	10^{-1}
Fatality possible but unlikely	0.01	10^{-5}	10^{-4}	10^{-3}	10^{-2}
Fatality possible but extremely unlikely	0.001	10^{-6}	10^{-5}	10^{-4}	10^{-3}

Figure 1 Matrix showing individual risk in deaths per annum.

Table 3 Listing of consequence models used for risk assessment

Hazard	*Consequence model*	*Effects and modeling*
Fire	Pool fire Jet fire Fireball Flash fire	Thermal radiation generated by fire can cause burns that can be lethal and models can predict exposure levels as a function of distance from source. Probit analysis can predict probability of death as a result of radiation dosage and exposure time.
Explosion	Vapor Cloud Explosion (VCE) Missiles and shrapnel generation Boiling Liquid Expanding Vapor Explosion (BLEVE)	Overpressure and momentum forces can result in lung and ear-drum damage and cause the collapse of buildings leading to death. Probit analysis can predict likely effects and probability of death as a function of overpressure. Simple models for missiles and shrapnel generation exist that indicate likely size, number, and range. BLEVEs are also modeled as fireballs.
Toxic vapor releases	Vapor dispersion	Vapor dispersion and dilution occur in the atmosphere and can be modeled as a function of distance from the source of the release for both neutrally buoyant and dense gases taking into account meteorological conditions, wind direction, and wind speeds. Probit analysis for specific gases can predict probability of death with dosage and time elapsed.

could increase the consequence if the exposure to the hazard is increased. Since there is often more than one source of risk, it is also relevant to consider total or integrated risk.

Thus, the overall integrated risk, considering n events and each event having its own specific consequences and frequency, can be expressed as

$$R_{\text{overall}} = \sum_{i=1}^{n} (C_i \times F_i)$$

where R_{overall} = integrated individual risk, in deaths per annum for n events in total.

Step 5: Determine the basis for benchmarking or judging what levels of risk can be considered as acceptable. In judging individual risk criteria, the criteria shown in Table 5 may be considered.

Societal risk, as opposed to individual risk, represents the integrated risk that may be posed to a group or multiple individuals located within a specific area or zone. Societal risk may thus be expressed mathematically as

$$R_{\text{societal}} = N \sum_{i=1}^{n} (C_i \times F_i)$$

Table 4 Modeling of frequency or likelihood of incidents

Method	*Basis*	*Data used*
Fault trees	Fault trees model events using a top-down approach to show top event as the undesirable event and all contributory factors and subevents that lead to the top event.	Available failure rate data, reliability data, and contingent factors analysis where no data are readily available.
Event trees	Proceeds from left to right starting with initial cause of incident and considers optional outcomes that can be assigned probabilities of occurring or failing to occur. A range of possible final outcomes is the end result.	Original causal event frequency is assigned based on failure rates of piping, gaskets, etc. Subsequent events likelihood use assigned probabilities based on available data, best judgments, and estimates.
Historical data	Use of available databases to provide frequencies of specific types of events.	Recorded data from same, similar facilities and recorded data available on a global basis.

Table 5 Risk tolerance criteria

Individual risk level in deaths/annum	*Tolerance level*
$>1 \times 10^{-3}$	Exceeding 1×10^{-3} deaths per annum is deemed intolerable
1×10^{-3}	Should not exceed 1×10^{-3} deaths per annum maximum for workers provided that As Low As Reasonably Practicable (ALARP) measures are in place
1×10^{-4}	Should not exceed 1×10^{-4} deaths per annum maximum for the public provided that ALARP measures are in place
$\leq 10^{-6}$	Individual risk criteria are broadly acceptable at 1×10^{-6} deaths per annum

Data from ALARP – Guidance on as low as reasonably practicable decisions in COMAH: Health & Safety Executive (HSE), UK.

where N = total number of persons exposed to the individual total risk and where risks vary depending on the numbers in different communities and their locations:

$$R_{\text{societal overall}} = R_{\text{societal overall},1} + R_{\text{societal overall},2} + R_{\text{societal overall},3} + \cdots$$

Although societal risk may be evaluated, the acceptability of criteria is more complex than that of individual risk. FN curves may be used for societal risk where the ordinate represents the cumulative frequency distribution of N or more fatalities and the abscissa represents the consequence (N fatalities). Although there are published data on FN curves, their acceptability has not been widely adopted. Currently of greater interest is the ALARP (As Low As Reasonably Practicable) criteria. This recognizes three regions. The first of these is the 'unacceptable region' where the activity is of such a high risk as to render it unacceptable. The second region is the 'broadly acceptable region' where the activity has a very low risk and no further measures are needed for risk reduction. The third region is the 'tolerable region' where the level of risk falls between 'unacceptable' and 'broadly acceptable' and has been reduced to the lowest level of risk as considered to be practicable.

Step 6: Apply risk management principles. Risk may be managed once the hazards have been identified. If the QRA route has been undertaken, then the calculated overall risk, R_{overall} or $R_{\text{societal overall}}$ should be compared to what may be deemed as tolerable. Depending on the level of tolerable risk, the decision to accept the risk or take remedial action(s) must be made. If the level of risk is within accepted margins, then no further action may be necessary. If the level of risk is excessive, then actions requiring remediation and costing plant modifications, procedural changes, as well as emergency response planning may be needed.

Risk Reduction and Risk Mitigation

Risk reduction is possible only if hazards are identified and then measures are taken to reduce these risks. Although it may be possible to reduce the risk to a level that is considered acceptable, it is rarely possible to eliminate risk altogether. When facilities are designed originally, there may be good opportunities to introduce design features that can minimize risk whereas if safety is addressed as an issue only late in the design it may be extremely costly to incorporate such features.

Safety in design is sometimes considered in terms of 'active' and 'passive' safety features. A passive safety feature requires no form of activation or initiation for the feature to be protective. For example, increased distance and spacing is valuable as a passive safety feature as would also improved road access, dikes around tanks containing flammable materials, and reduced inventories of hazardous materials. An active safety feature would be instruments, controls and automated trips, and most safety devices operated electrically, electronically, hydraulically, pneumatically, or even mechanically. Although both active and passive safety features are needed at a facility, passive safety features are much more dependable. On existing facilities, it may be difficult or impossible to add passive safety features and very often only additional active safety features can be incorporated where risk reduction is required.

Qualitative Risk Analysis versus Quantitative Risk Assessment

Risk may be analyzed either qualitatively or quantitatively. For the majority of cases where no significant risk is posed to adjoining communities, the qualitative analysis should be adequate. However, where the potential for encroachment by new housing communities is an issue, the quantitative assessment has merit for establishing recommended buffer zones around the facility.

It is often difficult to say where an assessment of risks ends and risk control begins or to assess risks without making a number of assumptions; at best, a risk assessment is an order of magnitude estimate and is directional as opposed to being absolute. Unless inputs and assumptions are very similar, the repeatability of risk assessment is hard to achieve.

Risk assessment is a tool for extrapolating from statistical, engineering, and scientific data, a value that people will accept as an estimate of the risk attached to a particular facility. There are many techniques for risk estimation, tailored to different applications that cover a wide range of different disciplines, such as toxicology, engineering, statistics, economics, and demography.

The true value of risk assessment, through the QRA, lies mainly in comparing overall risk levels both before and after risk remediation is incorporated. For example, suppose an overall level of individual risk is determined to be 10^{-4} deaths per annum for a facility and that after remediation it is reduced to 10^{-6} deaths per annum. This means that remediation has made the facility 100 times safer. This improvement may be considered to be more important than trying to determine exact levels of risk.

Risk Assessment and Emergency Response Planning

A QRA can identify situations where an Emergency Response Plan (ERP) or buffer zones or restrictions should be considered. The output of an analysis, of risk versus distance from the hazard source, can indicate hazard zones.

Depending on these findings, a detailed ERP may be needed. This will also address the Emergency Response Planning Guideline (ERPG) levels 1, 2, and 3 distances.

The distance to the ERPG-3 level corresponds to the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for 1 h without experiencing or developing life-threatening health effects. The distance to the ERPG-2 level corresponds to the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for 1 h without experiencing irreversible or other serious health effects or symptoms that could impair their abilities to take protective action. The distance to the ERPG-1 level corresponds to the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for 1 h without experiencing other than mild transient adverse health effects or perceiving a clearly objectionable odor.

In-Place Cleaning

M Walton, Society of Dairy Technology, Appleby in Westmorland, UK

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Cleaning in place (CIP) is a vital discipline within the modern food, dairy, and beverage processing industry. Dairy and beverage have tended to lead the way due to the major products being liquid and the process equipment lending itself to CIP. However, many food or pharmaceutical operations now incorporate CIP and the technology is therefore much more common.

In the 1990 edition of the Society of Dairy Technology (SDT) *Manual Cleaning In Place*, CIP was defined as "The cleaning of complete items of plant or pipeline circuits without dismantling or opening of the equipment and with little or no manual involvement on the part of the operator. The process involves the jetting or spraying of surfaces or circulation of cleaning solutions through the plant under conditions of increased turbulence and flow velocity." This was taken from the National Dairymens Association (NDA) Chemical Safety Code, 1985, and while the NDA has been superseded, their definition of CIP is still felt to be quite appropriate.

Practice in the Dairy Industry

The modern dairy plant, be it for liquid milk or the multitude of other dairy products, will have at least two CIP sets at its heart; it is generally accepted as best practice that raw and finished product should be segregated to avoid cross-contamination. The raw milk CIP set will be responsible for cleaning the raw milk silos and associated milk intake pipe-work along with any in-line coolers and filters including transfer lines to the pasteurizer. It is at this point that the segregation between raw and finished (pasteurized) products is maintained. In many cases the pasteurizer with its associated items of processing equipment such as homogenizer, separator, and standardization unit will be cleaned together. The cleaning operation can be single-stage or two-stage, but the principle of single use remains. In a few sites, a partial recovery system may be used. There are benefits and drawbacks in each type of system and these will be discussed in more detail later. The finished milk CIP set will clean all items of plant that are used to store, process, and pack finished or pasteurized product. It is vital that this cleaning equipment be maintained to the highest standards in order to ensure good plant hygiene and to avoid product contamination, either physical or microbiological, that would have an adverse effect on final product quality or shelf-life.

Outline of a CIP System

The main stages of CIP are similar to any other standard cleaning routine: removal of gross debris (product purge); pre-rinse; detergent (normally acid- or caustic-based); intermediate rinse; second detergent if applicable; intermediate rinse; disinfectant; and final rinse with potable water. The diluted detergents are generally stored in tanks as part of the CIP unit or CIP set and will be built up into a fully operational CIP set with valves, manifolds, and interconnecting pipe-work, including an automated control system.

The design of the CIP set will depend on the duty required. Other considerations such as available space and budget constraints do influence the design but making compromises at the design stage is not recommended, as poor CIP performance can have a significant impact on product quality. **Figure 1** shows a four-tank partial recovery system with a single channel or CIP route operation. On larger sets, there can be five or six separate channels linked by common inlet and outlet manifolds. Other configurations are possible, with or without a rinse recovery tank. It is quite unusual to find recovered disinfectant storage tanks as these require very close management and can easily become contaminated leading to potentially serious consequences; hence, the tank denoted as 'utility' in **Figure 1** when used for disinfection is likely to be of single use.

Most CIP sets have some degree of automation, the most basic being a set of timers to open and close automatic valves in a particular programmed sequence at specific times. More sophisticated sets incorporate significant levels of field instrumentation with sensors, usually mounted in-line to monitor flow, temperature, pressure, conductivity, turbidity, etc. Control of detergent concentration is usually automated and the most common configuration is a control conductivity probe situated in a recirculation loop to ensure good mixing when extra detergent is added to the solution.

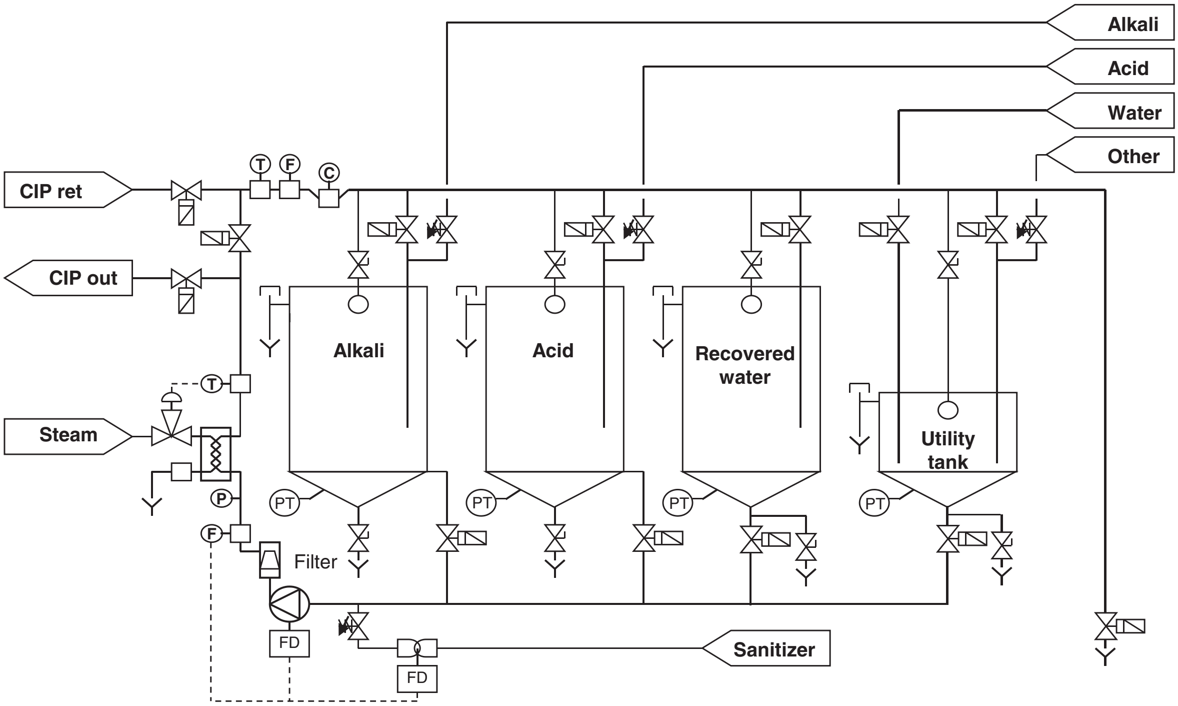

Figure 1 Single-channel, four-tank partial recovery CIP system.

Detergents and Disinfectants

In the dairy industry, the most common type of detergent is a caustic soda-based product, quite often containing a blend of sequestrants, surfactants, and other additives to assist with the cleaning task. The detergent also needs to be compatible with the prevailing water hardness conditions in order to prevent scale deposition, especially during rinsing. The selection of the correct detergent is a specialist activity and needs to take into account factors such as materials of construction, soiling type and levels, and product safety. The effectiveness of the caustic soda-based material is heavily influenced by the specific blend of additives and these are designed to remove dairy soils such as fat, protein, and more complex molecules and structures that are created by the process or simply by heat such as calcium carbonate. In certain circumstances, acidic detergents are used; these are often based on phosphoric or nitric acid or blends of the two and are found to be effective at removing inorganic deposits in dairy processing plants.

Disinfectant solutions can generally be divided into oxidizing and non-oxidizing products, the former being more common for CIP use as they tend to be more efficacious and have a lower tendency to foaming that can lead to rinsing difficulties. The traditional dairy disinfectant was sodium hypochlorite, a very cost-effective product for CIP disinfection but with the major drawback for dairy CIP of being corrosive to stainless steel. It is now more common to utilize an equilibrium mixture of hydrogen peroxide and acetic acid – *peracetic acid* – and this is commercially available, often supplied at 5 or 15% activity.

Application in Dairy Equipment

The four main types of equipment encountered in a typical dairy situation are pipelines, vessels, fillers, and cheesemaking equipment. These are all normally cleaned using CIP and it is important to ensure that each is cleaned in the correct manner, for example, to clean a pipe effectively, turbulent flow should be achieved. As a generally accepted 'rule of thumb' the flow rate required to achieve turbulent flow and therefore provide optimal cleaning is around 1.8 $\mathrm{m\,s^{-1}}$.

Fillers and complex items such as cheesemaking equipment will require purpose-built cleaning and spray systems installed within the plant to ensure good coverage. In some cases, there is a requirement to clean internal surfaces via CIP and also to include external surfaces, such as on a liquid milk filler, and utilize a specific, permanently installed foam cleaning system.

All tanks and process vessels will include a spray device of some description. Traditionally this was a simple spray ball, which is now being superseded by the use of rotating spray heads that provide a much more effective clean and have the added benefit of lower water consumption.

Agricultural Policy Schemes: Price and Support Systems in Agricultural Policy

H O Hansen, University of Copenhagen, Copenhagen, Denmark

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Agricultural support is a very important element in agricultural policy in many countries. Agricultural support is basically an instrument to meet the overall objectives of the agricultural policy – objectives set by society. There are a great number of instruments and ways of intervention in agricultural policy and they have different functions and consequences. Often, price mechanisms are used as support instruments, while direct income support is used in other cases. Choice of support system is of major importance and may have far-reaching consequences.

Objectives and Instruments in Agricultural Policy

Intervention through agricultural policy is a very important phenomenon in the agricultural sector in many countries. Often, the intervention takes place through the market, and the aim is to improve or stabilize the economic conditions. Intervention itself is not an objective, but it is an instrument to achieve the overall objectives and aims set by society.

Before the examination of the different instruments, it will be valuable to expose the underlying factors that legitimize those instruments, including support and price policy, of agricultural policy. There is a close correlation between the objectives and the instruments in agricultural policy.

Basically, society has set up a number of objectives, which lay down guidelines and directions for the development of agricultural policy. These objectives, which to a large degree are similar from country to country, explain and set the grounds for the instruments in agricultural policy.

There are a number of common features in the objectives that are found in agricultural policy in developed countries. In general, agricultural policy in developed countries aims at improving

- income in agriculture,
- income distribution among farmers,
- productivity in agriculture,
- efficiency in the processing and marketing chain,
- supply and price stability,
- demographic situation,
- environmental status, and
- export, employment, production, added value, and so on.

Many different types of instruments can be used to achieve the given objectives, and it is a very complicated relationship. Some instruments can be used to achieve several different objectives, whereas other instruments benefit the achievement of some and limit the achievement of others. Finally, important differences with respect to financing, effect on production and trade, transparency, and other elements are observed.

The instruments in agricultural policy can be divided into different groups:

Price Support

Support in the form of higher market prices than, for example, on the world market.

Deficiency Payments

Transfers from taxpayers to farmers corresponding to the production multiplied by the difference between the world market price and a given target price on the domestic market.

Support Coupled to Input Factors

- Area premiums
- Headage premiums
- Financial support
- Other supports to reduce costs

Direct Support Coupled with Other Factors

- Extensification
- Protection of landscape
- Support to enhance structural change
- Economic development in rural areas

Support Fully Decoupled from Production

- Compensation for the effects of drought and other calamities
- Income support, lump sum payments
- Early retirement schemes

Furthermore, one finds a number of other instruments that should not directly be used to achieve the objectives, but should be used to reduce supply and/or costs related to agricultural policy. Quotas and set-aside are examples of such instruments.

Price support and deficiency payments are the most important instruments in the agricultural policy of industrialized countries and account for about 75% of the total agricultural support.

High and Low Price Systems

Market price support and deficiency payments are two very important instruments in agricultural policy; however, they belong to two different support regimes or support systems. Market price support operates in the so-called high price system and is financed by consumers, while deficiency payments operate in the so-called low price system and are financed by taxpayers.

In the high price system, support is given mainly by means of import regulations, etc., which ensure a relatively high domestic price. In the low price system, support is given by means of direct support, while market prices are left undistorted at, or close to, world market level.

The two different support systems have very different implications for agricultural production, financing, markets, and aspects; still, there is an income transfer to agriculture in both systems in the short run.

The balance between market price support and direct payments varies greatly from country to country (**Figure 1**).

In countries like the United States, Ukraine, and Australia, agricultural support is granted mainly as direct payments financed by taxpayers, while market price policy, financed mainly by consumers, is predominant in countries like Japan, Korea, and Russia.

Figure 1 also shows the total level of agricultural support. Agricultural support includes transfers from consumers and taxpayers to agricultural producers arising from policy measures that support agriculture – producer support estimate (PSE). PSE is here measured as a percentage of gross farm income including support. The figure illustrates that countries like Iceland, Japan, Korea, Norway, and Switzerland have a high agricultural support level. On the other hand, countries like New Zealand, Chile, Brazil, South Africa, and Ukraine have an almost liberalized agriculture.

During the recent decades, agricultural support has changed significantly. The level of support has decreased – protectionism has weakened and liberalization has strengthened. At the same time, the composition of agricultural support has changed significantly. Consumer-financed market price support has decreased, and taxpayer-financed direct support has increased (**Figure 2**).

Structure and Function

As shown in **Figure 1**, countries like Korea and Japan use mainly the high price system in agricultural policy. In this system, support to farmers is given through high market prices maintained by different instruments like import tariffs (variable or fixed) or other import restrictions, export subsidies, and so on. These instruments ensure an artificially high price level compared to the price level that would result from the interaction of supply and demand in an undistorted market.

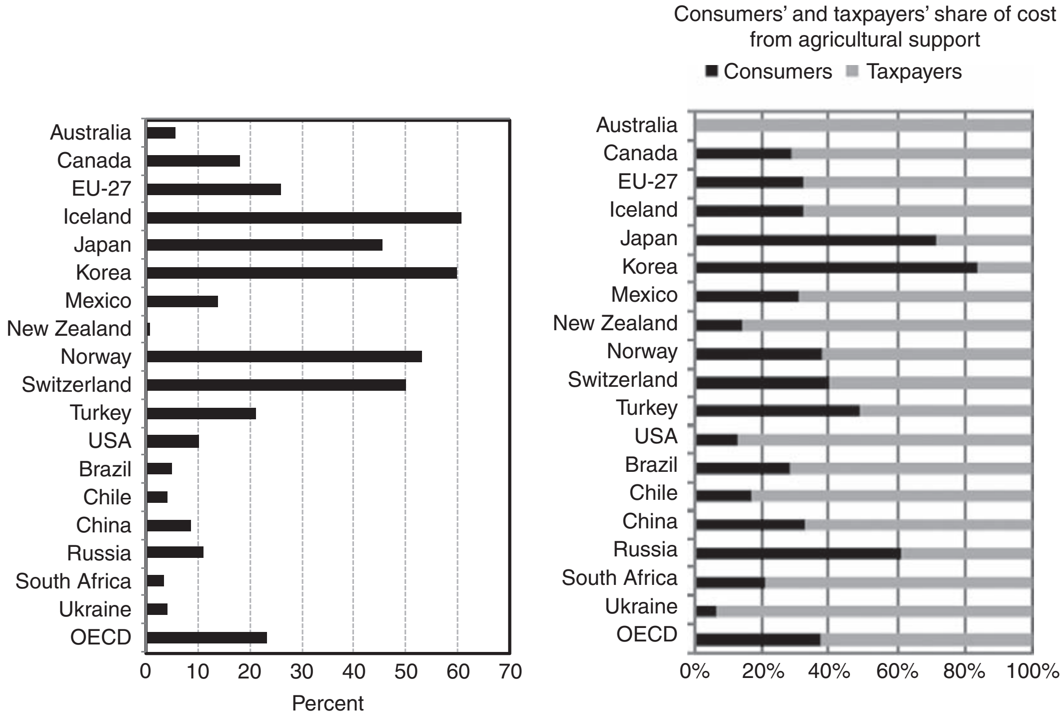

Figure 1 Level and composition of agricultural support (2007). From OECD (2009) producer and consumer support estimates, OECD database 1986–2008.

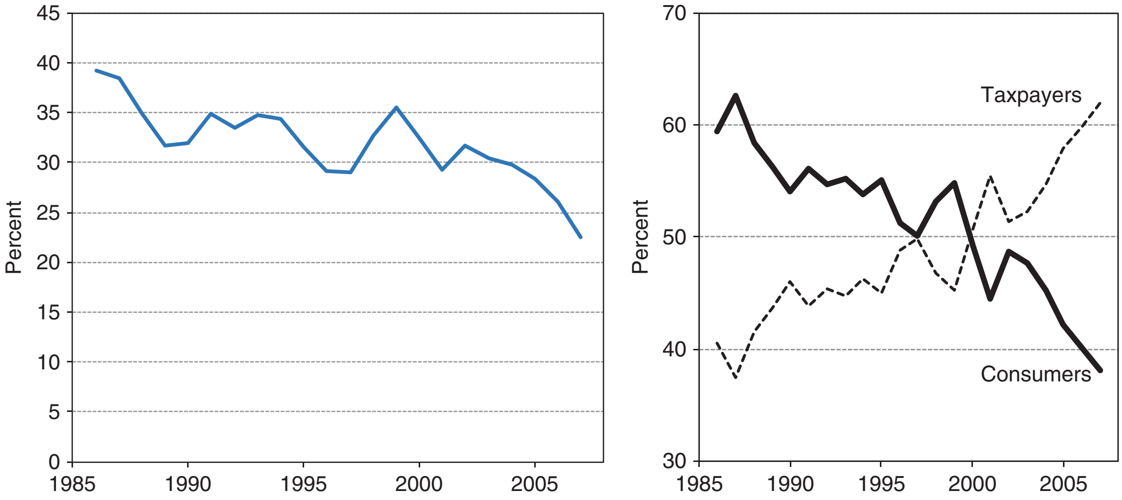

Figure 2 Level and composition of agricultural support in OECD (1986–2007). From OECD (2009) producer and consumer support estimates, OECD database 1986–2008.

Support in high price systems is financed by consumers through high consumer prices. Depending on the self-sufficiency rate, public costs and income are also affected. If the country is a net importer, the country will receive a revenue from the import tariff. On the contrary, a net exporting country will have to pay export subsidies to ensure the price level on the domestic market.

The low price system has for decades been the predominant support system in the agricultural policy in the United States. As a result of the recent reforms of the Common Agricultural Policy (CAP) in the European

Union and as a result of more focus on decoupled support in the World Trade Organization (WTO) negotiations, the European Union has moved toward more low price support and less high price support. Low price support system is now the most important support system in the European Union.

In low price systems, market prices are more or less unaffected, and farmers receive prices which in principle correspond to world market prices. Instead, market support payments are given directly to the farmers.

These payments can be coupled with production or they can be fully decoupled. Coupled support means that a farmer will receive a payment corresponding to the production multiplied by the difference between the world market price and a given target price on the domestic market. In this case, there is no major difference between a high and a low price system from a farmer's point of view.

If support is more or less decoupled from production, the economic transfer to farmers may have an element of income or social aid. Support can be coupled with the agricultural area or the number of animals belonging to the farm. In this case, support is still decoupled from production.

Low price systems are financed by the public budget, indicating that the taxpayers finance this kind of agricultural support in the end.

High and low price systems may have different modifications, individual structures, and so on. The income transfer can have various nuances giving different consequences in each case. However, the general structure of high and low price systems is shown in **Figure 3**.

It does not make sense – *a priori* – to determine whether one system is superior to the other. Support level is independent of the support system, and both systems have advantages and disadvantages. Therefore, it is necessary to compare these *pros* and *cons* with the objectives in the agricultural policy. It is evident that the choice of high and low price systems may have profound consequences within and outside the agricultural sector.

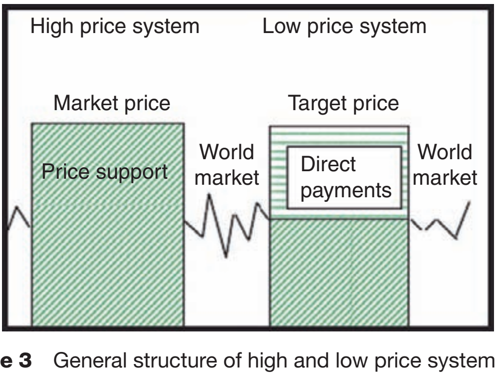

Figure 3 General structure of high and low price systems.

Consequences of High and Low Price Systems

Conditions and Competition in the (Processing) Food Industry

High price systems necessitate border protection of commodities traded internationally. This means that the border protection must comprise processed commodities and not the basic agricultural raw materials. This is the case for milk where border protection must cover the processed and traded goods like butter, cheese, and condensed milk.

In this way, the high price system will influence a major part of the food industry and not only the primary agricultural sector. This must be seen in relation to the fact that it is normally only the conditions in the primary agricultural sector that should be improved through the agricultural policy.

Especially if the food industry is very concentrated and having great market power, the farmers may not achieve the intended advantages of the high price system.

In other fields, a high price policy can be negative for the food industry. At first, the raw materials of the food industry will become more expensive, and unless this cost increase will be fully compensated through other systems, it will lead to worsening of the competitive power.

Such distortions of competition conditions in the food industry will not occur in a low price system. Here, a free world market price exists and is created by supply and demand without market intervention, and the food industry will automatically adjust correspondingly to the international comparative advantage of the sector.

Competition Conditions in the Agricultural Sector

Another problem with the high price system is that it is often difficult to grant the same subsidies to all products. It is most difficult to implement a uniform subsidy if it is a question about high and low processed products, and also, for some products there is only import protection and for others there may also be supply restrictions.

Furthermore, a general price increase for all agricultural products of, for instance, 10% will primarily benefit the crop production whereas gains for animal production will be lower. The explanation is that a major part of the production factors in animal farming consist of crop production, and in this way a general price increase will not have total trenchancy in these production areas.

For all industrial countries, there is a clear negative correlation between the grade of self-sufficiency and agricultural subsidy. This means, the higher the grade of self-sufficiency, the lower the agricultural subsidy.

It is characteristic that some countries often reduce the subsidy level for the products where the degree of self-sufficiency increases considerably to over 100%. With an increasing net export, the nationally financed agricultural subsidy increases, and therefore there will be a distinct incentive to reduce the subsidy. Apart from this, the self-sufficiency objective determines that one in particular protects the products where the grade of self-sufficiency is low.

In both cases, there are signs that one in particular protects the products that the agricultural trade already has poor possibilities to produce. On the other hand, the subsidy for the products that have the best natural conditions will be relatively low. It is assumed that a relatively high degree of self-sufficiency all in all is a sign of a comparative advantage.

Seen in a global perspective, the subsidy is highest in countries where the degree of self-sufficiency is low. Seen in a national perspective, it applies correspondingly that the subsidy is relatively the highest on products where the grade of self-sufficiency is relatively low. Both factors are part of a blurring of the comparative advantages and the result is welfare economic losses.

In the low price system, it can also be difficult to grant the same subsidy to all products; however, it is less complicated than in the high price system. One explanation is that the subsidy is granted directly and past the processing sector and in this way the real agricultural subsidy in the individual production areas is easier to calculate.

Apart from that, it is not seen in a low price system that price subsidy for one product has the effect as extra costs in another product area.

On the other hand, in a low price system, it can be very difficult to distribute a 'fair' subsidy independent of production among the farmers. Historic, structural, or social criteria are often necessary; however, they are rarely logical and they can be very static and not least they can be very difficult to control.

The Composition of Consumption

The composition of consumption is also affected by the choice between the high and low price systems. In the high price system, the consumers will, through higher food prices, primarily finance the agricultural policy. This means that food prices will increase compared to other products, and in this way the consumption of food will decrease compared to the consumption of other products. The result will be that the consumers' purchasing power will decrease.

At first, the consumers' loss as a result of the high price policy can seem great, approximately 25% of the agricultural production value is subsidy, and for the European Union 33% of the subsidy is consumer financed.

It should also be considered that the above-mentioned costs are calculated with the actual world market prices as reference basis. After both a one-sided and general liberalization, these prices will increase and thereby the consumers' gains will be smaller than the actual costs calculations show.

Even though the prices of agricultural products in a high price system are forced high, it will have far from full trenchancy on the food prices. This is due to the fact that only approximately 25–30% of the consumer price on food in highly developed countries traces back to the agricultural trade. The rest of the costs are wages in the processing industry, transport costs, and so on, and these costs are really independent of the subsidy level in the primary production.

Income Distribution in the Society

The choice between the high and low price systems will also influence the income distribution in the society.

A high price system, which will cause an increase in the food prices, will after all be the largest burden to the lowest income groups in the society. People with low incomes use a relatively large part of their earnings on food, which means that an increase on these products will limit their consumption possibilities relatively much. Higher prices on food and other necessary products as a result of political or economical measures will in this way have the same effect as a degressive tax.

On the other hand, the low price system builds on low prices to producers as well as consumers and that is why this form of protection will be the cheapest solution for the part of the population that have the lowest incomes. The financing of public expenses for income support, supplementary payments, and other supports is normally done by means of income tax, which in most cases is progressive. Contrary to the high price system, the costs of the agricultural policy in this case will be placed on citizens with higher incomes.

The State Expenses

High and low price systems have a significant impact on public costs and expenses. Market intervention often implies economic support, taxes, levies, and revenues, which means that public expenses will be affected.

For a net import country, the revenue of the state will at first increase by imposing a high price system based upon import tax. The state receives customs receipts, and at the domestic market the consumers finance the price subsidy to the agricultural sector.

On the other hand, there can be large costs for the state finances with the low price system where direct support to the farmers is a major instrument.

Finally, any intervention and protection measure will have a negative impact on resource allocation and economic welfare in society. Different measures have different consequences, but in general, coupled price support tends to be the most distorting measure imposing the highest loss of economic welfare in society.

The change in agricultural policy during the last decades in OECD countries – decreasing support and increasing role of taxpayer cost – has reduced the total cost, but the taxpayer cost has increased in relative and nominal terms.

Direct or Indirect Subsidy

The choice between the high and low price systems can also be of great importance as to how direct the subsidy systems are. In a high price system, the agricultural subsidy is given 'through the market', and therefore the subsidy is more indirect and invisible. In a low price system, where by means of tax collection the money is directly transferred to the agricultural sector, the transfer is much more obvious.

The low price system contains in this way a very direct subsidy to the farmer; however, the effect on international trade is more indirect and invisible. However, in most cases, the effect is the same for agricultural trade, and therefore it is only a pedagogical and comprehension problem. Still, it is certain that a low price subsidy is so visible that there will be a natural pressure from the surroundings (the taxpayers) to reduce the subsidy.

Production and Productivity Development

The choice between the high and low price systems can also be of great importance to agricultural production and productivity.

The high price system gives, at first, the farmers better sales prices, thus better terms of trade, and it will undoubtedly stimulate production. The size of the productivity increase will depend on the size of the supply elasticity. In general, the agricultural production responds relatively weakly to price changes. In the long term – and especially in case of price increases – it is characteristic that the agricultural production to a great extent adjusts itself to the changed price relations.

Normally, productivity will be improved through structural and political instruments, where through research, development, education, advising, and other means one can make the production more rational. However, the high price policy will also be able to affect productivity. On the one hand, there will be an incentive to increase production in relation to, for instance, the acreage effort. In this way, there will be an increased yield, and also the yield of the livestock production will increase. This will increase productivity.

On the other hand, the agricultural policy will also attract input factors which under normal conditions would be used in other sectors or which would not be used at all. For instance, poor soil will be cultivated and this will reduce the average yield. This will also be the case for other input factors, for instance, fertilizers, pesticides, capital, and labor.

The low price system has in principle the same consequences for production and productivity development provided that it concerns fully production-coupled subsidies. If, on the other hand, the payments to the farmers are partly or fully decoupled from the size of production, the consequences are crucially different. A totally independent income subsidy means that the farmers receive a relatively low price for their products, and that they have no incentives to increase production. It is only economically optimal to increase production as long as the marginal earnings are larger than the marginal costs, and this point is reached relatively fast with the low market prices.

At the same time, the income subsidy is assigned to the farmer regardless of the size of production, which means that production does not increase considerably.

However, it must be expected that even a decoupled production income subsidy in a low price system can seem encouraging to production. All agro-political measures will affect the resource allocation in the society, and in this way an income subsidy will maintain resources in the agricultural sector. In this way also the production will be affected to a larger or smaller extent.

Decoupled income subsidy will very much limit production development in the agricultural sector. Farmers will not be sufficiently urged (or forced) to introduce new technology or new production methods. At the same time, the more efficient farmers do not benefit sufficiently from the extra effort or risk which they undertake. The high and low price systems can, in this way, have different consequences for production and productivity development in the agricultural sector. One cannot in advance say that one consequence is better than the other.

Market Price Subsidy

The market price subsidy – where the market price is kept higher than on the world market – is still a common subsidy measure in the agricultural policies of the Western world (**Figure 1**). Among others, the European Union has through decades used the market price subsidy as an important instrument in the agricultural policy.

The use of the market price subsidy in a high price system demands, naturally, a considerable regulation of the markets. To secure the high price level, the markets are more or less isolated from the surrounding world, as

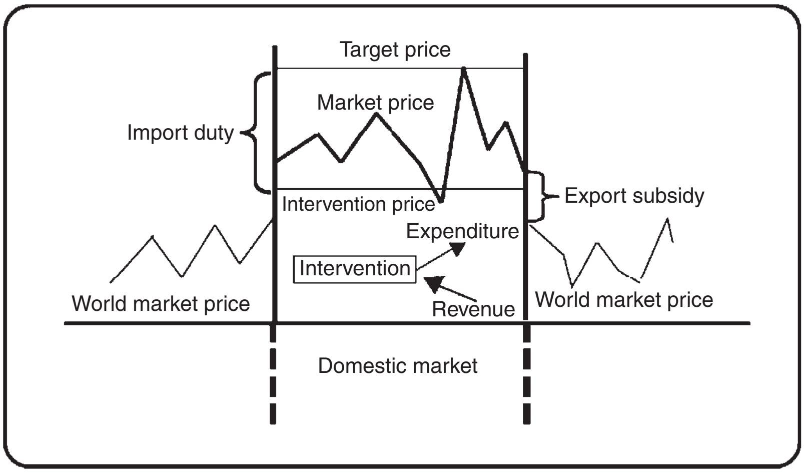

Figure 4 Instruments in a market price system (high price system).

free import or export will make the system collapse. Furthermore, there can be a need for public buying (intervention) or export support, dependent on the degree of self-sufficiency.

There are different types of market price subsidies but the most important one is a price system, where the state in different ways is adjusting the market with the purpose to ensure that the farmers on the market itself are able to obtain the aimed prices. This type of market systems can be schematically illustrated as shown in **Figure 4**.

The target price is the price aimed at for the producers to obtain on the market. The intervention price forms a safety net for the price formation on the market as the product can be sold within the European Union at this price. The actual market price will often be between the target price and the intervention price. If the market price levels drop below the intervention price, some suppliers begin to sell to intervention. This will reduce the supply on the market as the bought-up products will be stocked. This will normally lead to recovery of the market price. The intervention price and the intervention system are, in other words, a central part of the internal regulation of a high price market. However, intervention alone is not enough to secure the price, as there must also be a regulation by import and export.

When importing, an import duty is collected, which, in principle, is the difference between the price on the world market and the threshold price. In principle, it can be both a variable and a firm import duty. If the import duty varies, it can continuously be changed according to the world market price, and it therefore increases when the world market price is low and vice versa. In this way, the variable import duty can be a part of securing a constant price level on the internal market.

Previously, the variable import duty was often used, but as a result of the WTO agreements a gradual change in the tariffs has taken place. This means that the import barriers have changed to more firm tariff rates. When exporting, an export restitution (subsidy) is paid, which in principle is the difference between the price on the world market and domestic market price.

In the European Union, the market price subsidy works in such a way that the EU farmers have secure higher prices than on the world market. This is still the case for some products where reforms have not yet changed the original support system. This is naturally especially true for products where the market price subsidy is the most important measure and where the subsidy level is high. This applies for, among others, milk, whereas the market price subsidy on the cereal area has decreased considerably as a result of reforms in the EU agricultural policy (**Figure 5**).

Future Developments

Several conditions will influence the future development with regard to the agro-political instruments. The choice between the high and low price systems must not be seen from an economic and social point of view alone. The international negotiations in WTO are also of great importance. The explanation is that the high and low price policy influences the international trade in different ways.

First, it is important that the consequences for the size of production are different. All influences on the size of the production will directly influence the foreign trade, as for instance an increase in the production will make the import decrease or the export increase. In this way, these trade-influencing instruments are made objects of negotiations in, for instance, WTO.

As mentioned before, all agro-political measures will always influence the resource allocation and production,

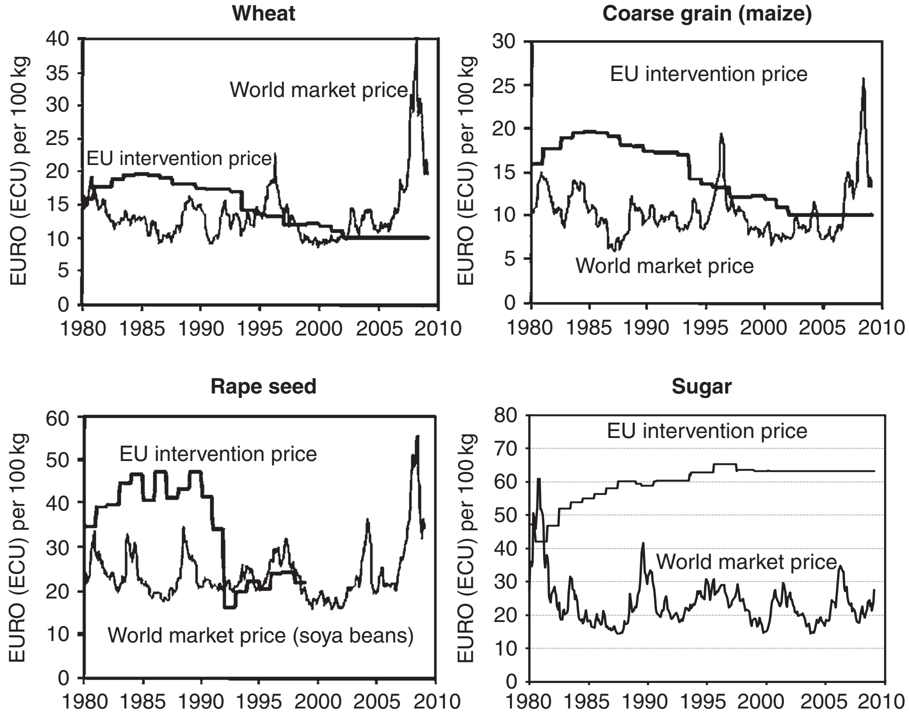

Figure 5 EU market prices and world market prices for agricultural products. In general, the intervention price system in the European Union has stopped or is diminishing.

and with this, also the foreign trade to a larger or smaller extent.

Still, in the international trade negotiations, there is talk about 'non-trade distortions', which are instruments with no influence on the trade. It is implied that some agro-political instruments have a less harmful influence on the international trade and that they in this way are more or less legitimate to use.

Second, it is important that in a high price system one is forced to introduce trade barriers, which in a very obvious way illustrate protection. The trade barriers can of course be of the same magnitude in a low price system, but here the trade protection is less transparent. Politically seen, the relationship to the trade partners can therefore favor the low price system.

The use of import duty, import tax, and especially export subsidy is normally necessary in a high price system, but they very clearly state that one wishes to protect the domestic producers against the surrounding world. This is probably also one of the explanations why the EU agricultural policy was so heavily attacked during the WTO negotiation rounds.

It is certain that the WTO rounds were a defeat for the high price system and a victory for the low price system. This fact must be seen in spite of the fact that the low price system does not necessarily create more free trade or greater economical welfare than the high price system.

On the other hand, the results of the WTO rounds, until now, mean that more countries in the future will be prompted to operate an agricultural policy based upon the low price system.

Also, more independent experts argue for a gradual change from the high price system to the low price system. The arguments are, for instance, that the subsidy rates will be more transparent and sometimes more trading neutral as well. Also, the instruments and the subsidy level in a low price system can easily be gradually removed and even completely replaced by pure social support arrangements.

Background

The Common Agricultural Policy (CAP) was established on the basis of the Treaty of Rome, with effect from 1 January 1958. Article 39 stipulates five fundamental objectives:

1. to increase agricultural productivity by stimulating technical progress and ensuring the rational development of agricultural production and the optimum utilization of factors of production, in particular labor;
2. to ensure a fair standard of living for the farming population, in particular by increasing the earnings of the persons engaged in agriculture;
3. to stabilize markets;
4. to assure the availability of food supplies; and
5. to ensure that supplies reach consumers at reasonable prices.

In the following years, the CAP gradually firmed up. It was based initially on the idea of a dual agricultural policy, consisting of structural measures on the one hand and price and market-related measures on the other hand. Eventually, the price and market policy became the overall dominating element of the CAP.

The price and market system comprises all the major agricultural products, including milk. In the original form, the policy was based on the following principles:

- free movement of goods within the European Union and common prices for the same good;
- common preferences in relation to third countries (common import duty system); and
- common financial responsibility for market and price policies of the European Community Fund via the European Agricultural Guidance and Guarantee Fund (EAGGF).

These principles were adopted at the Stresa Conference in 1958 and meant that the politically fixed prices became the central element of the CAP and the annual price negotiations of the EU Council of Ministers, which took place in April, started attracting great interest.

Up to the implementation of the General Agreement on Tariffs and Trade (GATT) in 1995, three prices of the principal products were fixed at the price negotiations: target prices, intervention prices, and threshold prices. The target price was the price aimed at in the market, but with no guarantee for the producers. The intervention prices for butter and skim milk powder, however, formed the safety net of the price formation in the market, as at worst the products – with various modifications – could be sold to the EU Commission at this price. As dairy produce consists mainly of fat and protein, the safety net really covers all products. Originally, the threshold price was the lowest acceptable import price for third-country products. The threshold price was used to calculate the variable import taxes, which, in principle, formed the difference between the world market price and the threshold price. However, the GATT agreement signed in 1994 meant that import taxes were frozen on 30 June 1995, which is why threshold prices are no longer fixed.

The fourth fundamental principle of the EU price and market system is export refunds. Refunds are paid on exports and in principle they form the difference between world market prices and the EU market price. The size of the fixed refunds is the same for all EU Member States, but may be differentiated by destination, if special conditions apply.

In connection with the reform of the EU CAP in 1992 (the MacSharry reform), far-reaching changes in price and market policies were introduced, particularly regarding cereals and beef. However, in the milk sector, the old system still applied (**Figure 1**) as the proposed reform was unacceptable to the EU Council of Ministers. Thus, there were no major changes in the milk regime until the implementation of the CAP Reform in 2003, as discussed later.

Financing of the CAP

The CAP system was financed by the EAGGF, which is divided into a guarantee section, financing the price and market policies, and a development section, financing the structural policies. From the start of the European Union, the CAP consumed by far the largest

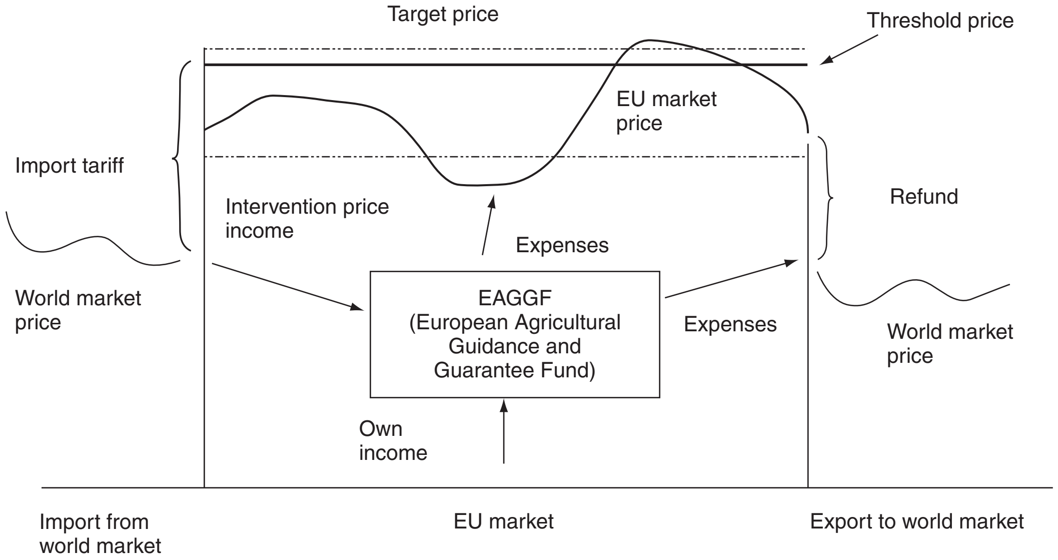

Figure 1 The EU market scheme.

share of the total EU budget. Relatively speaking, the expenses for the agricultural policies have been declining gradually since the 1970s, and now total about 40% of the total EU budget. This decline must be seen in the context of other EU policies and a growing request to stabilize farm expenses. Concurrent with restrictions on farm expenditure, larger funds have gradually been transferred to finance the development of other structural funds, with particular emphasis in recent years on energy, the environment, and new Member States. The EU revenues are based on

- contributions based on gross national income,
- contributions from all Member States on a value-added tax (VAT) basis,
- customs receipts, and
- various production levies.

The Price and Intervention Scheme for Milk and Dairy Products

The EU basic regulation on milk and dairy products was finally adopted in 1968 (EEC 804/68). The institutional prices for milk and dairy products were fixed for a whole dairy year, running from 1 July to 30 June. The target price was fixed for milk, with 3.7% fat carriage paid at any processing factory. The intervention prices were fixed for skim milk powder and butter and formed a safety net under the milk prices. In this way, the main ingredients, protein and fat, were safeguarded and stored in a form that could be controlled by intervention buying. While intervention prices continue to be fixed as in the past, the levels are now considerably lower following CAP Reform as discussed later. Up to 1987, the Intervention Boards of the individual Member States were obliged to purchase any product for sale at the fixed intervention price. Subsequently, various modifications have been made.

The System prior to CAP Reform 2003

Skim milk powder and skim milk (EC 1255/99 art. 7, 11, and 12)

During the winter season, from 1 September to 28 February, intervention with regard to skim milk powder is suspended. From 1 March to 31 August, intervention may be suspended; however, private storage of skim milk powder may be subsidized. Only first-class produce meeting the set requirements on age and packaging may be the subject of intervention. As of the market year 1995–96, a minimum protein content of 30% in skim milk powder for intervention was introduced. At a protein content of 34% and above, maximum subsidy is paid, whereas contents between 30 and 34% have 1.75% deducted from the intervention price for each percentage point below 34%. Products subject to intervention, which cannot be sold on normal market terms, may be subject to special stock disposal measures and sold at reduced prices. As for skim milk powder, its use in mixed feedstuffs for calves is subsidized (the most important scheme) as well as its use in mixed feedstuffs for pigs and poultry. Skim milk for processing into casein and caseinates is also subsidized. These products are used as the primary material for processing of various industrial products and foodstuffs, such as processed cheese. Subsidies for casein and caseinates are a production subsidy, as distinct from the price subsidy schemes.

The intervention system for butter (EC 1255 art. 6 and 13)

From 1987, the intervention system for butter has been a tender procedure. Tenders are submitted every 2 weeks, as the EU Commission fixes a maximum buying-in price. All bids below this price are purchased. Since 1987, the buying-in price has been steady at 90% of the formally fixed intervention price. Like skim milk powder, butter for intervention must meet certain requirements on quality, age, and packaging. When the market situation allows, subsidized butter pursuant to regulations is remarketed on terms that do not damage the competitive position of butter in the market. Butter subject to intervention is remarketed within the European Union under the special scheme for sale of butter at reduced prices, for use in the food industry and for the manufacture of pastry products, ice cream, and other foodstuffs. Analogous to the sale of subsidized butter for food manufacturers, similar subsidies are paid for the use of fresh butter and cream in the food industry. Butter for social institutions and hospitals is also subsidized, as well as for the armed forces. To safeguard the normal market supply and price of butter during winter months, private storage of butter and cream is financially supported. The storage period, fixed by the EU Commission, usually starts on 1 April and ends on 15 August. The stock disposal period is from 16 August to 28 February the following year. The storage period must be a minimum of 4 months.

The intervention system for cheese (EC 1255/99 art. 8)

In addition to the general intervention schemes for butter and skim milk powder, private storage of the cheese types Grana Padano, Parmigiano Reggiano, and Provolone may be subsidized in Italy. The special scheme was established as the production of these particular cheese types is a staple element of the Italian dairy industry.

Subsidies for sale of liquid milk (EC 1255 art. 14)

To stimulate liquid milk consumption, the European Union contributes to the implementation of the Member States' special aid schemes to supply milk and selected dairy products for schoolchildren at reduced prices.

The Import System for Milk and Dairy Products

Before the introduction of the GATT/World Trade Organization (WTO) agreement on 1 July 1995, third-country imports were subject to variable import levies. Now these levies are tariffed, that is, converted into a fixed tariff rate, payable in Euro per tonne or as a percentage of the import price. Pursuant to the agreement, the rates have been reduced by an average of 36% compared to the basic period from 1986 to 1988. Moreover, the GATT/WTO agreement imposes minimum import access quotas at reduced tariff rates, equal to 5% of consumption in the basic period. In addition, the European Union is obliged to give access to butter from New Zealand at a special low rate. This amount represents the average amount exported annually to the United Kingdom by New Zealand under bilateral agreements during the GATT/WTO basic period. Further to GATT/WTO obligations, the European Union has entered a number of bilateral agreements aimed at facilitating market access on a mutual basis. For instance, there are special quotas for the United States, Canada, Norway, Switzerland, South Africa, and others.

Export Schemes for Milk and Dairy Products

As a matter of principle, the European Union subsidizes most dairy products for export to balance the price gap between the European Union and the world market, except when this price gap disappears as in the 2007/2008 period. Non-Annex I products are subsidized as well; these are processed products containing agricultural produce, such as cereals, sugar, eggs, and milk. After the implementation of the GATT/WTO agreement, the refund system was somewhat restricted. Compared to the basic period of 1986–90, subsidized exports were reduced by 21%, in parallel with a 36% reduction of the refund budgets. The budget restrictions apply only to non-Annex I products. In order to ensure that the restrictions are met, all exports qualifying for refunds are subject to presentation of an export license, prefixing the refund. Export licenses are limited to the permitted quantity, which implies that it is a scarce commodity in times of great demand. The limited opportunity to use refunds means that export refunds for cheese no longer exist for a number of destinations. This generally applies to areas such as the United States, Canada, Australia, Switzerland, and Norway. In other areas, refunds for only selected products have been abolished.

The Milk Quota Scheme

As a result of the increasing imbalance between production and demand, the milk quota scheme was introduced in 1984. The purpose of Article 39 of the Treaty of Rome had long been accomplished and the choice was between a reduction of prices and limiting production. Production was chosen and the measures proved effective in limiting surplus production. Each Member State was allocated a national quota (reference quantity) for the quota year 1984–85, which as a rule equaled the total national milk production in 1981 plus 1%. Ireland, Italy, and Northern

Ireland got a somewhat larger quantity. The Member States were allowed certain latitude to implement the quota scheme in one of two ways, either as direct sales quotas or as dairy quotas. Under the direct sales quota scheme, the national reference quantity was reallocated to individual milk producers. Under the dairy quota scheme, the quota was reallocated to the dairies, which subsequently had to fix quotas for individual producers. In the event of milk production in excess of the quota, a superlevy was collected, totaling 115% of the target price. Regardless of the choice of management scheme, the producers who exceed their quota must pay the superlevy. The dairy quota scheme provides the option to use a net principle, allowing the underuse of quota by some producers to be converted into a deduction for producers who have exceeded their quota. In this way, the quota is fully utilized and the payment of a superlevy reduced.

Agenda 2000

Following nearly 2 years of discussion, the EU Heads of State finally made the decision to reform the EU CAP, entitled Agenda 2000, at the summit meeting in Berlin in March 1999. Agenda 2000 also embraced the budgetary framework of the European Union for the period 2000–06 and the plans for enlargement by the inclusion of central and east European countries as well as a reform of the structural policy.

The fundamental element of the agricultural reform was a reduction of refunds for the most essential agricultural products, as opposed to extended financial aid to producers by premium schemes, only partly related to production. For agricultural produce and beef, the 1992 reform was further expanded, whereas in the case of the milk and dairy sector it is a profound breach of previous policies.

The purpose of the reform was to

- improve the competitiveness of EU agriculture on both domestic and external markets,
- facilitate the progressive integration of new Member States,
- prepare the European Union for the next WTO round,
- ensure continuously stable farm incomes, and
- integrate environmental goals into the CAP.

The original intention was to implement the reform of the dairy sector in the period 2000–03. However, the final agreement between the Heads of State in Berlin postponed the implementation to 2005–08. The principal elements of the reform that was agreed were as follows:

1. A total 15% reduction in intervention prices for butter and skim milk powder, in three stages from 2005–06 to 2007–08.
2. To compensate for the price cut, milk producers were to be allocated a direct payment per tonne milk quota, fixed at €5.75 in 2005, €11.49 in 2006, and €17.24 in 2007.
3. In addition, each Member State would receive financial support by the so-called ‘national envelopes’, which may be allocated according to nationally determined criteria.
4. The total quantity eligible for direct payments in each Member State would be equal to the sum of all individual reference quantities for the 12-month period 1999–2000.
5. A total increase of milk quotas of 2.8 Million tonne (2.4%): in the years 2000–01 to 2001–02, the national quotas were increased for Spain (10%), Italy (6%), Northern Ireland and Ireland (3%) as well as Greece (11%). The increase for the remaining countries was to be 1.5% in the years 2005–06 to 2007–08.
6. The milk quota scheme would continue up to 2008. In 2003, a ‘mid-term review’ would be initiated.

CAP Reform (Mid-Term Review) 2003

In 2002, the Mid-Term Review of Agenda 2000 commenced. It concluded in June 2003 with a fundamental reform which provided for the decoupling of direct payments from production in the case of livestock production, milk production, and arable crops, with partial decoupling options for Member States that did not wish to decouple fully. Direct payments (coupled or decoupled) were made conditional on compliance by farmers with a range of food safety, environmental, and animal welfare measures.

With regard to the dairy sector specifically, the most important elements were as follows:

1. An asymmetric reduction in intervention price: 25% for butter (from €328.20 to 246.39 per 100 kg) and 15% (from €205.52 to 174.69 per 100 kg) for skim milk powder. The reduction was brought forward to 2004–05, with the butter price reduction spread over 4 years (7, 7, 7, and 4%) and the skim milk powder price reduction in three equal annual steps.
2. Partial compensation for the intervention price cut for dairy farmers: a direct payment of €24.49 per 100 kg of quota and a supplementary payment per Member State equivalent to approximately €11 per 100 kg. Such compensation is paid for the total of national quota as at 1999/2000. Originally, the coupled payments had been programmed in Agenda 2000 at a lower level. The payments were to be decoupled at the latest in 2007.
3. Discouragement of butter intervention: by introducing the possibility to open a tender for intervention buying-in after 30 000 tonnes at fixed prices have been bought in.
4. Expiration of production quotas on 1 April 2015.
5. Postponement by 1 year of the gradual quota increase of 1.5% in three steps of 0.5% for 11 Member States, as

already foreseen in Agenda 2000. The increase corresponds to 1.4 million tonnes of milk.
6. Reduction of the superlevy: in four steps from €35.63 per 100 kg in 2003/2004 to €27.83 per 100 kg from 2007/2008 onward.

Coinciding with the start of the dairy reform in 2004, 10 new Member States joined the European Union. This increased the EU base quota by 18.5 million tonnes and added 80 million consumers. Furthermore, in accordance with the accession agreements, a restructuring reserve of 0.67 million tonnes was established for eight of the new Member States. This additional reserve was added to their national quotas on 1 April 2006. In 2007, a further two new Member States with a total quota of 4 million tonnes joined the European Union, bringing the total amount of quota for the EU-27 to 142 million tonnes. Thus, by 1 April 2008, further to 103 million consumers, 24.5 million tonnes of additional quota will have been added to the EU total since 2003.

The aim of the 2003 dairy reform was to increase competitiveness and market orientation. It was intended that by reducing the guaranteed price for butter and SMP, these products would be less attractive to produce and this would give the industry an incentive to produce more value-added products like cheese and fresh dairy products. Increasing the quota at the same time would encourage additional production, facilitate restructuring of the sector, and encourage entrance into the sector of young farmers.

It will be recalled that the European Commission's proposal for the CAP Reform 2003 was to increase quota by 2% on top of the 1.5% increase already agreed in Agenda 2000. In the June 2003 compromise, however, the Council declared that "No additional quota increase in 2007 and 2008 will be decided now. The Commission will present a market outlook report once the reform is fully implemented on the basis of which a decision will be taken."

CAP Health Check 2008

As part of CAP Reform 2003, a mid-term review of policy was completed in 2008, which became known as the CAP Health Check. Agreement was reached among farm ministers in November 2008. The main points related to dairying were as follows:

1. Five annual milk quota increases of 1% each with effect from April 2009, prior to total abolition of the quota system as from 1 April 2015. As is now traditional, when it comes to milk quota, Italy will receive a special derogation that allows it to increase its quota by the full 5% in the first year.
2. The rate of modulation (shifting funds from direct aids to rural development aids) will be raised from 5% at present to 10% by 2012. The increase will be made gradually: 7% in 2009, 8% in 2010, and 9% in 2011. The progressive modulation concept has been watered down; only recipients of more than €300 000 will face a higher modulation rate: 4 percentage points higher than the standard rate. The resulting money will be allocated for 'new challenges' – climate change, energy, biodiversity, and water management – but it will also have to fund 'accompanying measures' for the dairy sector.

Conclusion

The EU CAP is and will remain a fundamental basis of EU cooperation. Financial problems, disputes about GATT/WTO principles as well as problems regarding the enlargement of the European Union have permanently placed reforms of the agricultural system on the EU political agenda. For the first time, the market scheme for milk and dairy products underwent fundamental change in 2003 and further changes may be anticipated in the decade ahead, particularly when milk quotas are finally abolished in April 2015.

Introduction

An active agricultural commodity policy was developed in the United States in the 1930s in response to economic conditions of the Great Depression. Major commodity programs for grains, oilseeds, cotton, peanuts, sugar, tobacco, and dairy that are in place today have their origins in the programs that began nearly 70 years ago.

Dairy policy in the United States comprises the following major components:

1. Border measures that create import barriers for most dairy products and export subsidies for a few manufactured dairy products.
2. Federal and state marketing orders that regulate milk prices at the processor and farm levels.
3. Government purchases of manufactured dairy products to support the farm price of milk.
4. Income support to dairy farmers through deficiency payments.

Federal, state, and local governments also have longstanding food safety and sanitation regulations for milk and dairy products. In addition, there are myriads of more recent environmental, land use zoning, labor, and other regulations or incentives that influence the dairy industry.

This article provides an overview of the key elements of US dairy policy, and provides some statistics to illustrate the economic effects of these programs.

Border Measures for Dairy Products

Trade barriers for many dairy products have limited US imports of these products to less than 5% of US consumption (**Table 1**). Import barriers have traditionally kept the domestic price of dairy products above the price for traded products in world markets, although the gap has narrowed recently (**Figure 1**). By insulating the domestic dairy economy from foreign supplies of dairy products, the import barriers also make possible the key domestic elements of the dairy program – milk marketing order pricing rules and the price support program (described in the following sections).

As a part of the Uruguay Round trade agreement that took effect on 1 July 1995, a system of absolute import quotas gave way to a system of tariff rate quotas (TRQs) that set a relatively low tariff on imports up to a determined quantity (the quota) and a relatively high tariff on over-quota quantities. Although the quantity of access expanded with the Uruguay Round agreement, the second-tier tariffs applied to over-quota imports remain prohibitively high; therefore, for the present, the effects of the TRQs remain the same as the absolute quotas that were replaced, although at expanded import quantities. Imports of fluid milk, cream, butter, cheese, milk powders, and many other dairy products are subject to TRQs. For those products subject to TRQs, imports accounted for 5% or less of domestic consumption, but for other products, including casein, milk protein concentrate, and some cheeses, imports are not restricted. Not surprisingly, imports of partly or fully unrestricted dairy products represent the bulk of US dairy imports – caseins, milk protein concentrates, and cheeses represented nearly 80% of total import value in 2009. Overall, the United States imports more than $2 billion worth of dairy products each year, and is a substantial importer as well as exporter in the world dairy market.

In addition to limiting import access to the domestic market for most dairy products, the US government continues to provide small amounts of direct financial subsidy for US exporters of dairy products. Subsidized exports, along with donations to domestic food programs and international food aid, have long been used to dispose of stocks of dairy products acquired under the price support program. Subsidized exports have been considered a market for US dairy products that does not disrupt domestic commercial sales. In addition to the disposal of government stocks, the Dairy Export Incentive Program (DEIP) has provided explicit price subsidies for commercial dairy product exports since the 1980s. Commodities eligible for DEIP (and annual Uruguay Round WTO maximum subsidized export volumes) are skim milk powder (68 000 tonnes), butter (21 000 tonnes), and cheese (3000 tonnes). With high world market prices for dairy products in recent years, DEIP subsidies have been infrequent. But very low world prices in 2009 triggered DEIP subsidization of 37 200 tonnes of milk powder, 17 400 tonnes of butter, and 1800 tonnes of cheese.

Table 1 US production, trade, and consumption of select dairy products, 2006–09

	2006	*2007*	*2008*	*2009*
All cheese				
US production (1000 tonnes)	4320	4433	4505	4583

Regional Milk Marketing Orders

The pricing of nearly all of the milk produced in the United States is regulated by milk marketing orders. In 2010, 10 federal marketing orders regulated the sale of about two-thirds of all milk produced in the country. California, which operates its own marketing order, regulates the sale of another 20% of the country's milk. Some of the remainder is regulated by other state marketing orders (Maine, Montana, Nevada, Virginia) and some (notably Idaho with 6% of US milk production) is not regulated by any marketing order.

State and municipal governments set separate sanitary standards for milk that may be used in fluid products and milk that may be used only in manufactured dairy products. Grade A milk is milk that meets sanitary standards for use in fluid products. Of all milk produced in the United States, 99% is grade A. Grade B milk is eligible for use in only manufactured dairy products and is not regulated by milk marketing orders.

Both federal and California milk marketing orders use price discrimination to raise the average price received by producers, setting minimum prices that processors must pay for grade A milk according to its end use (classified pricing). Federal orders distinguish between four end-use classes: fluid products, fresh and frozen products, hard cheeses, and butter and dry milk powder. Each month, federal orders set the minimum prices for milk used in cheese and milk used in butter and dry milk according to formulae that take into account the wholesale prices of these products. The minimum prices for milk used in fluid products (Class I) and soft and frozen products (Class II) are set as a specified differential over the manufacturing-use minimum prices. The differential for Class II is the same across all federal orders, but Class I differentials vary by order.

Although the details of the Federal Milk Marketing Order (FMMO) pricing rules have changed over time, the key element of price discrimination remains; the minimum price for milk used in fluid products is set at a premium over the minimum price set for milk used in manufactured dairy products. The California state order distinguishes among five end-use classes, and uses similar formulae to set minimum prices for each class.

In addition, each federal marketing order administers a revenue-sharing or 'pooling' scheme that distributes revenues from relatively high-priced Class I milk across all grade A milk. Each month, each federal order pools revenues from all end-use classes and announces a uniform, order-wide average price to individual farmers delivering milk to that order, regardless of how any individual producer's milk was actually used. The weighted average or pool price in any order depends not only on the class prices but also on the utilization rates of milk in the various end-use classes, which also vary from order to order.

California's revenue-sharing scheme differs from that used in the federal system. In California, a quota program determines how milk revenues from the various end-use classes are distributed among producers. The milk quota program in California does not restrict production or marketing. Rather, for each 100 kg of milk quota owned by an individual producer, the producer receives a fixed payment of $3.75 from the statewide pool of total milk revenues in a month. The remainder of total regulated milk revenues (i.e., what is left over after subtracting total quota payments) is distributed uniformly among all producers in the same way as federal orders. Overall, quotas cover about 22% of all the milk produced in the state.

To the extent they raise the average price of milk above what it would be in their absence, both federal and state milk marketing orders encourage milk production. By setting relatively high prices for milk used in fluid products, marketing orders reduce sales of fluid milk. As a result, marketing orders encourage production of manufactured dairy products such as cheese, butter, and milk powder.

Each marketing order regulates milk within a geographically defined marketing area. **Figure 2** is a map of the 10 federal marketing areas. The relationship of prices among federal orders is determined, in part, by the formulae used to set minimum prices in each order. By formula, the minimum prices for milk used in manufactured dairy products are the same across orders. However, the fluid differentials, and thus the minimum price for milk in fluid uses, are different for each order. Differentials range from a high of $13.23 per 100 kg in parts of Florida, to a low of $3.53 per 100 kg in parts of the Upper Midwest. **Table 2** lists the fluid differentials, Class I milk prices, and pool prices that were in effect for the 10 federal orders in 2009.

In order to maintain different minimum prices in each marketing order, regulations are in place to discourage the transport of milk across regions. Milk transported freely across marketing order borders would undermine the maintenance of separate fluid milk markets in different orders. Regulations on inter-order milk shipments ensure that there is little economic advantage to arbitrage across prices in different orders. Because marketing orders create separate fluid milk markets in different regions, the benefits and costs of milk marketing orders vary regionally.

Federal Price Supports for Dairy Industry

As early as 1935, the federal government was purchasing manufactured dairy products in order to support the farm price of milk. The Agricultural Act of 1949 required the

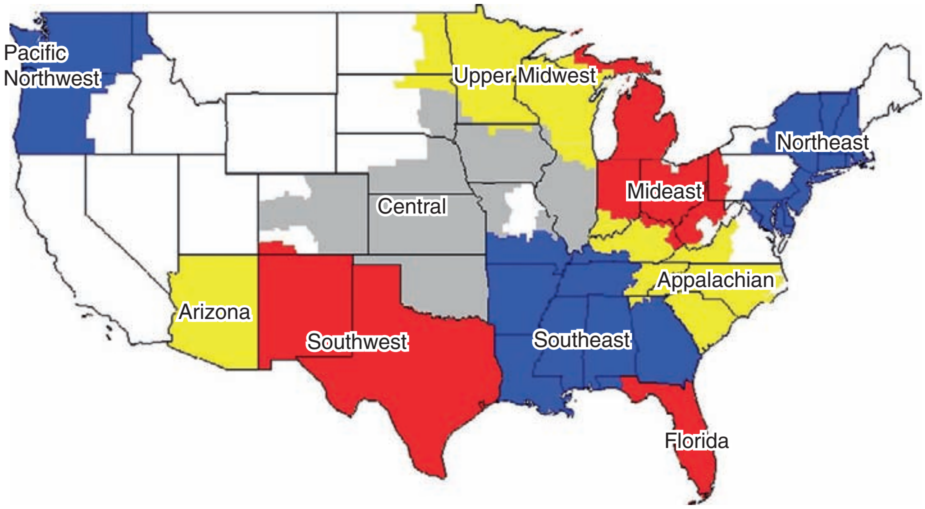

Figure 2 Map of the Federal Milk Marketing Order areas as of 1 January 2010. Differences in shading merely serve to differentiate between marketing areas. Reproduced from US Department of Agriculture, Agricultural Marketing Service, Dairy Programs.

[b] Pool price is the market-wide weighted average of all minimum end-use class prices. Data reproduced from US Department of Agriculture, Agricultural Marketing Service, Dairy Programs.

US Department of Agriculture (USDA) to continue to support the farm price of milk. Since that time, the USDA has purchased butter, non-fat dry milk, and cheese from processors at administratively determined intervention prices calculated to help ensure that the farm prices of manufacturing milk remain above the legislated support price. In 2008, the dairy price support program was modified to remove the requirement that USDA support a specific milk price, but intervention prices for eligible dairy products remained the same. The name of the support program was changed from the 'milk' price support program to the 'dairy product' price support program.

Table 3 lists the support price for milk and the government purchase prices for eligible dairy products from 2000 through 2009. Note that, on average, market prices exceeded intervention prices, but occasionally fell far enough below during the year to trigger government purchases. Annual purchases of butter, cheese, and non-fat dry milk are shown in **Table 4**.

Since 1990, dairy price supports have played a minor role and government purchases have been relatively small compared to the 1980s. The 1996 FAIR Act lowered dairy price supports by 33 cents per 100 kg to $21.83 per 100 kg through 1999, at which time the program was scheduled to be terminated. However, the price support program was extended and subsequently reinstated in omnibus farm legislation passed in 2002.

While the support price program plays a potentially important role in flooring prices for manufactured dairy products, the current intervention prices provide only the lowest of safety nets. Moreover, added costs of selling to the government (nonstandard packaging, mandatory federal inspection) mean that market prices for cheese often

Negative values denote net sales from government stocks. Values include DEIP subsidies in the form of product.

fall below the intervention price without triggering government sales. This further diminishes the ability of the program to provide a price floor.

Direct Deficiency Payments – The Milk Income Loss Contract Program

The 2002 US 'Farm Bill' introduced another dairy subsidy scheme in the form of the Milk Income Loss Contract (MILC) program. MILC is a target price-deficiency payment program that makes payments to all dairy farmers (subject to a production cap) in any month when milk prices fall below a target level. The initial base target price was $37.35 per 100 kg in reference to the Class I milk price announced for Boston. If the Boston Class I price in any month fell below $37.35, then all US milk producers were eligible to receive 45% of the difference.

An annual cap on the amount of milk per farm eligible for payment was initially set at 1.1 million kg, which represented the annual production of about 120 cows. The payment rate was reduced from 45 to 34% on 1 October 2005, but reinstated at 45% in the 2008 Farm Bill. That legislation also provided for an upward adjustment in the MILC target price if dairy feed costs exceed a base level and raised the annual farm production cap to 1.35 million kg.

MILC payments since the retroactive inception of the program through 2009 are shown in **Figure 3**. Payments closely follow milk prices. No payments were made during 2007 and 2008. The crash in milk prices in 2009 combined with a higher target price from the feed price adjuster led to record high payments during the first half of the year.

The MILC program has been controversial among producers, mainly because the production cap favors regions with a smaller average herd size. Large western dairies can exceed the production cap in a single month. Their owners argue that they have been forced to bear the brunt of adjusting milk supply to low prices because MILC payments insulate smaller producers.

Final Remarks

In the United States, the federal government and several state governments directly and indirectly subsidize milk producers and regulate dairy prices. These programs stimulate additional milk output, raise the price of beverage milk, and shift income from taxpayers and consumers to the dairy industry. Economic research has documented that costs to taxpayers and consumers are significantly larger than gains to producers as a group, but of course, any individual producer gains much more than the system costs a typical dairy consumer or taxpayer.

Introduction

Milk producers in many countries benefit from government interventions that increase the prices they receive for their raw milk production. In some countries, a system of milk production quota was established to control the growth of surplus production while maintaining the market price support. Below are reviewed the current dairy policies in Canada, Japan, Australia, and New Zealand. The review illustrates the very different policy approaches and the degree of dairy policy interventions.

The Organisation for Economic Co-operation and Development (OECD) collects and analyzes information regarding the level of support provided to producers through agricultural policies and calculates some measures of the monetary transfers caused by such policies – the producer support estimate (PSE). Since 2005, the total PSE is no longer broken down for individual commodities, which reflects the gradual shift (in many countries) away from direct commodity-linked supports. **Figure 1** shows the change in %PSE for selected countries and the OECD average during the periods 1986–88 and 2002–04. The %PSE expresses the monetary value of the support as a share of gross farm receipts. A notable feature of the %PSE for milk is the reduction in support since the early 1990s, although the reduction varies considerably among countries.

Since 2005, a new commodity-based indicator is calculated by the OECD, the so-called single commodity transfers (SCTs), which shows the annual monetary value of gross transfers from policies linked to the production of a single commodity such that the producer must produce the designated commodity in order to receive the transfer. For the countries reviewed below, the change from the commodity-specific PSE to the SCT indicator does not make much difference for New Zealand and Australia, where milk producers are supported either very little or not at all, while in Canada and Japan, a majority of the support (more then 90%) has been based on market price support (MPS), which continues to be reported in SCTs. The evolution of the SCT for milk production in the reviewed countries is illustrated in **Figure 2** for the period 1986–2008.

Canada

Background

Since the first dominion dairy commissioner was appointed in 1890, the Canadian Federal Government has played an active role in policymaking for the dairy sector. A milk supply management system was introduced in the early 1970s, and it remains the cornerstone of Canada's current dairy policy. Import restrictions at the border and milk production quotas are the main instruments allowing for a high level of support to the dairy sector, which continues to be the most heavily supported sector within Canada's agriculture. In 2004, around 35% of all support to Canadian agriculture (as measured by PSE) went to the dairy sector. **Figure 1** also illustrates that Canada's support to dairy farmers is higher than that in OECD countries on average. When considering the SCT, 33% of the total SCT was attributable to the dairy sector in 2008. **Figure 2** shows the relatively stable levels of SCT support, which declined notably after 2006 as international reference prices soared. (In 2009, the SCT level increased significantly following the dramatic price fall on the international dairy markets which has not been transmitted to the domestic market in Canada. The preliminary figures estimated by the OECD indicate an increase of % SCT to a level of 60%.)

Canada and Its Milk Supply Management System

The milk supply management system, introduced in the early 1970s, is the essence of Canada's dairy policy. The system is governed by the Canadian Milk Supply Management Committee (CMSMC). The committee is responsible for policy determination and supervision of the national milk marketing plan. The CMSMC annually sets a national production target, the market sharing quota

[1] The author is an agricultural markets and policy analyst at the OECD, Paris. The opinions expressed in this article are those of the author and do not necessarily represent those of the OECD or its member countries.

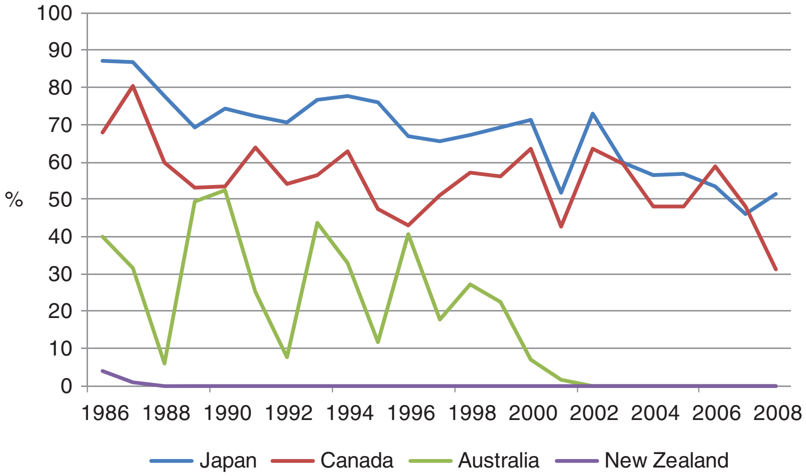

Figure 2 Single commodity transfers (SCTs) for milk over the period 1986–2008 in various countries. Source: OECD.

(MSQ), for industrial milk. The MSQ is set with the goal to achieve a domestic market balance in terms of butterfat, and is assigned to provinces largely on the basis of historical shares. In addition to the MSQ, each province controls its own production quota for fluid milk, and the entire milk quota – industrial and fluid together – is allocated to producers.

For the supply management to be effective there is a need to continue the policies of substantial border measures. In other words, a quota system allows a domestic market to be managed only if that market is isolated from external sources of supply. Under the 1994 Uruguay Round Agreement on Agriculture (URAA), the diverse forms of trade measures were converted to tariffs, and market access for sensitive products was provided through a system of tariff rate quotas (TRQs). Under the TRQ system, exporting countries have access to the Canadian dairy market to the tune of 5% of the domestic consumption. For most products, the final access quota quantities remain below 1000 tonnes (i.e., 1 kt), but are 3.2 kt for butter and dry whey, 20.4 kt for cheese, and 64.5 kt for fluid milk. While the in-quota duties are generally low, tariff rates applicable to over-quota imports are prohibitively high, ranging from 202% for skim milk powder to 246% for cheese and 299% for butter.

A strict control of supplies from domestic production and imports allows prices paid to producers to be supported at levels marginally above the costs of production. The Canadian Dairy Commission annually reviews and establishes a target price for industrial milk. This target price is supported by market intervention for butter and skim milk powder (SMP) at support prices set similarly on an annual basis. The support prices have been increasing steadily over the last decades. In 2009, the support prices for butter and SMP were raised to Can$7102.4 and

Can$6178.3 per tonne, respectively. For a comparison, the respective prices in 2000 stood at 5540.7 and Can$4684.2 per tonne, which translates to a 28 and 32% increase in the support prices over the 2000–09 period. (Over the same period, 2000–09, in the European Union the butter and SMP intervention prices declined by 25 and 15%, respectively. Using the October 2009 Can$/Euro exchange rate of 0.65, the butter and SMP support prices of Canada in 2009 would amount to €4611 and €4011 per tonne, respectively. The corresponding intervention prices for butter and SMP in the European Union were €2462 and €1764 per tonne, respectively.)

In 1995, a supplementary scheme was introduced that provided for the pricing of five classes of milk by virtue of a new permit system. The change allowed dairy processors to purchase surplus milk (over the quota milk) at a discount rate, determined by the government, for the production of dairy products for exports. The United States, joined by New Zealand, claimed that this in fact constituted an export subsidy, that it was in violation of Canada's commitments under the Uruguay Round, and requested investigation by a World Trade Organization (WTO) compliance panel. In December 2002, the WTO confirmed that Canada's approach to the export of dairy products constituted an export subsidy. On 9 May 2003, Canada announced that it had entered into an agreement with the United States and New Zealand, and eliminated the subsidies that violated the WTO rules.

The supply management system in Canada is sometimes used as an example of a functioning stable system that enables milk producers to receive good prices. Supply management might be considered the second best option in a narrow sense as it alleviates surplus accumulation resulting from a high market price support, but it is unlikely to be the long-term solution in the face of rapid technological and structural developments throughout the world. The problems linked to supply management include the inefficiencies that the system may create, the costs that it imposes on consumers, the difficulties and costs of administration that may arise for governments, the difficulty in setting the quota at a level that would match consumption, the vested interests that it generates (quota rent), and importantly the need to continue the policies of high border measures.

Japan

Background

Japanese domestic dairy policy focuses mainly on supporting milk destined for the production of dairy products, which procures a lower price than drinking milk and is subject to international competition. Up until 2001, government support was provided mainly through three programs: price support, voluntary program to limit supply, and import tariff rate quotas. Price support was administered via a system of deficiency payments on manufacturing-milk introduced in 1966. The deficiency payments, defined as the difference between a guaranteed price and the price paid by dairy plants for milk used in processing (standard transaction price), were limited to an annually fixed quota volume and to designated products such as butter, SMP, and condensed milk. A voluntary production quota for liquid milk was initiated in 1979 in an effort to regulate shipments from Hokkaido – the low-cost production region with over 80% of milk used for manufacturing – to higher-cost production regions. This quota is determined by the Central Council of Dairy Cooperatives and allocated between prefectural cooperatives, who in turn allocate a quota to each farmer. The allocation between prefectures takes into account production of the previous year and planned production for the coming year. Since the voluntary production planning system has no legal binding power, some 5% of dairy farmers choose to operate outside the production guidelines. As measured by the PSE, total transfers to dairy farmers relative to total gross receipts amounted to 73% in the period 2002–04. The support has declined from the levels calculated in the mid-1980s although the Japanese dairy sector remains among the most heavily supported in the world.

A Change in Dairy Domestic Policy in 2001

In April 2001, a policy change was introduced to deal with the rigidity of the guaranteed price system, increased budgetary cost, and the additional pressures to reduce domestic support resulting from Japan's commitments under the Uruguay Round. The policy abolished the guaranteed price and the standard transaction price along with the deficiency payment scheme, and a new direct-payment program was introduced instead; but the annually determined manufacturing-grade milk quotas were kept in place. The move away from a market-intervention system to a payment-based system was designed to improve the market orientation of dairy farms.

Producers' direct payments were to be set annually in light of the unit rate paid in the previous year and the changes in cost of raw milk production. In 2001, in order to ensure a smooth adjustment to the new policy, the direct payments were set equal to deficiency payments of 2000 at ¥10.3 per kg. The amount of manufacturing-milk eligible for payment was set at 2.27 mt. The evolution of deficiency payments and, from 2001, direct payments together with the eligible quantities is illustrated in **Figure 3**. The move to a more market-oriented system was compensated for by the introduction of emergency measures to protect farmers from

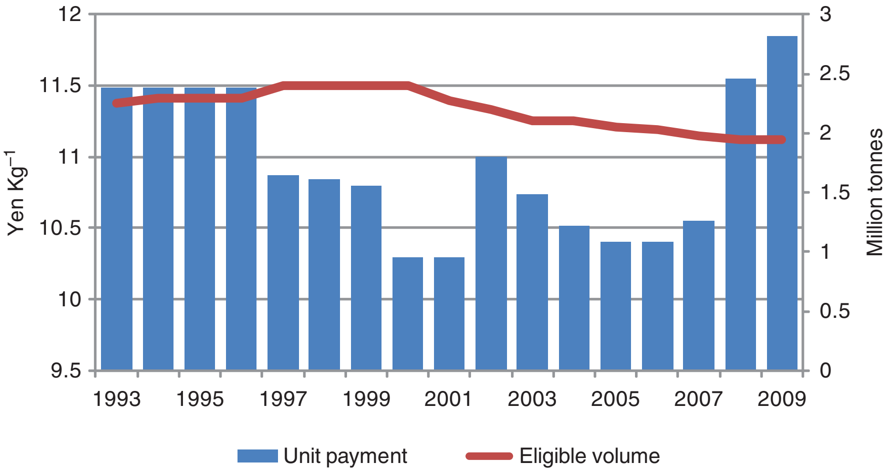

Figure 3 The evolution of deficiency and direct payments for milk together with eligible quantities, in Japan. Source: MAFF, Japan. Deficiency payments until 2000; direct payments afterward.

unforeseen fluctuations in the price of manufacturing milk. If the average market price falls, then 80% of the difference between the average market price and the base price (the average transaction price during the previous 3 years) is to be compensated from an income stabilization fund to which producers and the state contribute at the ratio of 1:3. An additional system of direct payments was introduced to provide incentives for environmental conservation under the land using-type dairy farming promotion project and the direct payment system in hilly and mountainous districts.

Japan manages imports of dairy products under TRQs by import licensing and state trading. Quantities under import license are allocated by the Ministry of Agriculture, Forestry and Fisheries (MAFF) to private importers based on historical records. The quota access at preferential tariffs for SMP and butter are set at 116 and 1.9 kt, respectively. Typically these quotas remain significantly underfilled. The in-quota *ad valorem* tariffs are set at 16, 24, and 35% levels for SMP, whole milk powder, and butter respectively. In addition to in-quota tariffs, the government of Japan or its sales agents are able to charge the so-called markup, which can amount to 392, 413, and 594% for SMP, whole milk powder, and butter respectively.

The tariffs for out-of-quota imports are set prohibitively high at 210, 316, and 733% levels for SMP, whole milk powder, and butter, respectively (Agricultural Market Access Database (AMAD)). Cheese imports to Japan are not subject to quota. There are various import tariffs for cheese depending on the use of the product, but the average rate is about 31.2%.

Although the policy change toward direct payments is in the right direction, the change is relatively small given the design of the policy. The support remains very high and continues to be paid by consumers. The primary reason for the very modest impact of the new policy is the lack of changes to dairy trade policy, which keeps Japan's dairy industry highly protected from cheaper imports. Due to very high border measures, the majority of support still falls under the market price support category. In 2008, the market price support stood at 93% of all SCTs.

Australia

Background

With the Kerin plan in 1986 and the Crean plan in 1992, Australia began a reform process of dairy policies including a gradual reduction in support and a planned elimination of support for manufacturing milk by 1 July 2000. In 1995, a redesigned plan was introduced to ensure that Australia complied with its WTO commitments on export subsidies under the Uruguay Round. The domestic market support (DMS) scheme was restructured so as to ensure that support was provided independently of export sales. In addition to this reform of support policies for manufacturing milk, a regulatory reform process for market milk was initiated in 1995, stipulating that in each state only farm gate price controls would remain in place by January 1999. In July 1999, a review of market milk regulations in Victoria concluded that there was no net public benefit from retaining farm gate price controls. An industry restructuring plan was developed to avoid possible interstate price wars and an industry collapse, which was implemented on 1 July 2000. Following the industry deregulation, support to the Australian dairy sector has declined dramatically and, measured by the PSE, the value of transfers to the dairy industry relative to gross farm receipts fell to 15% in the period 2002–04 (**Figure 1**). As measured by the SCT, after the deregulation, the direct market support to dairy industry has dropped to zero (**Figure 2**).

Policy Reform of the Dairy Industry in 2000 and beyond

A new policy reform package was introduced on 1 July 2000, which removed simultaneously the DMS scheme and fresh milk regulations, and allowed the market to determine milk prices. At the same time, a structural adjustment package was introduced through the Dairy Industry Adjustment Act to help producers to cope with the adjustment to lower prices or to choose to leave the industry. The adjustment package was to be funded by a levy of 11 cents (A$) per liter on all domestic sales of fresh milk for 8 years until the package would be fully funded.

The individual adjustment programs were called the dairy industry adjustment package, the dairy structural adjustment program, the dairy exit program, and the dairy regional assistance program. Dairy farmers were eligible for dairy structural adjustment program assistance and received a fixed quarterly payment over 8 years, with payments being based on milk production in 1998–99, and subject to income tax. Producers could also opt to leave the dairy industry altogether, and receive an exit payment of up to A$45 000 tax-free under the dairy exit program. The conditions attached to the program prevented the farmers from reentering the industry at a later date. Finally, the dairy regional assistance program was intended to assist dairy-dependent communities in generating alternative employment opportunities and to deal with any social dislocation from deregulation.

After the reform, the dairy industry has become fully exposed to world market conditions and emerged as a globally cost-competitive industry. However, following the deregulation, the dairy sector not only had to absorb the reform adjustment pressures but also had to cope with a series of severe droughts that resulted in increased herd contraction. Cow inventories in Australia increased in 2008/09 for the first time in 7 years, however contracted again in 2009/10 and the future industry growth remains sensitive to availability and management of water supply. To address these issues, in 2008 and 2009, the Australian government has strengthened the water policy reforms and environmental programs, and also announced an initiative, Australia's Farming Future, to help the industry through research and information to manage the impact of climate changes. The Australian Government is also committed to implementing the emissions trading scheme in 2011, which can be expected to impact the dairy sector. Nevertheless, at the same time, a program concentrating on reducing emissions from livestock has been initiated focusing on research into alternative feeds to reduce methane production or genetic approaches to developing low-emitting animals.

The industry does not use export subsidies to increase its market share of dairy products, although it has a strong focus on export sales. In 2009, the Australian government has announced a reform of the system of export quota allocations to the United States and the European Union. Under tariff rate quotas, certain amounts of Australian dairy products can be exported into the United States and the European Union at reduced or zero tariffs. The old system of distributing fixed shares of quota based on historical entitlements is replaced by a system in which exporters receive a share of quota based on 3-year rolling averages of export performance.

Australia has also entered into a number of free trade agreements (FTAs) that have been or are in the process of negotiation. The trade barriers between Australia and New Zealand were fully removed in the Closer Economic Relations Trade Agreement, which came into effect already on 1 January 1983. Australia has FTAs also with Singapore, Thailand, the United States, and Chile. Most recently, the negotiations between ASEAN, Australia, and New Zealand for a free trade agreement (AANZFTA) were concluded on 28 August 2008, and the agreement was signed on 27 February 2009. This was the largest FTA Australia signed to that date. A separate agreement is being negotiated with Malaysia, and there are plans to negotiate an FTA with Indonesia. FTA agreements are also being pursued with China, Japan, and the Gulf Cooperation Council.

New Zealand

Background

Prior to 1984, the support to farmers in New Zealand went as high as 40% of the farmers' income. Domestic farm support policies were scaled down dramatically during the 1980s with input subsidies eliminated in 1984 and government involvement in calculation of product prices withdrawn in 1988. The main dairy policy issue following the deregulation of 1984 was related to the export monopoly of the New Zealand Dairy Board (NZDB) and the potential for indirect subsidization of dairy exports. This potential existed as Section 27 of the Dairy Board Act allowed for pooling of revenues from domestic and export markets and, thus, cross-subsidization of lower revenue from export sales by higher revenue from domestic sales. This section was abolished in 1998. The dairy industry is one the most important elements of the New Zealand economy accounting for about one quarter of New Zealand's total export earnings. Measured by the PSE, total transfers to dairy farmers relative to gross farm receipts were close to zero in 2002–04 (**Figure 1**). As measured by the SCT, the direct market support to the dairy industry has been zero for more than 20 years (**Figure 2**).

Dairy Industry Restructuring Act

On 9 April 2001, the New Zealand Government passed the Dairy Industry Restructuring Act (DIRA), which agreed to the formation of a large cooperative Fonterra, originally called GlobalCo, through the merger of most of New Zealand's cooperative dairy processing companies. The act also stipulated that following the merger, the new company will absorb the activities of the NZDB. The NZDB, established through the Dairy Board Act in 1961, controlled the marketing of all export dairy products and was the largest exporter in New Zealand. An amendment to the Dairy Board Act in 1996 brought the status of NZDB closer to that of a company in which milk processing cooperatives own shares in proportion to their milk deliveries. Nevertheless, the NZDB remained subject to criticism for its export monopoly power. Given the trade agreements and its export power, the NZDB was able to extract quota rents from dairy exports (e.g., to the EU), which were then passed back to individual producers thus increasing the farmers' marginal returns. The DIRA ended the statutory export monopoly of NZDB and established 11 regulated dairy export markets. On a transitional basis, the act provided Fonterra with exclusive export access to these markets for a fixed period of time. In 2007 the New Zealand Government reviewed the regulated export market established in the DIRA and started the deregulation process to be concluded over the period 2007–10.

The DIRA also provided for a regulation that aimed to protect firms from Fonterra's monopoly pricing. The provision required that 5% of Fonterra's milk be made available at a predetermined price to other independent processors to allow for a level playing field. The review of this regulation conducted in 2008 concluded that independent processors were able to procure milk at a lower price than what Fonterra paid to its farmers. A new mechanism was proposed under the Dairy Industry Restructuring Bill; this bill (in reading as of October 2009) proposes that the margin be charged from the 2010/2011 dairy season and also provides for raw milk to be allocated through auctions in later years.

Government policy in New Zealand affects the dairy industry mainly via policy measures addressing agri–environmental issues. For example, the dairying and clean streams accord, which was agreed between Fonterra and the New Zealand Government in 2003, aims to achieve clean water, including streams, rivers, lakes, and ground water, and wetlands in dairying areas. Moreover, in September 2007, the government released a comprehensive statement on climate change and a range of initiatives across all sectors, including the Emissions Trading Scheme (ETS). Agriculture is likely to be part of the scheme from 2013.

New Zealand is the largest exporter of butter, SMP, and whole milk powder, and the second largest exporter of cheese in the world. New Zealand achieves this position without relying on production or market subsidies and without protecting the domestic market from overseas competition. In the absence of progress in lowering trade barriers on a multilateral level, New Zealand is seeking trade agreements on a bilateral basis. Apart from New Zealand's free trade agreement with Australia (already in place since 1983), more recent FTAs were concluded with Singapore, Thailand, the Trans-Pacific Partnership (involving Singapore, Brunei, and Chile), China, and ASEAN (signed in February 2009). Negotiations are currently underway with Malaysia, Hong Kong, and the Gulf Co-operation Council (Saudi Arabia, UAE, Oman, Qatar, Bahrain, and Kuwait). Negotiations are also due to commence for the enlargement of the Trans-Pacific Partnership and bilateral FTAs with Korea and with India.

Codex Alimentarius

C Heggum, Danish Dairy Board, Aarhus, Denmark

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Codex Alimentarius is Latin for food code and refers today to the international food code established under the United Nations. It is a collection of internationally adopted food standards that constitute a global reference point for national food legislators and control agencies, the international food trade, and food handlers and consumers. The code has a great impact on the approach to food quality management throughout the world.

The code is being developed by the Codex Alimentarius Commission (CAC), which is an international organization run jointly by the Food and Agriculture Organization (FAO) and the World Health Organization (WHO). One hundred and seventy-eight individual countries are members of the CAC (end of 2008). In addition, about 160 other international intergovernmental and international non-governmental organizations contribute to the work. The CAC's objective is to establish standards, codes of practices, guidelines, and recommendations concerning foods aimed at protecting consumer's health, ensure fair practices in trade, and facilitate international trade.

With the establishment of the World Trade Organization (WTO), the Codex Alimentarius has gained importance due to the fact that two WTO Agreements (the Agreement on the Applications of Sanitary and Phytosanitary Measures (SPS) and the Agreement on Technical Barriers to Trade (TBT)) refer to Codex Alimentarius texts as being the reference for dispute settlements and for application by national legislation.

The Establishment

The Need for Harmonization of National Food Regulations

The need for international food regulation has developed with international trade. Quality standards for individual commodities have been known since ancient times, but the first general food laws were established in the 1800s.

At the beginning of the 1900s, the establishment of international food standards began; it was of growing concern to food traders worldwide that the national standards and regulations developing independently (and sometimes spontaneously) in individual countries started to create trade barriers. As a response to this development, trade associations that were formed as a reaction to such barriers pressured governments to harmonize their various food standards so as to facilitate trade in safe foods of a defined quality. One of the earliest such associations was the International Dairy Federation (IDF), founded in 1903.

After World War II, there was heightened international concern about the direction being taken in the field of food regulation. Countries were acting independently and there was little, if any, consultation among them with a view to harmonization. In addition, and as a reaction to the food supply situation during the 1940s, many attempts were made to protect and support domestic food production. Food regulations in different countries were conflicting and contradictory, in particular with regard to nomenclature, and much legislation was not based on scientific knowledge.

Many efforts have been made to harmonize national food regulations. In the dairy field, the IDF developed during the 1950s a vast number of codes and standards intended to be applied by the dairy sector and to form the basis of national legislation. These efforts resulted in two initiatives being taken at the government level:

- the establishment of the 'Stresa Convention' – a multilateral agreement between a number of European countries that governed the naming and composition of a number of individual cheese varieties (*see* **Policy Schemes and Trade in Dairy Products**: Standards of Identity of Milk and Milk Products);
- the establishment of the Joint FAO/WHO Committee of Government Experts on the Code of Principles Concerning Milk and Milk Products (the 'Milk Committee') – a worldwide committee established to develop international identity standards for milk products, most of them prepared by IDF, within the framework of the Code of Principles Concerning Milk and Milk Products (*see* **Policy Schemes and Trade in Dairy Products**: Standards of Identity of Milk and Milk Products).

Catalyzed by the success of the Milk Committee, the 1961 FAO Conference decided to establish the Codex Alimentarius. The CAC was established in 1962 to govern the work. Due to the importance of the role of WHO in all health aspects of food, the WHO joined in 1963.

Since its founding, many food standards, codes of hygienic and technological practice, and maximum residue limits (MRLs) for food contaminants have been established by Codex Alimentarius (**Figure 1**).

The Codex Alimentarius

204 food standards for commodities

47 codes of hygienic or technological practice

2930 maximum limits for 218 evaluated pesticides

1112 maximum levels for 292 evaluated food additives

441 maximum residue levels for 49 evaluated veterinary drugs

Guidelines for 12 contaminants

Figure 1 Standards, codes, and recommendations established by Codex Alimentarius.

The Milk Committee, since its establishment in 1958, was integrated into the Codex Alimentarius system. However, its rules and procedures were different from those of Codex Alimentarius for many years. As late as 1993, the Milk Committee was replaced by the 'Codex Committee for Milk and Milk Products' and the rules and procedures were aligned with those applicable for the rest of the Codex system.

The Scientific Basis

The Codex Alimentarius is science based. Experts and specialists in a wide range of disciplines contribute to every aspect of the code to ensure that its standards withstand the most rigorous scientific scrutiny.

Much work is carried out in the form of collaborative studies between individual scientists, laboratories, institutes and universities, and joint FAO/WHO expert committees and consultations.

The membership of expert consultations is of critical importance. The credibility and acceptability of any conclusions and recommendations depend to a very large degree on the impartiality, scientific skill, and overall competence of the members who formulate them. For this reason, care is taken in the selection of experts invited to participate. Those selected must be preeminent in their specialty, have the highest respect of their scientific peers, and be impartial and objective in their judgment. They are appointed in their own personal right – not as government representatives or as spokespeople for organizations.

The Joint FAO/WHO Expert Committee on Food Additives (JECFA), the Joint FAO/WHO Meetings on Pesticide Residues (JMPR), and the Joint FAO/WHO Expert Meetings on Microbiological Risk Assessment (JEMRA) have generated a large amount of scientifically based food data.

JMPR was established in 1963 with the task of recommending MRLs for pesticide and environmental contaminants in specific food products. JMPR members are independent scientists who are expert in aspects of pesticides and environmental chemicals and their residues. There is close cooperation between JMPR and the Codex Committee on Pesticide Residues (CCPR). CCPR identifies substances requiring priority evaluation. After JMPR evaluation, CCPR discusses the recommended MRLs and, if they are acceptable, forwards them to the Commission for adoption as Codex MRLs.

JECFA was established in 1955 with the task of considering chemical, toxicological, and other aspects of contaminants and residues of veterinary drugs in foods for human consumption. JECFA provides the Commission and other Codex bodies with expert advice relating to food additives, contaminants, and residues of veterinary drugs. The Codex Committee on Food Additives (CCFA), the Codex Committee on Contaminants in Foods (CCCF), and the Codex Committee on Residues of Veterinary Drugs in Foods (CCVDF) identify food additives, contaminants, and veterinary drug residues that should receive priority evaluation and refer them to JECFA for assessment before incorporating them into Codex standards.

JEMRA was established in 2000 in response to the increasing need for risk-based scientific advice and information and tools to undertake microbiological risk assessment. The objectives of JEMRA are the development and optimization of the utility of microbiological risk assessment (MRA) as a tool to inform actions and decisions aimed at improving food safety and to make it equally available to both developing and developed countries.

Purpose and Organization

The task of creating a food code is immense. Food standards need to mirror the dynamic environment in which they will be applied. Product development, changes in trade and consumption patterns, consumer perception, and scientific progress make creation and review of food standards virtually endless.

Furthermore, it requires more effort and resources to create standards that, on the one hand, aim at protecting consumers and ensuring fair practices in the sale of food and, on the other hand, facilitating trade. The need to involve scientific experts from consumers' organizations, expertise from production and processing industries, and food control administrators and traders is obvious.

The finalization of food standards and their compilation into a code that is credible and authoritative requires extensive consultation followed up by confirmation of final results and, sometimes, a compromise to satisfy divergent but scientifically sound views.

The above comprehensive process makes developments slow. On the other hand, once a standard has been adopted, it reflects worldwide consensus and is therefore useful in practice.

Objectives of Codex

The objective of Codex is to conduct the Joint FAO/WHO Food Standards Programme, the purpose of which is

(a) to protect the health of the consumers;
(b) to ensure fair practices in the food trade;
(c) to promote coordination of all food standards work undertaken by international governmental and non-governmental organizations;
(d) to determine priorities and to initiate and guide the preparation of draft standards through and with the aid of appropriate organizations; and
(e) to finalize food standards and to publish them in a Codex Alimentarius as either regional or worldwide standards.

Structure of Codex

The CAC is the supreme body of Codex Alimentarius. It meets every year, alternately at FAO headquarters in Rome and at WHO headquarters in Geneva. Plenary sessions are attended by as many as 800 people. Representation at sessions is on a country basis. Senior officials appointed by their governments lead national delegations. Delegations may, and often do, include representatives of industry, consumers' organizations, and academic institutes. A number of international governmental and non-governmental organizations also attend in an observer capacity. Although they are 'observers', the tradition of the CAC allows such organizations to put forward their points of view at every stage except in the final decision, which is the exclusive prerogative of Member Governments.

The Commission is empowered to establish three kinds of subsidiary bodies:

1. Codex Committees, which prepare draft standards for submission to the Commission. These are classed as either General Subject Committees or Commodity Committees.

   The work of the General Subject Committees has relevance for all foods and applies across the board to all commodities. Therefore, these are sometimes referred to as 'horizontal committees'. They develop all-embracing concepts and principles applying to foods in general, specific foods, or groups of foods, endorse or review relevant provisions in Codex commodity standards, and, based on the advice of expert scientific bodies, develop major recommendations pertaining to consumers' health and safety. Currently, there are 10 General Subject Committees (see **Figure 2**).

   Commodity Committees have responsibility for developing standards for specific foods or classes of food. In order to distinguish them from the horizontal committees and recognize their exclusive responsibilities, they are often referred to as 'vertical committees'. Currently, there are 11 Commodity Committees (see **Figure 2**).
2. Coordinating Committees, through which regions or groups of countries coordinate food standards activities in the region, including the development of regional standards. Coordinating Committees play an invaluable role in ensuring that the work of the Commission is responsive to regional interests and to the concerns of developing countries. Currently, there are six Coordinating Committees (see **Figure 2**).
3. *Ad Hoc* International Governmental Task Forces are established to consider closely defined issues within a time-limited period. Currently, three such Task Forces are operating (see **Figure 2**).

Each worldwide committee and task force is hosted by a member country, which is chiefly responsible for the maintenance and administration cost of the committee and for providing its chairperson. Regional committees have no standing host countries; the Chair is elected at meetings.

The Codex Step Procedure

Typically, the Codex work program consists of revision of older, outdated texts and the development of new texts. The latter is usually initiated with the consideration of discussion papers.

Once a standard, a code, or a guideline is identified as a potential subject for work, it will be developed in three phases, normally comprising eight formal steps (**Figure 3**):

- the decision to initiate work (constitutes step 1), resulting in the adding of the subject to the work program and allocation of the responsibility to prepare a Proposed Draft Codex Standard, a Proposed Draft Codex Code of Practice, a Proposed Draft Codex Guideline, or another proposed draft Codex recommendation;
- the process of furnishing a draft text (constitutes steps 2–5), resulting in preparing an almost finalized draft, which is adopted as a Draft Codex Standard, a Draft

Codex Code of Practice, a Draft Codex Guideline, or another draft Codex recommendation; and

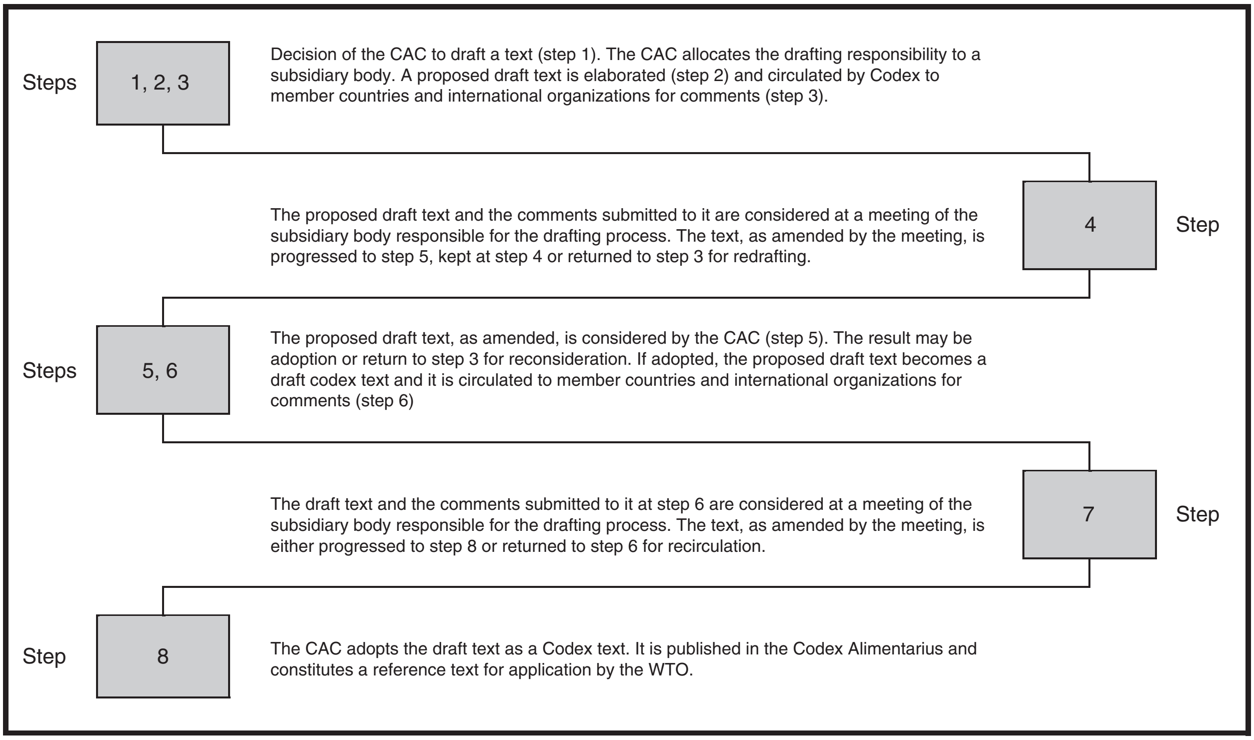
- the process of finalizing a text (constitutes steps 6–8), resulting in a Codex Standard, a Codex Code of Practice, a Codex Guideline, or another Codex recommendation.

Initiation of New Work

A proposal for a standard or another text can be submitted by any member country or any of the interested international organizations registered. In the dairy field, most proposals derive from the work of the IDF.

Prior to the approval of new work a project document that details the purpose and scope, its relevance, main aspects to be covered, need for any expert scientific advice, and timeline for completion is required. Furthermore, an assessment of the formal criteria for the establishment of work priorities is needed. For commodity standards, these are

1. consumer protection from the point of view of health and fraudulent practices;
2. volume of production and consumption in individual countries and volume and pattern of trade between countries;
3. diversification of national legislation and apparent resultant impediments to international trade;
4. international or regional market potential;
5. amenability of the commodity to standardization;
6. coverage of the main consumer protection and trade issues by existing general standards;



Decision of the CAC to draft a text (step 1). The CAC allocates the drafting responsibility to a subsidiary body. A proposed draft text is elaborated (step 2) and circulated by Codex to member countries and international organizations for comments (step 3).

The proposed draft text and the comments submitted to it are considered at a meeting of the subsidiary body responsible for the drafting process. The text, as amended by the meeting, is progressed to step 5, kept at step 4 or returned to step 3 for redrafting.

The proposed draft text, as amended, is considered by the CAC (step 5). The result may be adoption or return to step 3 for reconsideration. If adopted, the proposed draft text becomes a draft codex text and it is circulated to member countries and international organizations for comments (step 6)

The draft text and the comments submitted to it at step 6 are considered at a meeting of the subsidiary body responsible for the drafting process. The text, as amended by the meeting, is either progressed to step 8 or returned to step 6 for recirculation.

The CAC adopts the draft text as a Codex text. It is published in the Codex Alimentarius and constitutes a reference text for application by the WTO.

Figure 3 Standard elaboration procedure of Codex texts.

7. number of commodities that would need separate standards indicating whether raw, semiprocessed, or processed; and
8. work already undertaken by other international organizations in this field.

The first drafting is normally assigned to the Codex Secretariat, a Member Government, an *ad hoc* working group established among interested Member Governments and organizations, or, in the case of dairy standards, the IDF. Commodity standards follow a uniform format. The structure of codes of practices and guidelines varies according to the nature of the content and the traditions within the Codex Committee where the draft is developed.

A draft Codex text is sent to governments and international organizations a number of times in a stepwise procedure, which, if completed satisfactorily, results in the draft becoming a ‘Codex standard’. In an accelerated procedure, the number of steps required for the development of a standard varies from a maximum of eight to a minimum of five. In many cases, steps are repeated. Most standards take 8 years to develop.

Revision of Codex Standards

The Commission and its subsidiary bodies are committed to revision of Codex standards and related texts as necessary to ensure that they are consistent with and reflect current scientific knowledge. The procedure for revision follows the same procedure as used for the initial preparation of new standards.

The Commission can, however, decide to omit any other step or steps of the procedure where an amendment proposed by a Codex Committee is either editorial in nature or consequential to provisions in similar standards adopted.

Application and Role of Codex Texts

The Codex Alimentarius has relevance to the international food trade and also to domestic legislation and regulation. With respect to the ever-increasing global market, in particular, the advantages of having universally uniform food standards are self-evident. Texts developed by the CAC are applied in the following contexts:

1. as reference texts for the SPS and TBT Agreements of the WTO;
2. as reference texts and/or foundation for national legislation, regional regulation, and trade agreements; and
3. as reference texts for commercial trading parties.

SPS and TBT Agreements of the WTO

Both the SPS and TBT Agreements acknowledge the importance of harmonizing standards internationally so as to minimize or eliminate the risk of national legislation and regulation becoming barriers to trade.

The SPS Agreement

In its pursuance of harmonization, the SPS Agreement has identified and chosen the standards, guidelines, and recommendations established by the CAC for food additives, residues of veterinary drugs and pesticides, contaminants, methods for analysis and sampling, and codes and guidelines of hygienic practice. In other words, Codex texts are considered scientifically justified and have become an integral part of the legal framework as accepted benchmarks against which national measures and regulations are evaluated (**Figure 4**).

Codex texts have already been used as the benchmark in international trade disputes, and it is expected that they will be used increasingly in this regard.

As a consequence, interest in Codex activities and participation at the meetings of governments and international inter- and non-governmental organizations has increased.

There are no obligations for a government to use Codex standards, only an encouragement. However, as Codex texts by definition are recognized as being scientifically based, a government need not perform a formal risk assessment (*see* **Risk Analysis**) if a Codex recommendation is followed. Thereby, a government can save considerable resources. Otherwise, a government can be faced with the SPS requirement to defend and justify according to scientific evidence every deviating detail in their national legislation.

This possibility to choose Codex standards provides the opportunity for countries with economic limitations to follow Codex recommendations and simultaneously comply with the SPS requirements. In countries where the necessary resources are available, additional risk assessment might be carried out in order to justify desired deviations from Codex. A government can only implement stricter food safety requirements than those recommended by Codex, and if justified. This means that Codex recommendations relating to food safety serve as minimum provisions.

The TBT Agreement

The basic principle of the TBT Agreement is that any measure should be enforced only if a so-called legitimate objective exists (e.g., prevention of deceptive practices, meet quality and performance requirements). The legitimate objective should be transparent in order to avoid disguised protection of domestic production and to avoid arbitrary decisions.

The TBT Agreement does not make reference to any particular international organization to be used as the 'benchmark'. With respect to food, however, it is generally recognized that Codex Alimentarius serves this function (**Figure 5**).

It is relatively easy for a government to justify that a particular part of an international standard, for example, a

The SPS Agreement

The Agreement on the Application of Sanitary and Phytosanitary Measures acknowledges that governments have the right to take sanitary and phytosanitary measures necessary for the protection of human health. However, the SPS Agreement requires them to apply those measures only to the extent required to protect human health. It does not permit Member Governments to discriminate by applying different requirements to different countries where the same or similar conditions prevail, unless there is sufficient scientific justification for doing so.

Article 2.2 of the SPS Agreement states:

"Members shall ensure that any sanitary and phytosanitary measure is applied only to the extent necessary to protect human, animal or plant life or health, is based on scientific principles and is not maintained without sufficient scientific evidence ..."

Article 3.1 of the SPS Agreement states:

"To harmonize sanitary and phytosanitary measures on as wide a basis as possible, Members shall base their sanitary and phytosanitary measures on international standards, guidelines or recommendations, where they exist, except as otherwise provided for in this Agreement."

Figure 4 The Agreement on the Applications of Sanitary and Phytosanitary Measures (SPS).

The TBT Agreement

The Agreement on technical barriers to trade seeks to ensure that technical regulations and standards, including packaging, marking, and labeling requirements and analytical procedures for assessing conformity with technical regulations and standards do not create unnecessary obstacles to trade.

Article 2.4 of the TBT Agreement states

"Where technical regulations are required and relevant international standards exist or their completion is imminent, Members shall use them, or the relevant parts of them, as a basis for their technical regulations except when such international standards or relevant parts would be an ineffective or inappropriate means for the fulfilment of the legitimate objective pursued, for instance because of fundamental climatic or geographical factors or fundamental technical problems."

Article 2.5 of the TBT Agreement states

".... Whenever a technical regulation is prepared, adopted or applied for one of the legitimate objectives......., and is in accordance with relevant international standards, it shall be rebuttably presumed not to create an unnecessary obstacle to international trade."

Article 2.6 of the TBT Agreement states

"With a view to harmonizing technical regulations on as wide a basis as possible, Members shall play a full part, within the limits of their resources, in the preparation by appropriate international standardizing bodies of international standards for products for which they have either adopted, or expect to adopt, technical regulations."

Figure 5 The Agreement on Technical Barriers to Trade (TBT).

labeling requirement, is not appropriate in a particular country or that additional requirements are needed locally. It is allowed to deviate from Codex TBT-related provisions in both stricter and less strict directions, if an appropriate legitimate objective exists. Codex regulations, which are not aiming at protecting human health, are therefore merely to be seen as guidelines.

Codex standards may not be the only body that provides reference provisions, as objectives of the TBT Agreement are broader than those of Codex Alimentarius.

National Legislation and Regulation

The harmonization of food standards is generally viewed as a prerequisite to the protection of consumer health as well as allowing the fullest possible facilitation of international trade. For that reason, both SPS and TBT Agreements encourage the international harmonization of food standards.

While the growing world interest in all Codex activities clearly indicates global acceptance of the Codex philosophy – embracing harmonization, consumer protection, and facilitation of international trade – in practice, it is difficult for many countries to accept Codex standards in the statutory sense. Differing legal formats and administrative systems, varying political systems, and sometimes the influence of national attitudes and concepts of sovereign rights impede the progress of harmonization and deter the acceptance of Codex standards.

Most countries have, however, responded by introducing long-overdue or reviewed/aligned existing food legislation and Codex-based national standards and by establishing or strengthening food control agencies.

Regional Regulation and Trade Agreements

The Uruguay Round Agreements provide groups of member countries the opportunity to enter into trade agreements among themselves for the purpose of liberalizing trade. So far, three such agreements have been established, all of them having adopted measures consistent with the principles embraced by the SPS and TBT Agreements and which relate to Codex standards:

- NAFTA (North American Free Trade Agreement between Canada, the United States, and Mexico) includes two ancillary agreements dealing with sanitary and phytosanitary measures and technical barriers to trade. With regard to SPS measures, Codex standards are cited as basic requirements to be met by the three member countries in terms of health and safety aspects of food products.
- The Food Commission of MERCOSUR (Treaty of Asunción establishing the Southern Common Market between Argentina, Brazil, Paraguay, and Uruguay)

recommends a range of Codex standards for adoption by member countries and is using other Codex standards as points of reference in continuing deliberations.

- APEC (Asia–Pacific Economic Cooperation between 18 Asian and Pacific countries) has drafted a Mutual Recognition Arrangement on Conformity Assessment of Foods and Food Products. This calls for consistency with SPS and TBT requirements as well as with Codex standards.

In addition, the EU (European Union) directives and regulations frequently refer to the Codex Alimentarius as the basis for their requirements.

Commercial Trade

Besides providing the reference for national legislation, the texts established by the CAC, in particular the commodity standards, are frequently used as references in commercial trade, independent of legislation. Such reference points may be used for price setting and for specifying any deviations agreed.

Codex Texts Relevant for Dairy Production and Trade

The Codex Alimentarius includes general texts applicable across-the board to all foods (general standards, codes of hygienic practices), other codes of practices (technology, control), and commodity-specific texts (commodity standards, commodity-specific codes of practices).

Milk Product Standards

When Codex decided to adjourn the old Milk Committee in 1993 and replace it with the Codex Committee on Milk and Milk Products, it was agreed that the file of standards established earlier needed extensive revision. This task has almost been accomplished. Updated versions of the milk product standards are as follows (*see* **Policy Schemes and Trade in Dairy Products**: Standards of Identity of Milk and Milk Products):

- butter (2006);
- dairy fat spreads (2008);
- milk fat products (including butter oil, anhydrous milk fat, and ghee) (2006);
- cream and prepared creams;
- cheese (2008);
- unripened cheese, including fresh cheese (2001);
- cheese in brine (1999);
- individual cheese varieties (Mozzarella, Cheddar, Danbo, Edam, Gouda, Havarti, Samsø, Emmental, Tilsiter, Saint-Paulin, Provolone, Cottage Cheese, Coulommiers, Cream Cheese, Camembert, Brie, Extra hard Grating) (2008);
- whey cheese (2006);
- fermented milks (2008);
- evaporated milks (1999);
- sweetened condensed milks (1999);
- milk powders and cream powders (1999);
- edible casein products (2001);
- whey powders (2006); and
- lactose (now part of the standards for sugars) (1999).

Revisions have not yet been finalized for named variety processed cheese, processed cheese, and processed cheese preparations. The nonrevised standards date back to the 1960s and 1970s but are still valid as references.

Other Commodity Standards

From a dairy perspective, international standards for non-dairy foods that contain significant dairy ingredients and/or are intended to replace dairy products in consumption patterns are of interest. The most important of these commodities regulated by Codex are

- standards for chocolate, cocoa butter, coconut milk and three standards covering various blends of preserved skimmed milk and vegetable fat;
- standards for infant formula, follow-up formula, canned baby foods, and processed cereal-based foods for infants and young children; and
- vegetable protein products and soy protein products.

Food Hygiene

Food hygiene constitutes the cornerstone in Codex food safety activities. Microbiological hazards constitute the greatest risk for human health. In recent years, focus has been on the development of appropriate tools to assess and manage risks associated with the intake of microbiological hazards through food. New metrics have been identified and described, but they are not implemented as yet. Risk managers including Codex continue using general and specifically targeted good hygienic practices supplemented by the HACCP (Hazard Analysis and Critical Central Point) approach. Of particular interest to the dairy sector are the following Codex hygiene texts that build on well-established concepts:

- Code of Practice of General Principles for Food Hygiene (2003);
- The HACCP System and Guidelines for its Application (1997);

- Principles for the Establishment and Application of Microbiological Criteria (1997);
- Guidelines on the Application of General Principles of Food Hygiene to the Control of *Listeria monocytogenes* in Ready-to-Eat Foods (2007); and
- Code of Hygienic Practice for Powdered Formulae for Infants and Young Children (2008).

Other texts that introduce more risk-based approaches for food hygiene management include

- Code of Hygienic Practice for Milk and Milk Products (2004);
- Principles and Guidelines for the Conduct of Microbiological Risk Management (2007); and
- Guideline for the Validation of Food Safety Control Measures (2008).

From a dairy perspective, it is also worth noting the existence of the Codex Guidelines for the Preservation of Raw Milk by the Lactoperoxidase System from 1991. The guidelines for this system apply only where the infrastructure does not provide facilities for refrigeration.

Food Labeling

Labeling constitutes a significant part of most food regulations. A number of standards and guidelines for the labeling of foods, primarily prepackaged foods, have been developed. These standards and guidelines have gained widespread use worldwide and are implemented in the national legislation of most countries. For dairy products, the most relevant are

- General Standard for the Labelling of Prepackaged Foods (2008);
- General Guidelines on Claims (1991);
- Guidelines on Nutrition Labelling (2006); and
- Guidelines for Use of Nutrition and Health Claims (2008).

Among the issues currently being considered are issues related to nutrition labeling and labeling aspects of foods derived from modern biotechnology.

The General Standard for the Use of Dairy Terms is especially of interest from the dairy point of view. It provides guidance on where and how to use terms in the labeling and marketing of foods (*see* **Labeling of Dairy Products**).

Food Additives

Codex addresses food additives in horizontal texts as well as in commodity standards. Immense resources have been allocated to the establishment of a comprehensive General Standard for Food Additives. This standard is kept under constant review (*see* **Additives in Dairy Foods:** Consumer Perceptions of Additives in Dairy Products; Emulsifiers; Legislation; Safety; Types and Functions of Additives in Dairy Products).

Contaminants

Codex addresses contaminants in horizontal texts as well as in commodity standards. A comprehensive General Standard for Contaminants and Toxins in Food is the most important. This standard is kept under constant review. In addition, the Code of Practice for the Reduction of Aflatoxin B_1 in Raw Materials and Supplementary Feeding Stuffs for Milk-Producing Animals (1997) and a Code of Practice for the Prevention and Reduction of Dioxin and Dioxin-like PCB Contamination in Food and Feeds (2006) are of interest to the dairy sector.

Control of contaminant levels is also addressed in the HACCP System and Guidelines for its Application (*see* **Contaminants of Milk and Dairy Products**: Environmental Contaminants; Contamination Resulting from Farm and Dairy Practices; Nitrates and Nitrites as Contaminants).

Residues of Veterinary Drugs in Foods

Within the veterinary field, Codex has established a database on MRLs for individual foods and categories of foods, including those that specifically relate to milk. Also of specific relevance to the dairy sector are the Guidelines for the Establishment of Regulatory Programme for the Control of Veterinary Drugs in Food and a Code of Practice for Control of the Use of Veterinary Drugs (1993) and a Code of Practice to Minimize and Contain Antimicrobial Resistance.

Pesticide Residues

Codex has established a huge database on recommended maximum limits for individual foods and categories of foods.

Food Import and Export Inspection and Certification Systems

The objective of Codex to facilitate the free movement of foods is also pursued through the establishment of recommendations for food control and inspection agencies. For the dairy sector, the most relevant texts developed include

- Principles for Food Import and Export Certification (1995);
- Guidelines for Design, Production, Issuance and Use of Generic Official Certificates (2007);
- Guidelines for Food Import Control Systems (2006);
- Principles for Traceability/Product Tracing as a Tool Within a Food Inspection and Certification System (2006);

- Model Export Certificate for Milk and Milk Products (2008, amended 2010); and
- Guidelines for the Judgement of Equivalence of Sanitary Measures Associated with Food Inspection and Certification Systems (2008).

Methods of Analysis and Sampling

In principle, any criteria specified in an established Codex text need to be followed up by the identification of appropriate and validated methods of sampling and analysis. Codex frequently reviews and updates an inventory of endorsed methods (Analysis of Milk and Dairy Products).

See also: **Additives in Dairy Foods**: Consumer Perceptions of Additives in Dairy Products; Emulsifiers; Legislation; Safety; Types and Functions of Additives in Dairy Products. **Contaminants of Milk and Dairy Products**: Contamination Resulting from Farm and Dairy Practices; Environmental Contaminants; Nitrates and Nitrites as Contaminants. **Labeling of Dairy Products**. **Policy Schemes and Trade in Dairy Products**: Standards of Identity of Milk and Milk Products. **Risk Analysis**.

Standards of Identity of Milk and Milk Products

C Heggum, Danish Dairy Board, Aarhus, Denmark

© 2011 Elsevier Ltd. All rights reserved.

Introduction

When compared to other food sectors, the dairy sector has a distinct tradition of regulating production and trade through identity standards. This tradition derives primarily from the cooperative structure of the sector prevailing in the late 1800s and the beginning of the 1900s, and was introduced mainly by exporting countries in support of their trade activities and by countries with a significant domestic competition.

Since the mid 1980s, food legislation in general has been subject to substantial changes. General (horizontal) regulation supersedes commodity (vertical) legislation. This change is caused mainly by changed budgetary priorities at national governments level and by the entire focus on food safety issues. The general trend is that vertical legislation decreases, and specific dairy legislation even disappears in some countries.

Dairy legislation itself has changed as well. A few decades ago, dairy legislation was, in many countries, characterized by a positive approach (i.e., what is not specified is not permitted), the most significant result being a vast number of identity standards. Today, most dairy legislation has been aligned with the approach used for other food sectors, where everything considered safe and suitable is allowed in principle, and governed primarily by informative labeling. Identity standards fit into the latter approach by providing the specific conditions for referring to a regulated name without by themselves enforcing general restrictions.

The dairy trade needs some degree of international regulation to ensure fair practices and to minimize barriers to trade. For the enforcement of the WTO trade agreements, the international trade further needs a sound reference to enable monitoring of whether import restrictions are justified, and if not, to provide the tool for pursuing the goal of avoiding technical barriers to trade.

This article focuses mainly on the Codex standards of identity, as these have the greatest potential for widespread use.

Role of Identity Standards

Identity standards serve a multifunctional role as follows:

1. *As legislative reference texts*

   Nationally, such reference texts may be needed to facilitate understanding and management of other regulatory means (e.g., safety limits, additive provisions, inspection practices, certification, statistics, monitoring import/export quotas)

   Internationally, reference texts are intended to

   - enable the WTO system to solve trade disputes (Codex standards);
   - assist governments (and other parties concerned) in the elaboration and implementation of national food legislation in an appropriate manner; and
   - guide international trade.

2. *As facilitators of trade*

   International harmonization is a prerequisite for free movement of products, which can be achieved only through international cooperation. The result of harmonization is, as per definition, the minimization of barriers to international trade. The establishment of proper reference texts is a prerequisite for harmonization.

   If trade is to be facilitated, it is necessary to ensure that such reference texts are kept up-to-date with respect to technological, scientific, and practical knowledge. Otherwise, they may become obstacles to trade.

3. *As promoters of fair trade practices*

   The most important objective of an identity standard for milk products is to promote fair trade practices through specifying detailed conditions for the use of specific names reserved for well-defined milk products.

   International standards also assist in protecting against misleading presentations and practices, for example, a false description of the nature of the product in question.

   However, achieving international consensus is difficult, mainly because those involved in the process are also commercially competing on the world market. On the other hand, if no difficulties existed, there would be no commercial need for attempting harmonization!

   With regard to milk and milk products, the most important international text for supporting this objective is the Codex General Standard for the Use of Dairy Terms which reserves, with a few exemptions, names and terms related to dairy products for milk and milk products. Many dairy countries worldwide have established similar regulations.

Identity standards normally do not aim specifically at protecting public health, as this objective is typically regulated in more general legislative texts (e.g., Codes of Practices, hygiene rules, MRLs).

Standard Setting

National Standards

Several countries do, despite of the general change in the approach to food regulation, retain a significant number of specific identity standards for milk products in their national legislation. This is particularly the case in countries where the dairy industry has played and still plays a significant role in the national economy and retention is generally supported by the domestic dairy industries. On the other hand, very few new identity standards for milk products are being established.

Examples of dairy nations that retain a significant number of identity standards for milk products include Canada, Denmark, France, Germany, Greece, Gulf countries, Italy, Japan, MERCUSOR countries (Argentina, Brazil, Uruguay, and Paraguay), South Africa, Spain, Switzerland, and the United States. Certain countries, mainly European, have, in addition to generic identity standards, established systems for reserving certain product names as protected geographical designations.

In general, only the basic and the most significant milk products are regulated today by identity standards. Typically, national legislation that includes identity standards for milk products, retain such for drinking milk, traditional fermented milks characterized by specific microorganisms, individual cheese varieties, milk powders, and butter. The cheese varieties most commonly regulated by national identity standards are Brie, Camembert, Cheddar, Cottage Cheese, Cream Cheese, Danbo, Edam, Emmental, Gouda, Mozzarella, Parmesan, Provolone, and Tilsiter.

Regional Standards

The Stresa Convention

The first international standard-setting body within the dairy sector was the so-called Stresa Convention, named after the Italian city Stresa. The Stresa Convention, adopted in 1951, lays down a number of standards for individual cheeses and stipulates regulations for the use of these product names. The International Dairy Federation (IDF) played a significant role in its establishment. Originally, eight European countries ratified the Convention. Several of these have now left. For this reason, and since the standards regulated by the Convention have hardly been up-dated since their establishment, the Stresa Convention today plays an insignificant role. However, the principles contained therein have been adopted in other cheese regulations at national, regional, and international levels (**Figure 1**).

EU standards

With the establishment of the European Common Market, a number of regional identity standards have been developed, particularly during the 1970s and 1980s. Identity standards have been established for preserved milk products (milk powder, evaporated milks, sweetened condensed milks), edible casein products, butter, including reduced fat butters, and drinking milk. The EU standards are mandatory in all EU member states. At the beginning of the 1990s, the strategy for establishing regional standards was abandoned and replaced by a system of registering protected designations of origin and certificated products of specific character.

Gulf standards

The Gulf Cooperation Council (GCC), established in 1981, develops Gulf standards relating to foodstuffs, intended for adoption by its member states (Saudi Arabia, Kuwait, Bahrain, Qatar, Oman, and the United Arab Emirates). Their influence has become increasingly significant.

Most dairy products are currently regulated by the GCC identity standards: raw milk (cow, goat, and

Reservation of four cheese names to be used only by the country in which the names were first developed (Annex A): Rquefort (France), Gorgonzola (Italy), Parmiggiano Romano (Italy), and Pecorino Romano (Italy).

Mutual permission to use 30 cheese names on domestic and international markets, on the labels and by reference anywhere, provided adherence to the identity standards subordinated (Annex B):

Cheese name:	*Origin of name:*
Danablu, Danbo, Elbo, Fynbo, Havarti, Maribo, Mycella, Samsø, and Tybo	Denmark
Brie, Camembert and Saint Paulin	France
Gruyere	France and Switzerland
Asiago, Caciocavallo, Fiore Sardo, Fontina, Provolone	Italy
Edam, Frisian, Gouda, Leyden	The Netherlands
Gudbrandsdalsost, Nøkkelost	Norway
Ädelost, Herregaardsost, Svecia	Sweden
Emmental, Sbrinz	Switzerland

Figure 1 Main elements of the Stresa Convention.

camel), drinking milks (pasteurized, sterilized, UHT, flavored), preserved milk products (dried milk, evaporated milk, sweetened condensed milk, lactose, and caseinates), fermented milk including yogurt (with and without heat treatment after fermentation), cream, butter, milk fat products (anhydrous milk fat, butteroil, and ghee (samn)), processed cheese (including spreadable), cheese, whey cheese, and a number of individual cheese varieties, which besides all varieties standardized by Codex Alimentarius also include Feta, Domiati, Gruyere, Hallom, Kashkaval, and Ras. These standards are subsequently adopted by the GCC member states.

GMC standards

In 1991, the MERCUSOR (Treaty for the Organization of a Southern Common Market) was established with four countries participating (Argentina, Brazil, Uruguay, and Paraguay). To facilitate trade, harmonized food legislation is being developed by the Common Market Group (GMC). GMC standards are mandatory in all MERCUSOR member states. Identity standards for the following milk products have been established: butter, butteroil, dairy cream, dairy cream for industrial use, UHT milk, fluid milk for industrial use, powdered milk, *dulche de leche*, food caseinates, food casein, cheese, grated cheese, processed cheese, powdered cheese, and the individual cheese varieties Danbo, Tilsit, Mozzarella, Minas Frescal, Tybo, Cottage Cheese, Tandil, Pategras, Sandwich, and Prato.

International Standards

Codex Alimentarius

The elaboration of international milk product standards was initiated several years prior to the establishment of Codex Alimentarius. In 1958, on the initiative of the IDF, the FAO established the Joint Committee of Government Experts on the Code of Principles Concerning Milk and Milk Products. The establishment of this 'Milk Committee' showed the need for international cooperation in the area of food and triggered the establishment of Codex 4 years later.

The Milk Committee was active until 1990, during which period 52 international milk product standards and several other texts related to milk products were developed. However, as the running of the Milk Committee was financed by the FAO, financial priorities resulted in difficulties that hampered the continuation of the work. The Committee was very close to being adjourned at the beginning of the 1990s.

In the light of the elaboration of the new WTO trade agreements, however, a FAO/WHO Conference held in 1991 highly recommended the revision of all commodity standards developed by Codex. This was the main reason for establishing the new Codex committee for Milk and Milk Products in 1993. The new committee has almost completed its work after a thorough revision of all the existing standards as well as elaborating new standards for additional milk products. When the work is fully completed in 2010, approximately 34 specific identity standards for various milk products will have been described.

Codex standards are intended as recommendations for adoption by member states and for use by the commercial trade. However, they also serve as international references for application in trade disputes brought to the WTO for settlement (*see* **Policy Schemes and Trade in Dairy Products**: Codex Alimentarius).

World Customs Organization

The World Customs Organization (WCO) is an independent, inter-governmental organization, the purpose of which is to enhance the effectiveness and efficiency of customs administration on a worldwide basis. The most successful instrument developed by the WCO is the Harmonized Commodity Description and Coding System (Harmonized System).

The Harmonized System (HS) is a multipurpose international product nomenclature covering about 5000 commodity groups. Each commodity group is identified by a unique six-digit code and is defined in such a way as to facilitate uniform classification. In many cases, explanatory notes provide identity descriptions of individual commodities.

More than 177 countries use the system as a basis for determining customs tariffs and for the collection of international trade statistics. Other uses include the following: the basis for rules of origin; the collection of internal taxes; the basis for trade negotiations (e.g., the WTO schedule for tariff concessions), transport tariffs and statistics, and the monitoring of controlled goods (such as hazardous wastes, narcotics, and chemical weapons).

The majority of dairy products are found in Chapter 4 of the Harmonized System. However, Chapter 4 does not cover lactose (Chapter 17), ice cream, and dairy spreads (Chapter 21) or albumins, including concentrates of two or more whey proteins (Chapter 35).

The work of the WCO has become increasingly important as world trade in dairy products continues to grow. In particular, product definitions and classification within the Harmonized System greatly influence decisions in product development and marketing.

In addition, the Harmonized System is incorporated by individual governments into domestic operating procedures for a variety of purposes. Among these are internal taxes, monitoring of controlled goods, freight tariffs, transport statistics, price monitoring, quota controls, and more.

Product definitions developed by the WCO in support of the HS do not necessarily correspond with the definitions established in support of food legislation. The individual definitions serve different purposes and are usually developed independently from each other. Consequently, a product labeled with a name in accordance with the food regulation in force may not be classified accordingly by the HS and *vice versa.*

Codex Milk Product Standards

Key Prerequisites for Establishing a Codex Milk Product Standard

Consumer protection from the point of view of health and fraudulent practices is one of the key objectives of Codex activities. As health protection alone does not justify the establishment of a commodity standard as such, Codex commodity standards primarily aim at protecting the consumers from fraudulent practices and ensuring fair trade practices. Public health protection is covered by other horizontal and commodity-specific Codex texts concerning hygiene, additives, and contaminants.

Whether a risk of fraudulent practice exists depends on the following:

- The degree of consumer's recognition of the product (or designation), expressed as the number of countries in which the product is manufactured and consumed;
- The needs of importing-countries to require specific labeling to ensure that adequate consumer information is provided with regard to the nature of the product; and
- Existing differences in national definitions of the product.

An estimate of the global production may be needed to ensure that drafting resources are not wasted on products that are insignificant in international trade. Production and trade statistics are important tools for evaluating whether an international standard will be justified.

Information on the number of countries involved in the trade of the product in question is used for guiding the decision. Local trade between a smaller group of countries (e.g., within one trading block) is not a sufficient justification.

It is apparent that the number of countries having established national identity standards and/or industry standards governing the use of a certain product name constitutes a potential for trade problems. Significant deviation between such standards may alone trigger a need to harmonize at international level (**Figure 2**).

Principal Contents of Codex Milk Product Standards

Codex milk product standards aim at describing the nature (identity) of the products by addressing the essential characteristics associated with them. The areas covered by such standards are as follows:

- Identity characteristics (common understanding of the meaning of a product name including an end-product description, principal method(s) of manufacture, compositional requirements, and ingredients)
- Food additives that are safe and technologically justified
- Labeling provisions that are needed in addition to general labeling rules and/or that are considered necessary for the correct application of a general labeling principle.

This approach is based on the almost completed revision of the milk product standards developed in the 1960s and 1970s. The former versions contained primarily provisions that aimed at ensuring technical product quality and product identity.

Elements that are not justified as essential for the identity of the product cannot be addressed in the standards. Where found appropriate, such material can be provided as information on usual patterns of production in appendices to the standards. The content of an appendix (1) is intended to be applied by commercial trade parties (where found useful), (2) need not be implemented in national legislation, and (3) is not intended to be used by the WTO as reference material. Typical information provided in appendices indicates quality limits on nonhazardous contaminants (e.g., copper); technical quality guidelines; characteristic flavor and taste; nonessential sizes and shapes; and nonessential manufacturing practices.

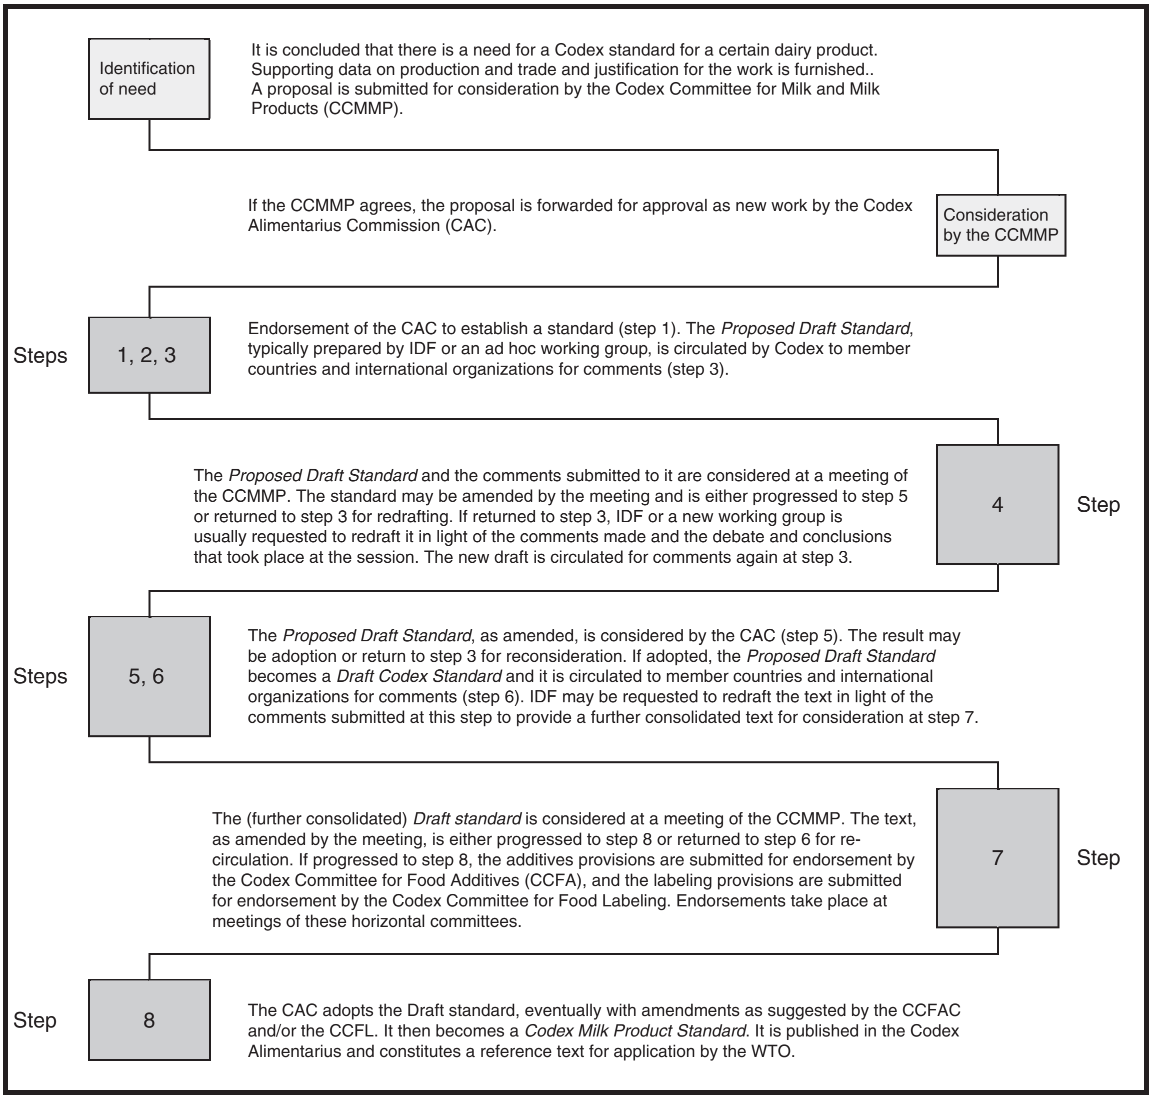
In addition to the principal contents, food safety and general labeling issues are addressed by the Codex milk product standards, mainly by identifying and referring to other relevant Codex texts applicable to the product (e.g., contaminants, hygiene, labeling, and methods of sampling and analysis).

General Approach to Codex Milk Product Standards

Scope

The Codex milk product standards apply both to retail products sold directly to the consumer and to non-retail products intended for further processing (e.g., as ingredients in other milk products and foods, or for processing into processed cheese, cutting/slicing, drying, fermentation, etc.).

Most of the standards do not address addition of non-dairy ingredients intended to provide specific non-dairy flavors (such as fruit preparations, meat, vegetables, spices, and sweeteners). The provisions governing such additions are located in the Codex General Standard for the Use of Dairy Terms (GSUDT). According to the GSUDT, such products are identified as 'composite milk products' and



It is concluded that there is a need for a Codex standard for a certain dairy product. Supporting data on production and trade and justification for the work is furnished.. A proposal is submitted for consideration by the Codex Committee for Milk and Milk Products (CCMMP).

If the CCMMP agrees, the proposal is forwarded for approval as new work by the Codex Alimentarius Commission (CAC).

Endorsement of the CAC to establish a standard (step 1). The *Proposed Draft Standard*, typically prepared by IDF or an ad hoc working group, is circulated by Codex to member countries and international organizations for comments (step 3).

The *Proposed Draft Standard* and the comments submitted to it are considered at a meeting of the CCMMP. The standard may be amended by the meeting and is either progressed to step 5 or returned to step 3 for redrafting. If returned to step 3, IDF or a new working group is usually requested to redraft it in light of the comments made and the debate and conclusions that took place at the session. The new draft is circulated for comments again at step 3.

The *Proposed Draft Standard*, as amended, is considered by the CAC (step 5). The result may be adoption or return to step 3 for reconsideration. If adopted, the *Proposed Draft Standard* becomes a *Draft Codex Standard* and it is circulated to member countries and international organizations for comments (step 6). IDF may be requested to redraft the text in light of the comments submitted at this step to provide a further consolidated text for consideration at step 7.

The (further consolidated) *Draft standard* is considered at a meeting of the CCMMP. The text, as amended by the meeting, is either progressed to step 8 or returned to step 6 for re-circulation. If progressed to step 8, the additives provisions are submitted for endorsement by the Codex Committee for Food Additives (CCFA), and the labeling provisions are submitted for endorsement by the Codex Committee for Food Labeling. Endorsements take place at meetings of these horizontal committees.

The CAC adopts the Draft standard, eventually with amendments as suggested by the CCFAC and/or the CCFL. It then becomes a *Codex Milk Product Standard*. It is published in the Codex Alimentarius and constitutes a reference text for application by the WTO.

Figure 2 Typical process of elaboration of a Codex milk product standard.

the milk product names can be used in combined designations of composite milk products, provided that the added nondairy ingredients are not intended to replace any milk constituent(s), in whole or in part.

Principal method of manufacture

Milk product designations often originate from descriptive terms that refer to the way in which they are manufactured, for instance, milk powder, evaporated milk, fermented milk, and so on. As a natural consequence, the principal method of manufacturing is reflected in the identity description of many milk products. This approach is often much simpler than attempting to describe all end-product characteristics in full detail.

One of the general principles in the WTO Trade Agreements is the principle of equivalence. Since methods of manufacture applied are not static, and because identity standards should not, unless specifically justified, constitute an obstacle for technological development, most Codex standards for milk products include appropriate wording that, in addition to the principal method of manufacturing, provides for alternative technologies that achieve an equivalent outcome.

Raw materials

The general approach is that all milk products derived from any milking animal species can be used as raw material for milk products. This means that milk products can be processed from milk derived from cows, goats, sheep, buffaloes, yaks, camels, reindeer, and so on. Corresponding provisions address whether the dairy species need be labeled (*see* **Labeling of Dairy Products**). However, many individual cheese varieties (but not all) are characterized by the origin of the milk (texture, color, flavor) wherefore restrictions on type of milk may be imposed.

Further, in general, any milk constituents and milk products, including intermediate products, can be used, including those needed for reconstitution and recombination, as long as the compositional criteria and other characteristics of the products are met. There are a few exemptions from this approach (e.g., milk powders).

Composition

The minimum and/or maximum requirements for the composition of end products constitute a core part of any identity standards. For all milk product standards established by Codex, such criteria comprise milk fat, and additional criteria as necessary according to the nature and characteristics of the product in question (see **Figure 3**).

The compositional sections of the standards typically specify the reference composition and, in addition, the limits and conditions for modifying the composition of the reference product, by specifying, for example, the range of composition permitted. Therefore, some compositional criteria are absolute (minima or maxima).

The Codex General Standard for the Use of Dairy Terms states that products that have been modified in composition beyond the composition of the reference product identified in the relevant standard are only allowed if the following principles are adhered to:

- That a qualifier that clearly describes the compositional modification made is placed in association with the name of the product
- That the modification is achieved only by the addition and/or withdrawal of milk constituents
- That such modification does not alter the basic identity of the product and is within the limitations identified in the Codex identity standard concerned.

See **Figure 4** for examples of modifications covered.

In some cases, compositional modification is not desirable, for instance, protein contents below the minima specified and fat reductions below the absolute minima, where such are specified (**Figure 4**).

Food additives

A positive list of justified and permitted groups of additives and/or individual additives is provided. Technological justification for each functional group of additives and for each additive, with a numerical ADI-value listed, is a prerequisite for acceptance by Codex. The IDF provides the information necessary for this purpose.

Labeling

The labeling section makes cross-reference to generally applicable labeling standards and lays down additional labeling provisions as well as practical guidance on the application of general labeling principles (*see* **Labeling of Dairy Products**).

Supporting methods of sampling and analysis

Any criteria specified in a Codex standard are to be supported by appropriate analytical methods for verifying compliance. Recognized methods are published in the Codex Alimentarius.

Milk product	*Milk fat*	*Milk protein*	*Moisture or dry matter*	*Solids-not-fat*	*Lactose*	*Ash*	*Other*
Creams	√						
Fermented milks	√	√					Acidity, microorganisms flavoring ingredients
Butter	√		√	√			
Dairy fat spreads	√			√

The Individual Codex Milk Product Standards

Drinking milk

Codex has not established, nor does it intend to establish, an identity standard for drinking milk. Although manufactured and marketed in most countries worldwide, drinking milk is primarily sold domestically. Hence, due to significant local differences in consumer perception, attempts to harmonize this area would probably fail.

However, some general principles governing drinking milk have been provided in the Codex GSUDT. These principles are targeted national regulations in this area. The GSUDT states that, in general, drinking milk that is modified in composition by the addition and/or withdrawal of milk constituents may be identified with a name using the term ‘milk’, provided that a clear description of the modification to which the milk has been subjected is given in close proximity to the name.

However, fat and protein adjustment may be permitted without such description only if

- the milk is sold where such adjustment is permitted in the country of retail sale;
- the minimum and maximum limits of fat and/or protein content (as the case may be) of the adjusted milk are specified in the legislation of the country of retail sale (the protein content shall be within the limits of natural variation within that country); and
- the adjustment methods permitted by the legislation of the country of retail sale are used. Such methods shall include only the addition and/or withdrawal of milk constituents without altering the whey protein-to-casein ratio (as achieved by traditional ultrafiltration technology).

Creams

The standard for cream addresses ‘cream’ (bulk) and ‘prepared creams’ intended for direct consumption. The standards include a definition of cream and descriptions of recombined and reconstituted cream, respectively. A number of specific consumer products are described, including prepackaged liquid cream, whipping cream, whipped cream, cream packed under pressure, thickened cream, and fermented cream.

The standard characterizes creams as milk products comparatively rich in fat (absolute minimum of 10% milk fat), in the form of an emulsion of fat in skimmed milk, obtained by physical separation from milk or by recombination/reconstitution of specified raw materials.

Fermented milks

The standard characterizes fermented milks as milk products obtained by fermentation of milk by the action of specific microorganisms and resulting in a reduction of pH with or without achieving coagulation. These specific microorganisms shall be viable, active, and abundant in the product. In addition, the standard includes specific categories of fermented milks that are additionally characterized by specific microorganism(s) used for the fermentation, which organisms during product shelf life are present in numbers exceeding 10^7 cfu g^{-1} (plain part of the end product). Specific categories will include yogurt, kefir, acidophilus milk, and kumys.

The products may be heat treated after fermentation, in which case the name shall be ‘heat treated fermented milk’. Reference to the specific names defined by minimum bacterial counts is obviously not relevant in these products.

The standard aims also at including fermented milks modified in composition by concentration of the protein to minimum 5.6% – identified as ‘concentrated fermented milks’.

This standard (being the only one at that) includes flavored products (i.e., plain fermented milk to which other foods/ingredients, such as fruit, sugar/sweetener, or cereals, have been added to obtain a characteristic nondairy flavor).

Butter and milk fat products

Three milk product standards for yellow milk fats exist: one for butter, one for dairy fat spreads, and a third for milk fat products (covering the names ‘milk fat’, ‘anhydrous milk fat’, ‘butteroil’, ‘anhydrous butteroil’, and ‘ghee’).

Butter is, according to the Codex standard, characterized by being a fatty milk product, principally in the form of an emulsion of the water-in-oil type, with minimum 80% milk fat, maximum 16% moisture, and maximum 2% milk solids-not-fat. These compositional criteria are specified as absolute. Unlike many national standards, no upper milk fat limit is specified. Instead, it is stated that fat contents above 95% trigger the use of a qualifier in association with the term ‘butter’; such a qualifier can be, for instance, ‘cooking’.

Dairy fat spreads are conceptionally butter with lowered fat contents above 10% and where milk fat constitutes at least two-thirds of the dry matter.

The milk fat products covered are characterized as fatty milk products obtained by means of processes that result in almost total removal of water and nonfat solids. For ghee, restrictions on milk ingredients as raw material are specified, and the product is further characterized by having a special flavor and physical structure, without further details being provided, however.

Preserved milk products

Standards for three categories of traditional preserved milk products have been established: for evaporated milks, for sweetened condensed milks, and for milk powders and cream powder.

In common, these products are characterized by being obtained by the partial removal (to various degrees) of water from milk (or cream) by the use of heat or other processes leading to the same composition and characteristics. Milk-based raw materials are restricted.

Sweetened condensed milk is further characterized by being preserved with the addition of sugar (sucrose alone or sucrose in combination with other sugars).

The adjustment of fat and/or protein is specifically addressed in all three standards, and can be done provided that it is achieved only by addition/withdrawal of milk permeate, milk retentate, and lactose, and provided that the whey protein-to-casein ratio of the milk subjected to adjustment is not altered.

Common to all three standards is also that the whole range of fat content is covered by a classification system and that the minimum protein content should be 34% of milk solids-not-fat. Corresponding criteria for milk solids-not-fat content are established for the liquid products, whereas a maximum moisture content of 5% is specified for the powders. These compositional criteria are specified as absolute.

Cheese

A general standard for Cheese supplemented by subordinated group standards for cheese in brine and unripened cheeses, respectively, has been established.

Cheese is primarily characterized according to the way it is manufactured. Cheese is the ripened or unripened, soft or firm, hard or extra hard, product obtained by

(a) coagulating wholly or partly the protein of milk, skimmed milk, partly skimmed milk, cream, whey cream or buttermilk, or any combination of these materials, through the action of rennet or other suitable coagulating agents, and by partially draining the whey resulting from such coagulation, while respecting the principle that cheesemaking results in a concentration of milk protein (in particular, the casein portion), and that consequently, the protein content of the cheese will be distinctly higher than the protein level of the blend of the above milk materials from which the cheese was made; and/or

(b) processing techniques involving coagulation of the protein of milk and/or products obtained from milk which give an end product with similar physical, chemical, and organoleptic characteristics as the product defined under (a).

Part (a) reflects the traditional manufacturing method which is still the dominating process used worldwide, and part (b) allows for other processing techniques such as recombination, reconstitution, protein standardization, and membrane filtration in general are covered by subparagraphs. Products complying either to part (a) or to part (b) are equivalent, that is, they are not to be distinguished in any way. Today, the cheese manufacturing process is a combination of (a) and (b).

The standard does not specify any compositional criterion but that (1) the protein content is distinctly higher than that of the milk used and that (2) the whey protein-to-casein ratio does not exceed that of the milk used. If the whey protein-to-casein ratio is higher, then the product is to be categorized as 'whey cheese'.

Cheese is generally classified according to principal ripening and firmness as follows:

Classification according to principal ripening

- Ripened cheese, which is cheese not ready for consumption shortly after manufacture but must be held for such time, at such temperature, and under such other conditions as will result in the necessary biochemical and physical changes characterizing the cheese in question;
- Mold ripened cheese, which is ripened cheese in which the ripening has been accomplished primarily by the development of characteristic mold growth throughout the interior and/or on the surface of the cheese;
- Cheese in Brine, which is ripened cheese that has been ripened and preserved in brine until delivered to, or prepacked for, the consumer; and
- Unripened cheese, which is cheese ready for consumption shortly after manufacture.

Classification according to firmness

- Soft cheese, which is cheese with a content of moisture on fat-free basis above 67%;
- Firm (or semihard) cheese, which is cheese with a content of moisture on fat-free basis between 54 and 69%;
- Hard cheese, which is cheese with a content of moisture on fat-free basis between 49 and 56%; and
- Extra hard cheese, which is cheese with a content of moisture on fat-free basis below 51%.

The general cheese standard applies to all cheeses, including individual varieties of cheese.

Individual cheese varieties

Subordinate to the general cheese standard, 17 standards for individual cheese varieties exist: Cheddar, Danbo, Edam, Gouda, Havarti, Samsø, Emmental, Tilsiter, Saint-Paulin, Provolone, Cottage Cheese, Coulommiers, Cream Cheese, Camembert, Brie, Extra Hard Grating, and Mozzarella.

Raw materials for the manufacture of these individual cheese varieties are restricted to milk and milk products derived from cows and buffalos. However, in the case of Extra Hard Grating, the dairy species permitted are goats, ewes, and cows (but not buffaloes), and in the case of Cream Cheese no restrictions in this regard apply. Further, each individual variety will, in addition to the general characteristics applicable to cheeses, be characterized by end-product description including classification according to principal ripening and firmness, as well as color, texture, structure, and ripening characteristics, where appropriate. In certain cases, characteristic elements of the manufacturing methods and dimensions are specified as well.

Compositional specifications are unique for each variety and include limitations for compositional modification of the fat content.

Specific milk constituents

Two milk product standards regulate whey powders and edible casein products, respectively. A group standard for sugars includes lactose.

Whey powders are characterized as being milk products obtained by drying whey or acid whey, where whey means the fluid milk product obtained during the manufacture of cheese, casein, or similar products by separation from the curd after coagulation of milk and/or of products obtained from milk. Reference to 'whey' without qualification indicates that coagulation is obtained through the action of rennet-type enzymes, while using the term 'acid whey' means that the coagulation is obtained by acidification.

Whey powders are further characterized by a reference lactose content, minimum milk protein content, and maximum content of moisture and ash. For whey powder and acid whey powder, the values of these criteria differ slightly. The two powders are principally distinguished by pH. In addition, the standard includes specific reference to demineralization and neutralization as being acceptable compositional modifications.

Edible casein products are characterized as being milk products obtained by separating, washing, and drying the coagulum of skimmed milk and/or of other products obtained from milk. The type of coagulation (acid precipitation or enzymatic coagulation) determines whether the product is classified as acid casein or rennet casein. Differentiation is further supported by specification of ash content (acid casein max. 2.5% and rennet casein min. 7.5% ash; both figures include P_2O_5). No additives are permitted (enzymes are categorized in milk product standards as 'ingredients').

Edible caseinate is characterized as being the milk product obtained by the action of edible casein or edible casein curd with neutralizing agents, followed by drying. Caseinates may be manufactured by the use of acidity regulators, including specific neutralizing agents, emulsifiers, bulking agents, and anticaking agents.

All casein products are further characterized by criteria for protein content, casein in total milk protein, moisture content, and milk fat content. All compositional criteria specified are absolute.

Lactose is characterized as a natural constituent of milk normally obtained from whey with an anhydrous lactose content of not less than 99.0% on a dry basis. Lactose may be anhydrous or may contain one molecule of water of crystallization, or may be a mixture of both forms. No additives are permitted.

Trade in Milk and Dairy Products, International Standards: Harmonized Systems

K Svendsen, Danish Agriculture and Food Council, Arhus, Denmark

The Historical Basis

In the aftermath of World War II, several organizations were established to secure, facilitate, and harmonize trade. The General Agreement on Tariffs and Trade (GATT), now the World Trade Organization, is the best known, but other areas have developed their own rules and objectives.

In September 1947, the 13 governments represented on the Committee for European Economic Co-operation agreed to set up a study group on the establishment of one or more European Customs Unions based on the principles of GATT. In 1948, the study group, established in Brussels, set up two committees, an Economic Committee and a Customs Committee.

The Economic Committee later became the Organization for Economic Cooperation and Development, and the Customs Committee became the Customs Co-operation Council (CCC), created on 15 December 1950, when the convention was signed in Brussels. It took 2 more years before the first session was held on 26 January 1953, a date that 30 years later became known as International Customs Day.

Customs Co-Operation Council or the World Customs Organization

The aim of this organization is to study all questions relating to customs cooperation and the technical and the economic aspects of customs systems to attain the highest possible degree of harmony and uniformity. This work is done through conventions like the Kyoto Convention on Simplification and Harmonization of Customs Procedures.

On the operational level, the work is carried out in technical committees, of which the Harmonized System Committee is central for the topic of this article.

In October 1994, the CCC adopted the working name World Customs Organization (WCO), thus mirroring the growing international significance of the organization and the development in world trade.

Nomenclature and Classification

With the growing world trade after World War II, the need for an internationally recognized common nomenclature became more and more obvious. This was discussed in CCC, and the Brussels Convention of 15 December 1950, on Nomenclature for the Classification of Goods in Customs Tariffs laid down the basics. It came into force on 11 September 1959, and was known as the Brussels Tariff Nomenclature (BTN). In 1974, it was renamed Customs Co-operation Council Nomenclature (CCCN).

The CCCN was divided into 1241 headings, 96 chapters, and 21 sections, each heading thus being identified by two groups of two digits, one for the chapter and the second for the position in the chapter. The CCCN served only one objective, tariffs, and was purely numerical.

At the same time, there were other classifications serving other purposes, the best known of which is the Standard International Trade Classification (SITC) for statistical purposes.

During the 1950s and 1960s, great effort was made to correlate these two nomenclatures, but it was still evident that there was a great need for international harmonization, especially concerning commodity description and coding.

Harmonized System Committee

In 1970, a study group was set up to prepare a Harmonized Commodity Description and Coding system that would handle classification in relation to tariffs, statistics, transport, and production, thus being a multipurpose international products nomenclature. The result of this work was the creation in 1973 of the Harmonized System Committee, which would prepare the Harmonized System (HS) on the background of the CCCN. This resulted in the Harmonized System Convention that entered into force on 1 January 1988. Since that day, an ever-increasing number of countries adhere to this system. According to the WCO, by August 2000 more than 177 countries were using the HS, and 98 countries were contracting parties.

According to Article 3 of the convention, contracting parties are obliged to ensure that their import customs tariffs and statistical nomenclature for imports and exports are in conformity with the six-digit HS. They are also obliged to make public their import and export statistics at or beyond that level (if at all).

The Harmonized System Committee is responsible for the development of the HS and takes care of dispute settlement whenever two contracting parties cannot agree on the nomenclature code for a specific product, a situation that can have substantial economic consequences for the involved parties.

The committee meets twice a year to discuss these problems and reach an agreement, eventually by voting on the subject. If one of the contracting parties does not agree with the decision taken by the committee, the party can transfer it to the council.

This means that the main tasks of the Harmonized System Committee are to propose amendments to the convention for updating the HS every 4–6 years and to prepare explanatory notes and classification opinions and other advice as guides to the interpretation of the HS and recommendations to secure uniformity in the interpretation and application of the system.

Harmonized System

The HS itself is thus a six-digit products classification system used by most countries in the world to collect tariffs and produce statistics. Some countries still have alternative systems for some uses, like the SIC codes for domestic production in the United States, but more and more the HS is being used for all purposes and by international organizations like the Organisation for Economic Co-operation and Development (OECD) and the World Trade Organization.

According to the HS, all goods can be classified in 21 sections but, for more precise classification, sections are divided into chapters. The HS consists of 97 chapters, of which Chapter 77 is reserved for future use. Furthermore, Chapters 98 and 99 are reserved for special uses by adhering countries.

To describe a chapter, two digits are always used (e.g., 04 for the chapter containing dairy products and 35 for the chapter containing casein, albumins, and others). The subdivision of chapters is done either by material (e.g., 02 – meat, 03 – fish) or by degree of manufacture or processing (e.g., 01 – live animals, 02 – meat and edible meat offals).

Titles in chapters are only guidelines; therefore two-digit chapters are not sufficient. Thus, to clarify and underline the differences between products in the same chapter, most of the chapters are divided into headings (four digits) and even subheadings (six digits), each level adding another pair of two digits to a total of six digits. In this way, the system lists more than 5000 product lines.

The HS as mentioned is dynamic. The latest amendments were decided at the 43rd Session of the Harmonized System Committee in March 2009. They were adopted by the WCO Council at its annual session in June 2009, and the recommendation is now being promulgated under the provisions of Article 16 of the Harmonized System Convention. This implies that HS contracting parties have 6 months during which they can object to a recommended amendment. The amendments will enter into force on 1 January 2012.

The Council Recommendation of 26 June 2009, with the HS2012 amendments is the fifth to amend the HS, though it is only the fourth recommendation to make major amendments to the HS since the WCO Council approved the Harmonized System Convention.

The main reasons for the latest set of 221 amendments are new environmental and social issues and the use of the HS as the standard for classifying and coding goods of specific importance to food security and early warning data falling within the ambit of the Food Security Information for Action Program of the Food and Agriculture Organization (FAO) of the United Nations.

Dairy Products in the Harmonized System

Let us take a closer look at the way dairy products are classified.

This happens in the first section of the HS, Section I – Live Animal and Animal Products. This section is divided into five chapters:

01. Live animals
02. Meat and edible meat offal
03. Fish, crustaceans, and other aquatic invertebrates
04. Dairy produce, birds' eggs, natural honey, edible products of animal origin, not elsewhere specified or included
05. Products of animal origin, not elsewhere specified or included

This is followed by the section on vegetable products.

In itself, the definition of Chapter 04 tells us that we have to be more specific to find the right code for a product. We therefore have to look at the headings:

04. Dairy produce, birds' eggs, natural honey, edible products of animal origin, not elsewhere specified or included
04.01. Milk and cream, not concentrated nor containing added sugar or other sweetening matter
04.02. Milk and cream, concentrated or containing added sugar or other sweetening matter

04.03. Buttermilk, curdled milk and cream, yogurt, kefir and other fermented or acidified milk and cream, whether or not concentrated or containing added sugar or other sweetening matter or flavored or containing added fruit, nuts, or cocoa
04.04. Whey, whether or not concentrated or containing added sugar or other sweetening matter; products consisting of natural milk constituents, whether or not containing added sugar or other sweetening matter, not elsewhere specified or included
04.05. Butter and other fats and oils derived from milk; dairy spreads
04.06. Cheese and curd
04.07. Birds' eggs in shell, fresh, preserved, or cooked
04.08. Birds' eggs, not in shell, and egg yolks, fresh dried, cooked by steaming or by boiling in water, molded, frozen, or otherwise preserved, whether or not containing added sugar or other sweetening matter
04.09. Natural honey
04.10. Edible products of animal origin, not elsewhere specified or included

This did bring us one step further, but it did not solve all our problems, as it is evident that, for example, the fat content of different milk powders would qualify for different tariff rates. We therefore have to be even more specific and add a level of subheadings before we can define the right tariff nomenclature code within the HS.

04. Dairy produce, birds' eggs, natural honey, edible products of animal origin, not elsewhere specified or included
04.01. Milk and cream, not concentrated nor containing added sugar or other sweetening matter
04.01.10 – Of a fat content, by weight, not exceeding 1%
04.01.20 – Of a fat content, by weight, exceeding 1%, but not exceeding 6%
04.01.30 – Of a fat content, by weight, exceeding 6%.

As per 1 January 2012, this last subheading will be replaced by the following:

04.01.40 – Of a fat content, by weight, exceeding 6% but not exceeding 10%
04.01.50 – Of a fat content, by weight, exceeding 10%
04.02. Milk and cream, concentrated or containing added sugar or other sweetening matter
04.02.10 – In powder, granules or other solid forms, of a fat content, by weight, not exceeding 1.5%
– In powder, granules or other solid forms, of a fat content, by weight, exceeding 1.5%
04.02.21 – – Not containing added sugar or other sweetening matter
04.02.29 – – Other
– Other
04.02.91 – – Not containing added sugar or other sweetening matter
04.02.99 – – Other
04.03. Buttermilk, curdled milk and cream, yogurt, kefir and other fermented or acidified milk and cream, whether or not concentrated or containing added sugar or other sweetening matter or flavored or containing added fruit, nuts, or cocoa
04.03.10 – Yogurt
04.03.90 – Other
04.04. Whey, whether or not concentrated or containing added sugar or other sweetening matter; products consisting of natural milk constituents, whether or not containing added sugar or other sweetening matter, not elsewhere specified or included
04.04.10 – Whey and modified whey, whether or not containing added sugar or other sweetening matter
04.04.90 – Other
04.05. Butter and other fats and oils derived from milk; dairy spreads
04.05.10 – Butter
04.05.20 – Dairy spreads
04.05.90 – Other
04.06. Cheese and curd
04.06.10 – Fresh cheese, including whey cheese, and curd
04.06.20 – Grated or powdered cheese, of all kinds
04.06.30 – Processed cheese, not grated or powdered
04.06.40 – Blue-veined cheese
04.06.90 – Other cheese

As exports of dairy products are done by a very limited number of important players, most of the countries using the HS for tariff purposes are importing countries satisfied with this level of specification, as tariff rates in general are rather uniform between these large groups of products. Some countries importing, exporting, and producing a large variety of dairy products do, however, use their right to supplement the six-digit HS codes with their own further subcodes. One example is the US subdivision of Chapter 04.06.20, grated and powdered cheese, into 38 10-digit subheadings according to cheese types, milk used, and tariff quotas.

Classification Principles

To classify a given dairy product under the correct HS nomenclature position, one must both consider some general principles and make reference to the explanatory notes given by the Harmonized System Committee. Formally, the descriptions in sections, chapters, and headings cannot be used to classify a product. One must go to the specific subheading texts.

As the HS is not very specific, this will solve most of the problems. However, when mixing products from different chapters, this may result in a totally different code under a third chapter. If, for example, butterfat is mixed with vegetable oil to make a mixed dairy spread, it will be classified in Chapter 21. This classification is independent of the production process. If vegetable fat is added to a dairy product, according to the explanatory notes it cannot be classified under Chapter 04. In principle, there are then two possible alternatives, Chapter 19 and Chapter 21. A product that needs to be distinguished from a normal dairy product falling under Subheadings 04.01–04.04 will fall under Chapter 19 according to the explanatory notes. This, however, is not the case for dairy spreads or cheeses where the milk fat part has been totally or partly replaced by vegetable fat. In this case, the final products will need to be distinguished from products falling under Subheadings 04.05 and 04.06 of the dairy chapter. Such products according to the explanatory notes must be classified under Chapter 21. In this case, more specific descriptions should come before more general descriptions.

This, however, does not mean that one cannot add anything from outside the chapter. If butter or cheese is mixed with small quantities of spices like garlic or cumin, it retains the character of butter or cheese and shall be classified as such.

These questions are very delicate as they could be used in an attempt to circumvent high tariff rates or tariff quotas for some products by adding rather neutral or very small quantities of substances that would place the final product in a different chapter with no tariff or unrestricted access. Therefore, this is an important part of the explanatory notes defined by the Harmonized System Committee.

Mixing products from within the same chapter is a different matter. If Blue cheese were mixed with processed cheese, the point of departure would be a general rule giving the nomenclature code of the substance with the highest position, in this case, the position of the processed cheese. If the two substances are identifiable, the principle would be to choose the position that makes up more than half of the quantity. However, if one of the substances has a very specific character, like a dominating taste, one should consider using the code for this substance even if it represents less than half of the quantity.

The principle of the highest code also applies within a chapter; this means that if a product fits into a subheading, it cannot be placed under a subheading that comes later under the same heading. If, for example, fresh cheeses like Mozzarella, be it the Italian type or the American variety, are grated, the resulting product remains under Subheading 04.06.10 as a fresh cheese and does not fall under Subheading 04.06.20 as a grated cheese.

This, however, does not mean that a fresh cheese cannot be processed with melting salt and classified as a processed cheese under Subheading 04.06.30, as this production process substantially alters the cheese used as raw material, so that this can no longer be identified as such.

Classification Examples

With these principles in mind, let us take a closer look at some dairy products and their classification. The author must stress that this relies on his personal opinions and experience and does in no way commit the WCO or the Harmonized System Committee. The official opinions of these bodies are to be found in the relevant texts issued by the WCO. In view of the developments in modern technology, the WCO does also have a website on the Internet (www.wcoomd.org). On this site, HS classification decisions can be found. The decisions will be published as soon as they are approved by the council under the provisions of Article 8.2 of the Harmonized System Convention. This will be about 2 months after the meetings of the Harmonized System Committee at which the decision is taken. The details published will include a complete description of goods, six-digit HS classification, and the legal basis for the classification decision.

On the website the user will also find useful information on contracting parties, HS amendments, and amendments to the explanatory notes and a compendium of classification opinions.

Heading 04.01

Under Heading 04.01 we find normal fresh drinking milk and cream, with no added sugar. However, we also find Ultra High Temperature (UHT) processed milk and sterilized cream, as these products are in no way concentrated or condensed, and thus cannot fall under Heading 04.02. If any flavor (e.g., chocolate) is added, this milk-based drink no longer falls under Heading 04.01 but under Heading 22.02.

Heading 04.02

Take some of the fresh milk or heat-treated products falling under Heading 04.01 and add some sugar, and you have a 04.02.99 product.

However, most of the products under Heading 04.02 are either milk powders or condensed milk, which in relation to the HS does not represent big problems. One should, however, bear in mind that lactose in a milk powder is not a sweetening agent. If lactose is added to a milk powder, it will, however, change position to Heading 04.04.90 (see below under Heading 04.04).

Heading 04.03

All fermented milk products fall under this heading, be it in liquid or solid form. This means that both buttermilk and buttermilk powder will fall under Subheading 04.03.90 in the HS.

Heading 04.04

All whey products, except whey butter, will fall under Heading 04.04.10 – as long as the total protein content by weight calculated on the dry matter does not exceed 80%. If it does exceed 80%, it falls under Heading 35.02, which is where you will have to classify whey protein concentrates.

In modern dairy production, a lot of products no longer contain the milk constituents in their natural composition. Lactose, whey, permeates, and other constituents are added or deducted. It is even permitted to add small quantities of non-dairy ingredients. These products fall under Heading 04.04.90. This does not mean that all milk powders fall under this heading if their composition is changed, this happens only if they no longer respect the normal natural composition. This problem will have less impact in the future because of the Codex Alimentarius Commission decision to allow protein standardization to a minimum of 34% in milk powders, as this will set a norm for the natural composition and avoid inferior products to be sold as 04.02 products.

Heading 04.05

Under this general heading 04.05.10 we find butter, also produced from whey or if recombined. Dairy spreads under 04.05.20 must not contain other fats than butterfat. These products would fall under Heading 21.06 if the butter is mixed with or replaced by vegetable fat. We also find butter oil in this chapter under Heading 04.05.90.

Heading 04.06

Here we find all kinds of cheese. As the HS is not very specific, the classification does not represent big problems. We have seen above that all fresh cheeses, also frozen or vacuum-packed Mozzarella, grated or not, will always fall under the Subheading 04.06.10.

Subheading 04.06.20 is meant mainly for cheese powder and Subheading 04.06.30 for processed cheese. Here, as was the problem with protein standardization before the Codex decision, the problem is not one of classification but of definition.

Another point worth mentioning is the fact that all Blue cheeses fall under Subheading 04.06.40, not only the tasty types like Roquefort and Danish Blue Cheese, but also very mild types and types with mixtures of blue and white mold. The decisive point is the presence of blue mold.

Combined Nomenclature

According to Article 3 of the Harmonized System Convention, any contracting party is allowed to establish in its customs tariffs or its statistical nomenclatures subdivisions classifying goods beyond the six-digit level of the HS, provided no changes are made to the HS level.

In the European Union, the introduction of the Harmonized System on 1 January 1988, was taken as an opportunity to modernize the European Union nomenclature system. Until that point, customers used the Common Customs Tariff while the statistical instrument was the NIMEXE statistical nomenclature. As per 1 January 1988, the Combined Nomenclature (CN) replaced these two nomenclatures.

The CN is, as it should be, based on the HS, but to form the CN one group of two more digits is added to create further subheadings covering some 10 800 eight-digit product groups compared with the approximately 5000 product groups of the HS. For certain import arrangements, the European Union supplements the CN code with a further 2-digit code giving the 10-digit European Union integrated tariff with 14,000 positions.

Dairy Products

As shown above, Chapter 04 of the HS contains in total 6 four-digit headings and 20 six-digit subheadings covering dairy products. These are also found in the CN, but at the eight-digit subheading level we now find 153 dairy positions (2009).

Within Headings 04.01 and 04.02, the subdivisions mainly take care of packet sizes. In Heading 04.03, the subdivision is made by fat content or sweetening of the product. In Heading 04.04, both fat and protein content and sweetening account for the subdivision. In Heading 04.05, products are at the CN level sorted out by some quality parameters: natural butter, recombined butter, or whey butter, and for the dairy spreads also the fat content. Finally, in Heading 04.06 for cheeses, the subdivision takes care of all the European Union specific varieties.

Classifying a product according to the CN is thus more complicated than according to the HS but follows broadly the same principles as mentioned above. Only in this case, the explanatory notes of the HS supplemented with the same notes from the European Union competent authorities on the CN become even more important.

Going through all these subheadings is beyond the scope of this article; one example, however, could be shown. As mentioned earlier, the United States is subdividing for import tariff purposes the HS heading 04.06.20, grated or powdered cheese of all kinds, into 38 ten-digit subheadings.

In the CN, the European Union is only subdividing this heading into 2 eight-digit subheadings:

04.06.20.10	Glarus herb cheese (known as Schabziger), made from skimmed milk and mixed with finely ground herbs
04.06.20.90	Other

Refund Nomenclature

At the European Union level, one further addition has been made to the CN to make up the Refund Nomenclature (RN). The RN is composed of the eight digits of the CN plus a four-digit extension, thus in total 12 digits. The purpose of the RN is to differentiate the export subsidy according to the real content of milk or milk substances in the final product. During recent years, substantial changes have been made to the RN to exclude positions with no products traded or no subsidy granted. If such a product with no subsidy is exported (e.g., Roquefort cheese), it shall be classified under the relevant CN heading, in this case 04.06.40.10.

If we turn once more to the example of the cheese powder chapter, in the RN we find the following subdivision:

Ex 04.06.20	–	Grated or powdered cheese, of all kinds
Ex 04.06.20.90	– –	Other
04.06.20.90.9100	– – –	Cheeses produced from whey
	– – –	Other
	– – – –	Of a fat content, by weight, exceeding 20%, of a lactose content, by weight, less than 5%, and of a dry matter content, by weight:
04.06.20.90.9913	– – – – –	Of 60% or more, but less than 80%
04.06.20.90.9915	– – – – –	Of 80% or more, but less than 85%
04.06.20.90.9917	– – – – –	Of 85% or more, but less than 95%
04.06.20.90.9919	– – – – –	Of 95% or more
04.06.20.90.9990	– – – –	Other

The logic here shows us that while the Schabziger cheese must be mentioned in the CN for import purposes – as it is produced in Switzerland – it is not needed in the RN as refunds are granted only on products of European Union origin.

Knowing the right position of a product in the RN is of very substantial economic importance to the exporter, as this decides his export subsidy, the refund. The same can be said of an importer's interest to have the right CN code on imports. It is therefore possible, according to regulation 450/2008 Article 20, to obtain a binding tariff information (BTI) or a binding origin information (BOI) from the customs authorities. With this information, an individual can be sure to use the right classification of his goods, thus knowing his rights or obligations.

Conclusion

The implementation in international trade of the HS has been of great help to customs officials as well as trading companies all over the world. Problems arising from different interpretations are discussed in a common forum, thus giving more stringent replies. For trading partners, this has led to a higher degree of knowledge of the economic conditions that apply to a specific trade action. The result of this is a general increase in world trade and thus, according to normal economic reasoning, in general welfare worldwide.

Introduction

The World Trade Organization (WTO) is the successor to the former General Agreement on Tariffs and Trade (GATT). The GATT organization was formed in 1948 after World War II as one of three legs in the international economic system; the other legs are the International Monetary Fund (IMF) and the World Bank. The GATT agreement was signed by 23 countries in 1947. In 1995, 123 countries in the multilateral trading system transformed the former GATT into the WTO. Membership by January 2002 is 144. A number of countries are negotiating for membership, amongst them Russia, the only major country of the international economy that is not already a member. China became a member in 2001.

Until 1995 the trading system was organized as an agreement, but with the WTO entering into force, the system now consists of a fully fledged international organization with rights and obligations attached to its members. The WTO has its head office in Geneva, Switzerland. The director-general is the former New Zealand minister Mike Moore who took office in 1999.

The core functions of the WTO are to ensure a non-discriminating, smooth, predictable, and free trade between member countries. At the heart of the organization are the following activities:

- administering WTO trade agreements
- forum for trade negotiations
- handling trade disputes
- monitoring national trade policies
- technical assistance and training for developing countries
- cooperation with other international organizations.

Both GATT and WTO evolved around trade negotiation rounds. So far there have been eight rounds of negotiations within GATT (**Table 1**). In 2001, negotiations were in progress on whether to start a new all-encompassing trade round in the WTO or to divide the negotiations into separate subject areas.

During the course of time the GATT and now the WTO have increased their agenda according to the developments in the surrounding society. The WTO now covers a wide number of different areas of trade under the three main headings GATT (trade in goods), GATS (trade in services) and TRIPS (trade in intellectual property rights). Within the areas of GATT and GATS there are a number of extra agreements, some of which are listed in **Table 2**.

The decision-making process in the WTO is fundamentally built upon consensus. The top decision-making body is the Ministerial Conference, which consists of the Member Countries' foreign ministers. This conference convenes at a minimum every second year. On a daily basis, the General Council is the central decision-making forum. All the Member Countries are represented in the Council by their ambassadors or a counterpart. The General Council also acts as Dispute Settlements Body and as Trade Policy Review Body.

Principles of the WTO

A number of fundamental principles govern the general agreements and the relations between Member Countries. At the core of these principles is antidiscrimination, amongst trading partners and between domestic and foreign producers of goods. The most important principles are as follows.

Most Favored Nation Status

The Most Favored Nation (MFN) clause stipulates that favors such as easier market access (lower duties) given to one country's produce should be multilateralized and therefore applicable to all member countries. All Member Countries should by this principle be entitled to equal treatment and equal access. The major exception from this rule is free trade areas, customs, economic and political unions that can apply for and under certain conditions be granted exemption.

National Treatment Clause

The National Treatment Clause stipulates that imports and domestic or local produce should be equally treated

Table 1 GATT trade rounds

Year	*Name of the round and place*
1947	Geneva
1949	Annecy
1951	Torquay
1956	Geneva
1960–61	Dillon Round (Geneva)
1964–67	Kennedy Round (Geneva)
1973–79	Tokyo Round (Geneva)
1986–94	Uruguay Round (Geneva)

Table 2 Agreements within the areas of GATT and GATS

The 'extra' goods agreements (under GATT)	*The GATS annexes (under GATS)*
Agriculture	Movement of natural persons
Health regulations for farm products	Air transport
Textiles and clothing	Financial services
Product standards	Shipping
Investment measures	Telecommunication
Antidumping measures	
Customs valuation methods	
Preshipment inspection	
Rule of origin	
Import licensing	
Subsidies and countermeasures	
Safeguards	

Source: http://www.wto.org

upon market entrance of the import products. Duties and import taxes are not regulated by this principle. This rule applies to goods, services, trademarks, copyrights and patents. In practice the National Treatment Clause undermines the possibility of governments giving preferences to nationally produced products over imports and is an important instrument in increasing the transparency of the nontariff barriers to trade.

Least-Developed Countries

More than 100 of the WTO member countries are developing countries. Within the WTO system there is special treatment for these countries with regard to their potential to fulfill their obligations according to the agreements, rules and regulations. For the group of least-developed countries, there are broad exemptions from the obligations. WTO has set up a system in order to help developing countries to gain knowledge and understanding of the organization and particularly to pass on experience with the trade negotiation system.

Dispute Settlement Body

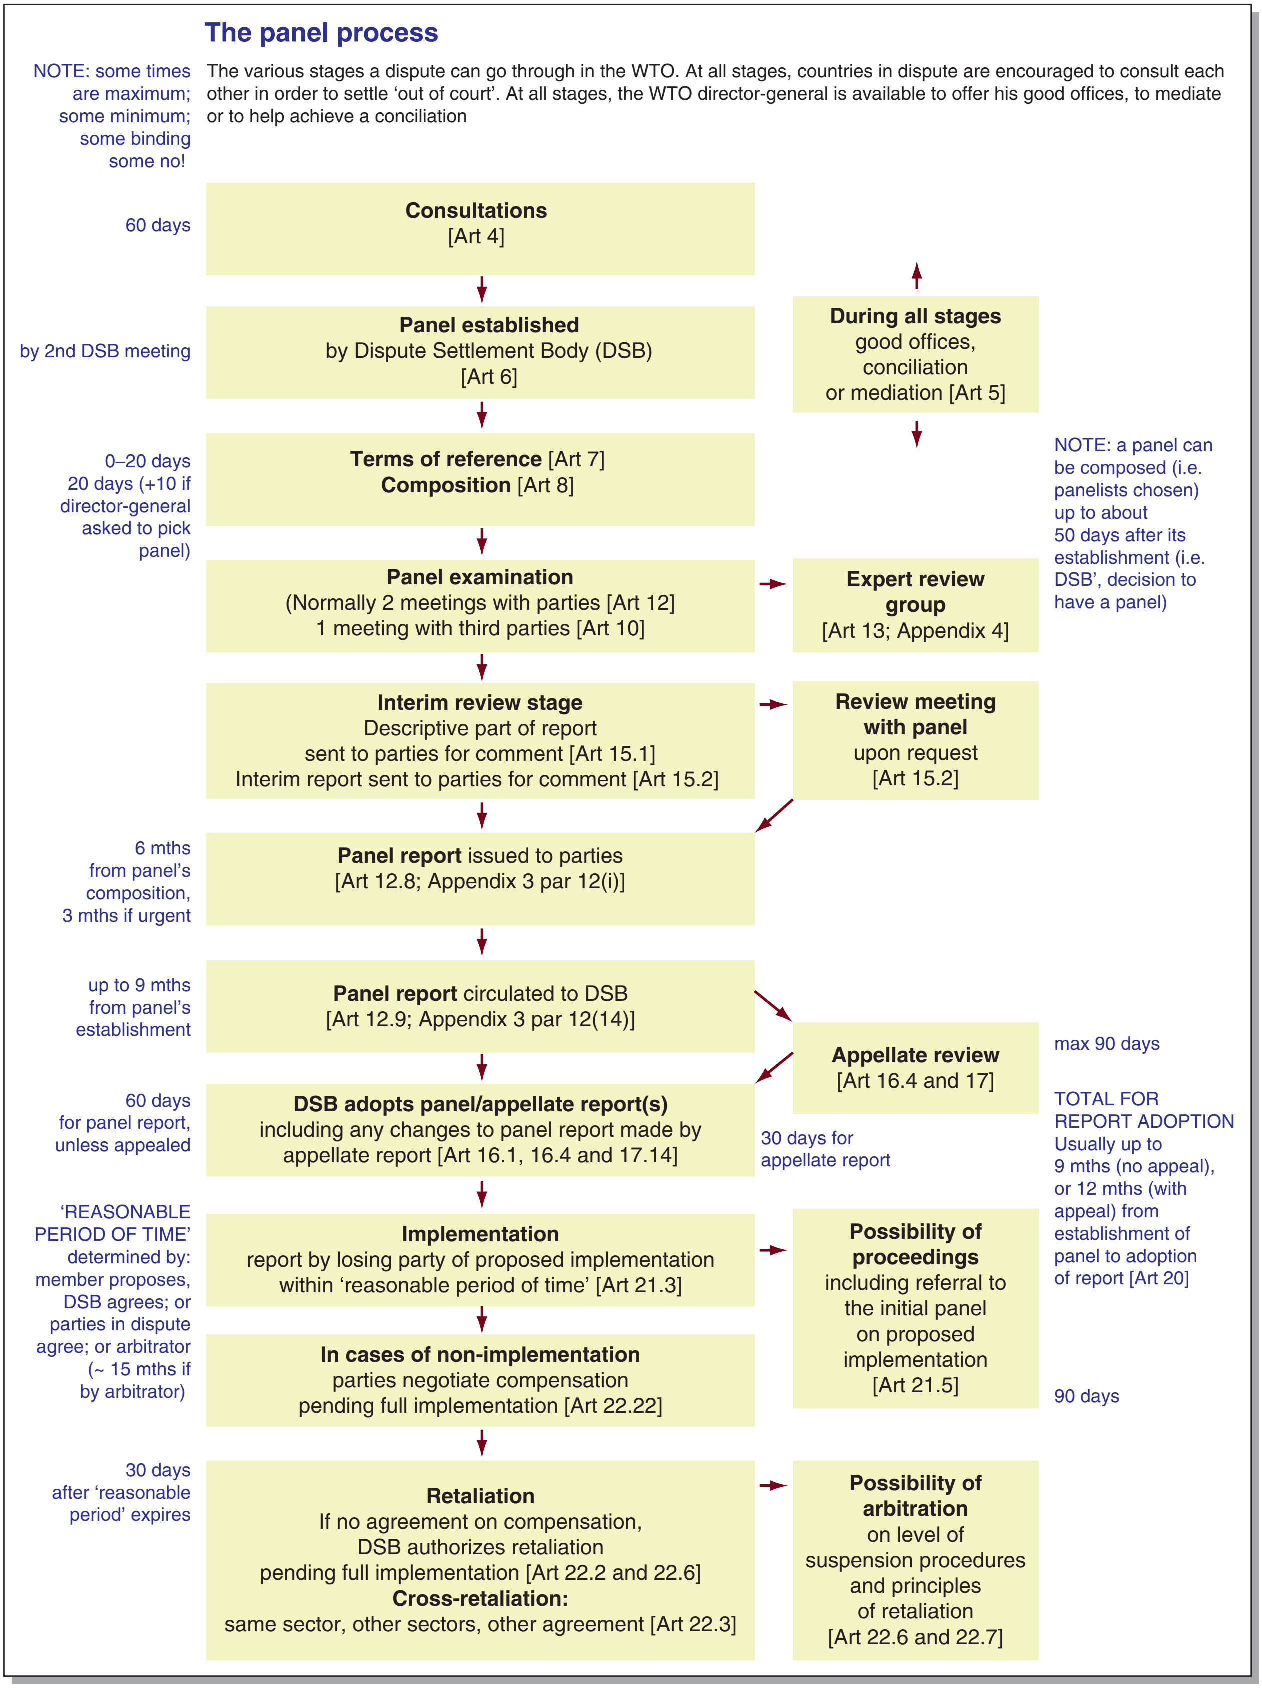
With the creation of the WTO, the trading system established a much more comprehensive dispute settlement system than was the case under the GATT, led by the Dispute Settlement Body (DSB). This dispute settlement system is based on the rule of law and with the strengthened possibilities of enforcement, the WTO has increased its regulatory and arbitrating powers. The Dispute Settlement Body is one of the cornerstones in the transformation from an international agreement to an international organization.

Arbitration between members is a vital task for the WTO in order to secure the adherence by members to different agreements and rules under the WTO, but also to obtain the support of the members for the policies for the development of the international trade regime. The Dispute Settlement Body mainly facilitates the process by which Member Countries obtain legal guidance and counseling to solve bilateral disputes concerning trade issues under coverage of the different agreements under the auspices of WTO. A trade dispute taken to the WTO follows a predetermined structural process with set deadlines and obligations to implement the rulings. This allows for the development of jurisprudence and case law precedent within the WTO, and creates a much more predictable trading system.

The different stages of a WTO case are shown in **Figure 1**. A panel makes first rulings in the WTO; their report is approved unless there is a consensus against this. The panel ruling can on legal grounds be taken to appeal to the appellate body. The appellate body's decision is final, unless there is a consensus against the decision. This procedure implies that no single country or party to a dispute can veto a final decision and by that hinder a ruling against its interest. Member Countries are compelled to implement rulings of the WTO or to pay compensation to cover the opponent's losses resulting from the illegal trade practice. The WTO may also allow for retaliation and introduction of sanctions, if a party to a case does not intend to follow the final ruling.

Non-tariff Barriers

In the early days of GATT the focus was on reducing tariffs and import duties in order to enhance trade and reduce protectionism. This goal has largely been achieved for industrial produce during the course of the numerous trade rounds. Tariffs within trade in industrial products have been reduced from approximately 40% to less than 5% in the period from the establishment of GATT to the current implementation of the Uruguay Round. This tariff reduction process is only in an early stage with respect to agricultural and food products.



The panel process
NOTE: some times are maximum; some minimum; some binding some no!
The various stages a dispute can go through in the WTO. At all stages, countries in dispute are encouraged to consult each other in order to settle 'out of court'. At all stages, the WTO director-general is available to offer his good offices, to mediate or to help achieve a conciliation
60 days
Consultations [Art 4]
by 2nd DSB meeting
Panel established by Dispute Settlement Body (DSB) [Art 6]
During all stages good offices, conciliation or mediation [Art 5]
0–20 days
20 days (+10 if director-general asked to pick panel)
Terms of reference [Art 7]
Composition [Art 8]
NOTE: a panel can be composed (i.e. panelists chosen) up to about 50 days after its establishment (i.e. DSB', decision to have a panel)
Panel examination (Normally 2 meetings with parties [Art 12] 1 meeting with third parties [Art 10]
Expert review group [Art 13; Appendix 4]
Interim review stage
Descriptive part of report sent to parties for comment [Art 15.1]
Interim report sent to parties for comment [Art 15.2]
Review meeting with panel upon request [Art 15.2]
6 mths from panel's composition, 3 mths if urgent
Panel report issued to parties [Art 12.8; Appendix 3 par 12(i)]
up to 9 mths from panel's establishment
Panel report circulated to DSB [Art 12.9; Appendix 3 par 12(14)]
Appellate review [Art 16.4 and 17]
max 90 days
60 days for panel report, unless appealed
DSB adopts panel/appellate report(s) including any changes to panel report made by appellate report [Art 16.1, 16.4 and 17.14]
30 days for appellate report
TOTAL FOR REPORT ADOPTION Usually up to 9 mths (no appeal), or 12 mths (with appeal) from establishment of panel to adoption of report [Art 20]
'REASONABLE PERIOD OF TIME' determined by: member proposes, DSB agrees; or parties in dispute agree; or arbitrator (~ 15 mths if by arbitrator)
Implementation report by losing party of proposed implementation within 'reasonable period of time' [Art 21.3]
Possibility of proceedings including referral to the initial panel on proposed implementation [Art 21.5]
In cases of non-implementation parties negotiate compensation pending full implementation [Art 22.22]
90 days
30 days after 'reasonable period' expires
Retaliation
If no agreement on compensation, DSB authorizes retaliation pending full implementation [Art 22.2 and 22.6]
Cross-retaliation:
same sector, other sectors, other agreement [Art 22.3]
Possibility of arbitration on level of suspension procedures and principles of retaliation [Art 22.6 and 22.7]

Figure 1 Flowchart of the dispute settlement process in the WTO. (Reproduced with permission from www.wto.org.)

As duties have diminished, the non-tariff barriers (NTB) have attracted increasing attention as they turn out to be as trade-distorting as flat rate tariffs. Non-tariff barriers consist of a number of different rules, regulations, standards, technical issues, administrative and bureaucratic procedures and other market-related obstacles that exporters meet while trying to gain access to a certain market. The WTO tries to highlight this area with a policy of transparency and information, but also with restrictions on the use of nontariff barriers.

Agreement on Technical Barriers to Trade

The Agreement on Technical Barriers to Trade (TBT) is closely tied to the above-mentioned non-tariff barriers. This agreement aims at creating a free flow of international trade by regulating the general use of technical standards in a protectionist way. The agreement installs the principle that technical regulations and standards concerning packaging, marking and labeling, and procedures for assessment of conformity with technical regulations and standards should be used in a nondiscriminative way, both in respect to different trading partners and with regards to domestic versus import products.

The agreement encourages the use of internationally recognized standards in national and local laws. At the same time member countries have to enhance transparency and public access with regard to applied and upcoming standards.

Agreement on Sanitary and Phytosanitary Standards

The Agreement on the Application of Sanitary and Phytosanitary Standards (SPS) defines and gives opportunities for Member Countries to adopt measures necessary to protect human, animal and plant life and health and at the same time regulates the use of these measures in order to avoid their discriminative use as barriers to trade.

In the SPS agreement the scientific principle prevails. Sanitary and phytosanitary measures restricting trade should at all times have a scientific foundation that is widely recognized. Concurrently, countries are to treat different rules and standards alike, if their ultimate effect is the same for the protection of the human, animal and plant life and health. The Codex Alimentarius is recognized in the SPS agreement as a standard-setting reference point in this area and in the case of disputes among member countries. The objective is to harmonize the basis for sanitary and phytosanitary measures and meanwhile to create transparency and access to information concerning different rules and demands within this area.

Agricultural Agreement

With the finalization of the Uruguay Round of trade negotiations agricultural trade fully came under the regulation of the WTO. The Agricultural Agreement is the first real attempt to achieve a common understanding of the trade mechanisms for agricultural and food products and the Agreement implements a number of regulations which in the last half of the 1990s and at the turn of the century set fundamental boundaries and rules for governance and policy-making within agriculture worldwide (**Table 3**).

The major elements of the Agreement fall under three headings:

1. Export subsidies and competition.
2. Market access/imports.
3. Internal/domestic support.

Together with the three central parts of the Agricultural Agreement, the Sanitary and Phytosanitary Agreement

Table 3 The outline of the support reductions in the agricultural agreement

The main demands for reduced agricultural supports 1995 to 2001		
Exports with support	*Imports*	*Internal support*
21% reduction in export quantities subject to support	All non-tariff barriers converted to tariffs	20% reduction in all trade distorting internal supports based on the AMS calculation
36% reduction in budgetary outlays for export subsidies	Average 36% reduction in tariffs including converted non-tariff barriers, at minimum 15% reduction pre product line	Base period: 1986–88
Base period: 1986–90	Minimum access at reduced tariff rates of 3% increasing to 5% of domestic consumption Base period: 1986–88	

Source: http://www.wto.org

(see above) constitutes an attempt to formulate an overall framework for agricultural trade and by that the domestic policies concerning production and regulation of food supply.

Within the WTO there are a number of different views concerning liberalizing versus protecting agricultural production and trade. The most vocal groupings in the agricultural negotiations are the United States, the EU and the Cairns Group, a number of food exporting countries with Australia and New Zealand at the forefront. The developing countries are with respect to their interests mainly divided into two main groups, net food exporters and net food importers.

A number of very important trade disputes concern trade in agricultural produce, such as bananas, hormone-treated beef or milk quotas, to mention just a few. These WTO cases between different Member Countries have been some of the most stringent tests to the dispute settlement system within the WTO. Agricultural and consumer-related issues have proved to be the most politicized cases in the short history of the Dispute Settlement Body of the WTO. But they are also acknowledged as the core challenge to the sustainability of the system and to the Member Countries' genuine support and acceptance of the WTO rules and governance.

Blair House Accord

The Blair House Accord between the EU and the United States is named after the presidential official guesthouse in Washington DC where the Agricultural Agreement was finalized. This agreement, reached in November 1992, was a breakthrough in the ongoing Uruguay Round of negotiations in GATT. The accord laid the foundations for the current trade liberalization within agriculture and also facilitated an ending to the very long and at times antagonistic negotiations for a general conclusion to the trade round.

The Blair House Accord sets the basic reduction factors both for exports and internal support measured in quantities and budgetary outlays. The accord also sets a 6-year implementation period and the reference periods. Alongside this, the EU and the United States agreed on solving a number of outstanding trade disputes particularly the one on oilseeds. The agricultural breakthrough in the GATT system is widely recognized to rest on the Blair House Accord and hence on the hard-won compromises and common understanding between the EU and the United States. The EU has a mandate to negotiate for all Member Countries of the European Union, which act as one within the WTO.

In December 1993, one year after the Blair House Accord, the final GATT agreement was reached and it was signed in Marrakesh in Morocco in April 1994. The Agricultural Agreement entered into force in 1995 running to 2001, with a peace clause extending it to 2003. The Agreement stipulated that further negotiations were to start in the WTO by 1999 in order to prepare for a new agreement. These negotiations are currently (2002) in process with all the parties outlining their specific interests and suggestions for a new agenda and ultimately an agreement.

Peace Clause

It was envisaged in the Blair House Accord that a new agreement might not be reached among the trading partners to take over from the Uruguay Round agreement exactly in 2001. Therefore it was decided to extend the results of the final stage of the implementation – the so-called year 6 (2000/2001) – onward to 2003 to provide some time for negotiations on a new agreement. From 2001 to 2003 no further developments in the levels of subsidies, import tariffs and internal support are anticipated unless a new accord is in place. At the same time, the agreed reductions will not be reversed.

The situation for the agreement on agriculture is, however, uncertain if a new deal is not in place by 2003. One option is to agree to extend the peace clause; however, a potential conflict is possible.

Traffic-Light Model – GATT Boxes and Decoupled Support

One of the main objectives of the Agricultural Agreement is to reduce support levels in general; however, support is divided into more and less trade-distorting types. The aim of the Agreement is to target the most distorting support forms which directly influence the international markets for agricultural products, and hence the competition situation between different agricultural producers.

Aggregated Measurement of Support

The Total Aggregated Measurement of Support (AMS) is a calculation of the total amount of support given to agricultural producers in one country, except for domestic support not subject to reductions, because of their nondistorting or decoupled nature. The AMS calculation is used to facilitate comparisons between countries and to equalize different types of support in order to obtain reductions in all types of distorting supports.

Traffic-light model

In popular terms the different types of agricultural support are labeled with different colors: red, amber, green – and blue. The red support forms should be stopped immediately, the amber ones should be phased out and the green ones can be left, as they are not seen as directly distorting. This rule-of-thumb makes for the name 'traffic-light model'. The different colors also give names to the box scheme, which is another way of describing the different support forms: amber, blue and green boxes.

Export subsidies

The export subsidies used by various countries fall into the amber box and must be reduced according to the agreement by 21% for supported export quantities and by 36% in total budgetary outlays. The reduction had to be linear over the implementation period, reaching the final commitments in Year 6, 2001. Developing countries must reduce their support by 14% in quantities and 24% in budgetary outlays with an implementation period of 10 years. Least-developed countries are exempt from this obligation. Member Countries have to keep account of the use of export subsidies for the individual product categories.

Decoupled support and blue box subsidies

In order to encompass the American deficiency payments and the EU animal and area premiums of the mid-1990s, the blue color was introduced. Blue color support forms are semi-decoupled, whereas the green ones are decoupled altogether.

The term 'decoupled' is used to describe the situation where the size and amount of support are not linked to the actual form and size of the agricultural production, as opposed to price support that is directly linked to the production output. Green box types of support are within the areas of research, disease control, government services and many more. Direct income support also falls in this category, as long as it is independent of the production. Semi-decoupled support can take the form of direct payments under production limiting programs with fixed references – area, yield or animal numbers.

The blue box supports are not targeted by reduction demands because of their limited trade-distorting nature. The introduction of categorized support forms has allowed for a dynamic agricultural policy reform process in different countries. The major agricultural production and trading countries have undergone a number of reforms since the GATT agreement, all directly related to the WTO policies, in order to enhance competitive powers and allow for a more fair trade with agricultural produce. In most WTO member countries development of agricultural policy instruments is under way in order to avoid potential disputes.

Imports and Market Access

The import rules in the Agreement specify that tariffs have to be reduced by an average of 36%, with a minimum 15% per product line from 1995 to 2001. Prior to the reduction all non-tariff barriers have to be converted into tariff equivalents to enhance transparency as to the actual level of trade restrictions. This conversion is termed tariffication. It is the overall tariffs (duties, levies, quantitative restrictions, non-tariff barriers and so forth – old and new ones) that are to be reduced by 36%. The tariff rates are listed in the country list for each country with initial and bound rates. Developing countries are only obliged to reduce tariffs by 24%, and they have an extended implementation period, to 2004. Least-developed countries are exempt from the agreement to reduce tariffs.

Minimum import access

In order to create some immediate effect for market access it was decided to create a certain minimum access to a preferential tariff far below the general and even reduced tariffs. This minimum quota is set in relation to the consumption in the base period 1986–88. At the beginning of the implementation in 1995 the quota was 3% of base period consumption for the respective products. This amount has gradually increased to 5% at the end of the 6-year implementation period in 2000/2001. Current access opportunities are to be maintained and supplemented with the above-mentioned minimum access in case the actual imports are below the 3–5%.

Trade in Dairy Products

It was widely believed that the WTO agreement would increase the international trade in agricultural products, including dairy produce. The actual development does indicate that the total trade is developing; however, what is more noticeable is the change in the trading patterns. **Table 4** shows the shift from an EU-dominated international trade in dairy products to a situation where Oceania is the predominant exporter. This situation is reflected in different claims and demands in respect of the ongoing negotiations on a WTO II agreement. It was also expected that the price for dairy products would be affected in an upward trend by the Agricultural Agreement and the increased trade, but this element is harder to deduce from the statistics. However, some signs in the market do indicate a general upward trend in prices for dairy products.

World Trade Organization and Other Factors Shaping the Dairy Industry in the Future

P Vavra[1], OECD, Paris, France

Introduction

How would dairy industry look like after the conclusion of WTO (World Trade Organization) Doha negotiations? Is there going to be a final deal? Is there a need for a Doha deal?

Starting with the last question, the answer is 'yes'. In my view it is not necessary to discuss here the importance of the Doha round and the advantages of a multilateral approach. Bilateral and not even regional agreements cannot match the multilateral system. Issues related to standards or dispute settlements are just two examples that need multilateral consideration. The value of WTO trade negotiations that seek broader consensus has also been underlined in empirical studies. For example, an OECD (Organisation for Economic Co-operation and Development) study pointed to the logical fact that the domestic supply adjustment for dairy sector can be expected to be the highest if a country reforms its dairy policy unilaterally. As more countries join the reform process, adjustments become smaller and would be least in the case of a multilateral reform.

As there is a need for a multilateral framework to govern global trade, it could be expected that there will be a final deal. However, in the aftermath of the global economic crises, the question mark after the word 'When' is not getting smaller.

The answer to the first question is even more complex. It is always difficult to predict how the world would look like after a specific event, and it is not easy to isolate the impact of that particular event from other factors influencing the evolution of the world. In the last decade the dairy industry has been going through remarkably dynamic changes worldwide, becoming truly global in scope. Would this have happened even without the WTO Uruguay Round Agreement on Agriculture? Or, was globalization in fact propelled by numerous border measures protecting domestic markets that provided incentives for foreign companies to circumvent national border measures through investment in protected markets?

A Doha deal could be expected to have an impact especially on those domestic markets that have relatively high market price support measures in place. But the actual impact depends on the global market situation and the way countries organize support to agriculture. Moreover, the forces of globalization, underpinned by economic growth, urbanization, and technology transfers, will likely continue to shape the dairy industry, be it pre- or post-Doha. This article will discuss not only concerns related to Doha but also other issues that are likely to have an impact on dairy markets in the near future.

Doha Round in the Context of WTO Negotiations

Established on 1 January 1995, the WTO replaced the GATT (the General Agreement on Tariffs and Trade) as the legal and institutional foundation of the multilateral trading system of its member countries. Although GATT has been providing the multilateral rules governing much of the global trading system since 1948, these rules were largely ineffective in disciplining key aspects of agricultural trade. The Uruguay Round was the first trade round that considered agricultural issues, and it became a turning point in the reform of the agricultural trade system. The Uruguay Round Agriculture Agreement (URAA) has accomplished the development and implementation of a framework to address barriers and distortions to trade in three major policy domains: market access, domestic support, and export subsidies. The diverse forms of trade measures were converted under the URAA to tariffs. Market access for sensitive products was provided through a system of tariff rate quotas (TRQs). The use of export subsidies was reduced by the agreement, while domestic policies that affect production and trade of agricultural products were constrained by a set of rules and bindings. The reduction in domestic support was implemented through a commitment to reduce the total aggregate measurement of support (AMS) for each country.

The URAA numerical targets for each policy domain in agriculture are summarized in **Table 1**. The table indicates that in the developed countries the total AMS support was scheduled to be reduced by 20% over 6 years, while in the developing countries the total AMS

[1] The author is an agricultural markets and policy analyst at the OECD, Paris. The opinions expressed in this article are those of the author and do not necessarily represent those of the OECD or its member countries.

Table 1 Uruguay round numerical targets for agriculture

	Developed countries	*Developing countries*
	6 years: 1995–2000	*10 years: 1995–2004*
Tariffs		
Average cut for all agricultural products	−36%	−24%
Minimum cut per product	−15%	−10%
Domestic support		
Total AMS cuts for sector (base period: 1986–88)	−20%	−13%
Exports

Subsidized quantities (base period: 1986–90)	−21%	−14%

Source: WTO.

support was scheduled to be reduced by 13% over 10 years. Moreover, the agreement required a reduction of tariffs by 36%, on average, for developed countries, and by 24% for developing countries. It is evident from the table that although the Uruguay Round achieved a historic change, the actual level of agricultural support was reduced only moderately.

Nevertheless, the achievement of the Uruguay Round should be seen in the establishment of rules for agricultural support and as a start of the process of long-term objective of substantial reduction in support and protection. This process was to continue in the new round of negotiations. At the Fourth Ministerial Conference in Doha, Qatar, in November 2001, WTO member governments agreed to launch a new round – the so-called Doha round – of negotiations. The round embarked on a very complex agenda with a focus on developing countries, trade facilitation, competition rules, environment, investment, liberalization of trade in services, and liberalization of trade in agriculture, which is likely the single most difficult item.

The Doha Ministerial Declaration has set several key dates for the negotiations. The modalities for countries' commitments were expected by 31 March 2003, and countries' comprehensive draft commitments by the fifth ministerial conference in September 2003 in Cancún, Mexico, with the overall deadline set for 1 January 2005. However, after a failed – the so-called – Harbinson proposal in March 2003, the fifth ministerial conference in September 2003 ended up in a stalemate. Ten months after the Cancún deadlock, an agreement on a framework for the modalities on agriculture was reached. The so-called July Framework gave a clearer shape to the modalities for the next phase of the negotiations.

The 2004 July Framework Agreement was a starting point toward a draft of the detailed modalities to be agreed at the WTO's sixth ministerial conference held in Hong Kong, from 13 to 18 December 2005. Rather limited progress was made in reaching an agreement on precise numerical formulae or targets for liberalizing agricultural trade, the original aim of the Hong Kong Ministerial. Perhaps the most tangible outcome of the Hong Kong Ministerial was the continuing support to eliminate all forms of export subsidies, and disciplines on measures with equivalent effects. The next deadline for reaching agreement on modalities was set for 1 August 2006. As no agreement could be reached, the negotiations had been suspended at the General Council meeting on 27–28 July 2006.

In 2007, the negotiations were resumed and a new set of modalities were circulated in July and August 2007. A series of working documents followed, as well as a series of revised draft modalities on 8 February and 19 May 2008, respectively. A revision of the previous versions was circulated on 10 July 2008. But the meeting of ministers in Geneva over 21–30 July did not reach an agreement. The disagreement occurred over the special safeguard mechanism (SSM) for agricultural products in developing countries. Safeguard mechanisms are used to restrict imports in special circumstances such as a sudden surge in imports. The unresolved issue was the size of the trigger allowing to invoke a special safeguard measure. In particular, the disagreement was related to the situation where the SSM raises tariffs above the commitments made by the countries in the 1986–94 Uruguay Round – the pre-Doha Round bound rates.

Some commentators viewed the July 2008 failure more as a collapse of negotiations; others noted the progress on issues other than the SSM. It is difficult to estimate what would happen if the questions of the SSM were resolved. In his report to the trade negotiations committee, the chairman of the special session of the committee on agriculture, Ambassador Crawford Falconer, noted that despite the fact that members were prepared to accept compromises it could not be taken for granted that even with the SSM agreement the rest could have fallen into place. There are still unresolved questions related to new tariff quota

Table 2 Overview of GATT and WTO negotiation rounds

Name	*Start*	*Duration*	*Countries*	*Subjects covered*
Geneva	April 1947	7 months	23	Tariffs
Annecy	April 1949	5 months	13	Tariffs
Torquay	September 1950	8 months	38	Tariffs

? – not yet known.

creation, tariff simplification, and issues related to cotton. These could be the other deal-breakers. Nevertheless, it was clear from the outset that the agenda is ambitious and that a lot of time and work would be needed to successfully conclude the round. Moreover, the time spent so far on negotiations cannot be considered excessive, despite the slow progress.

Table 2 summarizes the time-bound efforts of the previous GATT and WTO rounds.

Implications of the Doha Round for the Dairy Sector

The Doha round has not fundamentally changed the rules as agreed by the URAA, but larger reductions (or even elimination) have been considered. Although the actual modalities have not been agreed to and are subject to change, the key factors so far could be described as follows: (1) Elimination of export subsidies in all forms (already agreed in July 2004 Framework) and improved disciplines on all export measures whose effects are equivalent to those of export subsidies. (2) Depending on the base of Overall Trade-Distorting Domestic Support (OTDS), a reduction is envisaged in the range of 50–85% using a tiered formula; the framework also widened the range of support that would be disciplined in the Doha round; Blue Box supports are to be capped at no more than 5% of the value of a country's agricultural production, in the 1995–2000 period. (3) Tariffs shall be reduced using a tiered formula that requires deeper cuts for higher tariffs.

The least developed countries would not be required to make any reduction on domestic support and tariffs. The negotiated framework also provides a number of flexibilities intended to meet specific concerns of individual or groups of countries. These flexibilities, which are in fact numerous exceptions – such as the designation of sensitive products and special products for developing countries, special agricultural safeguard measures – have substantially increased the complexity of the negotiations and introduced doubts about the effectiveness and success of tariff cuts.

What would be the implication of the Doha round for the dairy sector? Dairy markets have traditionally been among the more distorted, and even after the full implementation of the URAA, dairy trade continued to be among the most protected agricultural sectors with high average bound tariffs, low minimum access requirements, a number of special safeguard provisions, complex systems of tariff-rate quotas (TRQs), and large domestic support and export subsidies and other export support measures. In almost all instances, tariffs on dairy products are above the country average for all agri-food products and are among the highest on agricultural products (**Table 3**). Thus, it could be expected that, after a Doha deal, countries with high tariffs would need to reduce them considerably, but, as noted above, dairy products could be listed as sensitive products falling under the exemption category.

Under the current legislation it has been possible to avoid reductions in dairy AMS by adjusting the AMS amounts in other sectors. Such compensation mechanisms are limited in the Doha framework, which specifies product-specific AMS limits and envisages capping of the product-specific funding. The product-specific AMS limits for all developed country WTO Members other than the United States shall be the average of the product-specific AMS during the Uruguay Round implementation period (1995–2000) as notified to the Committee on Agriculture. For the United States, the

Table 3 Average (scheduled) tariffs in 2000 for main commodities

	In-quota	*Out-of-quota*
Coarse grains	100	217.8
Wheat	73.2	184.4
Rice	15	197.5
Sugar	15.8	126.7

Skim milk powder	48.1	191.6
Whole milk powder	79.5	260.7
Whey powder	37.8	545.7
Average of all commodities	52.67	184.18

From OECD (2002) *Agriculture and Trade Liberalisation: Extending the Uruguay Round Agreement*. Directorate for Food, Agriculture and Fisheries, Committee for Agriculture. Paris: OECD.
Average tariff was calculated as an unweighted average of each tariff line for the following countries: Argentina, Australia, Canada, European Union, Hungary, Japan, Korea, Mexico, New Zealand, Poland, United States, Iceland, Norway, and Switzerland.

product-specific AMS limits shall be the resultant of applying proportionately the average product-specific AMS in the 1995–2004 period to the average product-specific total AMS support for the Uruguay Round implementation period (1995–2000) as notified to the Committee on Agriculture.

It is not necessary to go through all the details of modalities as these can be found in the original WTO document. However, an important point needs to be made here about the overall process. The WTO negotiations are not about eliminating agricultural policies but about shifting to more effective policies. Hence, countries will be able to implement or keep policies that do not distort trade. It follows that the green box is likely to remain in existence and act as a home for measures that are decoupled from production as far as possible and targeted at specific objectives and beneficiaries. (The green box support measures include those deemed to distort trade only minimally, or not at all, such as some forms of direct payments to producers, decoupled income support, and government financial support for income insurance and income safety net programs.)

The simulation results of studies that have analyzed the impact of further trade reforms on the global dairy sector have indicated that, following the reforms, world dairy prices would be lifted while supply would shift toward more efficient areas, although there would not be any significant change in total world milk production. It is however difficult to extrapolate these results in the context of recent developments as the agricultural markets have undergone dramatic changes. This is especially true of the dairy sector, which has been going through rapid structural changes for some time with several countries also embarking on policy reforms. As a consequence, international dairy markets have slowly shifted from a supply-driven paradigm distorted by price-depressing policies and serving as an outlet for excess supplies, to a more demand-driven paradigm, responsive to market signals and changing consumer preferences. The very recent events on the markets have further refocused attention on food security, availability, and safety. These profound market changes, some of which are believed to be structural and long-term in nature, will have a significant impact on the dairy sector, be it pre- or post-Doha. In order to get a better grasp on global dairy prospects it is essential to understand this shift.

Global Market Changes and Prospects

The prices of nearly all agricultural commodities have risen sharply in the 2007–08 period but the prices of dairy products were the first to start the climb. International dairy prices recorded strong gains in the first half of 2007, already peaking in the second half of that year well ahead of similar developments for other commodities (**Figure 1**). On a year-over-year basis between 2006 and 2007, world butter prices increased by 66% and cheese prices rose by 50%, while prices of milk powders soared by more than 90%.

The OECD–FAO Agricultural Outlook report expects that all dairy prices will weaken over the short-term as demand softens and supply, with some lag, reacts to the strong price incentives. Nevertheless, dairy prices in real terms are expected to average 20–30% higher as compared to those of the last decade. The prices in real terms are also expected to resume a modest declining trend, albeit from a much higher level than in the past (**Figure 2**). However, it is important to note that these projections are conditional on the underlying macroeconomic assumptions, most notably solid economic growths and high crude oil prices. **Figure 2**, which depicts butter and skim milk powder (SMP) prices in real terms, also illustrates two additional points. First, when viewed from the perspective of last couple of decades, the recent spike of prices in real terms is much less impressive, certainly for butter. Second, over the last several decades the value of milk components on the international market changed considerably and shifted toward non-fat solids away from fat. (The steady decline in milk fat value on world markets could be, to some extent, attributed to the policy decision in heavily protected countries to tilt butter/SMP support prices in favor of butter, which has favored the production of fat for which demand has been stagnating.)

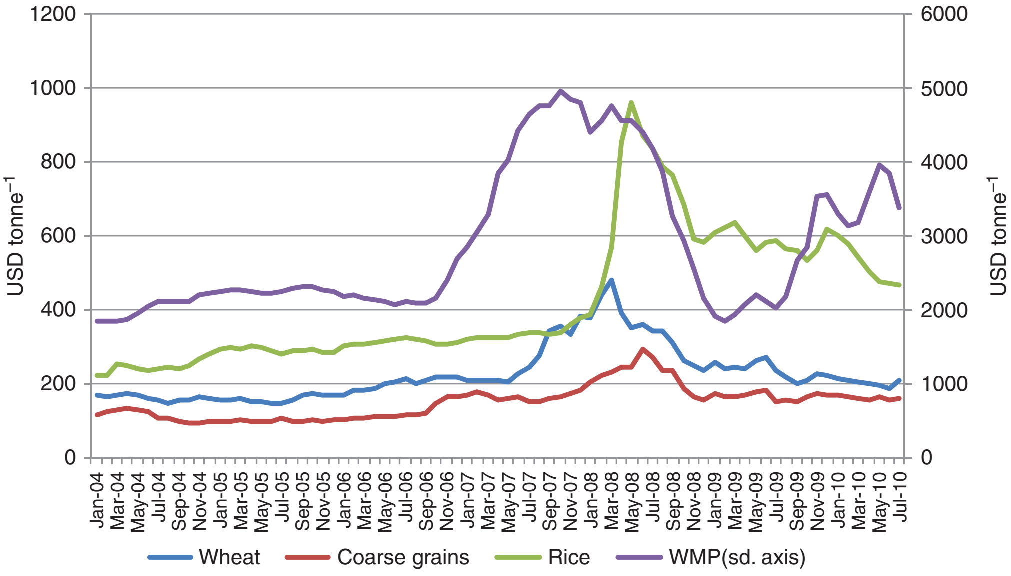

Figure 1 International monthly commodity prices. Source: OECD–FAO.

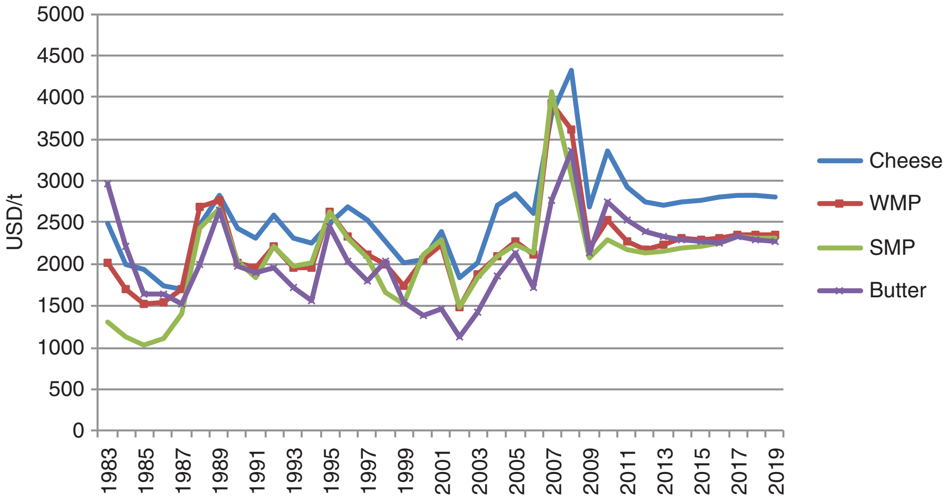

Figure 2 Historical and projected international prices (in real terms) of SMP and butter. Source: OECD.

The reasons for expectations of a higher plateau for global dairy prices merit a short consideration. Some of the factors behind the higher prices are related to more structural shifts while others could be considered as transitory. For example, a more permanent change in the markets relates to changes in demand patterns particularly in developing countries where consumers are switching to a more protein-based diet fueled by urbanization, westernization, and growth in per caput income. Consumption of milk and dairy products is rising nearly everywhere, exhibiting the highest growth rates among agricultural food commodities. The rise is particularly marked in rapidly growing economies of the Pacific Rim where an expanding middle-class population is consuming more sophisticated processed foods. Over the medium term, in developing countries, demand growth is expected for all dairy products with whole milk powder (WMP) consumption showing the strongest growth, followed by butter. Nevertheless, OECD countries continue to dominate cheese consumption and maintain their three-quarter share of the world total (**Figure 3**).

Another important development that slowly changed the usual picture was the decline in the importance of intervention products on world markets, particularly from the European Union and the United States. While in the period 2002–03 the share of EU and US SMP stocks alone amounted to half of the global exports of SMP, in the period 2005–07 this share dropped to below 10%, reducing the buffer against shocks in supply and demand (**Figure 4**). The lower stock levels have added to market and price volatility, and there is a strong nonlinear relationship of changes in stock levels to the changes in price. When ending stocks are sizable, large

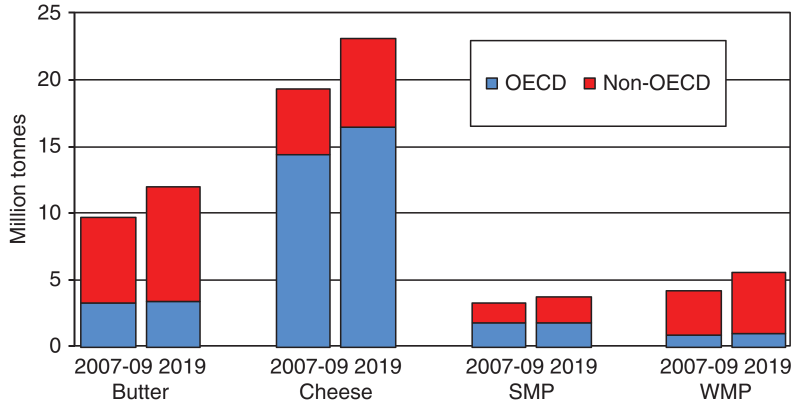

Figure 3 Outlook for dairy product consumption. Source: OECD.

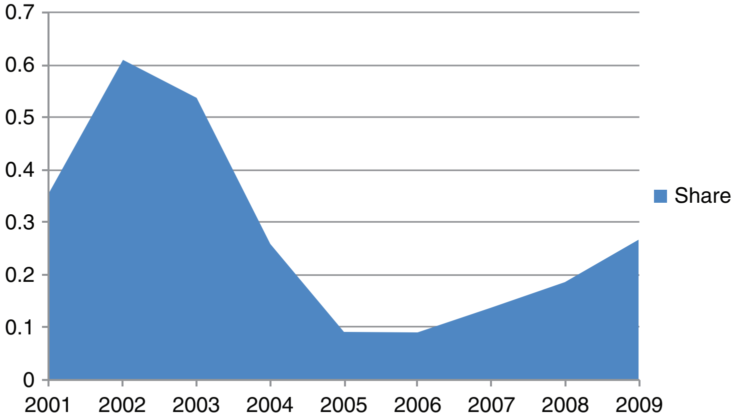

Figure 4 Ratio of EU and US stocks of SMP to global exports. Source: OECD.

changes in stock levels may be needed to change prices by a small amount. When stock levels are low, very small changes in stock levels can be associated with major price swings.

The tight situation on the market in 2007 was further aggravated by the decline in milk production in Australia and Argentina. Production everywhere was hindered by a strongly increasing cost of production – rising oil and feed prices. Oil, energy, and feed prices are critically important factors in the increased production costs for milk, and a higher plateau of these prices seems to be a more permanent factor that could keep prices above past average levels. The situation on the dairy markets was also to some extent exacerbated by policy decisions in certain countries to tax or ban exports. These *ad hoc* actions should be considered temporary, and introducing policies that create distortions and that undermine appropriate market responses should be avoided in the future.

Finally, an important factor, not unique to the dairy sector, has been the depreciation of the US dollar. Stronger currencies *vis-à-vis* the US dollar mitigated the producer price gains in local currencies and at the same time facilitated higher demand by importers, thus driving world prices higher in terms of US dollars. In general terms, when the dollar is weak, commodity prices tend to be higher, and when the dollar is strong, commodity prices tend to be lower (**Figure 5**).

Nevertheless, in discussing the prospects for the global dairy markets it is important to keep in mind that the most certain thing about the future is that it is uncertain. Weather, economic conditions, and the evolution of policies (induced by Doha deal or not) remain among the key factors influencing the dairy market's future, with a considerable uncertainty about them. For example, a slowdown in economic growth would moderate international prices. A severe drought in any important dairy-producing region could have a critical impact on the sector in any given year, pushing prices higher. These factors are uncertainties that to some extent form an integral part of the dairy markets. What are the other factors that will likely shape the dairy markets in the near future – be it pre- or post-Doha? Although the choice for the discussion might be subjective, it seems

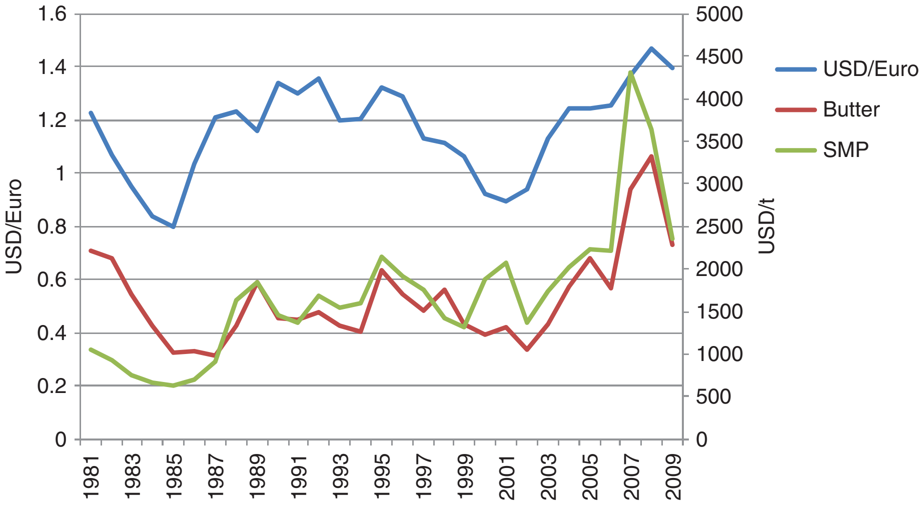

Figure 5 Exchange rate and global prices (in nominal terms). Source: OECD.

to me that the shifts in the markets will be reinforced by the following mutually inclusive factors: continued globalization, technological progress, and vertical integration of food supply chains.

Globalization

It is evident that the dairy industry is becoming more global in scope. It could be expected that globalization will continue to reshape the dairy markets in the future and will be fueled by the processes of economic growth, urbanization, technology transfer, and a convergence in consumption patterns. Moreover, the ability to expand, reduce costs, and secure milk supplies will remain additional drivers behind industry consolidation, and the development of discount stores and private labels will quite probably put additional pressure on milk processors, forcing them to look for further cuts in costs. Mergers, strategic alliances, joint ventures with foreign partners, and direct foreign investment and acquisitions will be the main vehicles of the structural change.

Competition among dairy firms in well-established developed markets is set to intensify with the focus turning to health and convenience, and increased penetration of foodservice, catering, and restaurant sectors. As a result, many firms will try to enter growing but less established markets in developing countries to source milk and dairy products from multiple locations while the original domestic market will become less relevant. This is also linked to the continued expansion of supermarkets, which will likely contribute to the further weakening of the position of local dairy firms but will help to spread international brands. Thus, for international dairy companies this means that a branded product can be promoted in multiple markets, but perpetuation of local products and catering for local tastes and preferences are to remain important.

Vertical Integration of Food Supply Chains

Globalization of the dairy industry goes hand in hand with the expansion of supermarkets and transformation of the agri-food sectors in general. It could be expected that the transition from independent markets toward much more tightly aligned food supply or value chains will continue. The profound changes in the global food system are marked by (1) increase of trade in food, (2) rapid rise of economic concentration of supermarkets, (3) shift to centralized procurement via distribution centers – from spot market procurement toward dedicated wholesalers and direct purchase from growers or grower associations, (4) creation of a multiplicity of private standards, often built on top of public standards, (5) rise of third-party certification of food production, (6) development of new technologies, biotechnologies, and process control throughout the entire chain, (7) shift toward nonprice competition among supermarket chains, (8) greater differentiation of food products by class, and (9) the development of new forms of contractual relationships between supplies and buyers. This transition has also been (and will be) accompanied by an increasing use of contracts. The results of several studies indicate an increased use of contracts in most agricultural sectors and dairy is not an exception. However, an increased use of contracts together with a rising upstream concentration in the supply chain could create concerns about the impact of this form of supply chain governance on farmers and issues related to market transparency and market power.

The growing market power in the supply chain might have an impact not only on farmers but also on established dairy companies. The growing power of retailers, and in particular the developments of retailers' private labels, will increasingly represent a challenge for established brands of dairy companies, forcing these firms to continuously innovate.

However, the overriding concern for the future seems to be the capability to assure the quality and safety of food. The importance of consumer confidence in the dairy supply chain is ever more evident following one of the largest food safety crises in recent years which spiraled as a result of milk adulteration with melamine in China. The toxic industrial chemical melamine has been added to milk to make it appear higher in protein. A number of babies died and thousands fell ill after drinking melamine-contaminated milk formula. It could be expected that this incidence will irreversibly change dairy markets and the way the milk and dairy production process is monitored and tested. The share of milk and dairy products in consumers' diets may suffer, so the dairy industry needs to remain proactive and innovative in order to maintain the image of a safe and healthy product. The substitution effect was evident in the recent melamine scare when Chinese consumers sought available alternatives, mainly soy milk. In fact, Starbucks in China announced that all milk used at its cafes in China will be soy-based for the near future. In fact, Starbucks in China announced after the incidence that all milk used at its cafes in China would be soya-based.

Technological Progress

Technology has been changing the dairy sector for decades, and only a true pessimist would say that the progress has arrived at the end of the road. Given the higher commodity price situation, more attention has been and can be expected to be paid to food production. It follows that private and public money flowing to research and development activities and agricultural extension services could push the technology frontier further. Productivity gains stimulated by increased automation of the production process, improved feed efficiency, improved health and longevity of cattle, and the ability to improve productivity via GM technology could be some of the alternatives.

In the milk-processing sector, the availability of ultrafiltration technology has enabled the development of milk component-based markets for milk solids with increasingly broad applications. This trend is expected to continue. Similarly, the growth of demand for dairy products as ingredients in other food products (particularly in pizzas, hamburgers, sandwiches, etc.) will continue.

The future will also see a myriad of new dairy-based products. Recent years have already witnessed product developments such as new functional foods; cosmeceutical, nutraceutical, and pharmaceutical products; and new beverages such as omega 3- and calcium-fortified milk. A promising recent development is also the introduction of a new lactose-free dairy drink produced by a special filtration process that removes half of the milk lactose. Lactose-free milk could be an important factor, driving higher milk consumption, particularly in Asia, where more than half of the population is believed to have some form of lactose intolerance. Finally, in the context of consumer-driven food safety and health concerns, traceability becomes the norm, and this will require the adoption of new technologies and tests for the analysis of residues.

Conclusions

In the context of the current global economic situation and the lack of progress in the Doha round negotiations, it is difficult to guesstimate when the final deal of the Doha round could be sealed. It could indeed be expected that the final modalities will impact future dairy markets. However, it is important to keep in mind that the Doha process is not about eliminating agricultural policies but about increasing transparency, fairness, and efficiency of agricultural trade. It follows that adjustment pressure, following the Doha round deal, on producers in developed countries that support domestic agriculture might not be excessive, although those domestic markets that have relatively high market price support measures in place will likely be affected more. But, the actual impact depends on the global market situation and the way countries organize future support to agriculture.

Many support policies decoupled from production are already in place and one could expect further shifts toward more effective policies better targeted at specific objectives, possibly including disadvantaged producers or production zones, and delivery of social benefits related to environmental and regional concerns. In fact, good agricultural policies do not need to depend on the WTO negotiations. Moreover, even without a Doha deal it seems that it would become increasingly difficult for governments to continue domestic support based on trade barriers for the traditional dairy products in the face of the rapidly evolving trade in new dairy product and dairy ingredient markets, and globalization of the dairy markets in general.

For example, the emergence of a sophisticated ultrafiltration process and expanding markets for milk ingredients have already diminished, to some extent, the importance of increasingly dated dairy support policies. Moreover, the process of globalization is crossing traditional trade barriers and is changing the structure of dairy markets, which have already started to be much more responsive to market signals and changing consumer preferences. Globalization of the dairy sector is set to continue, and international dairy companies will continue to penetrate the less developed markets to satisfy both local and growing export demand. The investments of multinational dairy processing firms will influence the development of new products and the transfer of technologies that improve market size and reach. The investments of multinational dairy processing firms will influence the development of new products and the transfer of technologies that improve market size and reach. These developments will however need to respect environmental considerations. It could be expected that increasingly important factors which are to influence dairy industry in the future are deterioration of natural grasslands, limited water resources and water pollution.

The attention on food security and safety will persist. Safety of milk and dairy products could be expected to become an overriding requirement for producers and dairy supply chain in the future. A related issue for the future dairy sector is the ability of milk and dairy products to keep a good-and-safe image in a broader sense. The industry will need to remain proactive and innovative in order to maintain the share of milk and dairy products in consumers' diets. Nevertheless, milk is a very unique product that contains very unique components, and it is difficult to see how the dairy industry would not be able to profit from this natural advantage.

Introduction

The human gastrointestinal tract becomes inhabited by a huge number of microbes immediately after birth. It has been calculated that in adults this complex open ecosystem, or the intestinal microflora formed in the colon (cecum to proximal and distal colons to rectum), is composed of some 10^{14} bacteria of hundreds of different species. The microflora as a whole or individual microbes are likely to play pivotal roles in the development of normal gut functions and maturation of mucosal immune system, and in the prevention and/or stimulation of intestinal disorders. The composition and metabolic activity of the gut microflora are influenced by various environmental factors, namely diet, age, stress, health status, and medication. Among all, dietary carbohydrates are the predominant carbon and energy sources for the gut microbes, and hence affect the growth of individual bacterial species in the colon.

It has been calculated that ~20–60 g of dietary carbohydrates ingested escapes digestion by human digestive enzymes daily, and they become substrates for fermentation in the colon. Among these nonabsorbed carbohydrates, 5–35 g is resistant starch, 10–25 g is nonstarch polysaccharides, and 2–8 g is nondigestible oligosaccharides (for terminology, see below). The diversity and amounts of these carbohydrates influence the composition and metabolic activity of the colonic bacterial ecosystem, which in turn strongly affect human health. The term 'prebiotics' was introduced by Gibson and Roberfroid in 1995 to describe the "nondigestible food ingredients that beneficially affect the host health by selectively stimulating the growth and/or the activity of one or a limited number of bacteria in the colon". A characteristic underlying the prebiotic concept is to increase 'indigenous' beneficial bacteria in the gut by virtue of feeding specific substrates that are preferentially utilized by these bacteria, in contrast to that of 'probiotics', which are themselves beneficial bacteria and therefore should directly influence the composition and metabolism of the gut microflora. In the past two decades a substantial number of food ingredients that definitely or possibly exert prebiotic effects have been described. The vast majority of them so far are short-chain carbohydrates that are not absorbed or are poorly digested by human enzymes, and are often called nondigestible oligosaccharides (NDO). In addition, recent extensive studies have revealed that certain nondigestible polysaccharides, which are often referred to as dietary fiber, exert health benefits through being fermented by a limited number of colonic bacteria into short-chain fatty acids, and so are capable of being prebiotics.

In this article, the current knowledge of prebiotics especially from a technological and biochemical point of view is summarized.

What Are Prebiotic Effects?

The principal effect of prebiotics is to improve the balance of the gut microflora by increasing the numbers of beneficial bacteria and decreasing those of potentially harmful bacteria, as defined above. This is achieved by the preferential utilization of prebiotic carbohydrates by beneficial bacteria such as bifidobacteria and lactobacilli. As a consequence of the alteration of the gut microflora composition, the metabolic activity and the systemic effects of the gut microflora will influence the host health status. In general, toxin production, intestinal putrefaction leading to production of harmful and carcinogenic substances, unbalanced immune response, (opportunistic) infection, and the overgrowth of harmful bacteria are suppressed, and the enterocyte activity, bowel movement, and the mucosal immune system are optimized.

It is widely accepted that lactobacilli and bifidobacteria are typically beneficial for human health. Primary fermentation products of bifidobacteria and lactobacilli from dietary carbohydrates are acetic and lactic acids. However, the final colonic fermentation products from dietary carbohydrates are short-chain acids (SCA) (mainly acetic, propionic, and butyric), some other organic acids (lactic and succinic), and gases (H_2, CO_2, and CH_4). The proportion of each organic acid in the cecal and fecal contents depends on the composition of the gut microflora and the amounts and forms of supplied carbohydrates. Main players of these diverse fermentation processes are bacteria of clostridia and *Eubacterium* clusters, which not only directly utilize dietary carbohydrates but also further ferment acetic acid and lactic acid to butyric acid and propionic acid, although the detailed characters of these bacterial groups are not well known yet.

There would be some other prebiotic effects based on the production of SCFA and other organic acids, for instance, improvement of mineral absorption in the colon, activation of colonocytes, acidification of cecal and fecal contents, or improvement of lipid metabolism.

Classification and Terminology of Dietary Carbohydrates

Carbohydrates are classified into monosaccharides, disaccharides, oligosaccharides, and polysaccharides based on the number of monosaccharide units contained in them (which is often referred to as degree of polymerization or DP) (**Table 1**). Oligosaccharides are defined as carbohydrates with a DP from 2 to ~10, according to the IUB–IUPAC nomenclature. However, some authorities recommend using the term disaccharides for those having two monosaccharide units (DP = 2). In fact, most disaccharides fit into simple digestible sugars, while there are some disaccharides that resemble longer oligosaccharides in physiological and biochemical characteristics; for example, they are poorly digested and absorbed in the small intestine, but fermented thoroughly in the colon like a sort of non-digestible oligosaccharides, as will be described later. It is difficult to find chemical, structural, and physiological reasons to fix the definition for oligosaccharides. In this article, oligosaccharides with a DP from 2 to ~10 that are not digested by mammalian digestive enzymes in the small intestine are defined as NDO.

The sources of NDO are diverse. Some are isolated from natural origins (human milk oligosaccharides (HMO), soybean oligosaccharides (SOS), levan-type fructans, etc.) and some can be enzymatically or chemically produced from polysaccharides (maltooligosaccharides and isomaltooligosaccharides (for both, α-glucooligosaccharides), oligofructose, xylooligosaccharides, chitin oligosaccharides, etc.) or from mono- and disaccharides (galactooligosaccharides (GOS), fructooligosaccharides (FOS), lactosucrose, gentiooligosaccharides, etc.).

Polysaccharides occur naturally and have more complex structures and lengths than oligosaccharides, and can be classified into starch (α-glucans) and nonstarch polysaccharides (NSP) (**Table 1**). In both classes, there are soluble and insoluble polysaccharides. Of the carbohydrates in foods 80–90% are starch consisting of α-1,4-linked amylose and α-1,4- and α-1,6-linked amylopectin, which are both principally hydrolyzed by human α-amylase. However, the physical structure and DP of starch are diverse, and thus not all starch molecules consumed are hydrolyzed by human digestive enzymes and absorbed in the upper small intestine. The undigested starch entering the colon is called resistant starch (RS) and provides colonic bacteria with a carbon and energy source. On the other hand, NSP are the sum of non-α-glucans and β-glycans mainly found in plant cell walls such as cellulose, hemicellulose, xylan, arabinoxylan, mannan, pectin, and lignin. Some NSP are intracellular polysaccharides of plant cells such as gums, mucilage, and inulin. All these NSP are poorly digested and absorbed in the small intestine, and hence enter the colon undigested and are readily fermented by colonic bacteria to various extents. Different bacterial groups consume different polysaccharides; bacteroides mainly utilize amylose, amylopectin, and pullulan, which are all α-glucan-type RS, while various anaerobic clostridial species utilize NSP.

The term 'dietary fiber' was originally defined by Trowell, in 1972, as remnants of plant cells remaining after digestion in the mammalian gastrointestinal tract. Nowadays a number of other indigestible carbohydrates of plant and animal origin have been proposed and considered for inclusion in the group of dietary fiber. Hence it is most likely that dietary fiber will be defined as food carbohydrate polymers that are not hydrolyzed by the mammalian digestive enzymes in the small intestine and includes NSP, RS, and NDO.

Among these, NDO occupy the most important position in prebiotic substances as they have been extensively studied and shown to be specific substrates for a limited number of colonic bacteria, especially bifidobacteria and/or lactobacilli, in colonic fermentation, and are more readily assimilated in the colon than NSP and RS. Therefore, NDO's exertion of the prebiotic effects could be quicker and more tangible than others' after they enter

Table 1 Classification of dietary carbohydrates

Carbohydrate classes (DP)	*Subclasses*	*Examples*	*Fate in the gastrointestinal tract*
Monosaccharides (1)	Sugar	Glucose, fructose, galactose	Absorbed in the small intestine Glucose gives rapid glycemic response
	Sugar alcohol	Sorbitol, xylitol, mannitol	Absorbed in the small intestine
Disaccharides (2)	Digestible sugar	Sucrose, maltose, trehalose, (lactose)[a]	Absorbed in the small intestine Digestible by endogenous hydrolyzing enzymes Rapid glycemic response
	Nondigestible disaccharides	(Lactose),[a] lactulose	Not absorbed Nondigestible, but fermented in the large intestine
	Sugar alcohol	Maltitol, lactitol	Poorly digested and absorbed in the small intestine Partly or fully fermented in the large intestine
Oligosaccharides (2–10)	α-Glucans	Maltooligosaccharides (isomaltooligosaccharides)[b]	Digestible but partly undigested in the small intestine and give rapid glycemic response
	Nondigestible oligosaccharides	Soybean oligosaccharides Galactooligosaccharides Fructooligosaccharides	Nondigestible Fermented in the large intestine No glycemic response
	Human milk oligosaccharides	Fucosyllactose Sialyllactose Lacto-*N*-tetraose, etc.	Nondigestible Partly fermented in the large intestine
Polysaccharides (>10)	Starch (α-glucans)	Amylose, amylopectin, pullulan	Digested and absorbed in the small intestine Rapid glycemic response
	Resistant starch (α-glucans)		Digestible but undigested in the small intestine Fermented in the large intestine
	Nonstarch polysaccharides (β-glycans)	Cellulose, hemicellulose, inulin, guar gum	Nondigestible Partly fermented in the large intestine

[a] Lactose may be both a digestible and nondigestible sugar.

[b] Isomaltooligosaccharides are less susceptible to digestive enzymes in the small intestine.

the colon. The other reasons are that they are easy to handle in food processing and have organoleptic characteristics as mild sweeteners, both of which are important causes for NDO to be widely spread as commercial products.

Disaccharides

A certain class of disaccharides characterized with a β-linkage between the two units could have a role as prebiotics. This class of disaccharides includes lactose, lactulose, lactitol, and several by-products from various oligosaccharide production processes (**Figure 1(a)**). These disaccharides are poorly or very slowly hydrolyzed by human digestive enzymes. Human studies, as well as *in vitro* growth analyses, published so far have shown their possible prebiotic effect particularly on stool habits.

Lactose

Lactose (4-β-D-galactopyranosyl-D-glucopyranose or β-D-Gal*p*-(1 → 4)-D-Glc*p* or Galβ1-4Glc) is the primary sugar of mammalian milk. Human milk contains ~7% lactose, and cow's milk ~4.8%. Even though lactose is the major carbon source for suckling infants, hydrolysis of lactose is rather a rate-limiting step. In addition, the lactase (β-galactosidase) activity in the small intestine gradually declines as an infant grows: According to a survey of Pima Indians in the United States, lactose malabsorption was seen in 40% by age 3–4 years, 71% by age 4–5 years, and almost 100% by age 8 years. The onset and degree of lactase deficiency are not homogenous among individuals and races. While most Caucasians in Northern European countries, Australia and New Zealand, and North America retain lactase activity, most Africans, Asians, and Native Americans are nonpersistent.

Therefore, a substantial number of people are lactose malabsorbers. In these populations lactose behaves like nondigestible carbohydrates especially in lactose maldigesters. While the adverse effects of lactose are extensively studied, few reports concerning the effect on gut microflora are available. Although lactose is utilized preferentially by bifidobacteria and lactobacilli in *in vitro* fermentation, additional human studies are still needed to elucidate its prebiotic effect.

Lactulose

Lactulose (Galβ1-4Fru) is a synthetic disaccharide produced from lactose by chemical isomerization under alkaline conditions in the presence of sodium hydroxide and boric acid. Lactulose also naturally appears in heat-treated cow's and human milks. The generation of lactulose during lactose preparation was first reported in 1930. In the history of searching growth-promoting factors for bifidobacteria (bifidus factors) in human milk, Petuely described lactulose as a bifidus factor in 1957. Since then there are a large number of reports published about the effects of lactulose on the gut microflora, stool habits, SCA production, fecal enzyme activity, gut physiology, and so on. Lactulose is not hydrolyzed by human digestive enzymes and is preferentially utilized by bifidobacteria and lactobacilli as well as by bacteroides and some strains of clostridia and Gram-positive cocci inhabiting the human gut. According to these extensive studies, lactulose is now widely used not only as a food additive but also as a drug for constipation, hepatic encephalopathy, and *Salmonella* infection worldwide.

Sugar Alcohol (Polyol)

Sugar alcohols are derivatives of mono- and disaccharides obtained by reducing a hexose moiety. Major sugar alcohols available and of commercial interest are the monosaccharide polyols sorbitol, mannitol, and xylitol, and the disaccharide polyols lactitol (Galβ1-4-sorbitol) and maltitol (Glcα1-4-sorbitol). In recent years, most of these sugar alcohols have been developed and widely applied for commercial use as noncariogenic sweeteners. They all have less sweetness than sucrose and lower calorific values than normal sugars. While the monosaccharide polyols are all efficiently absorbed from the small intestine, the digestion and thus the absorption of disaccharide polyols, namely, lactitol and maltitol, are much less than those of their parent disaccharides, lactose and maltose, respectively. The average rates of hydrolysis of lactitol and maltitol in human small intestine were shown to be ~1.5 and 10% of those of lactose and maltose, respectively. These disaccharide polyols are good substrates for fermentation with colonic bacteria. Lactitol exerts quite similar effects to lactulose in clinical situations and is also used as a drug for treatment of chronic constipation and hepatic encephalopathy, although it may show a colonic fermentation profile different from that of lactulose.

Oligosaccharides

The main and the most important constituents of prebiotics are NDO. Research and application of NDO have attracted much attention since the 1990s as the importance and the role of the gut microflora in human health are becoming more and more documented. As an intrinsic characteristic of NDO, they must escape hydrolysis by human digestive enzymes and be fermented by a limited number of colonic bacteria. Human pancreatic and intestinal digestive enzymes include those hydrolyzing the α-glycosidic bonds of various monosaccharide moieties like glucose, galactose, and fructose, except for lactase (β-galactosidase) (EC 3.2.1.108), which mainly hydrolyzes the β-linkage of lactose, whereas many colonic bacteria produce a variety of carbohydrate-hydrolyzing enzymes that act on oligo- and polysaccharides with β-glycosidic bonds. Therefore, the principal NDO are β-glycans (**Table 2** and **Figure 1(b)**). The calorific values of most NDO are about half of those of digestible sugars, namely ~2 kcal g^{-1}, which are calculated from energy values available by utilization of organic acids produced in the colon after fermentation. Major NDO that are commercially available or of physiological importance are listed in **Table 2**.

Production of Nondigestible Oligosaccharides

There are three ways to produce NDO: partial hydrolysis of polysaccharides, synthesis by transglycosylation from mono- and disaccharides, and extraction of naturally occurring oligosaccharides. **Figure 2** shows the fundamental processes of industrial production of the former two types of NDO. In the industrial transglycosylation process, a high concentration of a substrate solution of mono- or disaccharides at more than 40–50% is used, and more than 50 up to 70% of the crude products are the target oligosaccharides after enzyme reaction. On the other hand, when polysaccharides are used as substrates, oligosaccharides are obtained either by direct endoglycosidase treatment (fructooligosaccharides, xylooligosaccharides, chitin oligosaccharides) or by liquefaction with complete glycolysis followed by transglycosylation (isomaltooligosaccharides, pannose oligomers). The substrates and enzymes used in the production process are indicated in **Table 2**.

Table 2 Nondigestible oligosaccharides and their structural features

Name of NDO	*Structures*	*Sources*	*Methods of preparation*
Lactulose	β-D-Gal-(1 → 4)-D-Fru	Lactose	Isomerization in alkali
Galactooligosaccharides	[β-D-Gal-(1 → 4)]$_n$-D-Glc ($n = 2$ to ∼6) or[β-D-Gal-(1 → 6)]$_n$-β-D-Gal-(1 → 4)-D-Glc ($n = 2$ to ∼5)	Lactose	Enzymatic transgalactosylation with β-galactosidase (EC 3.2.1.23)
Fructooligosaccharides	α-D-Glc-[(1 → 2)-β-D-Fru]$_n$ ($n = 2$–4)	Sucrose	Enzymatic transfructosylation with β-fructosylfuranosidase (EC 3.2.1.26)
Inulin-type fructans	α-D-Glc-(1 ↔ 2)-β-D-Fru-[(1 → 2)-β-D-Fru]$_n$ ($n = 1$ to ∼8)D-Fru-[(1 → 2)-β-D-Fru]$_n$ ($n = 2$ to ∼9)	Inulin	Partial enzymatic hydrolysis with inulinase (EC 3.2.1.7)
Raffinose	α-D-Gal-(1 → 6)-α-D-Glc-(1 ↔ 2)-β-D-Fru	Sugar beet	Natural product
Soybean oligosaccharides	[α-D-Gal-(1 → 6)]$_n$-α-D-Glc-(1 ↔ 2)-β-D-Fru ($n = 1$, 2)	Soybean extract	Extraction
Xylooligosaccharides	β-D-Xyl-[(1 → 4)-D-Xyl]$_n$ ($n = 1$ to ∼6)	Xylan	Partial enzymatic hydrolysis with xylanase (EC 3.2.1.8)
Human milk oligosaccharides	α-L-Fuc-(1 → 2)-β-D-Gal-(1 → 4)-D-Glc, α-NeuAc-(2 → 3)-β-D-Gal-(1 → 4)-D-Glc, β-D-Gal-β-GlcNAc-(1 → 3)-β-D-Gal-(1 → 4)-D-Glc, etc.	Human milk	Natural products
Chitin oligosaccharides	β-D-GlcNAc-[(1 → 4)-D-GlcNAc]$_n$ ($n = 1$ to ∼5)	Chitin	Enzymatic hydrolysis with chitinase (EC 3.2.1.14) or acid hydrolysis
Lactosucrose	β-D-Gal-(1 → 4)-α-D-Glc-(1 ↔ 2)-β-D-Fru	Lactose, sucrose	Enzymatic transfructosylation with β-fructosyltransferase (EC 2.4.1.9)
Isomaltooligosaccharides (α-glucooligosaccharides)	α-D-Glc-[(1 → 6)-D-Glc]$_n$ ($n = 1$ to ∼3)	Starch	Enzymatic hydrolysis followed by enzymatic transglucosylation with transglucosidase (EC 3.2.1.70)

Gal, galactose; Fru, fructose; Glc, glucose; Xyl, xylose; GlcNAc, *N*-acetylglucosamine; Fuc, fucose; NeuAc, sialic acid.

Galactooligosaccharides

GOS are industrially produced from lactose by enzymatic transgalactosylation. β-Galactosidase (EC 3.2.1.23) of various origins such as *Bacillus circulans*, *Aspergillus oryzae*, and *Cryptococcus laurentii* is used for the industrial production of GOS. The enzymes from *Bifidobacterium* strains also have this transgalactosylation activity. The enzyme reaction basically proceeds by the addition of the galactose moiety to the nonreducing end of lactose and transgalactosylated oligomers, resulting in the production of tri-, tetra-, and pentasaccharides, traces of multioligosaccharides, and some disaccharide by-products with different β-glycosidic bonds. The products have mainly β1,4- or β1,6-glycosidic bonds between the added galactose moieties (DP from 3 to ~6) and a glucose unit at the reducing end of the molecule. GOS are physically stable in various conditions; they were not degraded at 160 °C at a neutral pH or at 120 °C at pH 3 for 10 min.

GOS are not digested by human digestive enzymes at all, but are readily fermented in the colon. From extensive studies of the utilization of GOS, it has been revealed that *Bifidobacterium* and *Bacteroides* strains predominantly grow utilizing GOS as the sole carbon source. The prebiotic effect of GOS was first demonstrated by the pioneering work of Tanaka and colleagues in 1983, which showed an increase in indigenous bifidobacteria and a decrease in Bacteroidaceae after a daily intake of 10 g GOS for 2 weeks, in a human study. This was further confirmed by additional human studies. The potential of GOS to improve defecation in subjects with a tendency toward constipation, to reduce harmful enzyme activities, to reduce the incidence of cancer, to stimulate bone mineralization, and to reduce the production of secondary bile acids in feces has been documented in human and/or animal studies.

Fructooligosaccharides

There are two different ways to produce FOS: one is to partially hydrolyze fructose polymers of plant origin, and the other is to transfer the fructose moiety onto sucrose. Fructose polymers occur naturally in a number of vegetables and fruits as β-2,1-linked inulin or β-2,6-linked levan. Inulin is mainly used for the production of FOS having a DP of 2 to ~10 by partial enzymatic hydrolysis using endoinulinase. This type of FOS, sometimes called inulin-type oligofructose, is a mixture of $\mathrm{Glc}\alpha 1\text{-}2\beta\mathrm{Fru}[1\text{-}2\beta\mathrm{Fru}]_n$ ($n = 1$ to ~8) and $\mathrm{Fru}[1\text{-}2\beta\mathrm{Fru}]_n$ ($n = 1$ to ~9). FOS are also industrially produced from sucrose by enzymatic transfructosylation using *Aspergillus niger* β-fructosylfuranosidase (EC 3.2.1.26). This type of FOS has a DP of 3–5 including an α-1,2-linked glucose residue at the terminal of each molecule, and thus is nonreducing. The stability of FOS at neutral pH is as high as that of sucrose, and FOS do not degrade up to 150 °C. However, FOS are less stable in acidic conditions; when boiled at pH 3, most FOS molecules degrade into smaller molecules within 15 min.

Adapted from Hayakawa Y and Committee for New Materials of Foods (eds.) (1998) *New Knowledge of Oligosaccharides*. Tokyo (in Japanese): Food Chem. Newspaper Co Ltd.

Bifidogenic effect and other prebiotic effects of FOS such as lowering pH in the colon, reducing potentially harmful bacteria, reducing putrefactive substances, and improving stool habit have been demonstrated in human studies. In addition, beneficial effects of FOS on lipid metabolism and mineral absorption have been suggested in animal studies. While the effect on calcium absorption was further confirmed in several human studies, evidence of beneficial effects on lipid metabolism in humans is not conclusive.

Raffinose, stachyose, and soybean oligosaccharides

SOS can be readily isolated from soybean extract and constitute raffinose (Galα1-6Glcα1-2βFru) and stachyose (Galα1-6-raffinose) as oligosaccharides, as well as sucrose, glucose, and fructose. The contents of raffinose and stachyose in SOS are usually $\sim$8 and 24%, respectively, whereas the content of sucrose plus glucose and fructose is $\sim$55%. Pure raffinose is also commercially produced from beet syrup.

Raffinose and stachyose (Figure 1(b)) are not digested in the human upper intestine, but are readily fermented by colonic bacteria, and so are NDO. Most strains of *Bifidobacterium* species except *B. bifidum* can grow in a medium containing SOS, raffinose, or stachyose as the sole carbon source, since they usually express α-galactosidase activity, which can hydrolyze SOS. The bifidogenic effect of SOS and raffinose has been shown in human studies, where the minimum effective dose could be as low as 0.5 g oligosaccharides equivalent day^{-1}. In addition, SOS have the potential to reduce fecal levels of ammonia, *p*-cresol, and indole, to reduce harmful enzyme activities, and to alleviate constipation at the dose of 1 g oligosaccharides equivalent day^{-1}.

Xylooligosaccharides

Xylooligosaccharides (XOS) are β-1,4-linked xylose oligomers with a DP of 3 to $\sim$8, and industrially produced exclusively in Japan from xylan by partial enzymatic hydrolysis using endoxylanase (EC 3.2.1.8). Xylan, a sort of hemicellulose, is usually found in plant cell walls in conjunction with cellulose and pectin. For the commercial production of XOS, plant materials containing large amounts of xylan such as bagasse and cottonseeds are used.

XOS is fermented by limited types of colonic bacteria such as *Bifidobacterium* spp., *Lactobacillus* spp., *Bacteroides vulgatus*, and *Peptostreptococcus products*. Bifidogenic effect *in vivo* has been shown in a couple of human studies where the effective minimal dose of XOS was as low as 0.4 g day^{-1}. Alleviation of constipation and stimulation of mineral absorption were also documented in human and rat studies, respectively.

Chitin Oligosaccharides

Chitin oligosaccharides (COS) are *N*-acetylglucosamine (GlcNAc) oligomers (DP = 2–6) with β-1,4-linkages, and are produced from chitin derived from crabs and shrimps by partial acid hydrolysis in a hydrochloride solution. COS can be produced by enzymatic hydrolysis of chitin using bacterial chitinase (EC 3.2.1.14) as well.

In addition to the beneficial effects on the gut microflora, attention has been paid to COS due to their immunomodulatory and antimicrobial activities, although the mechanisms behind these effects are mostly obscure.

Human Milk Oligosaccharides

A French pediatrician, Tissier, observed more than a century ago that bifidobacteria were predominant microbes in the feces of breast-fed infants but not of formula-fed infants, and had an idea that this bifidus flora played a role in the reduced incidence of infection in breast-fed infants. A number of possible substances as bifidogenic factors in human milk have been proposed and utilized to maintain the bifidus flora in formula-fed infants since then. Examples of substances that had been tried include lactose, *N*-acetylglucosamine-containing oligosaccharides, whey proteins, and vitamins, none of which, however, provided any evidence of modulation of the host gut microflora so far.

The composition of HMO is complex. A variety of neutral and acidic oligosaccharides are found in human milk and colostrum. Although the major carbohydrate component of human milk is lactose, the total HMO levels reach up to 20% of the total carbohydrates, or over 12 g l^{-1} in mature milk and 22 g l^{-1} in colostrum, depending on individuals and the stages when the milk/colostrum is collected. The core carbohydrates in HMO are lactose and lacto-*N*-tetraose (Galβ1-3GlcNAcβ1-3Galβ1-4Glu), which are usually fucosylated and/or sialylated at nonreducing ends and other sites. Genomic and molecular biology studies have revealed that strains of *Bifidobacterium longum* ssp. *longum*, *B. longum* ssp. *infantis*, *B. bifidum*, and *B. breve* have various combinations of genes coding for enzymes responsible for the utilization of HMO, while HMO are not digested and absorbed in human small intestine. Therefore, HMO are most likely to be the bifidogenic factor in human milk. A certain group of HMO share the structural motifs with the cell surface glycoconjugates (glycoproteins or glycolipids) and mucins to which pathogens adhere at an initial step of infection. Thus, HMO could also be important as absorbers of pathogens to prevent infection during breast-feeding.

A practical method to produce lacto-*N*-biose, one of the active bifidobacteria-specific carbon sources derived from lacto-*N*-tetraose, from sucrose and *N*-acetylglucosamine with the enzymes sucrose phosphorylase (EC 2.4.1.7), UDP-glucose-hexose-1-phosphate uridylyltransferase (EC 2.7.7.12), UDP-glucose 4-epimerase (EC 5.1.3.2), and lacto-*N*-biose phosphorylase (EC 2.4.1.211) in large quantities has been established. However, it is still to be confirmed what components in HMO are and to what extent the HMO are responsible for the predominant growth of bifidobacteria in breast-fed infants.

Other Oligosaccharides

Other commercially available oligosaccharides are malto-oligosaccharides (α-1,4-linked D-glucose oligomers) and isomaltooligosaccharides (α-1,6-linked D-glucose oligomers), both of which are often called α-glucooligosaccharides as well, palatinose oligomers (oligomers of 2–4 palatinose (Glcα1-6Fru) units), α-glucosylsucrose (coupling sugar), lactosucrose, nigerooligosaccharides (α-1,4-linked D-glucose oligomers with an α-1,3-linked D-glucose at the nonreducing end), gentiooligosaccharides (β-1,6-linked D-glucose oligomers), chitosanoligosaccharides (β-1,4-linked D-glucosamine oligomers), and so on. Although they have not been necessarily intended to be used as prebiotic food additives, but rather to be used as alternative sweeteners with low calorific values and a low sweetness, evidence is accumulating that some of them have bifidogenic activity. In addition, oligosaccharide fractions obtained from partially hydrolyzed NSP such as guar gum, acacia gum, and wheat bran are possible prebiotic agents.

Polysaccharides

Recent studies on dietary polysaccharides have revealed that a variety of dietary polysaccharides have physiological roles, which include significant fermentability by colonic bacteria leading to the production of SCA, influence on colonic microflora, stimulation of mineral absorption, and so on. While numerous studies have shown an increase in SCA production in the colon after the ingestion of RS, NSP, or even starch polysaccharides, an increasing number of studies have shown the effect of dietary polysaccharides on the gut microflora and other physiological parameters in humans or animals. In this section some examples of these polysaccharides are described.

Fructans

Fructan is the general name of soluble polysaccharides in which one or more fructosyl–fructose links constitute the majority of glycosidic linkages. Two types of fructans have been identified: one is inulin, which is mainly of plant origin and has a β2,1-linkage between fructosyl residues, and the other is levan, which is mainly produced by fungi and bacteria and has a β2,6-linkage. Both types of fructan are neither digested by hydrolases of human origin nor absorbed in the intestines. Inulin has been manufactured, and thus has been studied extensively, and is of industrial importance. The biosynthesis of inulin in plant cells involves two enzymes: sucrose-sucrose fructosyltransferase (EC 2.4.1.99) leading to the formation of 1-kestose (Glcα1-2βFru1-2βFru) followed by chain elongation by fructan-fructan fructosyltransferase (EC 2.4.1.100) leading to the formation of inulin (β-D-fructofranan). A number of plants contain fructans as storage carbohydrates, some of which we eat as vegetables and fruits; examples are onion, garlic, asparagus, artichoke, chicory, and bananas. Among all, the root of chicory and the tuber of Jerusalem artichoke are the exclusive, if not the only, materials utilized for the industrial production of inulin because of the simplicity of extraction and purification. While native chicory inulin has a DP of 3–70 (average, ~35), native inulin preparation from Jerusalem artichoke has a DP of 2 (sucrose) to 15 (average, ~7).

Inulin shows physiological properties as dietary carbohydrates similarly to the shorter FOS as evidenced in a number of studies published so far. Inulin has a bifidogenic effect like that of FOS, although inulin itself is not fermented by bifidobacteria in *in vitro* cultivation. This could be because the natural inulin preparation contains shorter oligomers like FOS in addition to longer polymers or because the fructosyl–fructose linkage in polymers may be labile in acidic conditions in the stomach or be digested to oligomers by other colonic bacteria, thereby being preferentially utilized by bifidobacteria. Its bifidogenic effect and fecal bulking with increased water content have been observed in human studies as well as in those using human fecal batch cultures or pure bacterial cultures.

Other preliminary physiological effects of fructans reported so far are improved bowel habit, reduced putrefactive fermentation in the large intestine, improved calcium and magnesium absorption, and reduced total serum lipids and cholesterol. All these predictive health effects still await further confirmation in well-designed human trials.

Resistant starch

RS is a generic term for starches that escape hydrolysis by human digestive enzymes and absorption in the upper gastrointestinal tract. Starches are storage carbohydrates of plant cells consisting of linear α1,4-D-glucan chains (amylose) and those having some additional α1,6-linkages (amylopectin). During food processing, extensive treatment of starches leads to breakages and conformational changes of starches to various forms, depending on the source and due the amylose-to-amylopectin ratio, resulting in the generation of retrograded starch with a crystalline structure. In addition, there is another type of RS that just escapes digestion in the small intestine due to its physical structure and due to other materials surrounding the starch. Englyst and colleagues, in 1992, classified RS into three groups: retrograded starch, physically indigestible starch, and RS granules.

The bifidogenic effect of RS was first suggested by a feeding study on rats, followed by synbiotic (both probiotic and prebiotic) application to pigs, in which concurrent feeding of high-amylose maize starch and bifidobacteria resulted in higher fecal excretion of bifidobacteria. However, this effect needs to be confirmed by human studies.

Other polysaccharides

It has been reported that germinated barley foodstuff (GBF), which contains low-lignified hemicellulose and cellulose, has the ability to increase the number of bifidobacteria in the gut microflora and to produce more butyrate in the colonic contents. This could be explained as the production of butyrate by the coordinated action of bifidobacteria and *Eubacterium*, because the batch culture with both *B. longum* and *Eubacterium limosum* strains in a medium with GBF as the sole carbon source resulted in the accumulation of butyrate in the medium, whereas no or little butyrate was detected in the single cultures. This indicates that cellulose and hemicellulose, which cousitute a major part of NSP, may have the bifidogenic effect through an indirect supply of fermentable oligosaccharides for bifidobacteria, which are generated by partial breakage of the polysaccharides by *Eubacterium*. As such, bifidogenic and/or prebiotic effects of various indigestible polysaccharides could be substantiated in the future, as the research in this field will proceed.

Conclusions and Prospects

After establishment of the definition of prebiotics in conjunction with that of probiotics, scientific research on food components and additives that influence the composition and function of human gut microflora in health and disease has been accelerated. While the ‘bifidogenic’ effect is recognized as a fundamental for prebiotics, other effects of oligo- and polysaccharides on the host health have been described. However, as it has been defined and revised later, the term ‘prebiotics’ should be used for the food components that have the ability to change the composition and/or activity of the intestinal microflora to healthier states.

Nowadays more than 10 different di- and oligosaccharides are considered as prebiotic agents due to their bifidogenic effect, and the number is still increasing as research and development on dietary carbohydrates proceeds. In addition, the health benefits of prebiotics or dietary carbohydrates are extended wider than previously expected. This is typically explained by the effect on mineral absorption, which may be attributed to the increased production of SCA or to the acidification of the intestinal contents, although the precise mechanism underlying the effect is still to be confirmed. However, there are substantial reports that also describe the stimulating effect of dietary polysaccharides (dietary fiber) on mineral absorption. As such, while a number of different prebiotics with health benefits have been developed, which are composed of a variety of monosaccharide units, with different linkages and lengths, and have different physicochemical properties, the mechanism of action and the outcome of the effects could be similar to each other’s. In this respect, we may need some common biomarkers and analysis procedures with which sound scientific evaluation of each prebiotic agent can be made.

Introduction

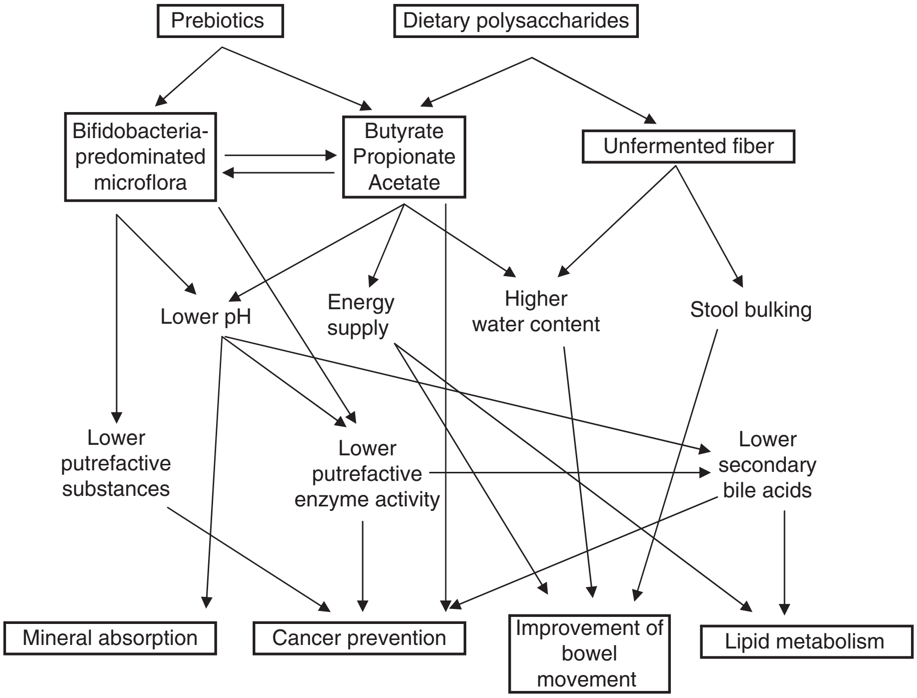
At the end of the nineteenth century, H. Tissier discovered a huge number of specific bacteria, bifidobacteria, in the feces of breast-fed infants. It was believed after his discovery and from the subsequent studies that the bifidobacteria-dominated microflora, called 'bifidus flora', played an important role in the reduction of infectious diseases in breast-fed infants. In the same line of evidence E. Metchnikoff speculated in his book *The Prolongation of Life* published in 1907 that fermented milk with lactic acid-producing bacteria could have a role in keeping the intestines healthy, thus leading to longevity. In addition, there was accumulating evidence indicating that the healthy gut microflora helps the animal to resist infections, which was hence called 'colonization resistance' or 'competitive exclusion'. All these observations in conjunction with practical applications of certain bacteria to treat infections in humans and animals generated an idea that certain beneficial bacteria can modulate the gut microflora to maintain a healthy balance of the flora, thus relieving the adverse effects of disturbed gut microflora and keeping the host animal healthy. R. Fuller proposed in 1989 to call these beneficial bacteria 'probiotics', and lactic acid-producing bacteria, namely, lactobacilli and bifidobacteria, have been recognized so far as typical probiotics.

Considering the determinants of the composition of the gut microflora, in turn, dietary components of our daily life strongly affect the growth and metabolism of the gut microbes; especially, dietary carbohydrates are the major energy and carbon source for the bacteria inhabiting the colon. Although the colonic bacteria as a whole have glycolytic activities against a variety of carbohydrates consisting of different monosaccharide units with different linkages and different lengths, the individual bacterial species/strains have a different set of enzymes with different substrate specificity. Therefore, the diversity of dietary carbohydrates has a strong influence on the composition of the gut microflora. As scientific evidence showing the effects of various carbohydrates on the composition of microflora accumulates, it has been recognized that certain carbohydrates can stimulate the growth of beneficial bacteria such as lactobacilli and bifidobacteria, and can provide the host with health benefits. Based on these observations, G. Gibson and M. Roberfroid proposed in 1995 the term 'prebiotic' for a food component that beneficially modulates the gut microflora to improve host health. As the research on prebiotics proceeds through the years, the health-promoting effects of prebiotics seem to be wider than initially expected. There have been published reports on a wide variety of dietary carbohydrates with various health benefits. The overall fate of prebiotics in the large intestine and their health benefits are briefly illustrated in **Figure 1**. In this article the possible health effects of prebiotics are described.

Definition of Prebiotics

A prebiotic is defined as "a nondigestible food ingredient that beneficially affects the host health by selectively stimulating the growth and/or the activity of one or a limited number of bacteria in the colon". As prerequisites of a prebiotic agent, the food ingredient must be neither degraded nor absorbed in the upper intestinal tract and be a selective substrate for a limited number of indigenous beneficial bacteria; thus it alters the balance of the gut microflora in favor of a healthier composition. While carbohydrates, proteins, lipids, and other minor components of foods like vitamins and minerals that are supplied unabsorbed through the small intestine could be candidates for prebiotics, only nondigestible carbohydrates of different monosaccharide units with a rather short chain length are recognized and established so far as prebiotic agents.

Among dietary carbohydrates, nondigestible oligosaccharides (NDO) including some disaccharides are the main prebiotics, which can either be extracted from natural plants and animals or be manufactured by enzymatic or chemical reactions (for a review, *see* **Prebiotics**: Types). Nowadays, a substantial number of NDO with different structures and lengths are commercially available. In addition, fewer differences between the effects of prebiotics and those of indigestible dietary polysaccharides (or dietary fiber) are detected now than in the past, as the research on both NDO and dietary fiber advance. Especially the production of short-chain fatty acids (SCFA) from these compounds and the subsequent physiological effects in response to SCFA are probably common for prebiotics and dietary fibers. In addition, certain indigestible polysaccharides were reported to be bifidogenic, thus being able to be prebiotics. As a conclusion, the bifidogenic effect is a key criterion to



Prebiotics
Dietary polysaccharides
Bifidobacteria-predominated microflora
Butyrate Propionate Acetate
Unfermented fiber
Lower pH

distinguish prebiotics from other fibers. However, it is conceivable that this definition may be open for revision in the future.

Composition of the Human Gut Microflora and Health

The human gastrointestinal (GI) tract, especially from cecum to rectum, is heavily colonized by microbes, reaching $10^{12}\,\mathrm{g}^{-1}$ contents or 10^{14} in total, with more than 200 species in a person or probably a total of 500–1000 species. This implies that about half of the solid content of the colon or feces is bacteria. After birth, the composition of the gut microflora of a newborn undergoes changes in response to factors such as changes of diet, health status, stress, age, and medication. The fetal GI tract is sterile, but the colonization initiates during birth. It is well understood that during the period of feeding with mother's milk, the composition of the gut microflora of the infant is rather simple and that the predominant microbes are bifidobacteria. At the weaning period, there is a drastic change in the composition of the gut microflora from the infant type to the adult type, which is characterized by a more complex composition with increased contents of *Bacteroides* and clostridia, and a wider variety of different species. These commensal bacteria, about 70% of which are still uncultivable or unidentified, not only interact with the host at the mucosal surface but also constitute a complex metabolic machinery that provides the host with a variety of metabolites.

The most numerous microbes isolated from the adult colon are obligate anaerobes such as *Bacteroides* (10^{10}–$10^{11}\,\mathrm{g}^{-1}$ wet feces), *Eubacterium* (10^{10}–$10^{10.5}\,\mathrm{g}^{-1}$), *Bifidobacterium* ($10^{9}$–$10^{10.5}\,\mathrm{g}^{-1}$), *Peptostreptococcus* (10^{9}–$10^{10}\,\mathrm{g}^{-1}$), and *Clostridium* (10^{9}–$10^{10}\,\mathrm{g}^{-1}$). Facultative anaerobes such as Enterobacteriaceae, *Enterococcus*, and *Lactobacillus* are also indigenous but less numerous (10^{5}–$10^{8}\,\mathrm{g}^{-1}$). Some aerobes such as *Bacillus*, *Staphylococcus*, *Pseudomonas*, and yeasts are occasionally isolated at very low levels (10^{3}–$10^{5}\,\mathrm{g}^{-1}$), and are thought to be transient passengers.

While the composition and the activity of the gut microflora of healthy persons are relatively stable in individuals, they could be easily disturbed by environmental changes such as illness, medication, stress, and a drastic change of the diet. For instance, antibiotic treatment often causes complete disruption of the composition of the gut microflora and severe diarrhea, and parenteral nutrition also disturbs the gut microflora as well as the gut functions.

The intestinal microflora is a complex open ecosystem where the inhabiting microbes in the highly dense microbial community interact with each other and with the host animal, thus constituting the front line of defense against infection or modulating the host mucosal immune system. This could generate a barrier function, which is often called 'colonization resistance' or 'competitive exclusion', against pathogenic agents. Based on numerous studies, it has been observed that there are beneficial as well as potentially harmful microbes inhabiting the human GI tract. Lactic acid-producing bacteria like *Lactobacillus* and *Bifidobacterium* are considered beneficial as they produce acids (lactic acid and acetic acid) that contribute to maintain an acidic condition within the intestines, produce vitamins, and potentially modulate the host immune system, whereas some species of *Bacteroides*, *Clostridium*, Enterobacteriaceae, and yeasts are potentially harmful as they produce toxins and putrefactive substances, and sometimes become opportunistic infectious agents. Furthermore recent studies have provided indications that some indigenous bacteria and yeasts could have roles in initiating and activating intestinal inflammatory responses. Therefore it is widely accepted that the homeostasis and improvement of the healthy gut microflora in the direction of increasing beneficial bacteria and decreasing potentially harmful bacteria are definitely valuable to keep the host healthy.

Fermentation of Prebiotic Carbohydrates in the Large Intestine

Production of Short-Chain Fatty Acids

It has been estimated that among the dietary carbohydrates a person consumes everyday, about 20–60 g escape hydrolysis by the intestinal digestive enzymes and become substrates for fermentation in the colon: 5–35 g are resistant starch (RS), 10–25 g nonstarch polysaccharides (NSP), 2–10 g unabsorbed mono- and disaccharides, and 2–8 g NDO. The pathway of carbohydrate metabolism in the colon is schematically illustrated in **Figure 2**. Most colonic bacteria have a variety of glycolytic enzymes with different substrate specificity. The major products of microbial fermentation of these carbohydrates in the large intestine are SCFA (mainly acetic, propionic, and butyric acids) and gases (H_2, CO_2, and CH_4). It is difficult to precisely measure the profile of fermentation of dietary carbohydrates in the colon, especially in human, because most SCFA produced are rapidly absorbed at the site of production. Many researchers have tried to estimate the amounts and available energy values of SCFA by using animal models, isotope-labeled substrates, and *in vitro* fermentation system, or by indirect calculations. The overall stoichiometry for the hydrolysis of dietary carbohydrates in the intestines can be drawn from G. Liversy and M. Elia's calculation using the following equation:

$$\begin{aligned}58C_6H_{12}O_6 + 36H_2O \rightarrow\ & 60CH_3COOH + 24CH_3CH_2COOH \\ & + 16\,CH_3(CH_2)_2COOH + 92CO_2 \\ & + 256[H^+]\end{aligned}$$

where H^+ will be further accepted by another H^+ or some other molecule, and the total yield of SCFA from 100 g of carbohydrates is calculated to be 64 g. This value is almost the same as that obtained from *in vitro* fermentation of starch using a human fecal sample. However, the fermentability and the molar ratio of acetic, propionic, and butyric acids produced from carbohydrate substrates vary considerably. Thus the yield of SCFA from mixed carbohydrates is usually between 30 and 50%.

In contrast, the contribution of prebiotics in the production of SCFA is different. Considering the predominant utilization of prebiotics by bifidobacteria and/or lactobacilli where the contribution of bifidobacteria is much more than that of lactobacilli due to their numerical advantage, the fermentation profile of prebiotics in the colon will be shifted to a bifidobacteria-driven one. The stoichiometric equation for the hydrolysis of hexoses by bifidobacteria is as follows:

$$2C_6H_{12}O_6 \rightarrow 3CH_3COOH + 2CH_3CHOHCOOH$$

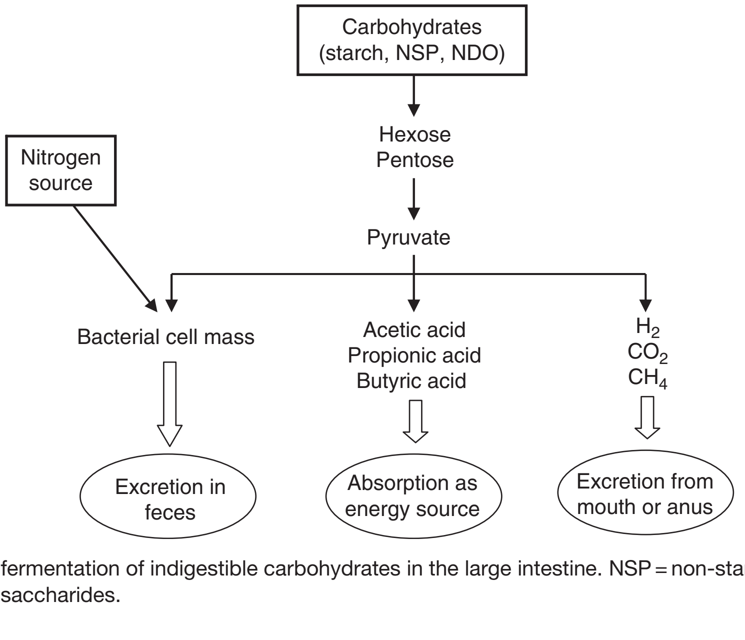

Figure 2 The pathway of fermentation of indigestible carbohydrates in the large intestine. NSP = non-starch polysaccharides, NDO = non-digestable oligosaccharides.

where the available energy value remaining as SCFA (acetic acid) is about 50%, since absorption of lactate in the colon is very slow. In this reaction, gases are not produced as primary fermentation products, although other colonic bacteria such as *Megasphaera elsdenii*, *Eubacterium hallii*, and *Anaerostipes caccae* can further metabolize lactate into butyrate plus hydrogen and carbon dioxide gases. The fermentation pattern by lactobacilli is somewhat different. There are two types of lactobacilli, homofermentative and heterofermentative, which produce only lactate and a mixture of lactate, acetate, and ethanol, respectively, from carbohydrates. The contribution of these lactic fermentations in the physiology of the lower small intestine could be substantial, because lactobacilli are the major inhabitants of that region, although that in the large intestine is probably negligible.

Nutritional Values

The SCFA produced in the fermentation process are rapidly absorbed from the mucosal surface of the large intestine and used as energy source in various ways. The calorific value of indigestible and fermentable carbohydrates has been a subject of debate due to the difficulty of direct measurement. Considering that the calorific values of digestible carbohydrates absorbed from the small intestine are 4 kcal g^{-1} (16.8 kJ g^{-1}), the yield of SCFA from indigestible carbohydrates that are completely fermented in the colon is approximately 60%, and the efficiency of availability of SCFA in the colon is about 0.85. The practical calorific values of indigestible but easily fermentable carbohydrates like NDO are calculated to be approximately 2 kcal g^{-1} (8.4 kJ g^{-1}) for most of these compounds.

The fates of SCFA in the body are distinctive: butyrate is exclusively utilized by the colonocytes, which derive 60–70% of their energy from butyrate; acetate is probably metabolized by skeletal and cardiac muscles and brain, is always detected in the bloodstream at the basal level of 50 μmol l^{-1}, and rises to 100–300 μmol l^{-1} after meals containing indigestible carbohydrates. Acetate is also utilized for the synthesis of long-chain fatty acids, glutamine, glutamate, and so on. Propionate is a major glucose precursor in ruminants, but the fate of propionate in man is much less known. Probably it is also a substrate for hepatic gluconeogenesis in man, and its effect on the lipid metabolism has been proposed.

Modulation of the Gut Microflora

A prerequisite characteristic of a prebiotic substance is to be utilized by a limited number of beneficial colonic bacteria. A fermentability profile of a variety of NDO by different colonic bacteria *in vitro* has revealed that most strains of the genus *Bifidobacterium* can utilize these carbohydrates efficiently, while the fermentation of NDO by other major genera inhabiting the colon such as *Bacteroides*, *Clostridium*, *Eubacterium*, and *Peptostreptococcus* is limited (for details, *see* **Bacteria, Beneficial**: *Bifidobacterium* spp.: Applications in Fermented Milks; Probiotics, Applications in Dairy Products. **Prebiotics**: Types). In fact, from the cell extracts of bifidobacteria grown in a medium with glucose as a sole carbon source, hydrolyzing activities against α-glucosyl, β-glucosyl, β-galactosyl, and β-fucosyl bonds have been detected. This is not necessarily achieved by different enzymes. A couple of β-galactosidases (EC 3.2.1.23) and β-glucosidases (EC 3.2.1.21) with diverse substrate specificity have been identified in various strains of bifidobacteria of human origin. In contrast, animal strains of bifidobacteria analyzed so far except for *Bifidobacterium animalis* produce fewer glycolytic enzymes, the phenomenon being possibly associated with the presence of complex oligosaccharides in human milk. The production of the enzyme β-fructosylfuranosidase (EC 3.2.1.26) responsible for the digestion of fructooligosaccharides (FOS) is induced by FOS in the medium. All these characteristics of bifidobacteria enable the identification of prebiotics as bifidogenic substances.

Numerous studies have been conducted to substantiate the bifidogenic effect of prebiotic preparations. Petuely discovered in 1957 that lactulose produced from lactose has a bifidogenic effect in formula-fed infants. Supplementation of lactulose in the cow milk-based formula causes the formation of the so-called bifidus flora and a reduction of fecal pH in formula-fed infants. It also reduces the production and absorption of ammonia in the colon, and hence is approved as a medicine for constipation as well as hepatic encephalopathy. The first oligosaccharide found to exert a bifidogenic effect was galactooligosaccharide (GOS). Tanaka et al. demonstrated that after 1 week of GOS intake at doses of 3–10 g day^{-1}, the fecal bifidobacteria increased in a dose-dependent manner, which often accompanies the change of the composition of the gut microflora from a Bacteroidaceae-predominant to a bifidobacteria-predominant one and/or a decrease in Bacteroidaceae. This is also the case for FOS, lactosucrose, xylooligosaccharides (XOS), sucrosylooligosaccharides (SOS), gentiooligosaccharides, and isomaltooligosaccharides (or α-GOS).

The generation of bifidus flora in breast-fed infants has been confirmed in recent studies with both the authentic plating method and the molecular method, indicating that human milk oligosaccharides (HMO) or certain components in human milk act as prebiotic substances.

Effective doses of prebiotics to exert the bifidogenic effect in man have been estimated to be approximately 3–10 g day^{-1} for most NDO. However, XOS has been reported to show the effect at a dose less than 1 g day^{-1}, and NDO having α-glycosidic linkages like isomaltooligosaccharides usually need more than 10 g day^{-1} to show the effect similar to that of β-linked NDO due to their partial digestibility in the upper intestine.

Physiological Effects

Improvement of Stool Frequency

Beneficial effects of intake of NDO on the nature of feces have been shown in several human studies. NDO improve both the frequency and the consistency of defecation after habitual intake. For example, administration of GOS at a dose of 2.5–5 g day^{-1} for 1 week led to a significant increase in the frequency of defecation in a group of women in a double-blind placebo-controlled trial. The effect was more apparent for subjects who tended to be constipated. The mechanism behind this effect is not precisely known yet. However the intake of prebiotics in addition to normal diet results in an increase in acids especially acetic acid and lactic acid due to the predominant utilization of the substrate GOS by bifidobacteria. In addition, it has been recognized that in some cases succinic acid also accumulates in the cecal and colonic contents after ingestion of GOS in rats with humanized gut microflora and in humans. Unlike the SCFA that are rapidly absorbed from the mucosal surface of the large intestine, lactic acid and succinic acid are less efficiently absorbed, and thus contribute to the decline of the pH of the colon and to the increase in fecal water content. All these alterations of the physiology of the colon could have a role in improving the stool frequency.

In contrast, it has been observed that FOS exert an effect to prevent traveler's diarrhea, which is probably due to the stabilization of bifidobacteria- and lactobacilli-predominated healthy gut microflora.

Reduction of Putrefaction

The colonic microflora is an agent for the metabolism of various substrates. It provides the host with a variety of enzymes, and the metabolic activity of the gut microflora is estimated to be as high as that of the liver. While dietary carbohydrates are fermented into SCFA and gases, proteins and amino acids that reach the colon are fermented into SCFA as well as branched-chain fatty acids, isobutyrate, isovalerate, and 2-methylbutyrate arising from valine, leucine, and isoleucine, respectively. In addition, proteolysis followed by amino acid catabolism causes an accumulation of ammonia, phenolic compounds, amines, and sulfur compounds, which are all putrefactive substances. These substances are absorbed into the bloodstream, and, either directly or after further metabolization in the liver, show detrimental effects on human health. In a study with rats approximately 40% of blood ammonia was derived from the intestine. It has been demonstrated that the amount of urea in rat urine, the final product of ammonia metabolism, is significantly lower in germ-free rats than in normal rats. In a human study with healthy volunteers, the ingestion of GOS not only reduced the fecal ammonia concentration significantly, but also reduced other putrefactive products such as phenol, *p*-cresol, and indole in the urine. The reduction of blood ammonia concentration by GOS was further confirmed in an additional study using hyperammonemia patients. Lactulose and lactitol have been approved as medicines for hepatic encephalopathy, because they are effective for reducing blood ammonia level of the patients probably due to their effect on intestinal putrefaction. Therefore it is concluded that NDO such as GOS and lactulose can modulate the gut microflora to reduce its putrefactive metabolic activity.

Colon Cancer Prevention

Several bacterial enzymes such as β-glucuronidase, β-glucosidase, and nitroreductase derived from the gut microflora can activate precarcinogens to proximal carcinogens. For instance, bile salts secreted from the liver are converted to secondary bile acids by the enzyme β-glucuronidase derived from bacteria, and the resultant products are potential promoters of colon carcinogenesis. In a couple of studies with human volunteers, a daily intake of GOS at a dose of 10 or 15 g significantly reduced the fecal β-glucuronidase activity.

In model systems using rats and chemical carcinogens, there are a few reports that have analyzed the suppressive effect of prebiotics on the development of cancer. In a model that monitored the development of colorectal cancer induced by 1,2-dimethylhydrazine (DMH) in rats, fully fermentable GOS appeared to be highly protective, while poorly fermentable cellulose was not effective. In another model, the effect of dietary carbohydrates including FOS and inulin on the development of aberrant crypt foci (ACF), which are recognized as early preneoplastic lesions in the colon, caused by the treatment with azoxymethane (AOM) was analyzed. The formation of AOM-induced ACF was significantly reduced by treatment with inulin, FOS, pectin, or coffee fiber (rich in arabinogalactan). The increase in butyrate concentration in the colon was suggested to be an effective change for the reduction of ACF formation in the colon, because only carbohydrates that resulted in the production of large amounts of butyrate reduced AOM-induced ACF formation. This supposed effect of butyrate on the suppression of cancer development could be explained in part by the inhibitory effect of butyrate on the proliferation of cells including colon tumor cells. In addition, FOS and inulin showed enhanced apoptotic effect in the distal colon of rats after treatment with DMH, where inulin was more effective than FOS. SCFA – acetate, propionate, and butyrate – can in fact induce apoptosis in colorectal tumor cell lines at a concentration of 0.5 mmol l^{-1}, where butyrate is the most effective agent. All these results imply that SCFA, especially butyrate, produced by the colonic fermentation of dietary carbohydrates may have a role in protecting against the development of cancer in the colon by inducing apoptosis in the injured cells or proliferating cells. However, the enhanced frequency of apoptosis may also imply that the colonic cells become more susceptible to the carcinogen by the increased butyrate concentration or that the activation of the procarcinogen was stimulated by the higher concentration of butyrate. There also appears a conflicting view that fully fermentable carbohydrates such as inulin, as compared with wheat bran, may enhance colon carcinogenesis in the distal colon based on the increased PKC activity and PKC $\beta 2$ level in response to increased diacylglycerol in the colon in rats fed with a high-fat diet with inulin. Thus, the suppressive effect of prebiotics and dietary carbohydrates on colon carcinogenesis is still inconclusive.

Immune Modulation

There have been very few reports suggesting modulation of the immune system by prebiotics and dietary carbohydrates. It is not likely that prebiotics directly impact the body's immune system; however, the improvement of the intestinal environment could enhance the immune system. As described above, prebiotics and dietary carbohydrate supplementation may reduce the development of colonic neoplasia. In general, cells having neoplastic lesions are excluded through the body's immunological defense mechanism. The fact that the supplementation of FOS, inulin, or GOS in the diet resulted in the reduction of colon carcinogenesis by chemical carcinogens in rats suggests that the immune system involved in this process may be activated by these substances. Stimulation by FOS and inulin of apoptosis of colonocytes induced by treatment with a chemical carcinogen supports this idea. The question remains whether or not, and if so how, prebiotics and dietary carbohydrates directly or indirectly affect the immune system.

An alleviation of the symptoms of atopic dermatitis in infants by raffinose has been reported. It could be mediated by the improvement of the colonic microflora; especially a reduction of *Candida* level in the gut microflora is supposed to be effective in alleviating the symptoms. However, this should be confirmed by additional sound scientific clinical studies.

Stimulation of Mineral Absorption

Evidence is accumulating showing the enhancing effect of NDO on the absorption of minerals including calcium, magnesium, iron, and zinc. An increasing interest is focused especially on the intake of calcium because of its role in preventing osteoporosis. From animal and human studies, it has been shown that indigestible polysaccharides, NDO, and other carbohydrate compounds stimulate mineral absorption, and that the major site of action for absorption of minerals is the large intestine. This implies that the large intestine has a significant capacity to absorb minerals.

Among NDO, inulin, FOS, GOS, lactulose, isomaltooligosaccharides, and raffinose have been demonstrated to stimulate mineral absorption in animal models. In normal rats, it has been shown that the enhancement of calcium and magnesium absorption was totally dependent on the reduction of cecal pH due to the enhanced production of SCFA by colonic bacteria, since simultaneous addition of neomycin with GOS did not show increased calcium and magnesium absorption. Increased bone mineralization and increased bone strength were also shown by using GOS, FOS, and lactulose in ovariectomized rat models.

Unlike the numerous animal studies, however, human studies with clear positive effects of NDO on mineral absorption are not yet available. Ingestion of 15 g day^{-1} of inulin, FOS, or GOS for 3 weeks did not affect mineral (calcium and iron) absorption significantly in 12 healthy young men. Feeding of a larger dose of inulin (40 g day^{-1}) significantly increased calcium absorption in nine healthy men. More recently by using postmenopausal women as subjects, it has been shown that feeding of 10 g day^{-1} of FOS significantly increased magnesium absorption. Since there have not been many human trials regarding the effect of NDO or dietary carbohydrates on mineral absorption and bone mineralization, more studies are clearly needed.

Modulation of Lipid Metabolism

The possibility that prebiotics may have some effects on blood lipid metabolism is an attractive idea. In rats it has been demonstrated that feeding FOS significantly reduced triglycerides in very low-density lipoprotein (VLDL), which is likely to be due to a reduction of lipogenesis in the liver. Regulation of hepatic cholesterol synthesis by SCFA and precipitation of bile acids due to deconjugation and acidification in the intestines have been proposed as likely mechanisms of this effect. However, only very slight effects have been observed in human studies using healthy volunteers, diabetic patients, or hypercholesterolemic persons, which are not yet conclusive. It is still an open question whether or not prebiotics can exert beneficial effects on lipid metabolism and cholesterol lowering.

Conclusion and Perspectives

Our daily diet is at the base of our healthy life. We eat a variety of foods derived from animals and plants every day, which basically include all the necessary components of nutrients we need. However, the balance of nutrients is not always sufficient to keep our health. Especially the modern dietary habits often cause the shortage of certain nutrient factors. A typical example is that of formula-fed infants who consume cows' milk-based foods prior to weaning. It has been demonstrated scientifically that cow's milk-based formula needs supplementation to fulfill completely the baby's needs to prevent infection and to keep the infant's gut microflora healthy. As the role of the gut microflora in human health is recognized more, the importance of management of the intestinal microflora will receive more attention.

In the last two decades, a variety of dietary carbohydrates that fulfill the criteria for prebiotics have been developed and have become commercially available. At the same time numerous studies have been conducted in animal models and in humans to show different health effects of prebiotics, thus increasing their health claims. However, we must recognize what the true health benefits of the prebiotics are, and which ones are supported by sound scientific evidence. Unfortunately not every health effect of each of the prebiotics described in this article is sufficiently substantiated in human clinical studies, not even the principal effects of certain established prebiotics. However, these putative effects may counteract any additional physiological effects of prebiotics, and the elucidation of the mechanisms underlying the effects may add a new insight into the field of nutrition.

Our knowledge of the composition and the function of the gut microflora is still limited. Recently established molecular identification techniques for bacteria have revealed that a number of bacteria even predominant in the intestinal microflora are still uncultivable. Although a prebiotic is required to be bifidogenic, the influence of the particular prebiotic on the fate of other bacteria is not precisely known. Considering the more than 200 or even 400 different bacteria inhabiting the colon, there may be other beneficial as well as harmful bacteria that preferentially utilize the prebiotic in the flora. Individual prebiotics are probably utilized by different sets of bacteria, thereby influencing the gut microflora and physiology in different ways. However, most physiological effects of prebiotics described so far are almost all possessed by every prebiotic uniformly. It may be very difficult to distinguish one prebiotic from another in their physiological characteristics, but when this will be achieved, the era of prebiotics will come.

Introduction

The genus *Arthrobacter* belongs to the ecologically and industrially important class Actinobacteria, family Micrococcaceae, which includes microorganisms that live in soil, subterranean cave silts, sea, glacier silts, sewage, water sludge, aerial surfaces of plants, vegetables, fish, and various animal species. In the environment, they are often the most numerous bacteria because of their versatility. Some species are psychrophilic and psychrotrophic, can use a wide range of organic substrates as sole or principal sources of carbon and energy, and do not require vitamins or other organic growth factors. Aromatic compounds can also be utilized. Arthrobacters are widespread in nature and they readily contaminate raw food, milk and milk products, meat and meat products, and fish and fish products. In food, arthrobacters may be recognized as indicators of sanitation or hygiene quality, or as contaminants of no particular importance. However, they may also grow and be involved in spoilage or ripening of food products. Some *Arthrobacter* strains have been isolated from human sources and consequently are considered to be opportunistic pathogenic microorganisms.

The taxonomy of the genus *Arthrobacter* has been redefined many times. Great difficulty has been encountered in identifying and classifying *Arthrobacter* and related coryneforms such as *Brevibacterium*, *Caseobacterium*, *Cellulomonas*, *Corynebacterium*, *Curtobacterium*, and *Microbacterium*. For these reasons, sometimes many isolates have been identified as arthrobacters or 'arthrobacter-like' simply because they showed the rod–coccus growth cycle (**Figure 1**) and staining reactions that are characteristic of the genus.

Strains of *Arthrobacter* can be readily recognized in different environments by their morphological properties, although they cannot easily be distinguished from closely related coryneform genera.

The development of taxonomy for the genus *Arthrobacter* is as follows:

1928 – isolation from soil;
1933–38 – similar microorganisms confirmed in soil;
1957 – genus included in the family of Corynebacteriaceae;
1986 – two groups distinguished: *A. globiformis*/*A. citreus* and *A. nicotianae*.

Taxonomy

The genus *Arthrobacter* is closely related to *Aureobacterium*, *Caseobacterium*, *Cellulomonas*, *Corynebacterium*, *Curtobacterium*, and *Microbacterium* and is more distantly related to *Brevibacterium*. Phylogenetically, it is a member of the high-GC Actinomycetes, and *Arthrobacter* species could not be separated from members of the genus *Micrococcus*. These are Gram-positive eubacteria. Only minor differences enable the genus to be distinguished from

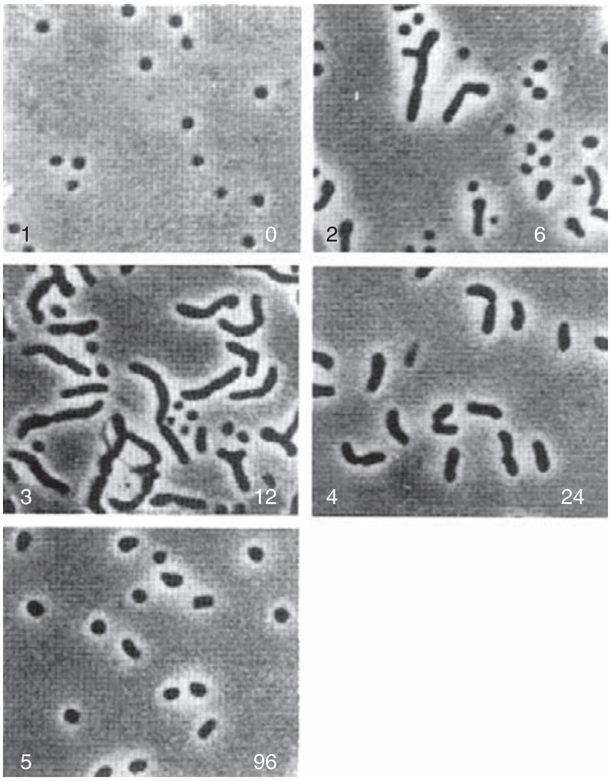

Figure 1 Growth cycles of *Arthrobacter globiformis* AC 166 starting from coccoid stage, on a rich medium at 25 °C. Reproduced from Crombach WHJ (1974) Morphology and physiology of coryneform bacteria. *Antonie van Leeuwenhoek* 40: 361–376, with kind permission from Kluwer Academic Publishers.

coryneform bacteria. Several tests must be employed simultaneously to classify and identify *Arthrobacter* spp. and avoid confusion with closely related genera.

Molecular and chemotaxonomic techniques are important for the characterization of coryneforms and *Arthrobacter* spp. because traditional methods based on morphological and physiological features only are insufficient to describe their biodiversity. In recent years, many methods have been developed to classify and identify arthrobacters. Traditional approaches are still used, but must be applied in conjunction with chemotaxonomic and molecular techniques, as the modern taxonomy of bacteria requires a multiphase classification strategy. The following approaches are the most recent and widely used approaches to *Arthrobacter* taxonomy:

1. Deoxyribonucleic acid (DNA) base composition and DNA–DNA homologies (DNA hybridization).
2. Analysis of particular cell constituents such as peptidoglycans, fatty acids, phospholipids (diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol), and glycolipids, and analysis for the presence or absence of teichoic acids. Numerous studies of the cellular fatty acid composition of coryneform bacteria have been used for their classification. In many cases, acyl types allow for a more precise characterization. Recently, the identification of cellular fatty acids has enabled the classification into four groups of coryneform bacteria belonging to the genera *Arthrobacter*, *Brevibacterium*, *Caseobacterium*, *Caseobacter*, *Cellulomonas*, *Corynebacterium*, and *Curtobacterium*.
3. Isoprenoid quinone analysis. It evaluates the presence of dehydrogenated menaquinones with 8 (MK-8), 9 (MK-9), or 10 (MK-10) isoprene units. This is another new method of characterization, but its application has given rise to several problems in distinguishing species and genera.
4. PCR analysis. It is a new method of identifying and classifying *Arthrobacter* based on the analysis of 16S rRNA by polymerase chain reaction (PCR) and various electrophoresis techniques, such as temperature-gradient gel electrophoresis (TGGE) or denaturing-gradient gel electrophoresis (DGGE). Comparative TGGE is considered more useful in taxonomic studies of coryneform soil bacteria because a high number of strains from the principal species of the genera *Aeromicrobium*, *Agromyces*, *Arthrobacter*, *Aureobacterium*, *Cellulomonas*, *Curtobacterium*, *Nocardioides*, and *Terrabacter* can be tested and characterized. In addition, positive results obtained by comparative TGGE can be confirmed by whole-cell fatty acid methyl ester analysis. Finally, PCR amplification of 16S rRNA gene (rDNA analysis), followed by sequencing, allows the identification of new species of *Arthrobacter* (**Figure 2**).
5. Biochemical and physiological characteristics. The phenotypic characteristics do not enable differentiation of *Arthrobacter* species.

The multiphase approach has led to the discovery of new species such as *A. rhombi* sp. nov. (**Figure 3**), isolated from the Greenland halibut (*Reinhardtius hippoglossoides*), in addition to *A. albus* sp. nov. and *A. luteolus* sp. nov., both isolated from human clinical specimens. It is only by simultaneous employment of several methods (biochemical characteristics, DNA G + C content, wall murein composition and structure, 16S rRNA gene sequence) that researchers can identify and classify old and new species of *Arthrobacter* with certainty, and distinguish them from closely related genera.

Morphological and Physiological Characteristics

The genus *Arthrobacter* includes a group of microorganisms with a rod–coccus growth cycle. Initially, the microorganisms grow as rods in a simple medium during the log phase, subsequently becoming shorter in the stationary phase and taking on the appearance of large cocci. In aged cultures, cells may have entirely coccoid conformations, but mixed rod–coccus types are often seen. When aged cells are transferred into fresh broths, they

Figure 2 Phylogenetic relatedness among authentic species of the genus *Arthrobacter*, which have been subgrouped based on the results of 16S rDNA analysis. Organisms the names of which are displayed in the same color exhibit the same peptidoglycan structure. Numbers within the dendrogram indicate the percentages of occurrence of the branching order in 500 bootstrapped trees (only values of 70 and above are shown). Sequences of the species of the genera of the family Micrococcaceae served as root. The scale bar represents 2 nucleotide substitutions per 100 nucleotides. Reproduced from Stackebrandt E and Schumann P (2006) Introduction to the taxonomy of Actinobacteria. In: Dworkin M, Falkow S, Rosembreg E, Schleifer CK, and Stackebrandt E (eds.) *The Prokaryotes: A Handbook on the Biology of Bacteria*, 3rd edn., Vol. 3, pp. 297–321. New York: Springer, with kind permission from Springer (New York, USA) and the authors.

become irregular rods, sometimes rudimentarily branched and arranged in V-shaped formations. Cell size is variable and the diameter can be anywhere between 0.6 and 1.2 μm.

This life cycle is observed in nonselective media, especially if seeded with food. Many studies have demonstrated that the life cycle matures within 24 h when the cells are isolated from mixed broth food and grown at 25 °C.

Both conformations are Gram-positive, but on aging, they may be rapidly decolorized and appear Gram-negative. The cell wall mureins contain L-lysine as the main dibasic amino acid.

All *Arthrobacter* strains are non-acid-fast and non-spore-forming. The rods are nonmotile or occasionally motile. They are obligate aerobes, catalase-positive and oxidase-negative, but a few soil and sea strains have been recognized as oxidase-positive.

A large number of arthrobacters are mesophilic, with optimum temperature of 20–30 °C. However, some strains are psychrophilic or psychrotrophic and may grow at 4–6 °C, or even at close to −5 °C (*A. glacialis*) or 0 °C, in some cases. Psychrophilic strains, usually isolated from soil or sea, are characterized by an optimum temperature of 20 °C. Mesophilic strains can be adapted to grow at 6 °C. Finally, a few strains can grow at 37 °C. Temperature seems to have a significant influence on the life cycle. At 25 °C, rod–coccus transformation takes place faster than at 15 °C. This effect does not seem to be restricted to *A. globiformis*. In contrast, pigment production appears to be unaffected by temperature. Orange, yellow, and pale red pigments may occur in *Arthrobacter*. Pigment development seems to depend on various factors such as the strains involved, exposure to light or dark, the growth medium, and the presence or absence of salt in the medium. Nevertheless, many *Arthrobacter* strains are not pigmented. The cells are rapidly killed by heating at 63 °C for 30 min in skimmed milk or in some other nonselective broths.

All *Arthrobacter* strains are chemoorganotrophic and strictly aerobic. Metabolism of carbohydrates and other carbon sources is exclusively respiratory and never fermentative. The most widespread strains of *Arthrobacter*, especially those from soil, can utilize glucose, saccharose, glycerol, acetate, and citrate. Numerous studies have demonstrated that *Arthrobacter* strains may utilize more than 90 different carbon sources. Furthermore, *Arthrobacter* strains seem to have no particular nutritional requirements. Only a few species require biotin, B-vitamins, amino acids, and a siderophore. Many arthrobacters are able to utilize as nitrogen sources either ammonium nitrogen salts or a mix of ammonium nitrogen salts and a single amino acid. In general, it seems that only strains isolated from cheese, sea fish, or food require organic nitrogen. *Arthrobacter* strains are not inhibited by 3–5% NaCl at pH >6. In contrast, growth slows down at pH <6. Acidic substrates inhibit growth, since pH is a selective factor. The salt tolerance of *Arthrobacter* strains enables them to grow in salty food such as cheeses and meat products, a parameter that may be used as a selective factor in isolation media.

Because of their great nutritional versatility, arthrobacters are frequently isolated from substrates with usual and unusual organic compounds, and have become important in bioremediation and environmental fields. It is known that some arthrobacters are able to dehalogenate 4-chloro-, 4-fluoro-, and 4-bromobenzoate, and to desulfurize heterocyclic organosulfur compounds. These properties mean they can be utilized as starters for the microbial degradation of haloaromatics or other carbon sources in the environment.

Figure 3 Unrooted tree showing the phylogenetic relationship of *Arthrobacter rhombi* sp. nov. within the genus *Arthrobacter*. The tree constructed using the neighbor-joining method was based on a comparison of approximately 1320 nucleotides. Bootstrap values, expressed as a percentage of 200 replications, are given at the branching points. Bar, 1% sequence divergence. With the exception of *A. rhombi* CCGU 38812, all other strains are type strains; accession numbers are given in parentheses. Reproduced with permission from Osorio CR, Barja JL, Hutson RA, and Collins MD (1999) *Arthrobacter rhombi* sp. nov., isolated from Greenland halibut (*Reinhardtius hippoglossoides*). *International Journal of Systematic Bacteriology* 49(3): 1217–1220.

Hydrolytic activities may also occur in *Arthrobacter* strains that hydrolyze gelatin, casein, and lipids, but not starch and cellulose. In particular, hydrolytic activities are marked in strains isolated from soil and cheeses; *Arthrobacter* strains are the major components of smear microflora of cheeses. Extracellular esterases, proteases, and proline iminopeptidases from *A. nicotianae* strains isolated from smear cheeses have been purified and characterized. The properties of these enzymes demonstrate that arthrobacters may play an important role in casein hydrolysis of smear-ripened cheese.

The characteristics of a chitinase enzyme of arthrobacters have also been studied. The aim was to propose an industrial application in the degradation of chitin, an insoluble linear β-1,4-linked polymer of *N*-acetylglucosamine (GlcNAc), which is one of the most common polysaccharides found in nature.

Arthrobacter Species

Arthrobacter agilis, *A. albus*, *A. atrocyaneus*, *A. aurescens*, *A. citreus*, *A. creatinolyticus*, *A. crystallopoietes*, *A. cumminsii*, *A. globiformis*, *A. histidinolovorans*, *A. ilicis*, *A. luteolus*, *A. nicotianae*, *A. nicotinovorans*, *A. oxydans*, *A. pascens*, *A. polychromogenes*, *A. protophormiae*, *A. ramosus*, *A. rhombi*, *A. sulfureus*, *A. ureafaciens*, *A. uratoxydans*, and *A. woluwensis* are all included in the genus.

The number of species identified may rise or fall. The taxonomy of the genus *Arthrobacter* and related genera has been redefined many times. It is well known that some strains isolated from cheese, and originally recognized as arthrobacters, have now been identified as *Brevibacterium* or coryneforms, and vice versa.

Almost all species have been isolated from soil, sea, vegetation, pure or sewage water, water sludge, glacier silts, and other natural environments where they play an active role in the degradation of various carbon sources. Recently, new species have been isolated from soil of cold areas, from the marine environment, and monuments. The main new species include *A. ardleyensis*, *A. castelli*, *A. defluvii*, *A. flavus*, *A. gandavensis*, *A. gangotriensis*, *A. humicola*, *A. kerguelensis*, *A. koreensis*, *A. monumenti*, *A. oryzae*, *A. parietis*, *A. pigmenti*, *A. psychrolactophilus*, *A. psychrophenolicus*, *A. radiotolerans*, *A. simplex*, *A. soli*, *A. stackebrandtii*, *A. subterraneus*, *A. russicus*, *A. roseus*, *A. tecti*, *A. terregens*, and *A. tumbae*.

Arthrobacter cumminsii, *A. woluwensis*, *A. creatinolyticus*, *A. luteolus* nov. sp., and *A. albus* nov. sp. are considered opportunistic pathogens because they have been isolated only from human clinical specimens such as skin, urine, and blood culture. Their role in diseases is not proven and their pathological significance has not yet been assessed.

Finally, some *Arthrobacter* species, such as *A. aurescens*, *A. arilaitensis*, *A. bergerei*, *A. globiformis*, *A. variabilis*, *A. citreus*, *A. uratoxydans*, *A. protophormiae*, and *A. nicotianae*, may also be found in food, especially cheeses.

Isolation of *Arthrobacter*

Arthrobacters are usually isolated from different environments by nonselective media, such as plate count agar. Especially where they do not represent the main species, an enrichment culture, containing a variety of organic substrates as sole carbon and energy sources in mineral salts solution, could be used. However, in order to achieve good results in isolation, the media must contain a sufficient amount of organic compounds and mineral constituents. Poor nutriments inhibit the growth of *Arthrobacter*.

To improve the isolation, sometimes antibiotics (nystatin 50 μg ml^{-1}, cycloheximide 50 μg ml^{-1}) have to be added to the medium in order to suppress fungal growth. The Winogradsky standard salt solution is recommended for their isolation from soil. A mix of soil extract with added yeast extracts, salts, glucose, and peptone is also often used. A selective medium, containing Trypticase soy agar, yeast extract, NaCl, cycloheximide, and methyl red, has been suggested. Cycloheximide (0.01%) inhibits fungal growth, a 2% concentration of NaCl inhibits the majority of *Streptomyces*, *Nocardia*, and Gram-negative bacteria, and methyl red (150 μg ml^{-1}) acts against other Gram-positive bacteria (bacilli and micrococci). The pH of the medium must be between 5.0 and 8.5, and the presence of Trypticase soy and yeast extract improves the growth of arthrobacters.

The cultures can be preserved in soil extract agar or in plate count agar for more than 2 months at 20 °C, or for several years if they are frozen on glass beads at −70 °C. Lyophilization is suitable for long-term storage.

Arthrobacter in Milk and Dairy Products

Arthrobacters contaminate meat and meat products, fish and fish product, fruit, vegetables, and milk and dairy products. Since they are obligate aerobes, arthrobacters grow mainly on the food surface and may result in spoilage, ripening, and colored smear or slime. Growth occurs when the storage temperature is 4–30 °C, the pH is over 5.5, and the redox potential is positive. The organic sources of food do not constitute a limiting factor for these microorganisms, which display great nutritional versatility. Antagonistic flora, including lactic acid bacteria, Enterobacteria, *Pseudomonas*, Micrococcaceae, and so on, may represent a potential limit. The competition of other microorganisms and the change in pH brought about by the production of lactic acid or other organic acids can inhibit or reduce the growth of arthrobacters. In addition, arthrobacters are rarely found in high concentration in food and never constitute the predominant flora. Where they can rapidly develop on food surfaces, arthrobacters produce colored smears, but they are always present in coculture with coryneforms, micrococci, staphylococci, and yeasts.

Arthrobacters may occasionally be isolated from the surfaces of refrigerated fruits, vegetables, and meat and meat products (such as sausages, cooked hams, and air-dried hams). The significance of their presence in these foods has not yet been clearly defined and, in some cases, more detailed investigations are required. Arthrobacters are always present in cocultures with strains of lactic acid bacteria, coryneforms, Micrococcaceae, *Pseudomonas*, *Brochothrix thermosphacta*, *Microbacterium*, *Moraxella*, *Acinetobacter*, and other psychrotrophic bacteria. On the above-mentioned food products, arthrobacters constitute an insignificant contamination whose growth depends on antagonistic microflora and on the presence of oxygen. Arthrobacters are more frequently isolated from milk and cheese. Several studies have demonstrated that soil- or environment-derived arthrobacters readily contaminate raw milk, where they may survive even if heated at 72 °C for 15 s. In milk, *Corynebacterium* and *Arthrobacter* strains are recognized as indicators of sanitation or hygiene quality. High numbers of both groups in pasteurized milk are never associated with spoilage, although they do indicate bad sanitation. In fact, *Arthrobacter* strains are usually considered contaminants of no particular significance. In cheese, they are responsible for either spoilage or ripening.

Arthrobacter aurescens, in coculture with *Zymomonas mobilis*, produces an abnormal yellow discoloration in yogurts and red-orange streaks on the surface of sliced Gorgonzola cheese. Other species, together with strains of *Brevibacterium*, *Rhodococcus*, *Micrococcus*, *Staphylococcus*, and *Corynebacterium*, and some yeasts such as *Debaryomyces hansenii*, *Galactomyces geotrichum*, *Kluyveromyces marxianus*, and *Pichia membranifaciens* play an important role in determining the characteristics and flavor of smear surface-ripened cheeses. Brie de Meaux, Epoisses, Germain, Pont l'Évêque, Reblochon, Saint-Nectaire, Tomme de Savoie, Fourme d'Ambert, Pur Brebis, Morbier, Cantal, Comté, Fromage fermier, Fromage montagne, Domiati, Ras, Edam, Gouda, Gruyère, Taleggio, Quartirolo, Limburger, Livarot, Rocamadour, Weinkäse, Harzer, Munster, Saint-Paulin, Appenzeller, Brick, Trappist, and Tilsiter are the best-known and most popular smear surface-ripened cheeses. *Arthrobacter nicotianae*, *A. globiformis*, and *A. arilaitensis* sp. nov. seem to be the main strains involved in aroma and color production in red smear cheeses. The ripening process begins with the growth of yeasts, which metabolize lactic acid previously synthesized by lactic acid bacteria, causing the pH to increase at the cheese surface. The pH alteration and the presence of growth factors from yeast autolysis stimulate the growth of a mixed population including *A. globiformis*, *A. variabilis*, *A. citreus*, *Brevibacterium linens*, and *Brevibacterium ammoniagenes*. This remarkable microflora grows mainly on the cheese surface since it is strictly aerobic, producing colored smears and low-molecular-weight compounds that are responsible for the typical aroma of the product. The growth occurs within the first 2 weeks of ripening and then stops until the time of consumption. Thereafter, the aromatic compounds spread from the surface into the cheese, a process that is necessary for the development of the characteristic flavor and taste of the product. More specifically, *Arthrobacter* and *Brevibacterium* strains cause casein and lactate breakdown, changes in pH, and the production of ammonia, methanethiol, sulfides, dimethyl disulfide, *S*-methylthioesters (*S*-methylthioacetate, *S*-metylthiobutyrate, *S*-methylthiopropionate, and *S*-methylthioisovalerate), other volatile sulfur compounds, and low-molecular-weight nitrogen compounds. The volatile sulfur compounds are products of L-methionine catabolism. The enzymes involved seem to be L-methionine demethiolase, L-methionine aminotransferase, and α-keto-γ-methyl-thiobutyric acid demethiolase. The microorganisms produce orange and reddish brown pigments, owing to their enzymatic activity on casein and amino acids. The proteinases of *Arthrobacter* spp. may play a significant role in the ripening of smear surface-ripened cheeses. Most notably, proline iminopeptidase seems to have a fundamental activity.

Some *Arthrobacter* species and related genera may also produce antilisterial compounds, an activity that has been demonstrated on solid media. The presence and growth of undesirable microorganisms, such as *Listeria monocytogenes*, on the surface of smeared cheeses is a severe problem for the dairy industry. Various studies are under way with the goal of selecting strains that are capable of carrying out antagonistic activities on cheese surfaces against pathogenic microorganisms. No starter culture with both ripening and antilisterial activity has been produced yet.

Because of high consumer demand for innovative, well-aged, territory-specific tastes, there is likely to be an increasingly widespread use of flavor-enhancing bacteria and yeast strains with a proteolytic enzyme activity. Arthrobacters are being more and more often proposed in cocultures, and also as part of starters, for cheese production. Starters including *Staphylococcus* and *Arthrobacter* strains, *B. linens*, and *D. hansenii* have been tested to improve the quality of experimental Tilsit, Raclette, and Kùssnachter cheeses. Relevant data demonstrate that the starters rapidly predominated on the surfaces and were able to reproduce the characteristic taste, flavor, and color of red smear cheeses. However, in the case of Raclette and Kùssnachter cheeses, it seems that *Arthrobacter* spp. do not necessarily need to be a component of the starter culture, while *B. linens* and *D. hansenii* are essential to produce the typical aroma and the red smear. Conversely, the presence of arthrobacters in Tilsit cheese seems to be necessary for both aroma and color.

Conclusion

The *Arthrobacter* genus is extensive and includes a large number of species that are widespread in nature. Because of their nutritional versatility, arthrobacters are commonly isolated from soil, sewage, food, and several other environments by using nonselective and simple media such as plate count agar. However, selective media and broths are also proposed. Strains with a rod–coccus growth cycle, which are strictly aerobic, and which have lysine as the cell wall diamino acid may be presumably identified as arthrobacters. The genus has great importance in environmental and industrial applications, as different strains are often used in bioremediation and in the degradation of heterocyclic organosulfur compounds, haloaromatics, and other carbon sources (herbicides, pesticides) from the environment. Most notably, *A. phenanthrenivorans* can break down phenanthrene, *A. nitroguajacolicus* breaks down 4-nitroguaiacol, and *A. defluvii* degrades 4-chlorophenol. Some *Arthrobacter* species may have an important role in phytohormone production, in dinitrogen fixation, and in lysing yeast and mold cells that trigger plant diseases. By chitinase production, some strains can be used as a biological control of *Fusarium* diseases. Moreover, other *Arthrobacter* strains are important commercially because they are used to produce glutamic acid, α-ketoglutaric acid, and riboflavin. Recently, some *Arthrobacter* strains have been successfully used as probiotic bacteria to preserve shrimp post-larvae from pathogens such as *Vibrio parahaemolyticus* and *Vibrio nereis*. Starter cultures supplemented with *Arthrobacter* spp. are used to improve the quality of alkaline noodles, a typical food of eastern Asia made with wheat flour, water, sodium chloride, and alkaline salts (sodium and potassium carbonates, bicarbonate, phosphates). The aim is to increase the degree of yellowness of the noodles and prevent the formation of organic acids, which cause a decrease in pH.

Arthrobacters also contaminate food, where they may have no significant role or else cause spoilage. Some *Arthrobacter* strains largely contribute to the production of the typical taste, flavor, and color of smear cheeses.

Morphology and Characteristics

Pseudomonads are Gram-negative, straight or curved rods, which are motile by polar flagella. They are aerobic and their metabolism is never fermentative. They are catalase-positive and the majority of species are oxidase-positive. *Pseudomonas fluorescens* is found predominantly in soil and water and it produces a diffusible fluorescent pigment, pyoverdin. The taxonomy of the genus *Pseudomonas* is complex and there is extensive genetic heterogeneity among its members.

Sources of *Pseudomonas* spp. in Milk

Contamination from Milking and Storage Equipment

Significant contamination of milk by pseudomonads occurs due to inadequately sanitized surfaces of milking and milk storage equipment. The organisms grow in milk residues present in crevices, joints, rubber gaskets, and dead ends of badly cleaned milking plants. Although many different bacterial types can be introduced into milk from milk mineral deposits present in milking equipment, the most important of these are the Gram-negative psychrotrophs, which predominate among the microflora that adhere to stainless-steel milk transfer pipelines.

Variations in cleaning regimes and levels of contamination from farm to farm lead to differences in the microflora found on milking equipment. The only effective way to limit the introduction of bacteria into the milk supply during milking is to ensure adequate cleaning and disinfection of all the equipment. The effectiveness of sanitation depends to a large extent on the design of the plant and on other factors such as the hardness of the water supply.

Generally, farm bulk tanks do not contribute greatly to the bacterial load of raw milk as they are easy to clean and, consequently, have a much lower bacterial content than the milk pipeline. However, ancillary equipment such as agitators, dipsticks, outlet plugs, and cocks can be difficult to clean and these may be a possible source of contamination. Any residual bacteria present have the potential for growth during storage. Milk may be collected from farms on alternate days, or even longer in some instances. Thus, at collection, part of the milk in the bulk tank may be 48 h old or more. Although alternate-day collection may have little effect on the bacteriological quality of milk rapidly cooled to 4 °C or below before addition to the tank, the growth potential of the raw milk microflora is significantly affected. Thus, milk collected on alternate days will contain a greater number of bacteria that are entering the exponential phase of growth when the milk arrives at the processing site, and the amount of time that this milk can be subsequently stored will be reduced. For example, it has been shown that *Pseudomonas* spp. isolated from milk that had been stored at 7 °C for 3 days grew 10 times faster at 7 °C, had 1000-fold more proteolytic activity, and were 280-fold more lipolytic than pseudomonads isolated from freshly drawn milk. However, the *Pseudomonas* counts in the milk increased by only about 1 log cycle during the storage period.

Contamination during Transportation and Storage at the Processing Facility

Adequate cleaning of any dairy equipment used for the collection, transport, and storage of refrigerated raw milk must be performed to prevent fouling with milk film, which can support growth of bacteria that then become a source of contamination to subsequent batches of milk. Milk is usually transported in insulated tanks or in refrigerated tankers, and may be transferred to larger vehicles for longer journeys. During transportation, the main cause of increased bacterial count is inadequately cleaned vehicles and growth of bacteria already present in the milk. The latter is dependent on the milk temperature and journey time. A twofold increase in count is common during transportation of milk from the farm to the processing site and this is due primarily to the growth of psychrotrophic bacteria, including pseudomonads. Critical sites in the milk tanker for cleaning have been identified as the air separator, the milk meter, the milk sieve, and the suction hose, and factors that contribute to inadequate cleaning include blockage of the cleaning-in-place (CIP) spray system and low water pressure and flow rate. These can lead to buildup of milk stone on the inner surface of the tanker.

Changes in dairy industry practices such as the introduction of a 5-day working week, and milk shortages at certain times of the year due to the adoption of quota systems, have led to milk being stored for longer times before processing. Thus, the temperature at which milk is stored becomes critical. It has been recommended that milk is cooled to, and maintained at, 3 °C on receipt at the processing plant before storage. The average psychrotrophic, aerobic bacterial count of silo milk at several dairies in southwest Scotland was 1.3×10^5 cfu ml^{-1}. The majority of bacteria present were pseudomonads (70.2%) but Enterobacteriaceae (7.7%), Gram-positive bacteria (6.9%), and other Gram-negative, rod-shaped organisms were also isolated. When the milks were stored for a further 48 h at 6 °C, the psychrotroph count increased by 2 log cycles to 1.3×10^7 cfu ml^{-1}. Psychrotrophic growth patterns were independent of whether milks were selected according to their initial counts, and whether they were stored in large air-agitated silos or small, paddle-agitated vats. Growth rates were highest during filling of the silos, due possibly to temperature fluctuation, and final bacterial numbers were dependent on initial counts and storage time, with the latter being the most significant factor affecting milk quality.

It has been shown that raw milk stored at low temperatures is spoilt exclusively by Gram-negative bacteria. In earlier studies where identification was primarily performed by phenotypic analysis, *Pseudomonas fluorescens* biovar I (32.1% of isolates), *Ps. fragi* (29.6%), *Ps. lundensis* (19.8%), and *Ps. fluorescens* biovar III (17.3%) were the most commonly isolated. However, more recent studies conducted in Belgium using molecular methods such as Repetitive sequence-based Polymerase Chain Reaction (REP-PCR) and 16S RNA sequencing identified *Ps. lundensis* and *Ps. fragi* as the most common proteolytic psychrotrophs isolated from milk and these two species accounted for 53% of proteolytic strains isolated. The authors of this study concluded that there was an overestimation of the prevalence of *Ps. fluorescens* in previous studies due to problems with the taxonomy of the genus leading to inappropriate identification methods being used.

There seems to be little difference between the types of spoilage microorganisms associated with bovine milk and ovine and caprine milks.

Postpasteurization Contamination

Although Gram-negative, psychrotrophic bacteria present in raw milk do not survive pasteurization, these organisms are commonly isolated from pasteurized milk and cream, again with *Pseudomonas* spp. being the most frequently encountered. Thus, the shelf life of pasteurized products is limited by postpasteurization contamination. The microflora of short shelf life milks (i.e., <5 days at 4–6 °C) comprise almost entirely of *Pseudomonas* spp. (approximately 90% of isolates), while those with shelf lives >10 days have a higher proportion of other types of microorganisms. In the latter milks, *Pseudomonas* spp. account for about 70% of isolates. More recent work using sequence analysis of denaturing gradient gel electrophoresis DGGE fragments to investigate the microbial ecology of pasteurized milk stored at 4 °C revealed high diversity among *Pseudomonas* spp. in the milk samples. *Pseudomonas putida* and *Ps. migulae* grew to high numbers during storage and *Ps. fluorescens* and *Ps. fragi* were also found.

A variety of sources of contamination by pseudomonads exist in the processing plant. However, personnel and air probably contribute little to the contamination of pasteurized fluid milk products by these organisms. It has been shown that *Pseudomonas* spp. are able to form biofilms. A likely cause of postpasteurization contamination is shedding of bacteria from biofilms formed on gaskets in pasteurized milk pipelines. Electron microscopy has been used to show that *Pseudomonas* biofilms can develop on the sides of gaskets, despite operation of CIP systems, and it is well accepted that sanitizer efficacy is greatly reduced against bacteria growing in biofilms.

There is substantial evidence that the filling operation has the greatest influence on the potential shelf life of pasteurized milk. Low levels of psychrotrophic bacteria (10–500 cfu l^{-1}) can be introduced into the product at this stage and these can have a profound effect on shelf life. Improvements to the design of fillers have resulted in dramatic effects on the keeping quality of milk. Aseptically packaged milk can be kept for about 48 days when stored at 3 °C.

Consequences of Growth of Pseudomonads in Raw Milk

In addition to being able to grow rapidly in refrigerated milk, psychrotrophs produce extracellular enzymes that can degrade milk components. Although most psychrotrophs present in milk are not heat resistant, in many cases the extracellular enzymes that they produce can survive pasteurization (70–80 °C) and even UHTs (120–140 °C). Both proteases and lipases produced by psychrotrophs, representative of a number of genera, retained 60–70% of their activity after heating at 77 °C for 17 s and about 30–40% of their activity remained after UHT treatment at 140 °C for 5 s. Recent work has shown that proteolytic activity of bacterial origin in milk has a *D*-value at 75 °C of about 360 min and a *z*-value of about 29 °C. The heat stability of these enzymes is influenced by milk proteins, which exert a stabilizing effect. Not all the pseudomonads found in milk are capable of synthesizing these enzymes and, even in those that do, the levels produced are affected by many factors, including growth phase, nutrient supply (such as iron availability), phase variation, and environmental conditions, including temperature and oxygen tension. In a Belgian study, the incidence of proteolytic psychrotrophs was lower in milks collected in winter than in summer but the strains isolated in winter exhibited greater proteolytic activity than their summer counterparts. It has also been demonstrated that the enzymatic activity of pseudomonads and hence their spoilage potential can be predicted by their ribotype.

Extracellular Enzymes

Psychrotrophic bacteria in milk produce many types of extracellular enzymes, including proteases, lipases, phospholipases, exopeptidases, and glycosidases. Proteases and lipases have been better characterized and are thus better understood.

Proteases

Most of the proteases isolated from pseudomonads are metalloenzymes, containing 1 zinc atom and up to 16 calcium atoms per molecule. There are reports of variable content of zinc and calcium, owing to the diversity of proteases from psychrotrophs. Analysis of the protease-encoding gene, *aprX*, showed that pseudomonads expressed proteases with a high degree of heterogeneity. Some strains of *Pseudomonas* have been found to produce more than one type of protease and strain-to-strain variability is common. Most proteases have milk-clotting activity, and are readily able to degrade κ-, α_{s1}-, and β-casein, yet have low activity on nondenatured whey proteins. Isoelectric pH values of proteases from *Ps. fluorescens* vary from 5.1 to 8.8. The pH optima of proteases fall into two broad categories: neutral proteases with a pH optimum of pH 7 and alkaline proteases with optima at pH 8–9. The molecular weights of most proteases range from 40 to 50 kDa. Temperature optima range from 30 to 50 °C; in all cases, activity decreases sharply at temperatures above the optimum but all proteases for which data are available retained activity at 4 °C. *Pseudomonas fluorescens* proteases are extremely heat stable but most are unstable around 60 °C. Stability data at high temperatures are not reported for all proteases. This is very important from a spoilage perspective because the presence of proteases following commercial pasteurization (72 °C for 12–15 s) and UHT processing (135–148 °C for 2–5 s) can lead to quality defects.

Lipases and Phospholipases

Lipolytic degradation of milk is not as predominant as proteolytic degradation. Lipases of *Ps. fluorescens* typically form aggregates with lipids, or lipase–polysaccharide complexes. It is generally thought that *Pseudomonas* produces only one lipase; however, a second lipase has been isolated from *Ps. fluorescens. Pseudomonas* spp. typically produce a lipase that is active on milk fat. Lipases from *Pseudomonas* spp. can actively hydrolyze a variety of natural oils and synthetic triglycerides ranging from tributyrin to triolein. One of the most important enzymes produced by *Pseudomonas* is lecithinase, a phospholipase, which is able to hydrolyze the protective membrane of milk lipid. The membrane, composed primarily of lecithin, maintains the globular structure of milk lipid. Hydrolysis of the membrane can lead to fat aggregation and render milk lipid susceptible to the action of native milk lipases. Although lipases from *Pseudomonas* share one or more of the same epitopes, they are structurally diverse, which severely limits the ability to design DNA- or antibody-based probes for their detection. The optimal pH range for lipases from *Ps. fluorescens* is 7–8; however, activity is maintained from pH 5 to 11. Reported temperature optima range from 22 to 55 °C, and activity has been found at −29 °C. The pH and temperature optima reported are dependent on the substrate type used for their determination. The molecular weights of most lipases range from 32 to 633 kDa.

Lipases appear to be less thermostable than proteases; however, activity has been found at temperatures as high as 130 °C. Although strain-to-strain variation prevents generalizing on the thermostability of lipases from *Pseudomonas* spp., there are several reports indicating that lipases produced by *Ps. fluorescens* can survive commercial pasteurization and UHT processing and can affect the keeping quality of dairy products.

Regulation of Extracellular Enzymes

A variety of factors, including quorum sensing, growth phase, and environmental and nutritional factors, are involved in the regulation of synthesis of extracellular enzymes. For example, pH, temperature, oxygen tension, adenosine triphosphate pools, presence of ions, organic nutrients, triglycerides, and many more have been found to influence enzyme synthesis. Surprisingly, the regulation of synthesis of extracellular enzymes by pseudomonads is not unequivocally established, and probably involves a variety of regulatory mechanisms acting in concert. This fact further highlights the complexity and diversity of *Pseudomonas* extracellular enzymes. Understanding the complex mechanisms that direct enzyme synthesis will provide strategies to target for control. For example, it has been shown that disruption of quorum sensing results in a decreased production of protease by *Ps. fluorescens*; however, synthesis of the enzyme is not entirely prevented. Heat-based processing methods that are currently employed to curb enzyme-related spoilage are also detrimental toward product quality.

One factor responsible for regulation of extracellular enzymes is the phase of growth. Related to this is a growing body of research on cell-to-cell communication termed quorum sensing, dealing specifically with coordinated timing of cellular events according to cell density.

Pseudomonads, like other Gram-negative bacteria, produce an autoinducer, an acyl homoserine lactone derivative. This autoinducer is produced throughout the growth cycle, but it is only when its concentration reaches a threshold level toward the end of the log phase and early stationary phase that it is able to regulate the expression of several genes, including, in part, those responsible for the synthesis of extracellular enzymes of *Ps. fluorescens*. It has been shown that mutants of *Ps. fluorescens* that are incapable of producing extracellular proteinase are also incapable of synthesizing the autoinducer molecule.

Significance in Milk and Dairy Products

In general, the overall keeping quality of milk (pasteurized and UHT) and other dairy products is mainly limited by the action of proteases and lipases. When approximately 10^6 psychrotrophs per ml are present in raw milk before UHT heat treatment, gelation of the product will occur in less than 20 weeks of storage. Psychrotroph counts in the raw milk of about 10^7 cfu ml^{-1} will result in gelation after storage of the UHT milk for 2–10 weeks, accompanied by a gradual development of 'lack of freshness' and bitter flavors. Pasteurized milk having previously supported growth of psychrotrophs to levels of 5.5 log cfu ml^{-1} has been described as having an inferior flavor. However, defects in pasteurized milk are not as prevalent as in other dairy products, which may be due to the short period of storage of raw milk prior to processing. The development of flavor defects is dependent on the strain of *Pseudomonas* and fat content of the milk. Cheese can be affected by both proteases and lipases, with the resultant reduction of yield and flavor defects (such as soapiness, rancidity, and bitterness). It has been suggested that the slight adverse effects of proteases on cheese quality might be due to their removal in whey. However, lipases appear to be retained in cheese, and, for this reason, lipid-associated flavor defects predominate rather than protease-related reduction in cheese yields, although the presence of free fatty acids resulting from controlled lipolysis of milk fat is necessary for the characteristic development of the cheese flavor. Excessive lipolysis of cheese typically results in off-flavors, usually associated with psychrotroph counts in raw milk of about 10^7–10^8 cfu ml^{-1}. Butter can also undergo considerable hydrolytic rancidity from heat-resistant lipases. The result is the production of rancid, putrid flavors due primarily to the growth of *Pseudomonas* spp. in water droplets. By virtue of its high fat content and the tendency of lipase to partition preferentially into the cream phase of milk, cream is very susceptible to lipases from psychrotrophs. Flavor defects are the most common complaint resulting from the growth of lipolytic psychrotrophs in cream. Yogurt and cultured dairy products have been described as having unacceptable flavor scores and bitter, unclean, or fruity flavors when made from milk having high levels of psychrotrophs. *Pseudomonas* spp. are also associated with spoilage of Cottage cheese and they are able to oxidize diacetyl to acetoin, a flavorless compound. This results in a product with a bland taste.

It is clear that the growth and presence of psychrotrophs in dairy products prior to heat processing can adversely affect the quality of the finished products. Postpasteurization contamination at very low levels by *Pseudomonas* spp., however, is more detrimental to the keeping quality of pasteurized milk at 4–8 °C than the number of psychrotrophic bacteria in raw milk.

Control of *Pseudomonas* spp. and Related Enzymes

There is general agreement that it is very difficult to prevent contamination of raw milk by *Pseudomonas* spp., probably due to their ubiquitous nature. Therefore, approaches involving control of extracellular enzyme production seem to be a more promising solution than methods for prevention. Examples of the wide range of methods currently proposed to control psychrotrophic bacteria and/or their extracellular enzymes include thermization (a heat process of 60–66 °C for 5–20 s), additives (CO_2, nitrogen), high-pressure treatment, modified atmosphere storage of raw milk, microbial antagonism, activation of the lactoperoxidase system in milk, addition of enzyme inhibitors, addition of bacteriocin-producing lactic acid bacteria, and low-temperature inactivation of enzymes, to name a few. Only one of the aforementioned processes (low-temperature inactivation of enzymes) specifically targets enzyme synthesis. Most practices currently employed in the industry focus on elimination of the bacteria by heat processing.

Enumeration

Two general approaches are used to enumerate psychrotrophic microorganisms. Both apply to enumerating *Pseudomonas* spp. from dairy products. The traditional method selects specifically for psychrotrophs by incubation of test samples at 7 °C for 7 days. Due to the lengthy incubation, it is not very suitable as a quality assurance measure in the dairy processing industry. A second, and more rapid, approach to enumerating psychrotrophs involves incubation at 21 °C for 25 h. Most colonies appearing on agar plates using this method will be psychrotrophs since their optimum growth temperatures are typically between 20 and 22 °C. The second method is more rapid and correlates very well with the traditional 7-day incubation at 7 °C.

Pseudomonas spp. grow well on nonselective media (e.g., plate count agar, tryptic soy agar, Luria-Bertani agar, blood agar, MacConkey agar, eosine methylene blue agar). There exist a variety of media for specifically targeting fluorescent pseudomonads. These media enhance production of the typical green fluorescent pigment, pyoverdin, and therefore allow for easy identification of colonies on agar plates exposed to ultraviolet light. Examples of media found effective for identifying fluorescent pseudomonads include medium B and various media containing penicillin G, novobiocin, and cycloheximide.

Considerable interference from other Gram-negative bacteria is encountered when attempting to isolate *Pseudomonas* spp. on a nonselective medium. One promising selective medium has been developed based on heart infusion agar with addition of the selective agents cephaloridine, fucidin, and cetrimide. This medium effectively suppresses growth of Gram-positive bacteria and inhibits growth of other Gram-negative bacteria. Following inoculation and spread plating, the agar is incubated at 25 °C for 48 h.

A polymerase chain reaction assay for protease-producing pseudomonads, which targets the *aprX* gene, has been proposed but, due to gene heterogeneity, it failed to detect *Ps. lundensis* strains.

Pseudomonas aeruginosa

Pseudomonas aeruginosa is a Gram-negative, aerobic rod, and is an opportunistic pathogen that causes urinary tract infections, respiratory system infections, dermatitis, soft-tissue infections, bacteremia, and a variety of systemic infections, particularly in victims of severe burns and in cancer and AIDS patients who are immunosuppressed. *Pseudomonas aeruginosa* may cause mastitis. The organism can be isolated from soil and water. *Pseudomonas aeruginosa* isolates may produce three colony types. Natural isolates from soil or water typically produce a small, rough colony. *Pseudomonas aeruginosa* produces two types of soluble pigments, pyocyanin and (fluorescent) pyoverdin. The latter is produced abundantly in media of low iron content, and could function in iron metabolism in the bacterium. *Pseudomonas aeruginosa* is primarily a nosocomial pathogen.

The organism has an optimal growth temperature of 37 °C but is unable to grow at 4 °C. This makes *Ps. aeruginosa* an uncommon contaminant of refrigerated milk.

General Considerations

Several species of Gram-negative and Gram-positive bacteria which have the capacity to spoil milk and other short shelf-life dairy products and can grow at or below 7 °C (**Table 1**) have been isolated from raw milk and freshly pasteurized milk and cream.

Compiled from: Craven HM and Macauley BJ (1992) *Australian Journal of Dairy Technology* 47: 38–45; Cromie SJ *et al.* (1989) *Australian Journal of Dairy Technology* 44: 74–77; Griffiths MW and Phillips JD (1990) *Journal of the Society of Dairy Technology* 43: 62–66; Suhren G (1989) In: McKellar RC (ed.) *Enzymes of Psychrotrophs in Raw Food*, pp. 3–34. Boca Raton: CRC Press; Ternström A *et al.* (1993) *Journal of Applied Bacteriology* 75: 25–34.

Commercial high-temperature, short-time (HTST) pasteurization (72 °C for 15 s) of raw milk of reasonable microbial quality essentially eliminates heat-labile psychrotrophic pseudomonads. Laboratory-pasteurized or pasteurized and aseptically packed milk and cream are free from postpasteurization contaminants but after prolonged cold storage become microbiologically spoiled, even at 1 °C (**Table 2**). Spoilage of such milk is mainly caused by sporeforming psychrotrophic and aerobic *Bacillus* spp. Unless aseptically drawn, good-quality raw milk contains after milking several thousand bacteria per milliliter, half of which are usually coryneform bacteria and *Micrococcus* spp. Psychrotrophic *Pseudomonas* spp. and other heat-labile Gram-negative psychrotrophs, such as *Flavobacterium*, *Alcaligenes* and *Chromobacterium*, are usually reported to be minor components of the microflora of good-quality fresh raw milk. Corynebacteria, *Micrococcus*, *Arthrobacter* and *Streptococcus* are frequently both psychrotrophic and thermoduric. Many of these species, along with spores of *Bacillus* and *Clostridium* spp., survive HTST pasteurization. The total number of bacteria that survive HTST pasteurization is often higher than 1000 ml^{-1}. The number of spores in raw milk is very variable but rarely exceeds more than 2% of the total microflora. The psychrotrophic *Bacillus* spp. may represent only a small part of total spore count. Frequently, the number of spores of psychrotrophic *Bacillus* spp. in freshly pasteurized milk is so low that it can be determined only by the most probable number (MPN) technique. Spores of *Clostridium* spp. occur in markedly lower numbers than spores of *Bacillus* spp.

The method recommended for the enumeration of total psychrotrophic count is the same as standard plate count except that plates are incubated at 7 °C for 10 days. Short methods with counts after 25 h based on incubation at an elevated temperature have also been developed. A way to obtain the proportion of bacteria present in milk as spores is to conduct viable count of a sample in which the vegetative cells have been killed by heat. Crystal violet or preparations of other selective inhibitors have been used to prevent Gram-positive bacterial growth. Procedures that include biotyping (examination of profile of biochemicals utilized by the cells) have been widely used for identification of dairy isolates of psychrotrophic nonpseudomonads. Many of the isolates have only been identified at the genus level. Computer-aided biotyping using miniaturized commercial kits has been introduced for identification of both Gram-positive and Gram-negative bacteria, including many nonpseudomonad psychrotrophs. Enumeration, detection and typing of *Bacillus cereus* group isolates from milk have been extensively studied. Biotyping, serotyping, phage typing, nucleic acid-based techniques, immunological methods, electrophoresis of proteins, gas chromatographic analysis of cellular fatty acids and pyrolysis have been used for the identification and/or typing of these microorganisms. Randomly amplified polymorphic DNA procedure which includes polymerase chain reaction (RAPD–PCR) has been used for subtyping of *Bac. cereus*, *Bac. licheniformis* and *Bac. thuringensis*. RAPD–PCR also allowed the tracing of contamination routes of *Bac. cereus* in dairy processing.

Growth at Refrigeration Temperatures

Compared with *Pseudomonas* spp., available data on the effect of temperature on the growth rate and properties of enzymes produced by other psychrotrophs are limited. Based on the comparison of generation times, it can be generalized that *Pseudomonas* spp. are more potent psychrotrophs than other genera (**Table 1**). However, minimum growth temperatures (T_{min}) calculated from the Ratkowsky 'square root' equation indicate that *Alcaligenes* spp. and *Chromobacterium* spp. are as likely to be psychrotrophic as *Pseudomonas* spp. (**Table 3**).

Table 2 Effect of temperature on the shelf-life and growth of thermoduric psychrotrophs in aseptically packed high-temperature, short-time (HTST) pasteurized milk

Temperature (°C)	*Shelf-life (days) terminated due to flavor defects*	*Count (cfu ml^{-1}) at the time of spoilage*	*Days to reach a count of 10^7 cfu ml^{-1}*
1	75	5×10^7	51
3	52	7×10^7	34
7	28	6×10^7	20
12	11	2×10^7	10

Adapted from Dommett (1992).

Both the lag time and the generation time of psychrotrophic *Bacillus* spp. vary considerably. *Bacillus circulans* can grow at 1 °C and has been found in independent studies to have a shorter lag time and generation time than six other species of psychrotrophic *Bacillus* spp. Psychrotrophic and thermoduric psychrotrophs may be simply variants of mesophilic organisms, which have adapted to grow at low temperatures.

The growth rates and lag times in ultra-heat treated (UHT) milk and pasteurized milk or single and double cream are similar for Gram-negative psychrotrophs as well as *Bacillus* spp. $T_{\min}$ for different bacterial cultures are similar in milk and other media. Spores of psychrotrophic *Bacillus* spp. show maximum germination activity at 15 °C, with a possible second maximum peak at 5 °C. Increasing the temperature of HTST pasteurization of milk may actually have an adverse effect on its keeping quality because temperatures higher than 72 °C may induce the germination of spores.

Spores of *Bacillus* spp. may germinate and grow rapidly during the first hours of incubation of fermented milks until the pH decreases to a value which is inhibitory to these organisms. Psychrotrophic yeasts and moulds can spoil fermented milks.

Psychrotrophic Pathogens

Listeria monocytogenes, *Yersinia enterocolitica*, *Bacillus cereus* and probably enterohemorrhagic *Escherichia coli* (*see* **Pathogens in Milk**: *Bacillus cereus*; *Escherichia coli*; *Listeria monocytogenes*; *Yersinia enterocolitica*) are psychrotrophic pathogens that can grow at or below 8 °C, but

Table 3 Theoretical minimum temperature (T_{min})a for selected bacteria

Organism	*T_{min} (K)*
*Acinetobacter*b spp. 55	266.6–267.0

only *Bac. cereus* is a significant determinant of shelf-life of pasteurized milk or fresh dairy products. Proteolytic psychrotrophs may stimulate the growth of pathogens in milk.

Incidence of Genera Other than *Pseudomonas* in Raw and Pasteurized Milk

Psychrotrophs that Survive Pasteurization

The incidence of aerobic sporeforming bacteria in milk is highly seasonal. Studies in several countries have shown the highest number of spores during late summer and early autumn. Soiling of the udder during grazing may be responsible for the high count of sporeforming bacteria.

Frequently, the total number of spores reported in raw milk is in the range 1–160 ml^{-1}. Occasionally, high numbers (>10^4 ml^{-1}) of spores or vegetative cells of *Bacillus* spp. have been reported. Both *Bac. cereus* group, *Bac. licheniformis* and *Bac. coagulans*, are the species of sporeforming bacteria predominantly in fresh raw milk. The number of spores in freshly pasteurized milk varies widely between dairy plants and on a daily basis in the same dairy plant.

The spoilage potential of thermoduric/sporeforming psychrotrophs has been well demonstrated by incubating milk or cream free from postpasteurization contaminants and therefore free from *Pseudomonas* spp. and other heat-labile microorganisms. Spoilage may occur at 3 °C after approximately 7 weeks of storage (**Table 2**). The shelf-life of pasteurized, noncontaminated milk is approximately three times longer at 7–10 °C than the shelf-life of commercially produced milk, which becomes contaminated after pasteurization and stored at 3–5 °C (**Table 4**). Coryneform bacteria dominate freshly pasteurized cream or milk (**Table 5**). Very often, only 0.05–1 spore of psychrotrophic *Bacillus* spp. is detected in freshly pasteurized milk or cream by the MPN technique. Vegetative cells of *Bacillus* spp. can probably be detected on a selective medium such as polymyxin–egg-yolk–mannitol–bromothymol-blue agar in every package of freshly pasteurized milk which has been preincubated at room temperature. Raw milk has been shown to be a markedly more important source of psychrotrophic spores than postpasteurization contamination. *Bacillus circulans* occurs in both raw and freshly pasteurized milk at lower numbers than *Bac. cereus*. However, data from different sources show that *Bac. circulans* dominates spoiled milk or cream, free from postpasteurization contaminants, stored at 3–7 °C. At 12 °C, a significant proportion of bacteria at the time of spoilage are *Bac. cereus*, coryneform bacteria, micrococci and streptococci (**Table 5**).

Incidence of Psychrotrophs in Commercially Pasteurized Nonaseptically Packed Milk

Postpasteurization contamination of commercially pasteurized, nonaseptically packed milk is unavoidable. Recontamination in modern dairy plants can be as low as one bacterial cell per liter, and frequently is in the range of the number of psychrotrophic *Bacillus* spp. spores in freshly pasteurized milk. Major contaminants are Gram-negative rods, especially *Pseudomonas* spp., which are the most significant bacteria determining shelf-life of nonaseptically packed milk stored at 7 °C or lower. The generation time and the lag time of microflora in pasteurized milks with an initial psychrotrophic count $<10\,\mathrm{l}^{-1}$ are markedly longer than in milk containing 100 psychrotrophs ml^{-1} after pasteurization. Milk spoiled by coliforms at 7 °C has also been reported occasionally. Pasteurized milk containing 1–100 coliforms ml^{-1} after preincubation at 21 °C is much more frequently unacceptable after 10 days of storage at 7 °C than milk in which coliforms have not been detected. In one study, at 10–12 °C, *Bacillus* spp. and Gram-positive cocci each comprised 32–35% of the total spoilage microflora. The plate count of postpasteurization contaminated milk preincubated at 21 °C with a mixture of crystal violet, nisin and penicillin has been used to estimate, within about 48 h, if milk will have satisfactory keeping quality at 6 °C. The test correlates well with a standard method, which requires 5 days' incubation at 6 °C. The shelf-life of pasteurized milk, which was free from postpasteurization contaminants, was predictable from the storage time of raw milk.

Wide daily fluctuations in the number, growth rate and germination properties of psychrotrophic thermoduric microorganisms and a variable level of postpasteurization contamination have been observed in pasteurized milk from the same processor. Large differences have also been observed between processors. Due to these variations, the correlation between shelf-life of cold stored pasteurized milk and the total count of microorganisms in raw milk is usually poor. A good index for predicting the shelf-life of contaminated pasteurized milk stored at different temperatures is the average $T_{\min}$ of its microflora, the value of which is variable and is influenced by the contribution of thermoduric and heat-labile psychrotrophs.

Product Defects Caused by Psychrotrophs and Their Enzymes

Milk usually shows flavor defects when the total count of *Bacillus* spp. and/or *Pseudomonas* spp. is 2×10^7–5×10^7 cfu ml^{-1}. Flavor defects occur in pasteurized, aseptically packed milk spoiled by thermoduric and sporeforming bacteria when the number of these microorganisms is $>10^7$ cfu ml^{-1} (**Table 2**). Occasionally, flavor defects are noted at a population of *Bacillus* spp. $<10^7$ cfu ml^{-1}. Extracellular enzymes and volatile metabolites have been detected in milk incubated with psychrotrophic *Pseudomonas*, *Alcaligenes*, *Bacillus* or with the indigenous flora, at populations around 10^6 cfu ml^{-1}. The threshold number for some psychrotrophic yeasts required to cause sensory changes in quark varies from 2.4×10^4 to 4.2×10^6 cfu g^{-1}. The pattern of volatile compounds analysed by gas chromatography or an electronic nose may be characteristic for spoilage organisms and may permit their identification.

The production of heat-stable enzymes at low temperatures is not limited to the genus *Pseudomonas*. At least 5% of extracellular proteolytic activity survives in cell-free supernatants from one or more species of *Bacillus*, *Enterobacter*, *Serratia*, *Alcaligenes*, *Flavobacterium* and *Achromobacter* after exposure to 140 °C for 5 s. Lipases with similar heat stability are secreted by *Bacillus*, *Enterobacter*, *Serratia*, *Citrobacter*, *Moraxella* and *Achromobacter*. More than 50% of the lipolytic or proteolytic activity of enzymes secreted by psychrotrophs other than pseudomonads can survive HTST pasteurization. For comparison, the D-value for *Flavobacterium* cells determined at 70 °C is 0.05 s while the D-value for spores of several *Bacillus* spp. was between 16.5 and 20.5 min at 85 °C. Some strains or species of *Bacillus*, *Flavobacterium*, *Alcaligenes* and *Aeromonas* also produce heat-stable phospholipase.

The secretion of heat-labile proteinases and lipases or phospholipases by strains of the above and other psychrotrophic genera have also been reported. Some strains were only proteolytic or only lipolytic. Some species (**Table 6**) secrete more than one proteinase. Low-temperature treatment at 55 °C, which effectively inactivates proteinases and lipases secreted by *Pseudomonas* spp., causes little reduction in the activity of proteinases and lipases from other genera of psychrotrophs.

Proteinases of *Pseudomonas* spp., as well as those of other psychrotrophs (both Gram-negative and Gram-positive), hydrolyze the major casein fractions with different specificity. Limited proteolysis produces an unclean flavor while advanced proteolysis causes gelation and sweet curdling of milk. Sweet curdling is associated with proteinase from *Bacillus* spp.

Some *Bacillus* spp. isolated from milk can ferment lactose. Flavor defects caused by different *Bacillus* spp. grown in milk at 7 °C have been described as fruity, sour, yeasty, gassy or unclean. The lipolytic activity of thermoduric psychrotrophs produces rancid and fruity off-flavors in milk products. Lipases from different genera show differences in specificity toward various triglycerides. Phospholipases, proteinases and glycosidases from *Pseudomonas*, *Citrobacter* and *Enterobacter* may act synergistically in damaging the milk fat globule membrane. The aggregation of fat globules, which produces bitty cream, has been linked to the specific activity of phospholipase from *Bac. cereus*. The defect is not caused by Gram-negative psychrotrophs and can be substantially reduced if cream is stored below 5 °C. Some psychrotrophic nonpseudomonad Gram-negative bacteria may be responsible for the reduction of diacetyl in buttermilk.

Spoilage of sterile products by heat-stable enzymes from *Pseudomonas* spp. has been studied extensively. However, very little is known about the significance of heat-stable enzymes of genera other than *Pseudomonas*, isolated from cold-stored milk, to the spoilage of UHT-sterilized milk. Enzymes and other metabolites accumulated during the postpasteurization growth of psychrotrophs are likely to be mainly responsible for shortening the shelf-life of pasteurized milk and cream.

Thermoduric Psychrotrophs and Extended Shelf-Life Dairy Products

Ongoing centralization of the dairy industry, resulting in the formation of large dairy plants, extends supply lines, while the new habit of consumers to shop less frequently calls for pasteurized milk and other cold-stored perishable dairy products with improved keeping quality. During storage and distribution, dairy products may be exposed to increases in temperature. It is therefore desirable that the products have built-in 'quality buffers' to minimize

spoilage at elevated temperatures. In the United States, extended shelf-life (ESL) (*see* **Liquid Milk Products**: Liquid Milk Products: Super-Pasteurized Milk (Extended Shelf-Life Milk)) products have become an acronym that refers to the total process which encompasses everything from raw product quality to final distribution. The International Dairy Federation has suggested a target shelf-life of 25–45 days for ESL products. With the improved control of postpasteurization contamination, psychrotrophic sporeforming bacteria have emerged as important causes of spoilage of both normal and ESL milk. A large portion of microflora at the time of spoilage is often represented by Gram-positive psychrotrophs. Apart from airborne contamination and contamination from the udder, inadequately cleaned milking equipment, pipelines, farm bulk tanks and product lines in dairy plants may be important sources of spores and thermoduric microorganisms. ESL milk with reduced or zero postpasteurization contamination may often be spoiled by *Bacillus* spp. only.

Elopak and APV have developed the Pure-Lac™ system that combines heating of milk at 130–140 °C for less than 2 s and instant cooling in a special steam infusion chamber with a packing system, which may reduce or completely eliminate postpasteurization contamination. The heating system substantially reduces the number of spores but does not denature much more whey proteins and does not cause more pronounced sensory changes than normal HTST pasteurization. Milk processed by this system is, according to European Union directive, termed as pasteurized at high temperature. Airborne contamination is avoided by surrounding the system with air filtered to remove bacteria and spores. Contamination from the package is eliminated by its sterilization using a solution of hydrogen peroxide at low concentration and UV light. Milk produced by the Pure-Lac system may have a shelf-life of up to 45 days at 10 °C.

Activation of the lactoperoxidase system, treatment with carbon dioxide, addition of bacteriocin-producing lactic acid bacteria and bacteriocin or antimicrobial peptides derived from lactoferrin may inhibit the growth of all types of psychrotrophs in cold stored milk. Microfiltration (*see* MEMBRANE SEPARATION) and centrifugation (bactofugation) markedly reduce the number of spores and psychrotrophic bacteria in milk. These techniques, combined with reduction or elimination of postpasteurization contamination, may assure the production of ESL milk and cream of the requisite keeping quality.

Contamination with spores of *Bacillus* spp. and their enzymes produced in raw milk will be increasingly significant for the keeping quality of ESL products. The development of a rapid method for the detection of contamination with psychrotrophic spores or enzymes from thermoduric psychrotrophs is warranted.

Introduction

The goal of a dairy heifer-rearing program is to provide a regimen that will enable the heifer to develop her full lactation potential at the desired age and at a minimum expense. The optimum age and size at first calving are heavily dependent upon the breed and the genetics for body size of the animal. With increased popularity of crossbreeding of dairy animals, defining optimum body size has become more challenging. Calving heifers at too young or too old an age is associated with reduced production. Studies from a population of US Holsteins found the optimum age of first calving to occur between 22 and 24 months of age. However, for earlier-maturing breeds, such as Jerseys, the optimum age for first calving may be 1 or 2 months lower. Similarly, the optimum age for larger breeds may be higher by 30–60 days. Optimum body size must be defined relative to parturition. Suggestions for desired body weights based upon US genetics of representative breeds are shown in **Table 1**. This table is not intended to be representative of breeds throughout the world but serves to demonstrate the expected changes in body weight relative to parturition. It should also be noted that genetics within breed has a large impact on body size. As an example, within the US population it is estimated that genetics accounts for approximately 35 kg of the variation in body weight at first calving.

In addition to body weight, height at the withers or hips has been used as an indicator of growth. More recently, hip heights have become the more preferred measure of height of the animal as measurements are more repeatable and less influenced by the position of the animal's head during measurement. Genetics is the major determinant of an animal's potential for growth in height. However, the feeding program has considerable influence on the animal's ability to achieve its genetically predetermined potential for growth. As an example, **Table 2** shows median, 75th, and 95th percentiles for weight and height of a national sample of US Holsteins. Note the variation observed in height in this population.

Ideally, body composition data would provide valuable information, which might be a better indicator of future lactation yield than body weight alone. One would expect heifers with greater lean tissue growth and moderate levels of body fat content to produce the most milk. Unfortunately, the noninvasive techniques utilizing urea space, ultrasound, and electrical conductivity have all proven to provide information of limited value in measuring composition in dairy heifers, partly due to low body fat content of dairy

Table 1 Desired body weights (kg) at first calving

	Time of measurement		
Breed	*Before calving*	*Postcalving*	*Peak lactation*
Ayrshire	563	509	486

heifers as compared to the beef breeds. The only reliable method to measure body composition is to sacrifice the animal and measure body fat directly. This technique is costly and eliminates the ability to obtain later milk production information.

Rate of Gain

Measurements of body size are not adequate to describe the influence of growth on performance and productive life of the dairy animal. The rate of gain in weight and height, and timing of growth must be considered. About 50% of the total gain in height occurs during the first 6 months of life, 25% from 7 to 12 months and the remaining 25% during the last 12 months. The proportion of body weight to wither height increases linearly and the increase in wither height as a proportion of height at maturity is greatest during the first 6 months. This shows that the young heifer has a propensity for rapid growth if properly nourished. Before proceeding further, it is beneficial to review the biology of heifer and mammary growth. At birth, the mammary gland is rudimentary with both the gland and teat cisterns evident and ducts present close to the gland cistern. From birth to 3 months of age, the gland grows at a rate similar to the rest of the body. However, beginning at approximately 3 months of age, the gland begins an allometric growth phase, where the mammary gland grows at a much faster rate than the rest of the body. This phase continues until puberty when once again the gland assumes the same rate of growth as the rest of the body. Just prior to parturition, the mammary gland once again grows at a rate exceeding the rest of the body. The timing of these shifts in differentiation and growth vary with breed and the hormonal events triggering them have not been fully elucidated. The influence of feeding programs and rates of growth during the first 2 years of life has been the subject of much research. There are indications that a higher rate of growth (over 800 g day^{-1} for large breed heifers) prior to weaning during the milk feeding period has a positive influence on mammary development. Studies have shown that the milk-fed calf is capable of rates of growth exceeding 1.5 kg day^{-1}. Using the test day model, Cornell researchers can attribute major positive differences in first lactation milk yield to the rate of gain during the preweaning period of life. However, there is a large body of evidence that indicates that rapid growth (over 950 g day^{-1} for large breeds and less for smaller breeds) after weaning and before puberty may have a negative

impact on mammary development. Heifers fed for more rapid rates of gain postweaning exhibit depressed levels of growth hormone and increased growth of the mammary fat pad. However, the influence of diet on growth of mammary parenchyma is less clear with some studies indicating minimal influence on growth of the secretory tissue. The critical rates of gain that may influence mammary development vary with breed as studies have shown that apparent decreased mammary development occurs at lower rates of gain in Jerseys and Red Danish heifers as compared to Friesians.

Rate of gain can also be considered in a stair-step fashion. In this scenario, heifers are reared in alternating periods of slow and rapid rates of gain during the second and third trimesters of gestation, respectively. During the restricted phase, energy is fed to 70% of requirements and during the rapid phase at 130% of National Research Council (NRC) requirements for protein and energy. The rapid phase of growth during the third trimester corresponds to a period of robust mammary parenchymal growth. Growth responses and milk production of control and stair-step-reared animals are shown in **Table 3**.

Table 3 Performance of Holstein dairy heifers reared at a steady rate of gain or in a stair-step manner

$^{**}P < 0.01$
Control = 750 g average daily gain (ADG).
Stair-step = alternating requirements at 70 and 130% of NRC requirements.
From Park CS (2000) Personal Communication.

In the stair-step management scheme, heifers grow more efficiently and the composition of the mammary gland reveals more secretory cell numbers and cell activity and less lipid as compared to heifers growing at a uniform rate. The stair-step rearing program shows great promise although it requires a departure from conventional thinking and it may present challenges to implement under practical feeding situations on many growing operations.

The challenge of adopting uniform growth standards is that dairy breeds vary widely in their genetic capacity for growth and mature size. The adoption of the targeted growth system recognizes that nutrient requirements are linked to an animal's rate of gain and current body size relative to mature size. In the 2001 Dairy NRC, target weights for breeding and calving are based upon percentages of mature size. Puberty usually occurs when heifers have reached 45–50% of mature size. Heifers should be pregnant by 55% of mature size and calve by 82% of mature size. **Table 4** demonstrates the breeding and calving weight targets for heifers of differing mature size based upon desired age at first calving. Requirements are predicted based upon the expected mature weight of the animal being fed, the desired age at first calving, the current weight of the heifer, and the chemical composition of the feeds and dry matter intake (DMI) of the diet.

Nutrient Requirements for Growing Dairy Heifers

Previous predictions for DMI and nutrient requirements for energy and protein have been expressed on a tabular basis. However, more recent research and the development of nutrition models for growth and production have led to the use of equations to predict intake and nutrient requirements based upon a variety of readily available animal, environmental, and dietary measures. The 2001 Nutrient Requirements of Dairy Cattle utilizes the following equation, based upon beef cattle data to predict intake:

Table 4 Application of the targeted growth system under different management scenarios based upon expected mature weight, current weight at 4 months, and targeted calving at 22–24 months of age

Mature body weight (Kg)	*Age at first calving (months)*	*Current age (months)*	*Current weight (kg)*	*Target postcalving weight (kg)*	*Target breeding weight (kg)*	*Target age at breeding (months)*	*Target growth rate 4 months calving (kg day^{-1})*
450	22	4	100	375	250	13	0.50
650	22	4	125	525	350	13	0.73
800	24	4	160	675	450	15	0.85

$$\text{DMI (kg day}^{-1}) = \text{Body weight}^{0.75} \times \frac{(0.2435 \times \text{NE}_\text{M} - 0.0466 \times \text{NE}_\text{M}{}^2 - 0.1128)}{\text{NE}_\text{M}}$$

where NE_M is net energy maintenance

However, another equation using over 5000 observations of DMI in Holstein heifers from various US locations was developed to predict intake that accounted for over 59% of the variation in daily DMI. The simplified model was DMI $(\text{kg day}^{-1}) = -29.86 + (-0.54\text{E-}05 \times \text{body weight}) + (0.157 \times \text{metabolic body weight}) + (2.090 \times \text{daily gain}) + (-0.118\ \text{daily gain}^2) + (0.730 \times \text{TDN}$ (total digestible nutrients)) $+ (-0.005 \times \text{TDN}^2) + (-0.001 \times \text{body weight} \times \text{daily gain}) + (-0.019 \times \text{TDN} \times \text{daily gain})$. This equation was subsequently verified with data sets representing multiple locations across the United States and found to be equally successful in predicting intake. This equation is most successful in predicting intake of heifers weighing 100–400 kg.

Energy requirements for maintenance are based on Mcal of net energy required to support basal metabolism with adjustments for physical activity and temperature regulation. A dynamic model adopted by the 2001 NRC considers body size, temperature, relative humidity, and hair coat condition in estimating energy requirements for maintenance. Determination of the nutrient requirements for growth of the dairy heifer is based upon targeted growth concept, which is used to estimate body composition at a given stage of growth. Body composition at birth and maturity is relatively predictable. However, younger animals have the capacity to deposit more lean tissue per unit of gain. As animals mature they deposit more fat than lean tissue per unit of gain. This principle is utilized to estimate nutrient requirements regardless of the breed. Since a gram of fat contains more calories than a gram of lean tissue, nutrient requirements for energy and protein will change as the animals reach maturity. As body weight increases, the energy content of gain increases and protein content of gain decreases because more energy is deposited as fat. Also, as the rate of gain increases, energy content of gain increases (more fat deposition) and protein content of gain decreases. As animals increase in weight, protein required does not decrease as rapidly as expected because the efficiency of protein absorption decreases.

The revised nutrient recommendations consider protein requirements of the animal in light of rumen microbial protein synthesis as well as dietary protein, which escapes degradation in the rumen to yield an estimate of metabolizable protein available to support growth and maintenance. The new models developed to estimate amino acid requirements have frequently resulted in recommendations for feeding lower levels of protein in the diet of older animals. Feeding higher levels of protein in diets of growing heifers is not recommended because as dietary protein levels increase the amount excreted via the urine and feces increases. This is not only economically inefficient, but also contributes to environmental pollution. Increasingly, the nutritionist is challenged to provide the amount of nutrients that foster optimal, economical growth with minimal detrimental influence on the environment.

Mineral requirements are estimated based upon the factorial method using revised estimates of bioavailability of mineral sources. Vitamins are typically supplemented in the diet without regard to amounts supplied by other dietary ingredients with the exception of fresh forage, which supplies abundant amounts of vitamins.

Examples of suggested ration specifications for large breed (Holstein) and small breed (Jersey) replacements are shown in **Tables 5** and **6**. These tables were

developed using the dynamic models utilized by the 2001 NRC for Holstein heifers gaining 800 g day^{-1} and Jersey heifers gaining 600 g day^{-1}.

Conclusions

1. The concept of targeted growth should be practiced when determining growth standards. This enables one to establish desired rates of gain based upon the expected mature weight of the animal.
2. Rate of gain during the first 2 years influences mature weight and height.
   a. During the first 6–9 months of life, large breed heifers should be fed to gain between 750 and 900 g of gain per day and small breed heifers should gain approximately 500–700 g per day.
   b. After puberty, rate of gain is not as critical as long as desired height and weight goals after calving are reached.
3. Growth standards can be applied to dairy heifers regardless of breeding based upon expected mature size. Stated in this fashion:
   a. Calves should double their birth weight by 56 days of age.
   b. Puberty can be expected to occur when heifers have achieved approximately 45–50% of mature weight.
   c. When heifers attain 55–65% of mature weight they should be bred.
   d. At first calving, heifers should have attained 82–85% of mature weight.
   e. Body weights at second and third calvings should be 92 and 96% of mature weight, respectively.
4. Desired rates of gain can be calculated by comparing the heifer's current weight and age with the desired weights at the benchmarks described previously.
5. Target calving ages are 22–24 months for large breed heifers and 22–23 months for small breed heifers.
6. Nutrient levels in the diet must be adjusted according to environment and the ability of the animal to withstand heat and cold stress.

Pre-Ruminant Diets and Weaning Practices

Introduction

The newborn calf is essentially a monogastric animal requiring highly digestible nutrients in the liquid diet, especially during the first month of life. During this time, the young calf has limited development of enzyme systems to digest ingredients supplying protein and energy. This dictates that the calf be fed protein and energy sources closely resembling those contained in milk products which will supply needed amino acids and energy from fat and lactose. However, within weeks, as the calf begins consumption of starch-containing grains, rumen microflora develops, which produces volatile fatty acids that stimulate preferential development of the rumen epithelium. Successful nutritional management of the calf is indicated when the following goals are met:

- Eighty-five percent of calves born on the farm achieve a serum immunoglobulin G (IgG) $>10\,\mathrm{mg\,ml^{-1}}$ or serum protein $>5.5\,\mathrm{g\,dl^{-1}}$ between 1 and 7 days of age.
- Ninety percent of calves double their birth weight by 56 days of age.
- Less than 30% of calves are treated for disease during the first 30 days.

Key factors to consider in the preruminant feeding program include

- colostrum management
- provision of high-quality liquid diets fed in sufficient quantity to encourage biologically normal growth and immunity
- weaning at a reasonably early age
- provision of adequate amounts of high-quality water and calf starter grain
- provision of a favorable rearing environment

Colostrum Management

Consumption of adequate quantities of high-quality colostrum early in life is the single most important factor determining health and survival of the calf. The first milk produced by the dam is a rich source of immunoglobulins (Igs), nutrients, and immune cells. As shown in **Table 1**, the level of Igs declines rapidly over the first three milkings.

Fortunately, the intestine of the newborn calf is able to absorb these Igs, unchanged for the first 6–24 h of life. Successful absorption is achieved by the consumption of 100–200 g of Ig as soon as possible after birth. Although the level of Ig is variable, good-quality colostrum contains approximately $50\,\mathrm{g\,Ig\,l^{-1}}$. The period of time that the calf is able to absorb colostrum Ig is also quite variable. It may cease within 6 h of birth, but generally ceases within 24 h. Reasons for cessation of absorption are unclear, but research indicates that the presence of large quantities of bacteria in the intestine may inhibit absorption of Ig. Feeding contaminated colostrum or a dirty calving environment may accelerate bacterial colonization of the intestine and impair Ig absorption. Thus, successful immunity transfer occurs when the calf consumes 3–4 l of 'clean' colostrum within the first 12 h of life. Colostrum may also be involved in the establishment of cellular immunity in the calf. Additional feedings of colostrum beyond the first day result in improved growth of the intestinal epithelium as well as improved absorptive capacity.

Liquid Diets for Calves

Many alternatives exist for feeding the neonatal calf after the first day. They include whole saleable milk, waste milk unsuitable for human consumption, and milk replacer. Milk replacers vary widely in nutrient content and ingredient composition. Before selecting an alternative, one should consider the benefits and risks of each alternative feeding program for calves.

Whole milk usually fosters the best growth of the calf as it contains high levels of protein (24% on a dry matter (DM) basis) and fat (28.7% on a DM basis) to support calf growth. In addition, it is likely that these nutrients are more highly digestible than those from other sources. However, in nearly all cases, whole milk is more expensive and there is a risk of transmission of disease to calves by feeding raw milk.

On most dairies, there is a supply of waste milk from cows that have calved within the past 3 days or from cows that have been treated with antibiotics. Generally, waste milk contains similar levels of protein, fat, and lactose as whole milk. However, fat levels can vary from 2.0 to more than 4% and protein from 2.5 to 4.0%. Field studies with dairies utilizing waste milk for calves indicate that the

supply of waste milk varies from 2.5 to 9 kg per calf per day. On many dairies, the supply of waste milk is adequate to meet the needs of less than 50% of the calves prior to weaning. Therefore, feeding programs based upon use of waste milk must make accommodations for supplementation with additional milk solids when the supply of nutrients is inadequate. In addition to challenges with varying supply and nutrient content, waste milk frequently contains antibiotic residues (in the United States) and microorganisms that are potentially harmful to the calf.

Fortunately, systems have been developed to effectively pasteurize either whole milk or waste milk, which renders waste milk less likely to cause disease in calves. Successful pasteurization occurs when milk is heated to a sufficient temperature for an adequate time period to destroy 98% of the microorganisms present. Most systems used for pasteurizing waste milk can be described as being batch or high-temperature short-time (HTST) units. Batch systems (**Figure 1**) are typically simpler and more suitable for feeding smaller number of calves (<100).

Batch systems heat a 'batch' of milk to a temperature of 62 °C for 30 min. The HTST units (**Figure 2**) utilize either heat exchange plates or tubes to heat milk more quickly to 72 °C for 15 s. These systems are more expensive but their operation and cleaning can be more easily automated. Either system can be successful if properly installed, maintained, and operated. Successful pasteurization is generally indicated when the aerobic plate count has been reduced to 20 000 cfu ml^{-1} or less. Pasteurization does not sterilize milk but reduces bacterial numbers by 98%. Therefore, it is important that waste milk be handled with the same care as that which is sold for human consumption. If the aerobic plate count prior to pasteurization exceeds 2 000 000 cfu ml^{-1}, then the goal of <20 000 cfu ml^{-1} after pasteurization may not be achieved. It is also important that all vessels receiving waste milk after pasteurization be thoroughly cleaned

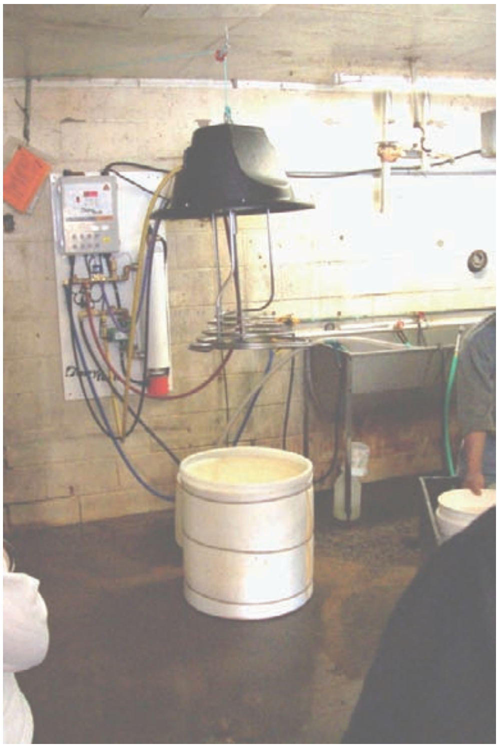

Figure 1 Example of a batch pasteurizer system (Dairy Tech, Windsor, CO).

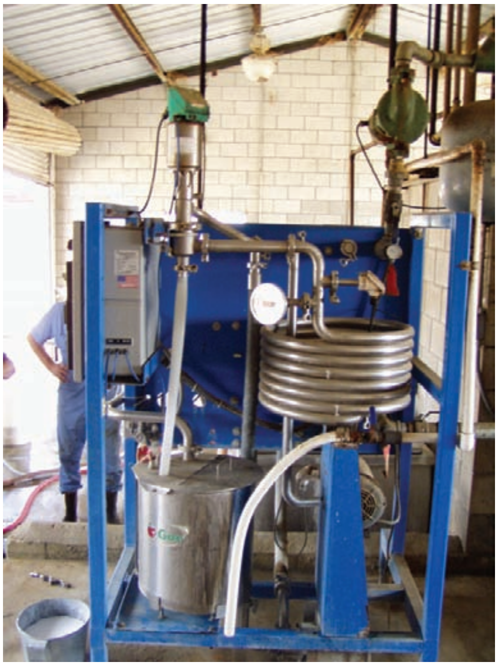

Figure 2 Example of high-temperature short-time pasteurizer (Goodnature, Orchard Park, NY).

and sanitized as microbial growth of pasteurized milk is very rapid when placed in unclean tanks or feeding bottles.

Adoption of a pasteurized waste milk-feeding program requires institution of stringent quality control programs to ensure that pasteurization has occurred and to account for variations in supply and nutrient content of waste milk. Samples of waste milk obtained after the last calf has been fed should contain less than 100 000 cfu ml^{-1}. Milk should also be tested for total solids and percentage of fat and protein. Additional milk solids should be added if waste milk contains less than 12.5% solids. Frequency of testing is determined by number of calves fed, but should be no less than once per month.

Milk Replacers

Milk replacers enable dairy producers to market more saleable milk. The objective of the formulation of a milk replacer is to provide nutrition to the calf that results in nearly equal growth and performance as that achieved with whole milk at less cost and with greater biosecurity. Typically, milk replacers are based upon the use of whey proteins, which are by-products of cheese manufacturing. The different whey products used in milk replacers include dried whey, delactosed whey, and whey protein concentrate, which contain progressively higher concentrations of protein. In an effort to further reduce costs, soy, wheat, and plasma proteins have been used as partial substitutes for milk proteins. Soy is treated to concentrate the proteins and reduce undesirable antigenic properties that can cause an allergic reaction in the intestine of the young calf. Milk replacers based upon milk proteins are recommended for calves less than 1 month of age due to their higher digestibility as compared to vegetable proteins. When vegetable proteins are utilized, it is recommended that they substitute for less than 50% of the milk proteins. The acceptability of various ingredients as sources of protein in milk replacers is shown in **Table 2**.

In the United States and most part of the world, lard and tallow are the primary sources of fat used in milk replacers. Due to concern over bovine spongiform encephalopathy (BSE), palm and coconut oil are used as a replacement for animal fats in EU countries. These oils appear to be of high digestibility and are well tolerated by the calf. Lactose is the primary carbohydrate used in milk replacers as it is of the lowest cost and is most efficiently digested by the calf.

Milk replacers are marketed as dry powders that contain 10–25% fat and 20–28% protein. In the United States, whole milk on average contains approximately 3.6% fat and 3.1% protein, which on a dry powder basis would equal 28% fat and 24% protein.

Liquid-Feeding Programs

There has been a substantial shift in the concept of liquid-feeding management of the dairy calf over the past 10 years. Traditional liquid-feeding programs for calves sought to minimize rearing expenses and encourage early development of the rumen to enable early weaning of the calf. A substantial body of work has demonstrated

Table 2 Ingredients used as sources of protein for milk replacers

Recommended	*Acceptable*	*Marginal*	*Not acceptable*
Dried whey protein concentrate	Soy protein isolate	Soy flour	Meat solubles
Dried skim milk	Protein-modified soy flour		Fish protein concentrate
Casein	Soy protein concentrate		Wheat flour
Dried whey	Animal plasma		
Dried whey product	Wheat gluten or isolate		

Bovine Alliance on Management and Nutrition Information Sheet (2008) A guide to calf milk replacers.

that feeding approximately 454 g of solids per day containing 20% protein and 10–20% fat appeared to be the best compromise between desired growth, calf performance, and encouragement of early consumption of dry calf starter grains. Under this traditional model, the calf grew modestly, especially during the first 2–3 weeks of age (<200 g day^{-1}), and began consuming dry grains by the end of the second week. Some rearing programs resulted in consumption of sufficient dry feeds to enable weaning by the end of the fourth week of life or earlier. Although it achieved a low daily feed cost, this practice ignored the influence of body size, environment, and ingredients utilized in the diet on growth and development as well as health of the preweaned calf. The concept of limit-feeding calves liquid diets is a departure from the approach of diet formulation used for older dairy animals, which considers requirements for maintenance, body size and expected growth, or other performance measures such as milk production. Rather the goal with the traditional limit-fed program in preweaned calves is to reduce nutrient intake early in life to stimulate premature intake of dry feeds and reduce cost.

Research over the past 10 years has resulted in the determination of nutrient requirements for body weight gain as well as the composition of gain in the growing calf. Using all-milk protein sources it appears that daily protein accretion in the calf plateaus at 28% crude protein (CP) on a DM basis, which is also similar to the protein content of whole milk. These studies have also shown that body fat accretion decreases with increasing protein in the diet and that the protein content of body weight gain increases with increasing protein intake of the diet. Energy intake is derived from lactose, fat, and to a lesser extent from protein. Most milk replacer diets contain 10–20% fat, considerably below that found in milk solids. Research has shown that growth rate is not appreciably influenced by differences in the proportion of energy provided as lactose or fat. However, as the fat intake increases, the accretion of body fat increases. When diets are formulated with regard to nutrient requirements for growth as well as maintenance, the amounts of solids recommended to be fed to the preweaned calf are considerably higher than 454 g day^{-1} common to traditional systems.

Nutrient requirements can be partitioned into requirements for maintenance and growth. Maintenance requirements are a function of age, body size, environmental temperature and exposure, and disease status. The thermoneutral zone for young adapted calves appears to be 15–25 °C. This means that the calf would require additional energy for maintenance when temperatures exceed this zone. Smaller, younger animals would require proportionately more energy to meet energy requirements than older, larger animals because smaller animals have proportionately more body surface area and thus lose body heat more readily. Therefore, during cold weather, both solids intake and fat content of the diet should be increased. **Table 3** demonstrates the influence of environmental temperature on maintenance requirements of calves of different body sizes. Note the increase in maintenance requirements and the amount of milk solids required to meet maintenance needs as temperature decreases.

The most recent edition of the *Nutrient Requirements of Dairy Cattle* has used a dynamic approach in determining nutrient requirements of the dairy calf that considers body size as well as temperature. **Table 4** demonstrates the influence of environment and composition of the diet upon expected growth of a 55 kg calf.

Table 4 demonstrates that limit feeding a 20:20 milk replacer during cold weather has a detrimental influence on calf growth with possible repercussions on health if body fat stores are depleted. Additional research has demonstrated that maintenance requirements of small-breed calves such as Jerseys may be at least 20% higher than the maintenance requirements of large-breed calves due to increased heat loss from the greater surface area of smaller calves as compared to larger calves. As a result,

Table 3 Influence of environmental temperature and body size on megacalories of net energy maintenance and gram of whole milk required to meet maintenance requirements of calves of different body sizes

	Environmental temperature (°C)

in milk replacer powders, fat levels of 25% may be warranted during cold stress experienced by small-breed calves.

There is a growing body of evidence that restricting calves to consumption of 454 g of milk solids per day may not be advisable. A recent study in the United States revealed that mortality from birth to weaning exceeded 8% in limit-fed calves while that of more liberally fed beef calves was less than 3%. These surveys of US dairy operations indicated that over 40% of calves were considered to be ill or unthrifty and required medication prior to weaning. A predisposition to illness could be caused by feeding calves at or below maintenance. In one study, calves fed 4 l of pasteurized waste milk daily experienced higher daily gains than calves fed a similar volume of milk replacer containing 20% CP and 20% fat reconstituted to 12.5% solids. In addition to better growth, the calves fed pasteurized waste milk experience lower levels of morbidity (12 vs. 32%) and mortality (2.3 vs. 11.6%). Differences in mortality and morbidity were more striking when comparing the influence of season; calves fed milk replacer experienced 21% mortality and 52% morbidity as compared to 2.8% mortality and 20.4% morbidity for calves fed whole milk during the winter season. Improved performance and health of calves fed pasteurized waste milk could be attributed to increased intake of protein and fat as compared to calves fed the milk replacer.

Growth rate of the calf prior to weaning may have a profound effect upon mammary development. Calves fed a milk replacer containing 28.5% protein and 15% fat for an average daily gain of 666 g had 32% more mammary parenchymal mass and 47% more parenchymal DNA than calves fed a 20% protein and 20% fat milk replacer for an average daily gain of 379 g at 8 weeks of age. Several studies have demonstrated that calves fed more liberally during the preweaning period produced more milk per day during first and later lactations than limit-fed calves receiving 454 g of milk replacer or an equivalent amount of solids from whole milk. The more liberal feeding programs have been commonly referred to as 'intensive' or 'accelerated' while 'more biologically normal' might be a better terminology as the more liberal feeding program more closely resembles what takes place when the calf is allowed to nurse the dam. Additional responses to more biologically normal feeding rates include indications for improved immune function. Insufficiencies of protein or energy are known to impair health and immune system function in other species. Nutritional insufficiency is likely to be much more problematic in smaller, younger, limit-fed calves during cold or heat stress when maintenance requirements are known to be higher.

More liberal feeding programs result in increased lean tissue growth and, when whole milk or milk replacers contain 20% or more fat, increased body fat deposition. In the young calf (less than 3 weeks of age), additional reserves of body fat may be a desirable trait. When calves become ill, intake is frequently decreased. Concurrently, an illness of infectious origin generally results in increased body temperature and increased energy requirements. If young calves are fed whole milk or milk replacers with higher protein and fat at higher intakes, the extra body fat may assist them in recovering from disease.

Practical Management of Milk-Feeding Programs

Limit Fed

There are numerous studies indicating that calves can be successfully reared when liquid feeding is limited to 4 l of milk or milk replacer containing the equivalent of 454 g of milk solids with 20% protein and 20% fat. The following management strategies increase chances for a positive outcome with this program. The environment needs to be optimal to minimize both cold and heat stress, which increase nutrient requirements for maintenance. During cold weather (<15 °C), the proportion of solids should be increased to provide additional energy and protein. Avoid the use of vegetable proteins for the first 3 weeks of life due to their lower digestibility. Outside of the EU countries, plasma proteins are an acceptable, lower cost partial substitute for milk protein. Due to the lower intake of milk solids, there is a stronger incentive for calves to consume dry starter feeds at an earlier age and there is a trend for early weaning. The greatest limitation to limit-feeding systems is that cost per pound of gain may be higher as significantly more nutrients are required for maintenance with less remaining to support growth. During cold and heat stress, there may be a higher risk of morbidity and mortality.

Intensive, Accelerated, or Biologically More Normal

Liquid-feeding programs that involve feeding 680–1150 g of milk solids (5.5–7.5 l) per day more closely resemble what takes place when the calves are allowed to nurse their dams. Consequently, their growth and feed efficiencies are more similar to other young farm animals such as piglets or lambs. It is essential that milk-derived proteins be used throughout the liquid-feeding period as a higher intake of less-digestible vegetable proteins may increase the risk of diarrhea. During the first week of life, intake of milk is generally limited to 4 l for small-breed calves and 6 l for large-breed calves. Milk replacers usually contain 26–28% CP and 16–25% fat. Higher fat levels are recommended for small-breed calves, especially during times of cold stress, which can amount to 6 months of the year when ambient temperature is less than 15 °C. Milk replacer powders are reconstituted by the addition of warm water to a final solid level of 12.5–17%. The higher level of solids enables use of 3 l nipple bottles for twice-daily feeding. Once calves reach full feed of 5.5–7.5 l day^{-1}, they are maintained at this level until weaning. The feed cost per kilogram of gain may be less with this program as nutritional requirements for maintenance comprise less of the daily nutrient intake leaving more nutrients to support body weight gain. The limitation of this feeding system is that the rearing cost per day is significantly higher. Intake of dry calf starter is delayed by several weeks, but once the calves begin consuming calf starter they generally compensate due to their larger body size at a given age as compared to limit-fed calves. Calf feeders will note that feces from more liberally fed calves are looser and should not be confused with increased diarrhea.

Calf Starters for Preweaned Dairy Calves

Calf starters should be formulated and delivered to the calf to encourage intake early in the calf's life. As they are replacing nutrients provided by the liquid diet, the ingredients should be highly palatable and digestible and encourage development of the rumen epithelium and musculature. Historically, producers believed that early consumption of hay was critical to rumen development. However, research has shown that the consumption of grains high in starch is responsible for stimulating exponential growth of rumen epithelium. Consumption of hay prior to weaning is not recommended as it is much lower in energy than grains and will reduce energy intake and possibly delay weaning. In addition, calves frequently waste large portions of the hay that is offered. Ground hay can be included in calf starter grain mixtures in limited amounts (5–10%) provided it is high in energy and protein and low in fiber. Unfortunately, difficulty in handling such ground hay and grain mixtures precludes them from being used in most commercial calf starter mixtures.

Calf starters typically contain 18–24% CP on a DM basis. The National Research Council (NRC) recommends 20% CP (DM basis) for calf starter feeds. When calves are limit-fed a 20% CP:20% fat milk replacer, little improvement is observed when higher CP% calf starters are fed. However, calves managed under a more liberal milk-feeding program using whole milk or higher protein milk replacers appear to adjust better to the diet postweaning with higher feed efficiency when a calf starter with up to 24% CP is fed. This is logical when one considers that the calf has received a higher protein liquid feed during the preweaning period. Little benefit accrues from prolonged feeding of higher-protein calf starter mixtures (>20% CP) beyond the first month after weaning.

Ingredient composition of calf starter mixtures influences palatability and digestibility. Soybean meal (48% CP) and corn appear to be the most reliable protein and energy sources. It is not uncommon to include crimped oats owing to their palatability. However, oats are lower in energy and starch content and frequently a more expensive ingredient. Various forms of corn have been used in calf starter grains. Research comparing whole, dry-rolled, roasted-rolled, and steam-flaked corn in calf starter mixtures resulted in no difference in weight gains, but feed efficiency and dry feed intake postweaning favored starter grain mixtures containing whole or dry-rolled corn. Molasses is commonly added to calf starter grains at 2–5% to improve palatability and reduce dustiness. Higher levels have been shown to reduce gain and solid feed intake. Molasses has a tendency to deteriorate during storage and causes clumping of the mixture thereby making handling of the starter difficult.

The addition of nonforage fiber sources such as beet pulp, soy hulls, wheat midds, corn gluten feed, and cottonseed hulls to calf starter diets at low inclusion rates (12–20%) is common. In most cases, feed intake is either not affected or increased only slightly. Since these feedstuffs contain less energy as corn or other high-starch grains, they commonly result in reduced feed efficiency. Improved gains when high-fiber starters are fed can be attributed to greater rumen fill and not necessarily improved lean tissue growth. If ground hay or nonforage fiber sources are included, they should be limited to 5–10% of the final mixture.

Fat is occasionally added to calf starter mixtures to reduce dustiness. Addition to calf starters at levels exceeding 3.5% of the mixture reduces intake and live weight gains.

Consistent improvement in live weight gains of calves has been observed when anticoccidial compounds such as decoquinate, lasalocid, or monensin are added to calf starter grains. They aid in controlling some types of coccidia. Lasalocid and monensin have also been shown to improve feed efficiency through an influence on rumen fermentation. The use of microbial probiotics and yeasts has resulted in benefits in some trials, but responses have been highly variable and less conclusive than with lasalocid or monensin.

Water Management

Provision of ample supplies of fresh, clean water to calves is essential to successful early consumption of calf starter and early weaning regardless of the liquid-feeding program. Water should be provided in a bucket separate from that used for feeding milk. The water bucket should be located a sufficient distance away from the calf starter bucket so that the calf cannot dampen the starter with water nor foul the water with calf starter.

Successful Weaning

Calves can usually be weaned successfully when they are consuming at least 1.5–2.0 kg of dry calf starter grain per day. Exceptions can be made during extremely cold weather when liquid feeding may be prolonged for a week or two longer. Weaning usually occurs at around 6–8 weeks of age. Calves can be encouraged to increase consumption of dry feeds in several ways. Maintaining a constant rate of liquid feeding from birth means that the liquid diet provides progressively less of their daily nutrient requirements as the calves grow larger. During the fifth or sixth week, the amount of nutrients obtained from the liquid diet can be reduced by feeding once daily, or in the case of milk replacers, maintaining liquid intake but providing half of the amount of milk powder in the same volume of water. The latter examples are commonly used and are very successful in stimulating dry calf starter intake and weaning. Calves should be maintained in their current environment until 1–2 weeks after weaning to minimize social stress. The highest quality dry hay has be to introduced 2–3 weeks after weaning.

Conclusion

Calves can be reared successfully with either limit-feeding or biologically more normal systems. However, the most important factor influencing success is obtaining adequate immunity from colostrum. This is achieved by feeding 4 l of colostrum containing at least 50 mg IgG ml^{-1} within the first 6–12 h of life. Whole milk, pasteurized waste milk, and milk replacers with higher levels of protein and energy can support gains of 500 g or more per day and promote excellent health and development. Early consumption of a digestible and palatable calf starter grain is essential regardless of the liquid-feeding program. Weaning is achieved when starter intake reaches 1.5–2 kg day^{-1}.

Introduction

Dairy heifers should be fed and managed to achieve 55% of their mature weight at first breeding and 82–85% of their mature weight at first calving. These principles enable the establishment of growth goals regardless of breed. In addition, heifers should have a body condition score after calving of 3.5 and be free of disease. Probably, no factor other than the feeding program influences achievement of these goals. The feeding program also comprises 50–70% of the cost of rearing heifers to first calving. Therefore, profitable heifer-rearing enterprises must concentrate on economical feeding programs.

The purpose of this article is not to provide a 'how to' description of heifer-feeding programs because available feed resources and facilities vary to a great extent. This article will focus on a discussion of decision-making areas with considerable importance to the financial success of the heifer-feeding programs. Managing the feeding program of the heifer enterprise is not unlike that of any other decision made on the farm. Good heifer managers maximize benefits, control expenses, and manage risk well. This article will concentrate on the major goals the heifer grower needs to achieve during the rearing period:

1. successful weaning from liquid diets to forage- and concentrate-based feeding programs with minimal stress and loss of weight, and transition to group housing management systems;
2. controlling the rate of gain during the prepubertal period to enable early breeding (12–13 months) while assuring desired mammary development;
3. sustained growth after breeding and optimization of economy of feeding; and
4. preparing the heifer for eventual calving.

The development of the feeding program should consider that approximately 50% of the total gain in height occurs during the first 6 months of life with 25% occurring from 7 to 12 months and the remaining 25% during the 12 months before calving. Feed cost is generally lowest per unit of gain during the first 6 months of life and then increases at a decreasing rate during the remaining 18 months. The proportion of body weight to wither height increases linearly and the increase in wither height as a proportion of total height is greatest during the first 6 months. This demonstrates that assuring adequate growth during the first 6 months is critical to success in growing the dairy heifer and is where nutrition and management must be optimal. Poor growth prior to puberty cannot be compensated for later in the rearing period. After puberty and when the heifer has attained early growth goals, opportunities for considerable economy of feeding exist. Profitable heifer management requires labor-efficient systems and the ability to evaluate ration dry matter intake (DMI) and animal performance. Periodic weighing of heifers with comparison to established growth goals is critical to achieving desired performance.

Heifer-feeding programs vary widely depending on the environment and available forage resources. In tropical and more temperate areas of the world, pasture-based systems are more popular because they provide nutrients at the lowest cost and promote excellent animal health. In other areas where land resources are more valuable, or the length of the grazing season is limited, confinement systems may be more conducive to economical heifer growth. In many areas of the world, a combination of systems where heifers are raised on pasture during the warmer months and moved to confinement during the winter is commonly practiced. Basic principles of nutritional management using pasture-based and confinement systems will be discussed.

Managing the Transition Calf

This stage refers to the time between 2 weeks prior to and 2 weeks after weaning. Success during this phase is dependent upon excellent housing and health programs. Regardless of the rearing system, it is assumed that the calf is consuming adequate amounts of a high-energy calf starter grain prior to weaning. When preweaned calves have been housed individually, it is recommended that calves be placed into small groups of 4–6 calves several weeks after weaning to allow them to adjust to competition for feed. However, when the environment is optimal, the author has observed newly weaned calves reared in groups of 20–30 with great success. Under this scenario, ventilation is outstanding, bedded pens are cleaned frequently, and calf starter grain is fed often to keep the feed fresh. Calves that have been fed their liquid diet in groups from mob or robotic feeders adapt to weaning quite well as there is no social stress associated with adapting to the group housing and feeding environment. Calf starter grains can vary widely, but should be highly palatable and digestible,

Table 1 Desired nutrient levels in a calf starter grain

Nutrient	*Amount recommended*
Crude protein (% of DM)	18.0–22.0
Fat (% of DM)	3.0
TDNs (% of DM)	80
Metabolizable energy (Mcal kg^{-1} DM)	3.1
Calcium (% of DM)	0.60
Phosphorus (% of DM)	0.40
Vitamin A (IU kg^{-1})	2200
Vitamin D (IU kg^{-1})	300
Vitamin E (IU kg^{-1})	24

DM, dry matter; TDNs, total digestible nutrients.

with nutrient concentrations as shown **Table 1**. Under more intensive liquid-feeding programs for calves, protein levels may be increased to 22% of dry matter (DM).

For calves that have been housed individually prior to weaning, Morrill suggests three transition pens after weaning. The first pen has 4–8 calves with 2.8 m^2 per calf and a starter the same as they had been receiving prior to weaning. Two weeks later, the calves are moved to a larger pen with more calves and with the same starter and about 15% chopped alfalfa hay added to the ration. In the next transition pen, the amount of chopped alfalfa is increased to 20% of the mixture. By the time the calves are moved to the last transition pen, they can be switched to a more economical grower concentrate mixture, with examples shown in **Table 2**.

Table 2 Examples of calf starter grain mixtures

Feed	*Grower 1*	*Grower 2*
Cracked corn	63.8	53.23
Rolled oats	9.9	
Rolled barley		20.48
Molasses	3.5	2.97
Soybean meal	20.4	
Canola meal		21.33
Limestone	1.2	1.08
Dicalcium phosphate	0.27	
Salt	0.18	0.18
Trace mineral mix	0.09	0.09
Vitamin E mix	0.09	0.09
Vitamin ADE mix	0.07	0.07
Additives	0.50	0.46

Values are percentage of total mixture on an as-fed basis.
Composition of trace mineral mixture (%): Co, 0.01; Cu, 1; Fe, 5; I, 0.06; Mn, 4; Se, 0.03; Zn, 4.
Composition of vitamin ADE mixture, per kg: A, 44 000 KIU; D, 990 KIU; E, 17 600 IU.
Vitamin E supplement contains 44 000 IU kg^{-1}.
Grower grain mixture should contain coccidiostat or other additive as desired.

Workers at North Carolina State University have successfully developed a self-fed calf starter grain utilizing cottonseed hulls to limit intake. Calves are offered the starter from birth through 4–6 months of age. Cottonseed hulls represent a uniform, consistent source of more slowly digested fiber that helps limit intake in the older heifers. Critical to success of the system is maintaining a reliable source of clean cottonseed hulls, keeping the self-feeders clean, and providing plenty of water. Nutrient content of these starter mixtures on a DM basis is 16–18% crude protein (CP), 76% total digestible nutrients (TDNs), 0.66% calcium, and 0.42% phosphorus. The ingredient composition is 493 kg ground corn, 300 kg cottonseed hulls, 184 kg soybean meal, 9 kg calcitic limestone, 5 kg tricalcium phosphate, and 5 kg white salt, ionophore, and a vitamin–trace mineral mixture. Although apparently successful, these starters are lower in energy and require higher intakes to meet the energy requirements for acceptable growth.

Managing Growth of the Heifer from Weaning to Breeding

Once the heifer has been successfully weaned and has transitioned to group housing, control of rearing rate is of primary concern. If one assumes that a goal of age at first calving of 22–24 months is desirable, breeding should be initiated at 12–13 months. Animals must be of adequate weight and body condition to accomplish this objective. **Table 3** demonstrates the challenges faced in feeding the large-breed heifer prior to breeding. It also demonstrates the difficulty in attaining ages at first calving below 20 months. Based upon these assumptions, it is assumed that rations for the large-breed heifers should foster a gain of 750–900 g day^{-1}. Smaller breed heifers require gains of 500–650 g day^{-1}. Excessive gains may increase the risk for problems with mammary development, particularly if protein is limiting in the ration.

Pasture-based systems

In many areas of the world, the greatest forage asset is the availability of abundant, low-cost land suitable for pastures. The best example for pasture systems exists in

Table 3 ADG necessary to achieve suggested 360 kg weight at breeding and postcalving body weight of 570 kg at varying ages

Age at calving goal (months)	20	22	24
Age at breeding goal (months)	*11*	*13*	*15*
ADG birth–breeding (g)	953	800	680
ADG breeding–calving (g)	884	884	884

Assumes 39 kg birth weight, 45.4 kg loss of weight at calving, and 280 days of gestation.
ADG, average daily gain.

Ireland, New Zealand, southern Chile, and Argentina, and similar climes that have cool temperatures with frequent, moderate rainfall during a large portion of the year. Less desirable examples of grazing systems are range management systems in arid areas, which require extensive land bases exceeding 20 hectares per animal and they support little more than maintenance nutrient requirements. In many areas of the world, the role of pasture in heifer-feeding systems is probably in between these extremes. It is important to evaluate realistically the advantages and liabilities of pasture systems and determine how best to optimize their benefits and minimize the risk of their shortcomings.

The biggest challenge faced in the pasture system is reliably estimating the carrying capacity of the land. If land is to be utilized for pasture, its use during the year must be maximized to provide the best compromise of yield of animal growth and forage nutrient yield. **Figure 1** shows the effect of grazing pressure on production per animal and per acre. Note that optimal growth per head is not the same as optimal growth per acre. Optimum growth per animal occurs at a point less than optimum for land utilization. When grazing pressure is low to medium, heifers graze on only the best quality forage. When pasture output is optimized at higher stocking rates, heifers are forced to consume some of the less nutritious forage and animal performance declines. This represents a challenge for the heifer grower or dairy producer.

Extremes in stocking rate are undesirable. Long periods of low grazing pressure lead to a loss of legumes in a stand and increased growth of weeds and less desirable species. Long periods of high grazing pressure result in temporary or long-term decreases in forage production as nutrient reserves of desirable forage species are depleted and plants become less dominant in the sward. For optimum grazing, one should maintain available forage at approximately 1122–1685 kg DM per hectare. This is the equivalent of a 7–10 cm high stand of bluegrass/white clover or 15–20 cm of tall grasses and legumes.

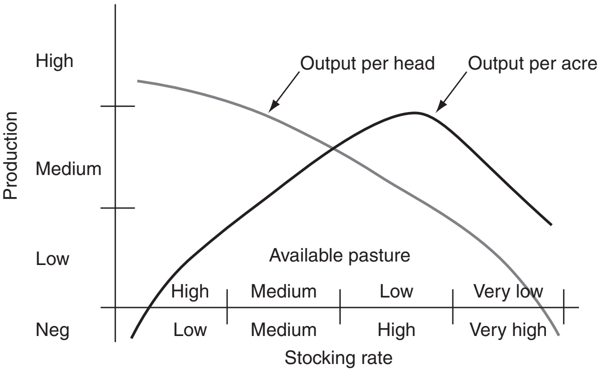

Figure 1 Effect of grazing pressure on production per animal and per acre. Reproduced from Hall MH (2009–2010) *The Agronomy Guide*. University Park, PA: Department of Crop and Soil Sciences, The Pennsylvania State University.

Continuous or rotational grazing?

Historically, continuous grazing has been the most popular grazing system since it is simple and requires little labor. Grazing pressure is adjusted by adding or subtracting animals or temporarily fencing off areas for hay harvest. However, continuous grazing is a land extensive system, and low production of gain per hectare makes it inefficient. In contrast, rotational grazing can dramatically increase animal performance and forage DM yield per hectare. In heifer feeding systems, intensive rotational grazing systems are probably not as important. Improvements in nutrient quality of forage accrued from more daily movement of fences or shifting heifers to new paddocks daily do not offset the labor and fencing expense and convenient provision of water. Many heifer growing systems include some combination of both continuous and rotational systems. A continuously grazed paddock may be used to house animals during the winter or during periods of drought to enable other areas to recover forage growth. Other paddocks are designed to enable movement of fences on less frequent interval of 3–14 days.

Supplemental nutrition of pasture systems

For many areas of the world, dairy heifers cannot be reared without significant nutrient supplementation during some portion of the year. The nutrient variation of grazed forage species represents one of the greatest challenges of grazing, particularly for animals less than 1 year of age. In the more temperate areas of the world, protein concentrations of pasture can vary from 6% to levels exceeding 20%, while the growing dairy heifer may require levels ranging from 12 to 18%. Similarly, energy values will range from those similar to corn silage to levels that more nearly resemble straw. Although heifer rearing regimes might tolerate some variation in growth, in today's economic climate it is important that heifers calve at an early age and with desired body size and condition.

When forage availability is adequate, but quality is lacking, provision of supplemental energy and protein through concentrate feeding is advised. At other times such as winter months or during severe drought, heifers require supplementation with both forages and concentrates. It is beyond the scope of this article to address adequately the supplemental nutrient needs of pasture-reared heifers.

Pasture-reared heifers require more energy than those in confinement due to their increased activity and exposure to environmental conditions, particularly during the winter. Research at Virginia Tech has shown that confinement-reared heifers require 12–25% less energy than indicated by National Research Council (NRC). They are also less influenced by severe cold and wet weather. Therefore, managers of pasture-reared heifers must make adjustments in nutritional strategies when environmental conditions are less than perfect. Factors such as cold weather, nonthermal resting areas, wind, rain, and snow increase demand for energy for maintenance thereby reducing that available for growth. Environmental conditions for heifers raised without housing may become so severe that it is not possible to maintain sufficient growth, even with substantial energy and protein supplementation. Supplementation of rations with energy must be based upon observed growth of heifers during inclement weather. Similarly, supplementation can often be reduced at considerable savings when pasture growth and environment are optimal.

The greatest challenge of pasture systems lies in the establishment of pastures that enable maximal grazing throughout the season and provisions for supplementation when pasture nutrients are insufficient to promote desired growth. Depending upon the climate and resources, successful growers utilize a mixture of swards containing cool and warm season perennial grasses and legumes.

Young calves readily adapt to pasture systems as they provide ample opportunity for exercise, excellent air quality, and when pasture growth is young and rapid, a plentiful supply of energy, protein, mineral, and vitamins. However, it is important to note that calves weighing less than 150 kg require nutrients at least as high as that for the lactating cow (>16% CP and >2 Mcal of metabolizable energy (ME) per kg of DMI). An additional consideration for younger calves is their susceptibility to parasitism. Aggressive parasite control programs are recommended because the young animals have not developed sufficient immunity more common in animals in their second grazing season. By 300 kg body weight, concentration of nutrients is less important as adequate intake (7 kg DM per day) of forage providing 12% protein and 2 Mcal ME per kg DMI is adequate for 700 g of gain per day. It is uncommon to formulate rations for grazing dairy heifers. Rather the manager assesses pasture quality and availability, and heifer growth to determine if supplemental nutrition is needed.

Confinement rearing systems

Young heifers, less than 150 kg body weight, require diets of high forage quality to enhance rumen function and promote economical growth. Forages must be free of mold and spoilage to ensure adequate ration intake. Fermented feeds and a wide variety of by-product feeds are readily accepted by heifers more than 150 kg body weight. Forage quality, as defined by nutrient content, becomes less important for the heifer over 150 kg body weight as intake is usually not the limiting factor in nutrition. Professional heifer growers have been especially aggressive in seeking ways to provide nutrients at the lowest possible costs. This strategy requires the grower to 'think outside the box' when it comes to selecting ration components. Rations are presented to demonstrate the possibilities for utilization of by-product feeds. They are based upon those used by several large heifer growers in Colorado and Texas as well as conventional rations used in heifer feeding trials at Virginia Tech.

Each ration was evaluated using the Cornell Penn Minor (CPM) program to determine expected gains based on ME and metabolizable protein (MP). Ration I relied heavily on by-products from vegetable processing, wet brewer grains, and low-cost alfalfa silage, which were of insufficient quality for lactating dairy cattle or export. Frequent weighing of heifers revealed growth of 800 g day^{-1}, while the CPM model indicated that ME supplied by the ration should provide for only 690 g of gain per day and sufficient MP for 1.17 kg of gain per day. Ration II used an exceptional array of by-product feeds. Alfalfa was of lower quality, as was the whole cottonseed. Outdated dairy products (ice cream, cottage cheese, yogurt, and other products) were also used as available in this ration. In comparison to ration I, this ration contained an abundance of protein of a very degradable nature. Sufficient ME and MP were present to support gains in excess of 1 kg day^{-1}, which supported observations on the feedlot of rapid gains, and heavy body condition. Ration III represents the traditional ration fed to dairy heifers in Virginia. MP and ME were present in sufficient amounts to support daily gains in excess of 900 g. These rations demonstrate the ability of heifers to grow at rates that support early calving at recommended body sizes at very low ration costs. The greatest limitation involved in the successful use of by-product feeds is personal prejudices and preconceived ideas of what will be successful. Once it has been determined that by-products contain no harmful substances and that product quality is predictable, many by-products serve as economical ingredients for heifer rations (**Table 4**).

Feeding the Breeding Age Heifer and Bred Heifer

Growers should not need to increase nutrient levels for the breeding age heifer, since she should already be on a high plane of nutrition promoting 750–900 g of average daily gain (ADG) for large-breed heifers or 500–650 g of ADG for small-breed heifers. Once the heifer is bred, it is important to maintain these growth rates, although it is possible to tolerate some variation as long as goals for growth are attained at calving. As shown earlier, attaining a breeding weight of 363 kg at 13 months of age requires an ADG exceeding 800 g. However, attaining

Table 4 Example rations for growing a 225 kg heifer at an average daily gain of 815 g

	kg DM	*CP (%)*	*RUP (% of CP)*	*TDNs (%)*	*ME (Mcal lb^{-1})*	*NDF (%)*	*Cost (\$ day^{-1})*
Ration I	6.0	11.2	45.4	66	2.2	46	0.72
Ground wheat straw, 1.45 kg; wet brewers' grain, 2.9 kg; carrots, 1.8 kg; wet beet pulp, 1.8 kg; corn screenings, 1.1 kg; alfalfa silage, 3.6 kg; Rumensin™ was included in the mix.							
Ration II	5.85	17.2	29.4	68	2.6	35.91	74
Cotton gin trash, 730 g; rolled corn, 1.27 kg; distillers' grains, 454 g; whole cottonseed, 363 g; alfalfa hay, 1 kg; wheat midds, 1.63 kg; cottonseed meal, 363 g; sorghum silage, 1.27 kg; waste dairy products, 1.82 kg.							
Ration III	13.6	12.0	33.9	67	2.44	41.3	90
Corn silage, 6.82 kg; soybean meal, 454 g; ground shelled corn, 1.6 kg; orchard grass hay, 2.27 kg.							

All rations were fed as total mixed rations for *ad libitum* intake, with prevailing feed prices as of August 2009.
DM, dry matter; CP, crude protein; RUP, rumen-undegradable protein; TDNs, total digestible nutrients; ME, metabolizable energy; NDF, neutral detergent fiber.

the postcalving weight of 570 kg requires heifers to continue to gain 750–900 g day^{-1}. Opportunities to utilize by-product feeds in total mixed rations continue. These heifers can tolerate variations in gain, and rapid compensatory growth prior to calving is well tolerated provided that heifers do not become overconditioned.

Feeding Management Considerations

Grouping heifers is a challenging issue to resolve, as it is a compromise between facilities, labor, and nutrient efficiency. Heifers should be placed in as many groups as is efficient from a labor standpoint. Suggested grouping are transition heifers, 4–8 months, 9–12 months, breeding-age heifers, and pregnant heifers. If possible, place heifers in groups within a range of 50 kg. Group heifers by size and body condition, paying close attention to note heifers significantly older within a group that may need to be culled. When multiple breeds are present in a herd, it is important to remember that smaller breeds mature more rapidly than larger breeds. If heifers are grouped by size, smaller breed heifers such as Jerseys will frequently become overconditioned. It is recommended that Jerseys and other earlier-maturing breeds are housed with slightly larger and older large-breed heifers. Provision of sufficient feed bunk space is an important consideration in such situations.

Factors influencing growth and feed efficiency of dairy heifers

A common misconception regarding dairy heifer nutrition is that published nutrient requirements provide sufficient nutrients to assure the stated rate of gain under a wide variety of environments. One must remember that these recommendations are based on the assumption that replacement heifers are clean, dry, fed *ad libitum*, free of disease and parasites, unbred, and raised at moderate temperatures. A survey of Wisconsin dairy herds showed that much of the variation in gains could be attributed to environment rather than feeding programs. Net energy maintenance requirements were 12–24% higher for fall/spring and winter as compared to summer. Failure to adjust for these added nutrient needs could decrease ADG by 90–180 g or more. Cold stress is especially problematic for smaller heifers or when the animal has lost insulating capacity of its coat due to excess mud or moisture.

Temperature has an influence on DMI. However, it was found that although temperature had a statistically significant influence on intake, it is of less importance than for lactating dairy cattle. In heifers, intake does not increase appreciably unless the temperature is less than –10 °C for more than several days. Likewise, heifers are not as prone to experiencing a meaningful depression in daily DMI during hot weather as they delay eating during the day and consume the majority of their ration during the cooler hours of the evening.

Housing type has a strong influence on growth and feed efficiency. Heifers housed in well-designed confinement systems are not subjected to wind, rain, snow, or solar radiation. Nutrient expenditures for exercise are also reduced compared to pasture or more open housing systems. Several studies at Virginia Tech conducted in a counter-sloped heifer barn have demonstrated that heifers reared in housing systems with a resting area of ~4.2 m^2 per head had 10–20% higher feed efficiency than expected according to published nutrient requirements. This is attributed to lower maintenance costs and less exercise. Similarly, housing can have a dramatic influence on animal performance in heifers changing from confinement systems to systems that are more extensive, such as might happen when heifers reared in confinement during the winter are moved to a pasture system. Research at Virginia Tech has shown that when Holstein heifers reared in a counter-sloped heifer barn with 4.2 m^2 or less per heifer were moved to a pasture system, they lost between 500 and 1000 g day^{-1} for the first 30 days. This was primarily due to increased activity of the heifers. This experience has demonstrated the need for transition housing under these circumstances and the need for substantial increases in energy in the diet during the transition.

The latest version of *Nutrient Requirements of Dairy Cattle* (2001) has included adjustments for environmental conditions in its estimates of nutrient requirements for growth. In addition to expected growth, the user is requested to enter estimates for previous temperature, coat condition, hair depth, and evidence of heat stress and nighttime cooling. These factors are considered when estimating maintenance requirements for the growing heifer and represent a significant improvement. In addition, the program may be used for grazing animals as it includes distance animals are expected to walk and the topography of the land being grazed in estimating energy requirements.

Unlike the high-producing dairy cow, the nutrient requirements of the growing heifer can be met at less than the animal's intake capacity. Recent research has demonstrated that feeding dairy heifers at less than *ad libitum* intake results in reduced fecal output and improvements in feed efficiency. Diets are formulated to provide adequate nutrients for the desired rate of gain at 80–90% of *ad libitum* intake using higher-quality forages and/or more-concentrate-type ingredients. Since these diets are typically consumed within a relatively short period of time, the limit-fed systems require that feeding facilities have sufficient feed bunk space for all animals to eat simultaneously and that the bedding used is not edible. In contrast, the advantages of balancing rations for *ad libitum* intake are that less expensive by-products and high-fiber feeds can be utilized to reduce ration cost. Growers and producers believe that it also encourages body development, but research has not confirmed this anecdotal observation. The economic advantages of either system depend upon ingredient costs and existence of facilities with sufficient feed bunk space. A significant negative side effect of limit feeding is that heifers become bored quickly and will readily consume fences and housing facilities if they are constructed of wood.

Probably one of the most important components of the heifer-feeding program is the implementation of a system to weigh and measure heifers on a routine basis. For the lactating herd, the dairy herd improvement (DHI) program has provided a valuable decision-making tool for herd management. Similarly, heifer weights and heights are essential to successful heifer growing systems. Scales should be electronic with facilities to enable weighing animals easily with minimal stress to the animal or grower. Such management information is necessary if the grower is to respond in a timely manner to the environmental and health-related factors that might impair heifer growth or lead to overfattening.

An excellent example of the effectiveness of routine body weight monitoring is the management system of the New Zealand Grazing Company that has contract raised over 300 000 heifers on pasture-grazing systems. All heifers are weighed (monthly up to 10 months of age and subsequently bimonthly) by a technician using electronic scales. Using an internet management system, the company is able to analyze the performance of each heifer compared to predetermined benchmarks, which means that the data are quickly translated into management information for the grower and enables a meaningful report to the owner of the heifers. This has enabled the New Zealand Grazing Company to guarantee performance of heifers and build a business that raises 5000–10 000 heifers annually. By 2009, the New Zealand dairy industry has widely accepted the principle of regular monitoring and reporting heifer growth performance, and consequently most dairy farmers outsource their dairy replacement growing allowing increased profitability from their dairy herd.

Feeding programs for heifers must first achieve the ultimate goal of providing an animal capable of expressing her genetic potential at a reasonable age. Current research indicates that this is somewhere between 22 and 24 months of age and a body weight of 550 kg after calving for Holsteins and 350 kg after calving for Jerseys. Future research may yield ways in which age at calving may be reduced without significant risk to mammary development. At the present time, average ages of first calving below 22 months are not advisable for large-breed heifers. The second requirement for success involves aggressively seeking out low-cost ingredients, which will enable attainment of growth goals. Profitable heifer-growing operations will thrive in locations adjacent to sources of by-products or low-cost pasture, which will enable economical feeding programs. The third requirement for success involves monitoring body weights of the growing heifers. Facilities must be incorporated into heifer management system that enable weighing and measuring animals.

Conclusion

Heifer feeding management requires a different mindset than feeding cows. Heifer performance is not monitored well enough and we are not sure of the effects of heifer management decisions on the heifer's ability to lactate.

1. The importance of forage quality declines in importance as the heifer ages. Significant opportunities for economy exist for growers willing to consider unusual by-product feeds and forages of insufficient quality to use in the lactating herd rations.
2. Transition to group housing requires well-designed facilities that permit easy accommodation of outliers from the average.
3. Control of the rate of gain from weaning to onset of puberty is critical. Too much energy and too rapid a rate of gain enhance the onset of puberty, but at the risk of impaired mammary development. Increasing protein avoids overfattening to a point, but still may not result in normal udder growth. Too little energy and protein or poor environmental conditions reduce gains and delay breeding and calving, resulting in significant increases in rearing costs.
4. Bred heifers offer significant opportunities for economizing feeding as nutrient density of rations is more moderate.
5. Feeding systems should be labor efficient, enable monitoring of intake and growth of heifers, and permit documentation of rearing expenses.

Value of Replacements

Heifers give birth to approximately 25–33% of all calves born on a dairy. This percentage can be increased by applying sex-biased semen from a number of superior sires, although conception rates are generally low, reaching about 60–80% of that achieved with conventional semen. Consequently, when using superior proven sires, heifers should represent the most advanced genetics in the herd. The genetic merit of artificial insemination (AI)-sired calves from heifers should be superior to that of AI-sired calves from older cows. Rearing and breeding of replacement heifers is critical to survival of the dairy farm because it represents 15–20% of total farm costs. Age at first calving is the single most important variable influencing the costs of raising heifers. Age at first calving could be defined as total days on feed since birth and is a function of the rate at which breeding weight (age) and conception are achieved. Once pregnancy is established, total days on feed become fixed. Costs associated with age at first calving include feed, labor, housing, interest on investment, breeding and veterinary health, and death loss. To reduce the costs associated with rearing heifers, one must reduce age at first calving or reduce feed costs because they represent approximately 60% of the total rearing costs. Reducing age at first calving is more easily achieved than saving on low-cost feeds given the lack of universal availability of inexpensive feeds to most producers. In a recent survey, the average cost to raise a home-grown heifer was US$100 more than that required to raise the heifer on a custom heifer-rearing operation.

Age at First Calving

Lifetime milk yield, 305-day lactation yields, and lifetime profit of replacement heifers are maximized when heifers calve for the first time between 23 and 24 months of age. An evaluation of 6 million US dairy cow records from 1960 to 1982, however, found no appreciable change in calving age for any of six dairy breeds. Mean ages (months) at first calving for 1960 and 1982 were as follows: Ayrshire, 28.4, 28.6; Brown Swiss, 28.2, 27.8; Guernsey, 27.6, 27.4; Holstein, 27.3, 27.8; Milking Shorthorn, 27.7, 27.8; and Jersey, 26.0, 25.9 months, respectively. Since 1980, however, age at first calving has decreased to current mean age ranging from 24 months for Jerseys to 28 months for Ayrshires, with the other dairy breeds falling in between these extremes. Holsteins had the smallest standard deviations for age at first calving (21.2–24.8 months) of any breed.

Puberty in heifers is dependent on many factors including, but not limited to, breed, age, and body weight. Nonetheless, age at puberty is generally not considered to be a limiting factor for age at first conception and thus age at first calving. Most dairy breeds achieve puberty by 11–12 months of age or sooner as long as they are fed according to the minimum standards suggested by the National Research Council for energy, protein, minerals, and vitamins.

Heifers less than 1 year of age should be fed to maximize growth without achieving excess body condition. Increased nutrient intake and average daily gain from 4 to 10 months of age improved feed efficiency and increased structural growth rates with a small increase in body condition of heifers by 10 months of age.

Feeding a high-energy diet for a short duration (3 or 6 weeks beginning at 11 weeks of age) altered body growth and fat deposition in a time-dependent linear manner consistent with feeding a high-energy diet for a long duration (12 weeks).

Feeding prepubertal heifers a high-energy diet for a longer duration resulted in a linear decrease in both the percentage of mammary epithelial cells that were proliferating and the mass of fat-free mammary parenchyma per unit of carcass. High-energy feeding and excessive prepubertal body gain hastened puberty and reduced the first and later lactation performance attributable to decreased mammary epithelial cell proliferation in areas of active ductal expansion.

Because feeding heifers a high-energy diet will likely reduce mammary parenchymal mass at puberty, controlling the rate of body weight gain is likely a key to reducing mammary tissue loss resulting from excess body condition. Feeding dairy heifers a high-concentrate (75%) diet (beginning at 125 kg of body weight and continued for 245 days) did not affect most structural growth characteristics and puberty attainment, and equaled or improved 150-day milk and milk component yield after calving compared with heifers fed a high-forage (75%) diet as long as both diets were fed for equal average daily gains. Little biological rationale exists opposing the use of high-concentrate rations for dairy heifers, provided the daily gain is controlled and feed ingredients can be used to maintain a healthy rumen environment. Heifers on pasture have increased maintenance requirements, and depending on the nutrient quality of the pasture, less pasture nutrients may be available to support growth. If heifers have adequate high-quality forage, supplementing concentrates may not be necessary, particularly in pasture-based dairy systems. Therefore, monitoring and supplementing diets of pastured heifers before anticipated breeding occurs may prevent their underdevelopment before first breeding.

Attempts to reduce age at first calving much less than the recommended 23–24 months should be avoided. Unless grown adequately, heifers calving at younger ages (<22 months) are more likely to experience dystocia and are subsequently 3–4 times more likely to have a retained placenta, metritis, reduced reproductive efficiency, and are likely to be culled from the herd. In addition, first lactation milk yields may be compromised.

Reproductive Cycle and Breeding Standards

Research indicates that breeding for milk yield is more important than breeding for size because genes that control body size seem to be independent of those for milk yield. Dairy heifers reach puberty as indicated by the regular occurrence of estrus. The period of estrus and a new (or first) estrous cycle usually begins when heifers first stand to be mounted from the rear by another heifer. This period is about 10–18 h in duration and begins each new estrous cycle (day 0 of the cycle). About 90% of cycling heifers show a slightly bloody discharge (bloody tail or metestrual bleeding) from the vulva 1–2 days after estrus whether or not they were inseminated or conceived. This bloody discharge is a sign that they were in estrus.

The estrous cycle is about 21 days in duration and normally ranges from 18 to 24 days. The cycle consists of four stages: estrus (estrogen is the dominant hormone and initiates mating behavior), metestrus (time of ovulation and early corpus luteum development), diestrus (progesterone is the dominant hormone as the corpus luteum grows and matures), and proestrus (decreasing progesterone, increasing estrogen, and final follicular maturation). Cycles shorter than 18 days may occur in heifers after they experience their first estrus at puberty. The estrous cycle is cyclical because in the absence of fertile mating or AI during estrus, estrus will recur in approximately 3 weeks.

During normal estrous cycles in heifers, follicles grow in either two or three wave-like patterns, with the majority of heifers exhibiting three waves (**Figure 1**). Follicular waves are induced by increased follicle-stimulating hormone (FSH) secretion. The largest or dominant follicle of the third wave generally matures during proestrus because of increased pulse secretion of luteinizing hormone (LH) and secretes estrogen to induce estrus. A preovulatory surge of LH secretion then causes ovulation. Ovulation occurs approximately 24–32 h after the beginning of estrus and subsequently the oocyte (egg) is released into the oviduct. At the site of ovulation, the ruptured follicle transforms into a corpus luteum. The corpus luteum produces progesterone necessary to prepare the uterus for a potential pregnancy. In the absence of a viable conceptus about days 16–17 of the 21-day cycle, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) is secreted by the uterus to cause death or regression of the corpus luteum (known

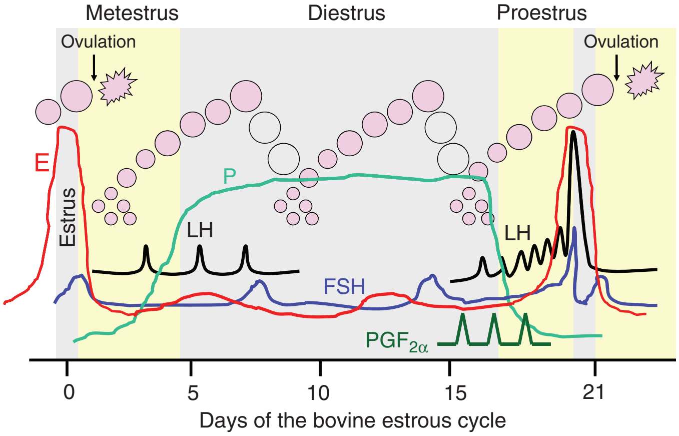

Figure 1 Characteristics of the bovine estrous cycle. Four stages of the cycle are illustrated (estrus, metestrus, diestrus, and proestrus) in addition to various hormonal changes that occur. Three follicular waves are illustrated (repeating patterns of circles) with the third wave producing the ovulatory follicle. Large dominant follicles of the first two waves become atretic and never ovulate during a normal cycle. E, estradiol or estrogen; FSH, follicle-stimulating hormone; LH, luteinizing hormone; P, progesterone; $PGF_{2\alpha}$, prostaglandin $F_{2\alpha}$.

as luteolysis). Diestrus ends as luteolysis is initiated and proestrus begins. Otherwise, the conceptus secretes a pregnancy signal (interferon-τ) to preserve the corpus luteum to allow pregnancy to continue. As the corpus luteum regresses in the absence of pregnancy, the dominant follicle continues to mature and will ovulate just after the heifer goes out of estrus, producing the egg that potentially will form a new conceptus upon fertilization. Thus, the cyclic nature of the estrous cycle continues, only to be interrupted by pregnancy.

The recommended age to begin a breeding program with heifers is about 12–14 months, provided the heifers are adequately grown and cycling. Growth rates are important to reach targeted body weights and frame sizes (skeletal growth measured by wither height) by breeding age as well as expected calving at 22–24 months of age (**Table 1**). Breeding body weight as a percentage of first postcalving body weight should be in the range of 60–65% for most breeds. Hence recommended median body weights and median wither heights at first insemination of replacement heifers are as follows: Ayrshire (318–340 kg and 117–122 cm); Brown Swiss (340–363 kg and 122–130 cm); Guernsey (318–340 kg and 117–124 cm); Holstein (340–363 kg and 122–127 cm); Jersey (238–261 kg and 109–114 cm); and Milking Shorthorn (340–363 kg and 117–122 cm), respectively. If heifers are inseminated too young or before adequate growth occurs, their first lactation yields will be compromised.

Furthermore, overconditioned (fat) heifers do not reproduce well and will not produce milk to their genetic potential. Waiting to inseminate heifers when older than 14–15 months negatively affects their lifetime milk production. It is important that heifers calve at or near 2 years of age, which reduces their rearing costs and also results in milk production at an earlier age.

Proper feeding management for adequate growth is necessary to ensure puberty has occurred before breeding age. Adequate growth is even more critical for seasonal breeding systems because the window of opportunity for breeding and hence timely calving is limited. It is needless to say that growth rates of heifers on pasture should be similar to those raised in confinement. Thus, raising cattle on pasture necessitates management decisions about grazing and forage systems and supplementation regimens to support proper growth of dairy heifers.

Collectively, in addition to age, body weight of heifers at breeding and immediately before or after calving plays a role in their subsequent lactational performance. Thus, age at first calving is considered to be less than 24 months and postcalving body weights of at least 82% of mature weight is recommended for all breeds. In seasonal breeding dairy systems, calving at the beginning of the calving season is more critical to survivability and economic return than age at first calving.

Management of Breeding

Age at first breeding and at first calving may be managed more precisely through the combined management of estrous cycle before AI. Well-managed heifers exhibit greater conception rates than lactating cows, resulting in lesser costs per pregnancy generated and per replacement heifer produced. Therefore, the most effective management strategy to increase genetic progress and maximize profitability on a dairy is to use estrus or ovulation synchronization before AI. This is particularly critical in seasonal, pasture-based dairy systems that require heifers to calve at the beginning of the herd-calving season when forage supplies are optimal. Seasonal breeding requires an efficient and effective use of labor and other resources

related to detection of estrus, breeding program, and calving at specific times of the year.

Before 1980, a few or no hormonal products were available to synchronize estrus and ovulation in heifers. Therefore, breeding of heifers entirely depended on visually detecting estrus before AI. Today, various products include orally active (feed additive) or intravaginally placed progestins, gonadotropin-releasing hormone (GnRH), and $PGF_{2\alpha}$. Managing the estrous cycle to the convenience of the breeder is now possible even in large heifer developer operations where replacements are raised on contract for individual dairy producers or are raised for sale to other producers.

Progestins

Feeding melengestrol acetate (MGA: 0.5 mg per heifer per day) for 14 days synchronizes estrus (see (1) in **Figure 2**). Depending on the stage of the estrous cycle in which any heifer begins the MGA feeding period, a few may have a functional corpus luteum after 14 days of feeding. Most heifers show estrus within 2–6 days after withdrawing MGA from the feed. This estrus is quite infertile in those heifers that began MGA feeding after day 10 of the cycle. Because the identity of the less fertile heifers is unknown, this first estrus after MGA withdrawal is passed over and heifers are given an injection of $PGF_{2\alpha}$ 17–19 days after MGA withdrawal. Insemination of heifers based on detected estrus usually occurs between 2 and 5 days after $PGF_{2\alpha}$ administration. It is possible to time inseminate any noninseminated heifers at 72 h after $PGF_{2\alpha}$ administration but conception rates will be approximately 60–75% of those achieved based on observed estrus.

Progesterone Inserts

Insertion of a progesterone-impregnated intravaginal insert (progesterone-releasing intravaginal device (PRID) or controlled internal drug release (CIDR) insert) in addition to $PGF_{2\alpha}$ effectively synchronizes estrus in a short-term, 5- or 7-day period (see (2) in **Figure 2**). $PGF_{2\alpha}$ lyses any functional corpus luteum when injected at removal of the insert. Generally, inseminations occur after detected estrus during a 2- to 5-day period after its removal.

In an attempt to further control estrus and ovulation, ovulation can be synchronized by inducing synchronous emergence of a new follicular wave in the presence of high blood concentrations of progesterone. This method is similar to the previous method (2); however, the progesterone insert is placed intravaginally in conjunction with a first injection of GnRH, and $PGF_{2\alpha}$ is injected with removal of the insert 5 or 7 days later. If timed AI (TAI) is desired, a second injection of GnRH should be administered 48–56 h after $PGF_{2\alpha}$ injection and insert removal, with AI occurring 12–20 h later.

Prostaglandin $F_{2\alpha}$

A simpler and less expensive method (see (3) in **Figure 2**) includes detection of estrus during 6 days and then inseminating any estrual heifers according to the signs of estrus. On the seventh day, $PGF_{2\alpha}$ is injected into any noninseminated heifer to induce luteolysis and estrus for subsequent insemination. The success of this method depends on the accuracy and efficiency of visual detection of estrus.

A more complicated method involves administering two injections of $PGF_{2\alpha}$ 14 days apart. One can inseminate only estrus-detected heifers after the second of two injections (see (4) in **Figure 2**) or inseminate after both injections (see (5) in **Figure 2**) and reduce the number of second injections to all noninseminated heifers. Timing of inseminations without regard to detected estrus at 72–80 h after $PGF_{2\alpha}$ produces lesser conception rates than those made after detected estrus.

Prostaglandin $F_{2\alpha}$ + Gonadotropin-Releasing Hormone

Another technique (see (6) in **Figure 2**) combines injection of GnRH to induce the release of FSH and LH plus injection of $PGF_{2\alpha}$ 7 days later followed by visual detection of estrus and AI. The GnRH injection in some heifers better controls follicular development and synchronizes it with luteolysis that follows $PGF_{2\alpha}$. About 10% of heifers show estrus within 24 h of $PGF_{2\alpha}$, and therefore, for optimal results, detection of estrus should begin 24–48 h before $PGF_{2\alpha}$.

An alternative (see (7) in **Figure 2**) to the previous method allows for a single TAI after the injection of $PGF_{2\alpha}$. This protocol (i.e., Ovsynch) synchronizes ovulation (rather than estrus), thereby allowing for AI at a fixed time without detection of estrus. One gives a second injection of GnRH to all heifers at about 48–56 h after $PGF_{2\alpha}$ and then inseminates about 12–20 h later without regard to detected estrus. Of course, if estrus is observed before $PGF_{2\alpha}$ or the second GnRH injection, one may inseminate the heifer based on visual signs and discontinue the remainder of the injections.

It is apparent that in all systematic breeding programs, the conception rate at first AI will not reach 100%. First-service conception rates should range from 50 to 70% in heifers. Therefore, some heifers will need additional inseminations in order to become

Figure 2 Seven programs for synchronization of estrus or ovulation are illustrated for dairy heifer replacements. (1) Feeding of melengestrol acetate (MGA) for 14 days and passing over the estrus expressed upon MGA withdrawal followed by an injection of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) given 17–19 days after MGA. AI, artificial insemination; GnRH, gonadotropin-releasing hormone; TAI, timed AI. (2) Intravaginal insertion of a progesterone-releasing insert (progesterone-releasing intravaginal device (PRID) or controlled internal drug release (CIDR) insert) for 5 or 7 days with $PGF_{2\alpha}$ injection administered at insert removal; or injection of GnRH at insert placement, injection of $PGF_{2\alpha}$ at insert removal, followed by second injection of GnRH given 48–56 h after $PGF_{2\alpha}$ with one TAI 12–20 h later. (3) Visual detection of estrus for 6 days before injecting all noninseminated heifers with $PGF_{2\alpha}$ on the seventh day. (4) Two injections of $PGF_{2\alpha}$ given 14 days apart with inseminations occurring after the second injection or (5) inseminate after either injection. (6) An injection of GnRH 7 days before an injection of $PGF_{2\alpha}$. (7) Same as (6) but a second injection of GnRH is given 48–56 h after $PGF_{2\alpha}$ with one TAI 12–20 h later.

pregnant. Producers should pay close attention 18–24 days after AI to detect heifers that return to estrus. All of these breeding programs only synchronize estrus or ovulation for the first AI. Subsequent estrous periods, however, are fairly well synchronized in those heifers that fail to conceive to the first AI. Estrus detection aids such as tail chalk or tail paint, heat mount detectors, or more sophisticated electronic devices can be used to detect estrus before insemination. Because heifers tend to display very pronounced signs of estrus, they can be easily detected by consistent twice-daily visual observations. About 5% of heifers eventually fail to conceive for various reasons and must be culled.

Early detection of pregnancy allows identification of those heifers that are not pregnant so that prompt reinsemination can occur. Pregnancy can be accurately determined by transrectal ultrasonography as early as day 28 after insemination or by transrectal palpation of the uterine contents by days 35–40. The other available tool is a blood test to measure the presence of a pregnancy-specific protein (pregnancy-specific protein B or other pregnancy-associated glycoproteins (PAGs)). These PAGs are produced by the conceptus and can accurately determine pregnancy status as early as 18–30 days after breeding. The objective of this diagnosis is to find nonpregnant heifers so that they can be treated promptly to induce a new fertile estrus. Treatments utilized on nonpregnant heifers can include any of those short-term hormonal methods described previously. Historically, when transrectal palpation occurs, the heifer is given an injection of $PGF_{2\alpha}$ when a functional corpus luteum is palpated and subsequent behavior is monitored for visual signs of estrus. When synchronization of estrus is performed before first AI, the day of estrus is generally known when palpation occurs. If palpation occurs at 35 days after AI, one is generally correct in assuming that an estrus was not detected at 20–21 days post-AI; hence the heifer is on cycle days 14–15 when pregnancy diagnosis occurs. This is an ideal time to give $PGF_{2\alpha}$ to induce a fertile estrus. Given similar costs of palpation and a $PGF_{2\alpha}$ injection, any nonpregnant heifer is generally given $PGF_{2\alpha}$ and observed for subsequent signs of estrus. Injections of $PGF_{2\alpha}$ cause abortions in pregnant heifers, so caution is warranted.

Management of Pregnancy

Once pregnant, replacements should not be forgotten and allocated to pasture or other areas without observation. Some embryonic and fetal losses occur after conception. It is recommended to reconfirm pregnancy by 90–100 days of pregnancy to preclude maintaining an open replacement until she is found not pregnant at her projected calving date.

Pregnant heifers should continue to grow at rates recommended by the National Research Council to achieve adequate body weight and size by calving time. Depending on the breed, ration formulations to attain daily gains of 0.50–0.80 kg are usually adequate to achieve desired first-calving weights.

Regardless of when first breeding begins in heifers, once pregnant, heifers should be fed to calve in good body condition. Without adequate body reserves of fat, it becomes very difficult to achieve good first-lactation milk yields. Which heifers will use body reserves to maximize milk yield is difficult to predict. Those that consume greater amounts of dry matter tend to be those that produce more milk.

Precautions should be taken to prevent disease and injury to gestating heifers. Adequate shade during hot months of the year prevents low birth weights and subsequent poor milk yield and reproductive performance after calving. Furthermore, adequate shelter to eliminate windchill during cold months minimizes frostbite to teats when udder and tissue edema occur during late gestation.

Immunizations before first breeding and again between 50 and 60 days before expected parturition for prevention of infectious bovine rhinotracheitis (IBR), parainfluenza (PI_3), bovine viral diarrhea (BVD), bovine respiratory syncytial virus (BRSV), clostridial spp., leptospirosis (five way), and calf scour pathogens (*Escherichia coli*, *Clostridium perfringens* (type C), rotavirus, and coronavirus) are recommended. Reimmunization against calf scour pathogens is recommended at 3 weeks precalving. Depending on the location of heifers (pasture vs. concrete confinement facilities), dewormers (to prevent gastrointestinal roundworms) should be administered at or near calving.

Parturition

In addition to milk yield, milk components, and physical type traits, sire selection for heifers is critical for what occurs at calving. It is recommended to choose calving-ease sires for heifers. The United States Department of Agriculture (USDA) produces sire summaries with calving-ease information on all sires whose semen is available for purchase from semen-producing organizations or bull studs. The information reported is the percentage of difficult births in heifers as reported by observers attending calvings. Calving difficulty scores assigned at calving range from 1 to 5 (1 = no assistance; 2 = slight problem; 3 = needed assistance; 4 = considerable force; 5 = extreme difficulty). The calving-ease percentage reported for each sire is based on the percentage of births in heifers when the calving difficulty scores were 4 or 5. In the Holstein breed, the average calving-ease percentage is about 9%. For heifers, one should use sires with calving-ease percentages that are less than average while not compromising selection for excellent production traits of sires. Preventing calving difficulty or dystocia is important. Dystocia may predispose heifers to placental retention, metritis, breeding inefficiency, and greater culling rates.

Most births do not require assistance (82%) and rushing delivery can injure the dam; however, waiting too long, after the water breaks, may deprive the calf of sufficient oxygen and cause death. Heifers should be observed frequently as due dates approach because some heifers may need assistance at calving. Observation of calving can reduce the number of stillborn calves and increase survival rates. The calf is born with no protection from disease or infection; hence, every effort must be made to limit its exposure to pathogens. Passive immunity is bestowed on the newborn by ingesting colostral milk antibodies shortly after birth.

Calving areas should be clean, dry, well lit, draft free, free of hazards, provide good footing, and spacious to allow the heifer to move about and position herself without pinning herself against an obstruction in the calving area in which the calf has no room to be delivered. When assistance is required for a large calf, twins, or breech births, arms, hands, and instruments should be sanitized. Plenty of lubricant should be used. When a calf jack or obstetrical chains are used, one should only pull when the abdominal muscles of the mother contract, therefore working with her contractions. Applying too much force can injure the heifer and damage the calf. Heifers and calves that experience difficulty need extra attention.

The absolutely most important measure and end point of successful reproduction is survival of the calf at birth and at various intervals thereafter. Immediately after birth, proper management of the newborn is critical to its survival. This includes high-quality colostrum (IgG concentrations >60 mg ml^{-1}) feeding immediately after birth, navel-dipping (7% tincture of iodine) to prevent navel invasion of microorganisms, immunizations, and other treatments. Delay in colostrum feeding can significantly diminish or preclude immunoglobulin absorption through the gut. Moreover, calves should be immediately identified for good record keeping. It is extremely important to disinfect calving pens between calvings. All contaminated bedding should be removed and the surface cleaned with a disinfectant.

Conclusion

Because replacement heifers represent the future genetic investment of any dairy herd, their management is critical to herd survival and longevity. Associated costs and investments in replacements are significant at 15–20% of all farm costs. Timeliness of establishing pregnancy can be significantly improved by using various hormonal schemes to program the estrous cycle to facilitate the use of AI and ensure a greater proportion of heifers calve by 23–24 months of age. The key to efficient reproduction is proper growth and body weight by calving time. Sire selection should emphasize production traits and calving ease to maintain good production but facilitate fewer problems at first parturition. Because heifers are more fertile than their lactating counterparts, the best available proven sires should be used with a much greater cost–benefit ratio. Perhaps, the most effective management strategy to increase genetic progress and maximize profitability on a dairy is to use synchronization of estrus and ovulation before AI in all dairy heifers. Furthermore, using gender-selected semen in replacement heifers available from several of the AI companies is the most cost-efficient application of this new technology because of the greater fertility in heifers than in lactating dairy cows. However, one can expect a reduction in fertility associated with gender-selected semen of 60–80% of that achieved with conventional semen, with the realization of 85–90% of the resulting calves to be females.

Introduction

Replacements are the future of the dairy industry. Focusing on improving health management of replacements will yield tremendous returns through decreased losses of animals with the greatest genetic potential on the dairy, decreased costs of medication, improved growth rates, improved feed efficiency and earlier entry into the milking herd.

Precalving and Calving Management

Health management of dairy replacements begins before the replacements are born. Several factors, such as nutrition of lactating and dry cows, vaccinations of lactating and dry cows, length of dry periods, cleanliness of the calving environment and disease status of the dams, will ultimately affect disease resistance and health of replacements. It is important to note, however, that cows that are overfed tend to have difficulty calving because of being excessively overconditioned. Cows that are underfed, which results in mineral or vitamin deficiencies or lack of body condition, may produce inferior and low-volume colostrum. They also may experience difficulty calving. Protein deficiency in cows during the dry period may lead to low birth weights, low metabolic rates and poor vigor of calves, resulting in poor survivability. Some research also indicates that inadequate protein and energy nutrition of the dam results in poor absorption of immunoglobulins from colostrum by the calf. Cows that lose condition during the dry period are also at greater risk of experiencing calving difficulty. Calves that experience difficult births require more time before being able to stand, experience an increase in the time to voluntary suckling and have a decreased ability to absorb immunoglobulins. All these problems result in decreased transfer of passive immunity from the dam to the calf and increased risk of disease in calves. As the degree of calving difficulty increases, the risk of mortality for calves increases. Proper nutrition of dairy cows during lactation and the dry period will help decrease disease risks for replacements.

Vaccinations of the dams will also impact disease resistance of dairy replacements. Proper vaccination of the dairy herd will increase the concentration of antibodies (immunoglobulins specific for diseases) in colostrum. Dams may be vaccinated during the dry period against pathogens that are common causes of diarrhea in calves, such as *Escherichia coli*, rotavirus and coronavirus. Vaccination of the dams increases the concentration of antibodies against these pathogens in colostrum, thus providing increased protection for calves, resulting in decreased incidence or duration of diarrhea. Vaccination of the dams during the dry period is more effective for prevention of disease in calves than vaccination of calves at an early age. The immune system of neonatal calves is unable to respond quickly to a vaccination or an infection because the immune system of the newborn is immature at birth. Both numbers and effectiveness of antibody-producing cells are lower in calves at birth than in adult cattle. Therefore, it is important for calves to obtain antibodies against common diseases of calves by consumption of colostrum rather than from an attempt to vaccinate calves at an early age. Vaccination of the dams against pneumonia may also help to decrease the incidence or severity of this disease in replacements.

Another important factor that may affect the health of replacements is the length of the dry period of the dam. A dry period that is too short, i.e. less than 6 weeks, may not provide enough time for involution of the mammary gland and preparation for the next lactation. Cows with shortened dry periods produce small quantities of colostrum that may also have low concentrations of immunoglobulins. It is important for health of replacements, therefore, that cows have at least a 6-week dry period for production of high-quality colostrum.

Management of the calving environment has a tremendous impact on the health of replacements. It is important for calves to be born in a clean, dry environment. Wet, sloppy stalls provide a perfect environment for growth of bacteria. Calving on a grass lot may be the best alternative when the climate is dry and mild. If a maternity barn is used, it is important to clean stalls thoroughly between calvings to prevent transfer of disease. Maternity stalls should only be used for calving and never for housing sick cows. Maternity pens and sick pens should be kept in separate facilities in order to prevent transfer of disease to highly vulnerable neonates and periparturient dairy cows. It is also important for the cows to be as clean as possible at calving in order to prevent calves from contracting disease organisms when suckling or attempting to suckle their dams. Preferably, calves should be separated from dams prior to suckling in order to prevent the calf from ingesting pathogens present on the legs, belly, flanks or udder of the cow as the calf attempts to nurse. Separating the calf from the dam and feeding colostrum by bottle also ensures adequate intake of colostrum for transfer of passive immunity from the dam.

Finally, it is important to know the disease status of cows prior to calving. Diseases such as Johne's disease, bovine viral diarrhea (BVD), and bovine leucosis virus (BLV) may be passed *in utero* or through colostrum. Calves should only be fed colostrum from cows known to be free of these diseases. It is important, therefore, to maintain a supply of frozen, high-quality colostrum from cows free of such diseases.

Care of Young Calves

The importance for baby calves of adequate consumption of immunoglobulins from colostrum has been reviewed elsewhere (*see* **Replacement Management in Cattle**: Pre-Ruminant Diets and Weaning Practices). Mortality resulting from lack of consumption of adequate amounts of immunoglobulins is commonly greater than 35% and has been reported to be as high as 60%. Others have indicated a 74-fold increased risk of mortality when calves do not consume colostrum. Along with economic losses from high mortality rates as a result of lack of colostrum consumption, there are also increased costs associated with increased medication and poor feed efficiency. Transfer of passive immunity (absorption of immunoglobulins from colostrum) can be determined using commercial kits that measure immunoglobulins in the blood. For adequate protection of calves, blood immunoglobulin concentrations should be at least $10\,\mathrm{mg\,ml^{-1}}$. Serum protein concentrations in calves are also highly correlated with the concentration of immunoglobulins in blood and can be used to determine adequate transfer of passive immunity. A hand-held refractometer can be used to measure serum protein; levels greater than $5.0\,\mathrm{g}\ 100\,\mathrm{ml^{-1}}$ by 24 h of age indicate adequate consumption of colostrum. The use of colostrum substitutes and replacers may help improve disease resistance in calves when high-quality colostrum is not available.

The most prevalent health problem of calves on most farms in the United States is diarrhea. Organisms such as *Cryptosporidium parvum*, rotavirus and coronavirus that cause diarrhea will not respond to antibiotic treatment. For cryptosporidiosis, the only means of prevention is sanitation, which includes controlling flies. For rotavirus and coronavirus, the most effective prevention is vaccination of the dam to increase antibodies in the colostrum against these organisms. Other organisms, such as *E. coli* and *Salmonella* sp., may be resistant to many of the commonly used antibiotics. Producers often give antibiotics to calves during episodes of diarrhea in order to prevent secondary infections; however, this practice often does more damage than good, killing beneficial gut microflora and damaging the gut lining. The first step in caring for calves with diarrhea is to provide fluids for hydration and electrolytes for mineral loss, while continuing to provide milk for protein and energy. An electrolyte solution can be fed from 20 min to 2 h after each feeding of milk or milk replacer until feces return to normal. Secondly, the organism causing diarrhea should be identified to determine whether antibiotic treatment is needed.

Pneumonia is the second most prevalent health problem of replacements, especially for replacements raised indoors. Research has shown that calves raised in individual hutches (plastic, fiberglass or wooden structures providing individual housing) perform very well and have fewer health problems, especially pneumonia, than calves raised in closed buildings. Open-front housing for older heifers should also help prevent pneumonia. Adequate, draught-free ventilation is important for prevention of pneumonia. Hutches, pastures and open-front housing for replacements provide optimal ventilation. In addition, hutches can be moved from location to location, giving producers the opportunity easily to remove old bedding and to break disease cycles. No matter what type of housing is used for replacements, cleanliness, dry bedding and adequate ventilation are essential to decrease incidence of disease.

Another important factor for controlling disease in replacements is grouping of heifers. Most producers in the United States house young calves individually. In other areas, housing calves in groups and using mob-feeders is an efficient method of rearing calves during the liquid feeding phase. After weaning, calves should be housed in small groups of 10 or fewer until they have successfully made the transition from liquid feed to dry feed and the transition from individual housing to competing for food. Additionally, by housing in small groups (rather than mixing large groups of animals at one time), producers can limit the exposure of calves to disease organisms and match calves more closely by size. As calves age, they can be housed in increasingly larger groups; however, animals should be grouped so there is not more than 50 kg difference in size of animals up to 6 months and not more than 90 kg difference in size for older animals.

Biosecurity

All dairy producers must actively institute biosecurity measures to prevent introduction of disease into the herd and to minimize spread of disease within the herd. For replacements, it is extremely important to prevent exposure of younger animals to older animals that may have Johne's disease. Exposure is not limited merely to animal-to-animal contact, but also includes articles of transmission, such as manure on hands, clothing and boots of workers, manure from older animals on equipment for feeding and handling replacements, or water that has been contaminated by older animals. In addition, flies can transfer diseases from older to younger animals. Producers must determine whether to have a closed herd or to allow introduction of new animals to the farm. If new animals are brought to a farm, the producer should work closely with a veterinary surgeon to determine which vaccinations animals should receive prior to coming to the farm. Once new animals arrive on the farm, or animals return to the farm from contract-growers or exhibitions, they should be quarantined for at least 30 days. This will allow time to determine if the new animals are likely to become ill and to allow the new animals to be exposed more slowly to any disease organisms currently on the farm.

Other potential sources of disease entry into replacements are visitors, vehicles removing dead animals, feed-delivery vehicles, wild and domestic animals, and birds. Within the herd of replacements, diseases can be transferred by using needles on more than one animal or using the same glove to palpate more than one animal. Producers must identify potential sources for transfer of disease-causing organisms within the herd and from outside the herd and institute a management plan to control them.

Digestive Disorders

Digestive disorders can occur in dairy replacements, resulting in problems such as acidosis and overeating diarrhea. Overeating diarrhea is found in replacements during the liquid feeding phase and may be prevalent in systems using accelerated feeding programs. This form of diarrhea can be treated by decreasing the amount of dry matter offered to calves in the liquid diet until the consistency of the feces returns to normal. Care should be taken to determine whether increased fluidity of the feces is caused by overeating or by disease organisms. If caused by disease organisms, treatment should include administration of an electrolyte solution and may require use of antibiotics.

Acidosis can occur in replacements if they consume large amounts of grains. Forages comprise the basis for diets for replacements after 3 months of age. Animals that gain access to fields of maize or bags of feed by accident will often suffer acidosis leading to laminitis (founder) or even death. Animals that are affected will generally have severe diarrhea. They can be treated by withholding grain until feces return to normal, followed by gradual reintroduction of grain into the diet.

Internal Parasites

Several types of internal parasites are found in dairy replacements. Perhaps the most common problem is coccidiosis. Coccidiosis causes diarrhea, which may be severe, resulting in weight loss, dehydration and anemia. Animals can be treated with a coccidiostat, such as amprolium, for severe coccidiosis. Coccidiostats such as decoquinate or lasalocid may be included in grain rations or even in milk replacers to help control coccidiosis.

Another common internal parasite of calves is *Cryptosporidium parvum.* This organism causes diarrhea in young calves at 7–10 days of age that lasts approximately a week. There are no cures for cryptosporidiosis and no means of prevention other than sanitation to decrease the pathogen load. Treatment involves electrolyte solutions along with continued milk feeding.

Replacement animals are very vulnerable to internal parasites (especially worms) during their first grazing season. Deworming of heifers yields economic returns in growth rates and feed efficiency. Producers should consult their veterinary surgeon to determine the most effective method of treating internal parasites both to decrease the parasite load in the animals and to prevent shedding of eggs onto pastures. Depending on geographical location, different deworming strategies are needed to control internal parasite populations. Producers should be aware that cold temperatures cause larvae to undergo arrest, even when ingested into the host. During this arrested stage, the larvae are resistant to most deworming agents.

External Parasites

Many external parasites, including various species of flies, affect health and growth of replacements. Several species of blood-sucking flies affect replacements. Horn-flies can be a major problem for cattle. They can cause substantial blood loss, transmit diseases including mastitis to replacements and decrease growth rates. Use of forced back rubs is probably the most effective method of decreasing populations of horn-flies. Additionally, removal of manure, which is the major breeding habitat for horn-flies, helps decrease populations. Another type of fly, the stable-fly, breeds in wet feed. Severe infestations of stable-flies can cause up to a 50% decrease in milk production. Counts of 25 flies per animal cause economically important losses in milk production and growth. Removal of waste feed from under feed troughs and other areas to decrease breeding areas is the most important mechanism for control. Horse-flies and deer-flies are also blood-sucking flies and may be responsible for spread of several diseases but are impractical to control.

Common house-flies are not blood-sucking insects but feed on muzzles, eyes and open wounds. They can be contaminated with more than 30 viruses and 175 bacteria, as well as other disease-causing organisms. The main form of control for common house-flies is sanitation and removal of breeding material because many house-flies are resistant to insecticide sprays. Cattle grubs are another parasite common in North America. The main damage to cattle is caused by the migration of the grubs through host tissues and production of cysts on the animals' backs. Growth rates can be adversely affected with infestations of cattle grubs. Appropriate insecticide treatment will kill grubs; however, care must be taken not to administer insecticides when large numbers of grubs may have accumulated in the spinal canal. Killing of large numbers of grubs at once can lead to anaphylaxis in cattle. Other external parasites that may affect dairy cattle include fleas, lice, ticks and mites. Itchiness and formation of scabs should be examined by a veterinary surgeon who can prescribe appropriate forms of treatment.

Vaccinations

Many disease occurrences can be prevented or at least minimized by appropriate vaccination programs. The program that is appropriate, however, will vary from region to region, and even farm to farm. Establishment of a vaccination program requires knowledge of diseases prevalent in the area, history of diseases on the farm, history of diseases in the herd, vaccinations used previously in the herd and an assessment of the risk of contracting economically important diseases based on management of the herd (open or closed). Producers should, therefore, consult their veterinary surgeon to develop a vaccination program appropriate for their animals, management and location.

Timing of vaccinations is important for replacement animals. If the colostrum consumed by the calf contained antibodies against the disease organism present in the vaccine, the vaccine will not generate a sufficient immune response in the replacement animal. Maternal antibodies obtained from colostrum may be present up to 6 months of age, preventing an adequate response to vaccinations. It may be beneficial to wait until 6 months of age or greater for many initial vaccinations in calves in order to avoid interference from maternal antibodies. Additionally, many vaccines are not effective in neonatal calves because their immune system is not sufficiently developed to generate a protective response.

Common mistakes made in vaccination programs are lack of booster vaccinations at the appropriate time and lack of frequent vaccinations. If the vaccination protocol calls for an initial vaccination followed by a booster vaccination within 2 to 3 weeks, maximum protection will not be achieved without the booster vaccination. Essentially, the money spent for the first injection is wasted. The second problem, lack of frequent vaccinations, is seen especially with leptospiral vaccines. Leptospiral vaccines should be administered every 6 months to achieve adequate protection. It is also important for heifers to start receiving leptospiral vaccinations at 6 months of age so that they have received two vaccinations by the time they are used for breeding.

Conclusions

Health management of replacements requires attention to many different areas, ranging from nutrition and management of late lactation and dry cows to vaccinations of replacements. Health management of replacements is an area that is often overlooked because producers do not see an immediate return on their efforts and prefer to spend their time improving management of the milking herd. For health management of replacements, however, the old saying that “an ounce of prevention is worth a pound of cure” really holds true.

Introduction

The term puberty is derived from the Latin word *pubescere*, which is translated to mean 'becoming covered with hair'. Puberty originally referred to the appearance of body hair at the time of sexual maturation in humans. Today, puberty refers collectively to all of the physiological, morphological and behavioral changes that occur in animals as their gonads undergo the transition from the infantile to adult condition. The so-called onset of puberty refers to the time at which an individual gains the capacity to reproduce. Onset of puberty is the result of a series of developmental events that occur within the reproductive endocrine system. This article focuses on sexual development in females with emphasis on the dairy heifer.

Characteristics and Importance

Heifers are said to have attained puberty when they first exhibit estrus, followed by a viable ovulation and an estrous cycle of normal length (18–25 days). First estrus is not accompanied by ovulation. Rather, it is followed by luteinization of an ovarian follicle and a short estrous cycle (<18 days). An accurate determination of puberty onset in heifers requires not only estrus detection, but also examination of the ovaries and/or assessment of circulating concentrations of progesterone to confirm the presence of a corpus luteum.

The average age at which heifers attain puberty is 11 months of age. However, average age at puberty varies greatly, ranging from approximately 8 to 24 months (**Table 1**). In general dairy heifers (e.g. Holstein) attain puberty earlier than beef heifers (e.g. Angus, Hereford). It is not unusual for Holstein heifers to attain puberty at 8–9 months of age, whereas English breeds of beef cattle attain puberty at 10–14 months of age. It is important to emphasize that age at puberty is profoundly influenced by plane of nutrition. For example, in an early study done at Cornell University, Holstein heifers fed a low, medium or high plane of nutrition exhibited first estrus at 20.2, 11.2 and 9.2 months of age, respectively.

Age at puberty is an extremely important economic trait in production systems where reproductive

Table 1 Differences in age at puberty among various breeds of cattle

Breed	*Age*
(months)	
Jersey	8
Guernsey	11
Holstein	11
Ayrshire	13
Beef (European)	10–15
Zebu	17–27
Water buffalo	15–36

efficiency is a primary goal. One of the greatest costs in dairy production is feed. Generally, feeding animals that are not productive reduces production efficiency. In most intensive dairy production systems, producers strive to have heifers calve by 24 months of age and produce one calf each year thereafter. In order to accomplish this a heifer must become pregnant by 14 months of age, have sufficient body size for pregnancy and dystocia-free parturition and sufficient body energy reserves to return to oestrus following calving. An understanding of mechanisms controlling onset of puberty should facilitate management of heifers to optimize production efficiency.

Review of the Reproductive Endocrinology of the Female

The major anatomical components of the reproductive endocrine system of females include the hypothalamus, anterior pituitary gland, ovaries and uterus. These are endocrine organs and therefore produce hormones which permit communication among the various reproductive tissues. To understand the physiological mechanisms governing onset of puberty it is necessary to understand how the hypothalamus, anterior pituitary gland and ovaries interact in an endocrine fashion (**Figure 1**). Discussions of the role of the uterus in reproduction are included in other articles.

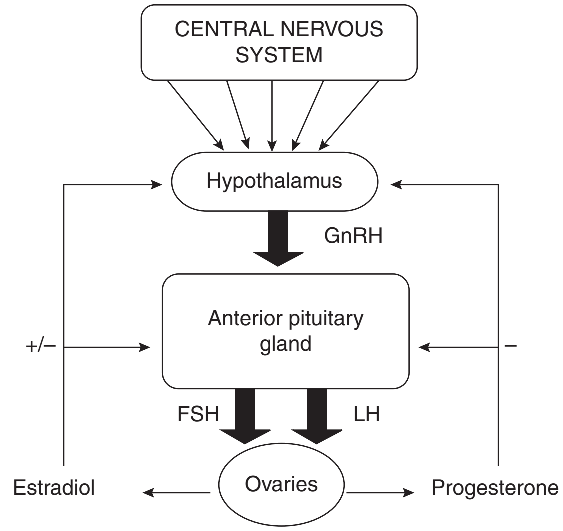

Figure 1 Endocrine interactions within the hypothalamic–pituitary–ovarian system. Various inputs conveying information about the external and internal environments converge on the hypothalamus. The hypothalamus transduces these neuronal signals into an endocrine signal, i.e. the pattern of GnRH secretion. GnRH regulates release of FSH and LH from the anterior pituitary gland. These gonadotropins regulate ovarian function which includes the synthesis and secretion of the steroid hormones estradiol and progesterone. These steroids feed back to regulate gonadotropin secretion. In prepubertal heifers, low concentrations of estradiol exert a negative feedback effect on pulsatile release of LH. Estradiol also inhibits release of FSH. High concentrations of estradiol (i.e. those present during estrus) induce a preovulatory surge of LH. Progesterone is the major negative feedback hormone controlling LH secretion in the adult female.

The central nervous system, which includes the hypothalamus, plays a pivotal role in regulation of reproductive function. Higher centers of the brain receive neuronal inputs from a variety of sensing systems that monitor internal and external environments (e.g. ambient temperature, day length, nutritional status). Information carried by these systems is integrated in the hypothalamus and transduced into a neuroendocrine signal. A small number of neurons in the hypothalamus produce gonadotropin releasing hormone (GnRH), a decapeptide which is secreted into capillaries located in the median eminence of the hypothalamus. GnRH enters these capillaries and is carried to the anterior pituitary gland via portal vessels, which drain into another capillary bed. The major action of GnRH is to stimulate release of gonadotropins, i.e. luteinizing hormone (LH) and follicle stimulating hormone (FSH). GnRH is secreted in a pulsatile manner and has been shown to cause the pulsatile release of LH and possibly FSH. The pulsatile pattern of LH release can be demonstrated by measuring circulating concentrations of LH at frequent intervals for several hours. The pulsatile release of GnRH has been documented by measuring concentrations of this hormone in blood collected from the pituitary portal vessels. During pulsatile secretion concentrations of a hormone increase abruptly within minutes. This increase is followed by a slower decrease, which reflects the clearance of the hormone from circulation. Pulsatile secretion is typically characterized by quantifying the frequency of pulses (number of pulses in a given period of time) and the amplitude of pulses (difference between the peak of a pulse and the previous nadir). **Figure 2** illustrates pulsatile LH secretion.

The gonadotropins, LH and FSH, are released into the general circulation by gonadotropic cells in the anterior

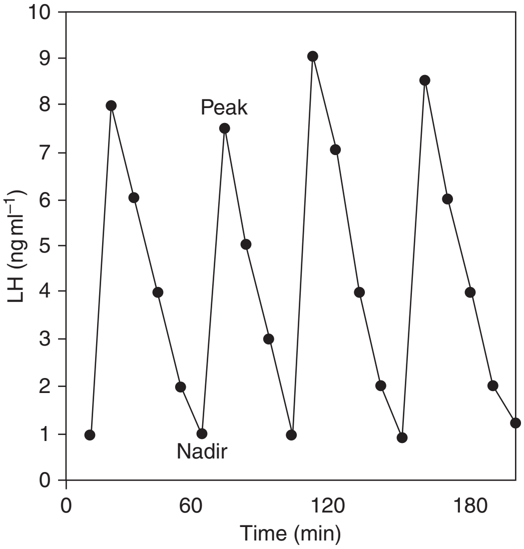

Figure 2 Example of pulsatile patterns of LH in a series of blood samples collected at 10-min intervals for 180 min. Each pulse is characterized by a rapid increase in concentrations, followed by a slower decrease. Pulsatile release of LH is typically characterized by quantifying the pulse frequency (number of peaks per unit time) and average pulse amplitude (difference between the peak concentration and preceding nadir).

pituitary gland. These hormones regulate ovarian function. It is generally accepted that the pulsatile release of LH is necessary for the initiation and maintenance of ovarian activity. With respect to onset of puberty, LH plays important roles. First, a high-frequency mode of LH secretion (>1 pulse h^{-1}) is necessary for follicle maturation. Second, an LH surge, which accompanies estrus, is necessary for ovulation and formation of the corpus luteum. The role of FSH in onset of puberty is not well defined. It is generally accepted that FSH is important in stimulating early follicle development (prior to maturation to the preovulatory stage).

The gonadotropins regulate production of ovarian steroid hormones, which in turn regulate gonadotropin release, uterine function, sexual behavior and expression of secondary sex traits. LH and FSH act together to regulate production of estradiol by granulosa cells of ovarian follicles, whereas LH alone appears to govern progesterone synthesis by the corpus luteum.

An appreciation for the regulation of gonadotropin secretion by ovarian steroids is critical to understanding sexual maturation (**Figure 1**). In prepubertal heifers, oestradiol is the major negative feedback regulator of LH secretion. In postpubertal females, progesterone is responsible for most of the inhibitory effects of the ovary on LH secretion. Estradiol inhibits LH secretion by suppressing pituitary responsiveness to GnRH, and by inhibiting release of GnRH by the hypothalamus. Progesterone appears to act at the level of the hypothalamus to inhibit GnRH release. Little is known about the regulation of FSH secretion during the prepubertal period. Estradiol and inhibin, a peptide hormone produced by granulosa cells of follicles, appear to regulate FSH release via feedback inhibition.

Whereas low levels of estradiol inhibit pulsatile LH secretion in prepubertal heifers, high levels of this steroid (i.e. those present during estrus) facilitate LH secretion. The high levels of estradiol produced by the preovulatory follicle induce an LH surge, which results from enhanced pituitary response to GnRH, as well as an increase in GnRH release.

Development of the Hypothalamic–Pituitary–Ovarian System

An understanding of the mechanisms controlling sexual maturation in heifers has been gained by systematically examining the development of the reproductive endocrine axis. The experimental approach has been to identify the physiological and/or anatomical component(s) that are rate-limiting in terms of the timing of puberty onset.

Hypothalamus and Anterior Pituitary Gland

It is generally accepted that the hypothalamic–pituitary axis and the capacity of this system to synthesize and secrete GnRH and gonadotropins is fully competent long before onset of puberty. The hypothalamic–pituitary portal vascular system appears to be developed and functional prior to birth. GnRH secretion has not been measured directly in heifers. However, bull calves exhibit GnRH pulses in portal blood by 2 weeks of age. In heifers and bull calves, pulses of LH appear in the peripheral circulation by 2 weeks of age. Collectively, these results support the idea that the neuroendocrine mechanisms controlling the pulsatile release of GnRH/LH are competent by 3–5 weeks of age. This casts doubt on the notion that development of this system is the rate-limiting step in onset of puberty.

Ovaries

The ovaries of heifers appear to be functionally competent long before the onset of puberty. Vesicular follicles are present by 2–4 weeks of age, and reach a peak in average size by 12–16 weeks of age before declining to an average size that varies little until the peripubertal period. These follicles will respond to exogenous gonadotropins. Treatment with FSH and LH induces ovulation in heifers by 1 month of age, but number of induced ovulations increases between 1 and 5 months of age.

Between birth and puberty follicles grow in waves, meaning that at regular intervals, dominant follicles emerge from pools of growing follicles, and then regress before reaching the preovulatory stage. The size of the dominant follicle increases with age; the largest dominant follicles are found during the peripubertal period.

The dominant follicles of the late prepubertal period produce sufficient estradiol to induce estrous behavior and LH surges. The first of these estrous periods are not necessarily followed by ovulation and a normal estrous cycle. Peripubertal heifers may exhibit oestrus in the absence of a subsequent estrous cycle. First ovulation is normally preceded by one or two LH surges followed by elevations in progesterone that are lower in magnitude and shorter in duration than those expressed during a normal luteal phase. These short luteal phases are attributed to ovarian follicles that become luteinized, but do not ovulate.

Ovarian Control of Gonadotrophin Secretion

As mentioned previously, the ovaries regulate gonadotropin secretion via steroid hormones. Ovulation is induced by a surge of LH which is caused by elevated concentrations of estradiol. This important positive feedback system appears to be fully developed prior to onset of puberty. In beef heifers, injections of estradiol induce preovulatory-like surges of LH in prepubertal heifers as early as 5 months of age. This suggests that onset of puberty may be limited more by development of events leading up to the LH surge (i.e. elevated levels of estradiol) than by development of the capacity to produce an LH surge. Although dominant, vesicular follicles appear in waves throughout the prepubertal period, they do not produce enough estradiol to induce an LH surge. At this point it is important to reiterate that both the ability of follicles to respond to gonadotropins as well as the ability to elicit an LH surge appear to be fully developed months before onset of puberty. Therefore, the rate-limiting step in sexual maturation appears to be appearance of the endocrine signal that stimulates follicle development to the preovulatory stage. This signal appears to be the high-frequency mode of LH secretion.

Examination of LH pulse patterns between birth and puberty reveals that LH pulse frequency increases between birth and 3–5 months of age, but then declines and remains relatively low until a few weeks prior to onset of puberty. The frequency of LH pulses before this peripubertal increase in LH secretion is much lower than that of the follicular phase of the estrous cycle, when LH pulses occur with a frequency of approximately once per hour. This observation begs an important question: why does LH pulse frequency remain low even though the mechanisms necessary for the pulsatile release of LH appear to be fully developed by one month of age?

Pulsatile secretion of LH is regulated by the negative feedback actions of ovarian steroids. In heifers a rise in LH concentrations following ovariectomy has been demonstrated as early as 1 month of age, suggesting that ovarian negative feedback is present at this age. Estradiol appears to be the major negative feedback regulator of LH secretion before the onset of puberty. In ovariectomized heifers, physiological doses of this steroid lower concentrations of LH to preovariectomy levels.

The transient increase in pulsatile LH secretion between 3 and 5 months of age may reflect development of the estradiol–LH negative feedback loop. Although the estradiol negative feedback system may be present by 1 month of age, it may not be expressed at this time due to extremely low levels of estradiol. The increase in LH concentrations during the first several months of age may be attributed to ovarian estradiol reaching a threshold for inhibiting LH secretion.

By 3–5 months of age, the ovaries produce enough estradiol to suppress LH secretion. However, the ability of estradiol to suppress LH release changes with advancing age in prepubertal heifers. Physiological doses of estradiol suppress concentrations of LH in ovariectomized heifers until the age at which ovary-intact heifers attain puberty (**Figure 3**). At this time estradiol becomes less effective in suppressing LH pulses, i.e. animals appear to escape estradiol negative feedback.

Little is known about the cellular and molecular mechanisms regulating the negative feedback actions of estradiol. It seems likely that such changes are attributed

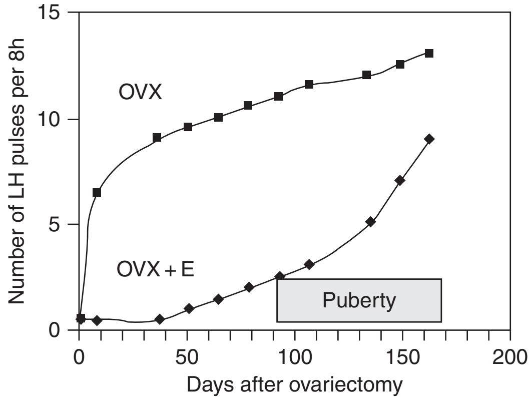

Figure 3 Circulating concentrations of LH in prepubertal beef heifers that were either ovariectomized (OVX) or ovariectomized and treated chronically with physiological concentrations of estradiol (OVX + E). Ovariectomy results in an immediate increase in LH due to removal of ovarian negative feedback. Replacement with estradiol prevents the postovariectomy increase in LH suggesting that this steroid is the major negative feedback hormone regulating LH secretion in prepubertal heifers. Eventually heifers become less sensitive to this negative feedback and LH concentrations increase. This escape from negative feedback coincides with the onset of puberty in ovary-intact animals. (Based on data from Day *et al*., 1984.)

to changes in GnRH neurons and/or neurons that regulate GnRH neurons. There is evidence to support the idea that changes in response to estradiol negative feedback reflect changes in number of estradiol receptor in neurons that regulate secretory activity of GnRH neurons.

Theory of Puberty Onset

The observations discussed above serve as the basis for the widely accepted theory of puberty onset summarized in **Figure 4**. The central claim of this theory is that a cascade of endocrine events is required for ovulation, i.e. a high-frequency mode of LH secretion which stimulates growth of a dominant follicle to the preovulatory stage, which results in production of enough estradiol to induce estrus and a preovulatory surge of LH. The prepubertal heifer has the capacity to express this cascade by 5–6 months of age, but does not due to a high sensitivity to estradiol negative feedback which maintains a low-frequency mode of LH secretion. Onset of puberty can occur only after the hypothalamic–pituitary axis escapes estradiol negative feedback, or when this negative feedback effect is overridden by administering exogenous GnRH or LH.

It is unclear whether the decrease in sensitivity to estradiol negative feedback is strictly a developmental event. Recent evidence suggests that the timing of this change in sensitivity may be more a function of metabolic status than one of age. Restriction of dietary energy delays onset of puberty, apparently by delaying escape from estradiol negative feedback. Moreover, precocious puberty in heifers appears to be related to favorable energy status and high growth rates. Preliminary studies suggest that in beef heifers, high-energy intake early in life (birth to 6 months of age) induces transient but cyclic luteal function, suggesting that the estradiol negative feedback system may have been prematurely inactivated. Additional studies are required to test this hypothesis. Nevertheless, these observations reinforce the idea that the hypothalamic–pituitary–ovarian system is functionally mature by 5–6 months of age.

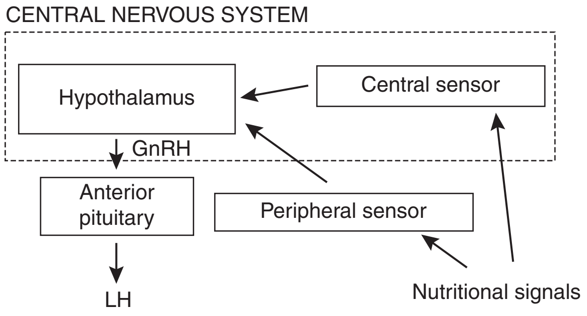

Figure 4 Summary of the prevailing working hypothesis explaining how nutrition influences timing of puberty onset. According to this hypothesis, various blood-borne signals reflecting nutritional status (e.g., metabolites, metabolic hormones) are detected by sensors in the peripheral and/or central nervous systems. These sensors trigger various neuropathways that converge on the hypothalamus, where they are transduced into signals that regulate pulsatile secretion of GnRH and LH (e.g., response to estradiol negative feedback). In this way, nutritional status influences the timing of the increase in LH pulse frequency that is critical for onset of puberty.

Timing of Puberty Onset

Although the endocrine events leading to onset of puberty have been well characterized in heifers, it remains unclear why puberty occurs at a particular age in individual animals. It seems reasonable that timing of puberty onset is a function of genetic and environmental factors, as well as genetic×environment interactions. Although breed type has been shown to influence age at puberty, there has been no attempt to understand these effects in terms of the endocrine mechanisms controlling puberty onset. In other words, we know little about the effects of breed on the endocrine mechanisms timing onset of puberty.

Of the studies that examine effects of environment on sexual development most have focused on the effects of nutrition. A few studies examined the effects of season on sexual development.

Nutrition, Growth and Onset of Puberty

Research in the 1950s and early 1960s established that age at puberty is inversely related to growth rate in dairy heifers. This was later documented in beef heifers. Most studies dealing with growth and puberty focus on the effects of plane of nutrition on age at puberty. For example, beef heifers fed to sustain an average daily gain of 0.23 kg reached puberty later than those fed to sustain an average daily gain of 0.82 kg. In one study, postweaning growth rates were inversely related to age at puberty in heifers fed to gain an average of 0.2 kg day^{-1}, but not in heifers fed to gain 0.4 kg day^{-1}. This lead to the hypothesis that growth rate has little effect on sexual development above a certain critical body weight, or that puberty onset occurs at a critical body weight. However, the fact that heifers maintained on different planes of nutrition typically attain puberty at different body weights casts doubt on this 'critical body weight hypothesis'. Nevertheless, it is clear that sexual development is somehow linked to growth and/or nutritional status.

Mechanisms Linking Onset of Puberty and Nutrition

It is beyond the scope of this article to review the voluminous research concerning the possible endocrine mechanisms linking nutrition and sexual development. However, it is generally agreed that nutrition influences sexual development via signals that influence the pulsatile release of LH. A working hypothesis illustrating how nutritional status might influence sexual development is summarized in **Figure 5**. Using this framework, there appear to be four major areas of focus for research in this area: nutritional signals, peripheral and central systems that sense these signals, neuropathways that transduce these nutritional signals into neuroendocrine signals, and GnRH/LH secretion. In cattle attention has focused primarily on mechanisms controlling LH secretion. In beef heifers, it has been demonstrated that a delay in onset of puberty caused by undernutrition is accompanied by a delay in escape from estradiol negative feedback. Moreover, underfeeding induces a decrease in LH pulse frequency and cessation of estrous cycles in sexually mature heifers suggesting that the effects of nutrition on reproductive activity are not confined to sexual development. Although it can be concluded that undernutrition suppresses the pulsatile secretion of LH in heifers, we know very little about the signals that reflect nutritional status or how these signals are detected and transduced into signals that influence LH secretion.

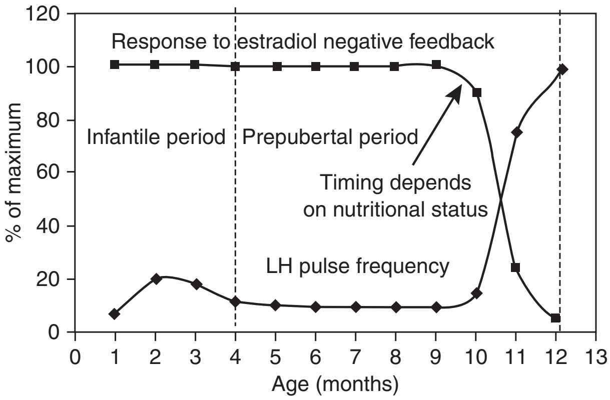

Figure 5 Summary of the prevailing theory explaining control of puberty onset in the heifer. During the early infantile period pulsatile LH secretion increases slightly due to limited follicle development and minimal estradiol secretion. This promotes vesicular follicle development and estradiol secretion. Due to a high sensitivity of the hypothalamic–pituitary axis to the negative feedback actions of estradiol, pulsatile LH secretion decreases and remains low throughout the prepubertal period. The end of the prepubertal period is heralded by a decrease in response to estradiol negative feedback, and a resultant increase in LH pulse frequency. The timing of this escape from negative feedback is dependent on nutritional status; heifers on high planes of nutrition escape at an earlier age than those on low planes of nutrition. The increase in LH pulse frequency is critical to onset of puberty because it stimulates follicle development to the preovulatory stage, thereby inducing estrus and a preovulatory surge of LH.

Season and Sexual Development

Sexual development in seasonal breeders

Seasonal breeders exhibit a well-defined anestrous period each year. Short-day breeders such as sheep and goats exhibit regular estrous cycles in late summer, when day length is decreasing, and enter a period of anestrus in early spring, when day length is increasing. Extensive research has supported the theory that in these species, photoperiod regulates reproductive activity by affecting the pulsatile release of LH. During the anestrous season, LH pulse frequency is suppressed due to enhanced responsiveness to estradiol negative feedback, as well as a steroid-independent effect on GnRH secretion. This inhibition is lifted during periods of short day lengths. The transition from the anestrous to the breeding season resembles the transition from the prepubertal to pubertal state, i.e. increased frequency of LH pulses, maturation of a dominant follicle, increased production of estradiol, onset of estrus and induction of an LH surge.

In temperate climates, lambs are typically born in late winter and early spring and attain puberty in late summer and early autumn. As in heifers, puberty in ewe lambs is the result of an escape from estradiol negative feedback which allows pulsatile LH secretion to increase. As might be expected, season influences onset of puberty in seasonal breeders. For example, ewe lambs born during the autumn attain puberty at 10–12 months of age (during the subsequent autumn), whereas lambs born in the spring reach puberty at 5–6 months of age (during the autumn). Although it is beyond the scope of this article to describe details of how season influences onset of puberty in sheep, a few general comments seem appropriate. First, it seems clear that photoperiod is the major mediator of the effect of season on puberty onset in sheep. In order for puberty to occur at a normal age (5–6 months of age), lambs must experience several months of long day lengths before exposure to short days. Second, the delay in puberty onset experienced by autumn-born lambs is associated with low LH pulse frequency, due to high sensitivity to oestradiol negative feedback. Third, the pineal gland and its pattern of melatonin secretion appear to be important in mediating the effects of day length on sexual development.

Effects of season on sexual development in cattle

Cattle are not seasonal breeders. Nonpregnant heifers and cows will exhibit regular estrous cycles throughout the year. However, there is evidence to suggest that season influences sexual development in heifers. Early studies described an effect of season of birth on age at puberty in dairy heifers. Heifers born during the spring and summer were younger at first estrus than those born during autumn and winter. Similar observations were reported for beef heifers; heifers born in the spring were younger at puberty than those born in the winter. Examination of year-round reproductive records in Wisconsin revealed that the winter environment appears to delay onset of puberty in autumn-born heifers. Autumn-born heifers that failed to attain puberty before the subsequent winter did not attain puberty until the subsequent spring and summer. It appears that both season of the first 6 months of life and season of the second 6 months of life influence sexual development. Heifers born near the time of the autumnal equinox (23 September) were younger at puberty than those born near the time of the vernal equinox (21 March). In both autumn- and spring-born heifers, exposure to spring–summer conditions (i.e. increasing day length and temperature) resulted in an earlier onset of puberty compared to autumn–winter conditions (i.e. decreasing day length and temperature).

The environmental variable(s) responsible for the seasonal effects on puberty in cattle remain(s) unidentified. Artificially lengthening photoperiod (16L:8D) during the winter months hastens onset of puberty in heifers and bull calves suggesting that day length may be important, as it is in seasonal breeders.

Few studies have addressed the physiological mechanisms whereby season influences sexual development in heifers. Based on the importance of pulsatile LH secretion in regulating onset of puberty, it is reasonable to hypothesize that seasonal effects on sexual development are somehow mediated by changes in LH patterns. However, support for this hypothesis remains elusive.

Summary

Puberty in dairy heifers is a gradual process involving maturation of the endocrine mechanisms controlling ovarian development. Although puberty does not occur until 8–14 months of age, the hypothalamic–pituitary–ovarian system appears to be functionally competent as early as 5–6 months of age. By this time the estradiol–LH negative feedback loop is established and secretion of estradiol by ovarian follicles is sufficient to maintain pulsatile LH secretion in a low-frequency mode. As long as this mode of LH secretion is sustained, follicle development will not progress to the preovulatory stage. When the hypothalamic–pituitary axis escapes this inhibitory effect of estradiol, pulsatile LH secretion enters the high-frequency mode, allowing a dominant follicle to mature and release enough estradiol to induce estrus and a preovulatory surge of LH. It is likely that both genetic and environmental factors influence timing of puberty onset in cattle. We understand very little about genetic variation in the physiological mechanisms that regulate onset of puberty. While the effects of nutrition on puberty onset clearly involve effects on pulsatile LH secretion, the mechanisms mediating the effects of other environmental factors such as season remain unclear.

Introduction

The estrous cycle represents the cyclical nature of ovarian activity that facilitates female animals to go from a period of reproductive receptivity to nonreceptivity ultimately allowing the establishment of pregnancy following mating. The normal estrous cycle in cattle is 18 to 24 days. The cycle consists of two discrete phases: the luteal phase (14 to 18 days) and the follicular phase (4 to 6 days). The luteal phase is the period following ovulation when the corpus luteum (CL) is formed, while the follicular phase is the period following the demise of the corpus luteum (luteolysis) until ovulation. During the follicular phase final maturation and ovulation of the ovulatory follicle occurs which leads to the release of an oocyte (the female gamete) into the oviduct allowing the potential for fertilization.

Commencement of regular estrous cycles in cattle occurs at the time of puberty. Heifers reach puberty between 6 and 24 months of age typically at 50% of mature body weight. At the onset of puberty, the first estrous cycle tends to be of a short duration (3 to 12 days) and follows a silent ovulation (that is not associated with expression of behavioral estrus). Estrous cycles cease during pregnancy due to the prolonged presence of elevated progesterone from the CL. Following parturition estrous cycles recommence after a variable period of anestrus and anovulation. Similar to the transition from prepuberty to puberty, the resumption of ovarian cycles postpartum is usually associated with a silent ovulation followed by a short cycle (*see* **Reproduction, Events and Management**: Estrous Cycles: Postpartum Cyclicity).

Behavioral Changes throughout the Estrous Cycle

Estrous behavior in cattle is closely related with time of ovulation and allows successful mating to occur prior to ovulation to maximize the chances of conception. During estrus, heifers and cows will stand to be mounted by herd mates or a bull, if present. Estrus is expressed at 18- to 24-day intervals and lasts for 8 to 24 h. Estrus is caused by the secretion of the proestrus estradiol surge from the preovulatory dominant follicle.

The estrous cycle may be divided into diestrus, proestrus, estrus and metestrus. During diestrus, cyclic animals will not show signs of estrous behavior. During the preovulatory period there is a peak in butting activity and attempted mounting without standing. During estrus heifers will stand to be mounted and also show increased mounting activity. Levels of investigatory behavior (including sniffing, rubbing, licking, chin-resting and orientation) occurs at similar intensities both before, during and after the period of standing to be mounted. Standing to be mounted is considered to be the definitive sign of estrus in cattle. A number of other qualitative signs of estrus have been described including: mounting of other cows, ruffling of the rump hair or abrasion of the rump skin, vulval relaxation and moistness, estrous mucus appearing from the vulva, sensitivity to palpation of the rump and general restlessness; however, none of these signs are as definitive as standing to be mounted. Cows or heifers that are in proestrus, estrus or metestrus simultaneously within a herd usually form sexually active groups that will include a bull if present (*see* **Reproduction, Events and Management**: Mating Management: Detection of Estrus).

Follicular Growth and Development

The growth, development and maturation of ovarian follicles is a fundamental process for effective reproduction in farm animals. Primordial follicles are established in the ovary during embryonic development. A fixed number of primordial follicles are established during fetal development. During the lifetime of the female, primary follicles enter a growing pool. Initial stages of follicle growth occur independently of gonadotrophic hormones; antral follicles then become responsive to and subsequently dependent on follicle stimulating hormone (FSH). The pattern of follicle growth in cattle has been clearly characterized with the use of transrectal ovarian ultrasonography. Several detailed studies have demonstrated that there are either two, three or occasionally four waves of follicle growth during the normal estrous cycle of cattle. During each wave of follicle growth, a cohort of two to five follicles emerges to grow beyond 4 mm in diameter to medium (5–9 mm) size classes (emergence) (**Figure 1**). From the pool of medium follicles that emerge a single follicle is selected to become the dominant follicle (selection). Selection is a hypothetical physiological process whereby 'excess' follicles are reduced to the ovulatory quota. This determines the species-specific ovulation rate in females thereby playing a major role in determining the number of offspring born per pregnancy. The selected dominant follicle continues to grow in size, while other follicles in the cohort undergo atresia. Dominance is a process that enables the 'selected' follicle to suppress further growth of other follicles, escape initial atresia and continue to grow until either atresia (during the luteal phase) or ovulation (during the follicular phase). The preovulatory dominant follicle undergoes a period of final maturation, following CL regression and increased luteinizing hormone (LH) pulse frequency, and it then ovulates. After ovulation, a CL is formed which secretes progesterone throughout the luteal phase of the cycle.

The number of follicular waves during the estrous cycle is affected by breed and management of animals. In dairy cows two waves of follicular growth per estrous cycle are more common, while in beef heifers up to 70% of ovarian cycles consist of three follicular waves. During the transition from prepuberty to puberty and from anestrus to resumption of ovarian cycles in postpartum cows, the short ovarian cycle that typically occurs is associated with a single follicular wave.

Endocrine Regulation of Ovarian Function

Ovarian activity throughout the estrous cycle is controlled by the hypothalamic–pituitary–ovarian–uterine axis (**Figure 2**). Gonadotropin releasing hormone (GnRH) is secreted in a pulsatile manner by neurons of the hypothalamus into the hypophyseal portal blood system. It is transported to the anterior pituitary where it controls the secretion of LH and FSH, collectively known as the gonadotropins. Pulsatile secretion of GnRH from the hypothalamus is virtually 100% coincident with pulsatile secretion of LH from the anterior pituitary.

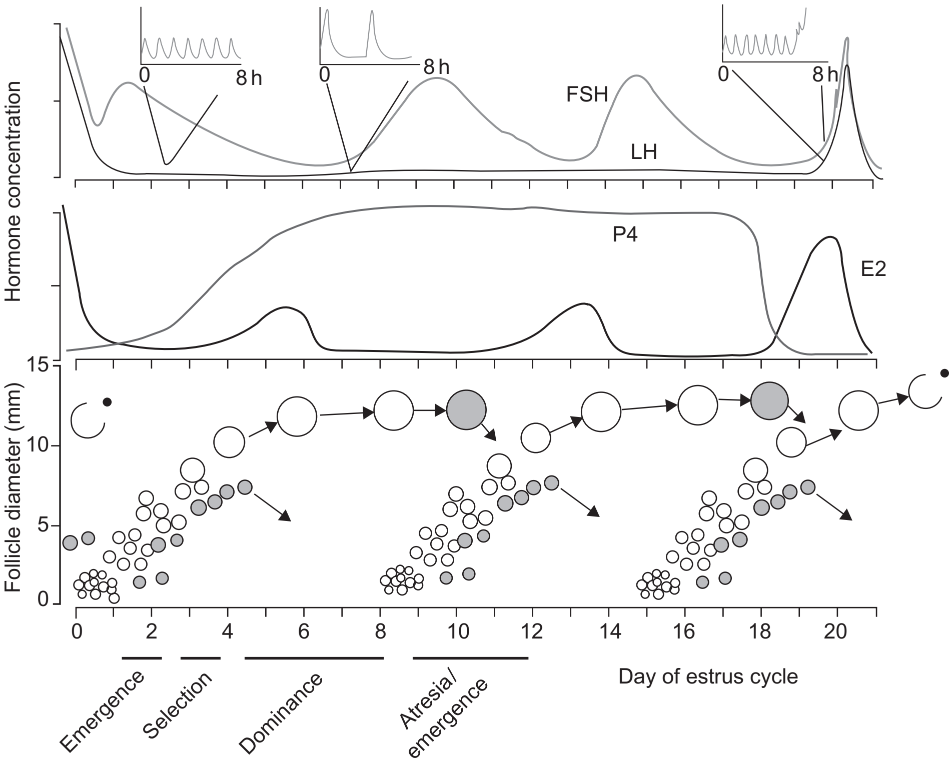

Figure 1 Schematic depiction of the pattern of secretion of follicle stimulating hormone (FSH), luteinizing hormone (LH), progesterone (P4) and estradiol (E2); and the pattern of growth of ovarian follicles during the estrous cycle in cattle. Each wave of follicular growth is preceded by a transient rise in FSH concentrations. Healthy growing follicles are shown as open circles, atretic follicles are shaded. A surge in LH and FSH concentrations occurs at the onset of estrus and induces ovulation. The pattern of secretion of LH pulses during an 8-h window early in the luteal phase (high frequency, low amplitude), the mid-luteal phase (low frequency, low amplitude) and the follicular phase (high frequency, building to the surge) is indicated in the insets in the top panel.

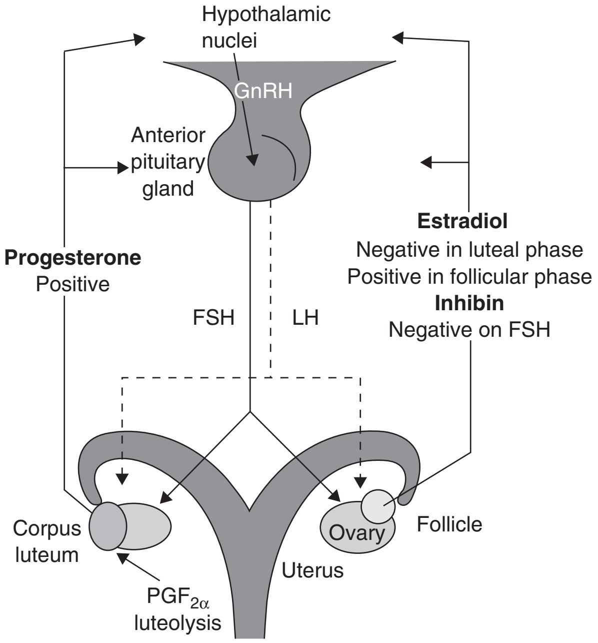

Figure 2 Schematic diagram depicting the endocrine feedback mechanisms of the hypothalamic–pituitary–ovarian–uterine axis regulating the estrous cycle in cows. Luteinizing hormone (LH) and follicle stimulating hormone (FSH) are both secreted from the anterior pituitary gland. LH pulses are tightly associated with pulses of gonadotropin releasing hormone (GnRH) from the hypothalamus. GnRH and hence LH pulse frequency are regulated in a negative feedback mechanism by estradiol and progesterone during the luteal phase, while in the follicular phase there is a positive feedback of estradiol (in the absence of progesterone) from the preovulatory follicle inducing the GnRH, LH and FSH surges. Secretion of FSH requires GnRH pulses, but is regulated by feedback mechanisms of estradiol and inhibins.

Secretion of FSH is also regulated by GnRH and other endocrine and paracrine mechanisms. The gonadotropins when secreted from the anterior pituitary enter general circulation and have their major biological effect at the gonads. In heifers, receptors for LH have been located in the CL, the theca cells of healthy growing follicles and the granulosa cells of large growing follicles ($\geq$8 mm in diameter). Receptors for FSH are present in the granulosa cells of healthy antral follicles.

Follicle stimulating hormone is the main hormone that stimulates follicular growth. Follicle stimulating hormone concentrations are related to follicular growth throughout the estrous cycle in heifers. Associated with each new wave of follicular development, FSH concentrations increase as emergence occurs (**Figure 1**). This transient rise in FSH concentrations occurs over a period of 1 to 2 days during emergence of each new wave of follicle growth. Thus, in a typical three-wave estrous cycle, recurrent FSH rises occur on days 0.5 to 1.5, 9 to 11, and 13.5 to 15, whereas in a two-wave estrous cycle only the first two recurrent FSH rises occur. During all physiological states where follicle waves occur (that is, cyclic cattle, postpartum cows during anestrus, and prepubertal heifers), associated transient increases in FSH concentrations coincide with follicle wave emergence. The process of selection of the dominant follicle occurs during a period when FSH returns to nadir concentrations. The physiological mechanisms that allow one follicle to become selected and continue growing while other follicles in the cohort undergo atresia in, the presence of declining FSH concentrations remain to be elucidated. However, early survival factors have been identified and they include development of LH receptors by the granulosa cell layer allowing a switch away from FSH dependency toward LH dependency and an increase in the amounts of bioavailable insulin-like growth factor-I (IGF-I). The increase in bioavailable IGF-I is thought to be mediated through a decrease in insulin-like growth factor binding proteins. Final maturation and either atresia or ovulation of a selected dominant follicle is then dependent on the prevailing LH pulse secretory pattern.

The precise pattern of pulsatile LH during each wave of follicle growth has been less clearly described. However, during the early luteal phase low amplitude and high frequency (20–30 pulses 24 h^{-1}) LH pulses occur, in the mid-luteal period LH pulses are high amplitude and low frequency (6–8 pulses 24 h^{-1}) and the preovulatory surge occurs on day 18/19 with high frequency and high amplitude pulses occuring during the surge (**Figure 1**). The LH pulse frequency is at a minimum during the mid-luteal phase (days 7–13 of the estrous cycle; 2.7 to 3.4 pulses per 12 h window); LH pulse amplitude increases from early (0.5 ng ml^{-1}) to mid-luteal phase (1.04 to 1.3 ng ml^{-1} on days 8–11); subsequently decreases to 0.7 to 0.8 ng ml^{-1} on days 12–14; and recovers to about 1.0 ng ml^{-1} from days 15–19.

There also appear to be subtle changes in pulsatile secretion of LH during the different phases of a follicular wave. LH pulse frequency decreases between day 5 (first day of dominance; 7.5 ± 0.4 pulses 12 h^{-1}) and day 8 (end of growth phase of the first dominant follicle; 5.7 ± 0.8 pulses 12 h^{-1}) while LH pulse amplitude increases between day 5 (0.45 ± 0.04 ng ml^{-1}) and day 11 (loss of dominance of the first wave dominant follicle; 1.1 ± 0.2 ng ml^{-1}). Thus, there are good characterizations of the pattern of LH secretion during the estrous cycle. However, the relationship of LH pulse pattern to the stage of the follicle wave has only been characterized for the first wave, so the precise role of LH in controlling follicular dynamics throughout the entire estrous cycle remains somewhat unclear. Nonetheless, it is hypothesized that LH pulse frequency decreases once a follicle is selected to become dominant, with an associated increase in LH pulse amplitude; an increase in LH pulse frequency and a decrease in amplitude occurs when a nonovulatory dominant follicle undergoes atresia or both frequency and amplitude increase as a dominant follicle proceeds to ovulate during the follicular phase. Further evidence for the role of increased LH pulse frequency at later stages of follicular development is provided by the fact that LH receptors are acquired by granulosa cells of growing 'selected' follicles once they reach 8 mm in diameter. This is further supported by the fact that dominant follicles may be maintained for prolonged periods of time following artifical induction of luteal phases using low levels of progesterone (in the absence of endogenous CL) during which an increase in LH pulse frequency occurs. The pattern of secretion of LH at the time when a dominant follicle is selected is responsible for determination of the fate of that dominant follicle. Luteal phase LH pulse frequencies allow dominant follicles to turn over and undergo atresia; whereas, follicular phase LH pulse frequencies are associated with dominant follicles that ovulate.

Ovarian steroid secretion is also controlled by LH and FSH. Estradiol is secreted predominantly by the physiologically active dominant follicle. Cyclical changes in estradiol that correspond to the periods of growth of each follicular wave have been reported. Estradiol concentrations in the utero-ovarian vein increase during the follicular phase reaching a peak coincident with the LH surge. This is followed by a second increase in estradiol 3–7 days after the LH surge and a mid-luteal increase in estradiol (days 13–15 of the estrous cycle). These increases in estradiol in the utero-ovarian vein coincide with the first and second dominant follicles that develop during the estrous cycle. Furthermore, estradiol concentrations in plasma collected from the posterior vena cava are pulsatile, throughout the estrous cycle, with each pulse of estradiol following a LH pulse. Androgen secretion occurs in the thecal cells and appears to be controlled by LH in both sheep and cattle. In the granulosa cells, androgens are converted to testosterone which is aromatized to estradiol-17β under the influence of FSH. Serum estradiol concentrations are elevated 1–2 days prior to the LH surge reaching a peak of 9.7 pg ml^{-1}. This increase in estradiol in the follicular phase acts in a positive feedback mechanism (**Figures 1** and **2**) to induce the LH (and FSH) surge required for ovulation.

Once the corpus luteum is formed after ovulation, progesterone secretion from the CL increases and remains elevated throughout the luteal phase of the cycle. Both estradiol and progesterone act in a feedback mechanism to control gonadotropin secretion. Estradiol and high progesterone concentrations during the luteal phase of the cycle act to decrease pulsatile secretion of the gonadotropins. In the presence of low progesterone concentrations during the follicular phase, GnRH and LH pulse frequency increase ultimately reaching a GnRH and LH (and FSH) surge required for ovulation.

A further hormone family termed inhibins, secreted by the granulosa cells of follicles, is also implicated in the control of gonadotropin secretion. Inhibin has been defined as a hormone which selectively suppresses the synthesis and secretion of FSH. Inhibin is a dimeric glycoprotein consisting of two subunits, termed α and β, linked by disulfide bridges. Both subunits are secreted as large precursor molecules and can occur in many sizes and combinations. For example, >160, 108, 95, 78, 57, 47, 32 and 29 kDa forms of inhibin have been isolated. However, bioactive inhibin is usually defined as being the 32 kDa form of the α–β dimer. There is a lot of confusion as to the exact mechanisms by which all the inhibin forms control and affect follicular growth. Evidence exists that inhibins have a local as well as a systemic role in controlling follicular growth.

Corpus Luteum Function

The CL forms from the collapsed preovulatory follicle after ovulation. In the cow, the weight and progesterone content of the CL increase rapidly between days 3 and 12 of the estrous cycle and remain relatively constant until day 16. The main function of the CL in cattle is to secrete progesterone. In cattle progesterone and its metabolite δ-pregnene-20β-ol-3-one are the major progestagens secreted by the CL. Progesterone is secreted both from CL formed during normal estrous cycles and pregnancy. During pregnancy, progesterone plays a similar role in decreasing gonadotropin secretion and prevention of behavioural estrus as occurs during the luteal phase of the estrous cycle.

Luteinizing hormone is the major luteotropic hormone in cattle and is responsible for stimulating luteinization of the theca and granulosa cells of the preovulatory follicle into luteal cells. Luteal cells may be classified into small and large cell types both of which secrete progesterone. Small bovine luteal cells appear to secrete progesterone in response to LH stimulation, while large bovine luteal cells produce greater amounts of progesterone under basal conditions and are generally insensitive to exogenous LH stimulation.

Luteolysis of the Corpus Luteum

Prostaglandin $F_{2\alpha}$ (PG) is secreted by the uterus in cows. It is the major luteolytic hormone in ruminants. During the late luteal phase of a normal cycle PG is secreted in a pulsatile pattern from the uterus, but during the equivalent period of early pregnancy, pulsatile PG secretion is attenuated. The presence of an embryo prevents luteolysis by suppressing the ability of the uterus to release PG in a pulsatile manner rather than reducing the ability of the uterus to synthesize PG. This pulsatile secretion of PG induces luteolysis. Uterine PG reaches the CL through a local mechanism of countercurrent exchange between the uterine vein and the ovarian artery (**Figure 3**).

Oxytocin plays an integral role in induction of PG release required for luteolysis. It stimulates the uterine endometrium to secrete PG *in vitro* and *in vivo*. Oxytocin along with estradiol potentiates the release of PG from the uterus; estradiol from the ovulatory dominant follicle appears to stimulate the development or formation of oxytocin receptors in the uterus and enables increased binding of oxytocin, which in turn stimulates PG synthesis from the nonpregnant uterus. Pulsatile PG secretion in ruminants is associated with pulsatile oxytocin secretion. Pulses of oxytocin occur concurrently with PG during luteolysis and most of this oxytocin appears to be luteal in origin. Uterine PG and luteal oxytocin comprise a positive feedback loop, and PG can stimulate luteal oxytocin secretion. The trigger for luteolytic pulses of PG to be secreted from the uterus has not been identified but oxytocin from the posterior pituitary has been suggested by some authors to be involved.

In species such as cattle that require PG for luteolysis, oxytocin can only stimulate the uterus to secrete pulsatile PG during the late luteal phase. Thus, one or more components of pulsatile PG release must be absent in the uterine endometrium during the nonresponsive stage of the estrous cycle. Endometrial oxytocin receptors only increase approaching the time of luteolysis and their absence is thus a likely candidate for limiting the responsive period for PG secretion. The control mechanisms of induction of oxytocin receptors in the uterine endometrium and the secretion of PG appear to involve the steroid hormones progesterone and estradiol. In ovariectomized ewes or cows, oxytocin will only stimulate PG secretion after the animal has been exposed for 7–10 days to luteal phase progesterone concentrations. Some of the processes that are required to supply precursors for PG secretion appear to be progesterone-dependent, such as accumulation of lipid droplets and triglycerides in the uterine endometrium. Estradiol administration during the mid-luteal phase of the cycle will induce premature CL regression. In sheep, acute treatment with estradiol on days 9 and 10 of the cycle induces an increase in endometrial oxytocin receptors within 12–24 h and premature luteal regression. Thus, progesterone and estradiol both appear to be necessary in the development of uterine oxytocin receptors.

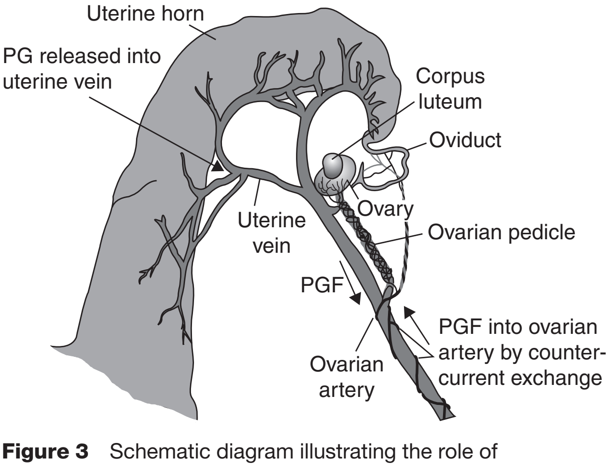

Figure 3 Schematic diagram illustrating the role of prostaglandin $F_{2\alpha}$ (PG) in controlling luteolysis. Prostaglandin released from the uterine endometrium into the uterine vein is picked up by the ovarian artery through countercurrent exchange and is delivered back to the CL as a local mechanism where it causes luteolysis. (Adapted and reprinted from CD-ROM *Learning Reproduction in Farm Animals*, with permission of Rodney D. Geisert, Oklahoma State University.)

Estradiol appears to have the additional role of enhancing secretion of oxytocin from the posterior pituitary and infusion of low doses of estradiol to ovariectomized ewes results in pulsatile secretion of oxytocin from the posterior pituitary. Thus, the mechanism of luteolysis appears to be initially triggered by increased estradiol from the dominant follicle that increases oxytocin pulse frequency from the posterior pituitary, which in turn will stimulate PG secretion from the uterus during the late luteal phase, i.e. when oxytocin receptors are present on the endometrium. The initial secretion of PG stimulates luteal oxytocin secretion which in turn stimulates further PG secretion from the uterus and causes the uterus to become temporarily refractory to oxytocin for 6–8 h, thus establishing a pulsatile pattern of uterine PG secretion at 6–8 h intervals.

In cattle and sheep, the presence of an embryo appears to inhibit the formation of oxytocin receptors in the endometrium, thereby preventing pulsatile release of PG required for luteolysis. The presence of certain proteins from the developing embryo in the uterus, e.g. trophoblast protein-1 (interferon-τ), prolongs the estrous cycle, presumably because they inhibit pulsatile release of PG by some mechanism. Interferon-τ is now recognized as the key mediator of maternal recognition of pregnancy in cattle.

Conclusions

It is concluded that the estrous cycle in cattle is typically 18–24 days in duration, with estrous behavior being expressed for an 8- to 24-h period during the late follicular phase. During the normal estrous cycle there are typically two to three and occasionally four waves of follicular growth each involving a period of emergence and selection followed by either atresia or ovulation of the dominant follicle. The gonadotropin hormones FSH and LH are the main regulators of folliculogenesis and steroidogenesis with LH being the major luteotropic hormone. LH pulse frequency is the major determinant affecting the ultimate fate of a selected dominant follicle. Pulsatile prostaglandin $F_{2\alpha}$ of uterine origin is the main hormonal signal that induces luteolysis of the corpus luteum and the switch from the luteal to the follicular phase.

Estrous Cycles: Postpartum Cyclicity

Introduction

In dairy cows, the interval from calving to resumption of ovulatory ovarian cycles has increased and fertility has decreased over the past half century as average milk production per cow has increased more than threefold. Understanding the physiological processes that regulate ovarian follicular development and ovulation is a necessary prerequisite for shortening the interval to first ovulation, increasing fertility, and optimizing reproductive management in modern dairy operations.

During pregnancy, cows have a corpus luteum (CL) and do not ovulate additional follicles. Nevertheless, follicular growth in waves continues throughout pregnancy. Wave activity decreases as pregnancy progresses and dominant follicles are less prominent. Coincident with the reduction in follicular wave activity during pregnancy is a reduction in the pulsatile release of circulating luteinizing hormone (LH) in blood. Following parturition, ovarian follicular growth and ovulatory follicular cycles must be reinitiated if the subsequent pregnancy is to be established within a reasonable amount of time. The mechanisms associated with the resumption of ovulatory waves postpartum are complex and there is a large variation in the interval from parturition to first ovulation in lactating dairy cows. This article will review the timing of postpartum ovarian cyclicity in dairy cows and the mechanisms associated with normal and abnormal ovarian cycles during the postpartum period. The cellular and molecular mechanisms regulating ovarian follicular development and ovulation as influenced by body condition and energy balance will be discussed.

Ovarian Follicular Dynamics during Estrous Cycles in Cattle

The characteristics of estrous cycles in cattle have been reviewed (*see* **Reproduction, Events and Management**: Estrous Cycles: Characteristics). However, a brief summary here is pertinent to the discussion of postpartum ovarian activity. The dynamic nature of ovarian follicular growth in cattle was unknown for a considerable period of time. A typical estrous cycle in cattle has two or three waves of follicular growth. The initiation of each follicular wave (recruitment) is characterized by the growth of a cohort (usually 2–6) of small follicles from approximately 2–4 to $\geq$5 mm in diameter. The initiation of each wave of follicular growth is preceded by a transient increase in circulating follicle-stimulating hormone (FSH). The recruited follicles continue their growth to approximately 7–8 mm in diameter. At this time, one follicle is typically selected (selection) to continue to grow to ovulatory size (14–18 mm in diameter; dominant follicle). The remaining subordinate follicles undergo atresia. If the cow is in the luteal phase of the estrous cycle, the dominant follicle maintains its maximum size for 3–6 days, but undergoes atresia and another wave of follicular growth is initiated. The dominant follicle in the second or third wave will ovulate if luteal regression occurs during the growing phase.

Postpartum Follicular Growth

Gonadotropins

At parturition, concentrations of LH, but not FSH, are low. In particular, mRNA expression of the β subunit of LH is low, and there is little LH in the pituitary or in blood circulation. With increasing time following parturition, synthesis and release of the gonadotropins increase. There is little release of LH following gonadotropin-releasing hormone (GnRH) injection for the first week postpartum, but the mean concentration of LH and the pulsatile release of LH increase thereafter, and a GnRH-induced release of LH capable of inducing ovulation is possible within 2 weeks postpartum. Similar to initiation of follicular waves during normal estrous cycles, a transient increase in FSH precedes initiation of waves of follicular growth postpartum. The first wave of follicular growth is usually initiated within 5–10 days postpartum. Growth of follicles to approximately 9 mm in diameter follows the stimulation of the transient increase of FSH. Growth beyond this size is dependent upon additional stimulation with LH in addition to the FSH. When adequate concentrations of LH are present, follicles continue their growth to ovulatory size.

Follicular Growth

Waves of follicular growth following calving are similar to those seen in normal estrous cycles and are usually initiated within 10–14 days. With each wave of follicular growth, a cohort of follicles is recruited to grow above

5 mm in diameter and the follicles continue their growth to about 7–8 mm in diameter, whereupon one follicle is selected for further growth. The selected follicle of the first follicular wave follows one of three fates: (1) it continues its growth to ovulatory size and ovulates (cyclic cows); (2) it grows to various sizes but not ovulatory size, stops growth, and undergoes atresia, following which a new wave of follicular growth is initiated (anovulatory anestrous cows); or (3) it surpasses ovulatory size and develops into an ovarian follicular cyst (cystic cows).

Postpartum Ovulatory Follicles

Postpartum follicles that ovulate probably do so through the stimulatory effects of normal levels and secretory patterns of FSH and LH. Dairy cows that ovulate the first wave dominant follicle postpartum are generally in good body condition and are not experiencing extreme negative energy balance. Cows in poor body condition, in extreme negative energy balance, or with metabolic or infectious diseases at calving often have delayed initiation of follicular waves, multiple follicular waves before first ovulation, and extended intervals to first postpartum ovulation.

Postpartum Anovulatory Follicles

In some cows, the first follicular wave postpartum does not end in ovulation, but instead ends in atresia. In cows that do not ovulate the first wave dominant follicle that occurs following parturition, initiation of follicular growth may occur at the same or at a later time than those that ovulate the first wave dominant follicle. Recurrent follicular waves usually occur in postpartum cows that do not ovulate the dominant follicle (**Figure 1**). While the processes of recruitment, selection, dominance, and atresia of follicles in anovulatory waves are generally similar to those observed in ovulatory waves, some differences have been noted. Anovulatory follicular waves are usually longer than ovulatory waves, and the maximum size of the selected follicle is usually smaller. The growth rate from recruitment (5 mm in diameter) to selection (7–8 mm in diameter) and to maximum size of the anovulatory dominant follicle is usually similar to that of the ovulatory follicle. Instead of reaching ovulatory size (16 mm in diameter), however, the anovulatory follicle usually stops growing when it is 10–14 mm in diameter. The smaller-sized follicles produce less estradiol than the larger ovulatory follicles, and the amount of estradiol produced is likely less than the threshold amount needed to induce the preovulatory LH surge. The reason that anovulatory follicles stop growing at the smaller size and have decreased synthesis and release of estradiol may be because of decreased LH secretion or decreased responsiveness of follicles to LH support. These mechanisms will be discussed in the following sections.

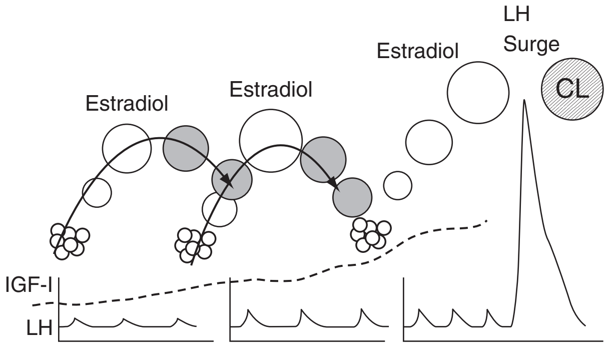

Figure 1 Development of ovulatory follicles in postpartum cows. Ovarian follicles grow in waves during the postpartum period. Successive waves produce larger dominant follicles that secrete greater amounts of estradiol. The luteinizing hormone (LH) surge is induced and the corpus luteum (CL) is formed when estradiol concentrations reach a threshold level. Blood concentrations of insulin-like growth factor I (IGF-I) (dashed line) and LH (pulses) increase during the postpartum period from basal levels (first few days postpartum) to greater levels (3–4 weeks postpartum). The postpartum increase in LH and IGF-I depends on the nutrition and body condition of the cow. The LH and IGF-I synergistically promote follicular growth and development.

In some dairy cows, the initiation of follicular waves is delayed for extended periods of time after parturition. Cows that do not initiate follicular waves postpartum are usually in extremely poor body condition at calving or have severe metabolic or infectious diseases that cause excessive loss of body condition and poor health. In general, any deleterious postpartum health problem increases the interval to initiation of follicular waves and ovulation, and decreases fertility (**Table 1**) .

Mechanisms Associated with Ovulatory and Nonovulatory Postpartum Follicles

Initiation of postpartum ovarian cyclicity is related to body condition at calving and to negative energy balance following calving, which affects the change in body condition during the postpartum period. Cows should be in good

Table 1 Influence of health status on reproductive performance of dairy cows

	Healthy cows (n = 38)	*Cows with major health problems (n = 26)*
Days to first estrus	37.7	51.2
Days to first insemination	58.7	68.4
Days to pregnancy	71.9	84.1
Cumulative pregnancy rate (%)	88.9	63.2

Adapted from Barton, *et al*. (1996) *Journal of Dairy Science* 79: 2225–2236.

body condition at calving (body condition score (BCS) should be 3–3.5 on a 5-point scale, where 5 is obese and 1 is very thin). High-producing dairy cows are usually in a negative energy balance following parturition because there is a dramatic change in energy requirements to meet the energy demands of lactation. There is an immediate shift in metabolism from nutrient partitioning toward body reserves and fetal mass to one of nutrient mobilization of energy and protein stores to meet the demands of lactation. Energy and feed intake are not maximized in lactating dairy cows for a few weeks following parturition. It is during this time that negative energy balance reaches its maximum, and the resumption of postpartum cyclicity is dependent upon the severity of the negative energy balance and body condition of the cow. The effects of various nutritional and environmental factors on postpartum cyclicity are described below.

Body Condition

Attaining the optimum BCS of 3.0–3.5 during the dry period is important for reestablishment of ovarian cyclicity during the postpartum period. Cows that are overly fat (BCS near 5) have a decreased appetite following parturition compared with more ideally conditioned cows (BCS 3.0–3.5) and, thus, are in a greater negative energy balance and have a much larger change (decrease) in BCS. Cows that have increasingly larger negative changes in BCS during the postpartum period take a longer time to achieve first ovulation postpartum, and fertility is decreased.

In addition, some cows calve with less than optimum body condition. Cows calving with BCSs of 1.5 or less have a longer interval to first ovulation than those that calve in better condition. Cows in very poor body condition do not have energy stores available to mobilize for maintenance and lactation requirements. It has long been known that the body diverts energy from reproductive processes when conditions do not meet the needs for maternal survival. Cows that experience the greatest change in body condition after parturition take longer to achieve ovulation than those that have less change in body condition, and conception rates of cows with a greater BCS loss are lower than those of cows with less BCS loss postpartum. Similarly, cows in a lesser negative energy balance or in a positive energy balance have greater conception rates than those with a more negative energy balance.

Energy Balance

As stated previously, high-producing dairy cows are in a negative energy balance following parturition. The negative energy balance increases for a period of time as milk production increases faster than feed intake. When the amount of negative energy balance decreases, events leading up to the first ovulation begin. Ovulation of a dominant follicle postpartum is dependent upon stimulation through increasing mean concentration and pulsatile release of LH (**Figure 1**). Pulsatile release of LH is greater in cows that ovulate a dominant follicle in the postpartum period than in those that have recurrent follicular waves, and the size of the ovulatory dominant follicle is usually larger than the nonovulatory dominant follicles. In most cases, follicles that fail to ovulate do not reach full ovulatory size. Low energy availability decreases LH pulsatility and, thus, follicular stimulation and estradiol synthesis are less. Also the responsiveness of follicles to LH may be decreased because of lower concentrations of circulating insulin-like growth factor I (IGF-I) (**Figure 2**). The concentrations of circulating IGF-I are directly correlated with energy status. Cows in a greater negative energy balance have lower concentrations of circulating IGF-I. The IGF-I concentrations are greater in cows that are ovulating.

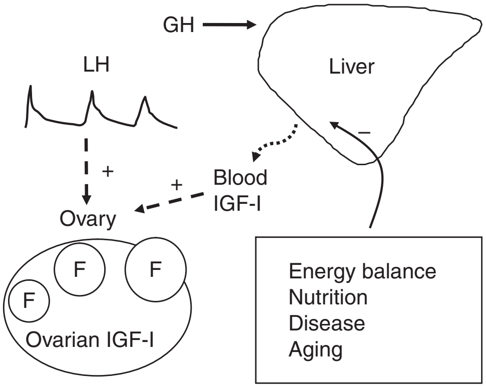

Figure 2 Control of follicular growth by luteinizing hormone (LH) and insulin-like growth factor I (IGF-I) secretion in postpartum cows. At parturition, pulses of LH and concentrations of IGF-I in blood are low. Blood growth hormone (GH) concentrations are elevated and GH drives nutrient partitioning for milk synthesis. Most of the IGF-I in blood is derived from the liver and is released in response to GH. In early postpartum cows, the GH–IGF-I axis is uncoupled so that high concentrations of GH do not lead to elevated blood IGF-I. Negative energy balance, undernutrition, disease, and aging increase the amount of uncoupling and reduce IGF-I synthesized and secreted from the liver. The GH–IGF-I axis is recoupled postpartum so that the synthesis and secretion of IGF-I into the blood are increased. Pulses of LH increase postpartum and stimulate follicular growth. The greatest LH pulsatility is found in cows with better body condition and less negative energy balance. The effects of LH on the ovary are synergistic with IGF-I in blood. Greater IGF-I and more LH pulsatility postpartum act in a synergistic manner to increase the growth and development of ovarian follicles. Factors such as negative energy balance may decrease IGF-I by preventing the recoupling of the GH–IGF-I axis. Negative energy balance may also inhibit LH pulses. Collectively, low IGF-I and low LH pulsatility may not provide adequate stimulation for the development of a preovulatory follicle.

Abnormalities of the Puerperium

Cows must be healthy for efficient postpartum reproduction. Diseased cows are less fertile and the effects of disease on reproductive performance are greater than any other factor. Both metabolic and reproductive diseases and disorders can negatively affect reproduction. Cows with metabolic and reproductive diseases are usually in poorer general health, lose a greater amount of body condition, and experience delayed postpartum ovarian cyclicity. Thus, cows with abnormal puerperium require additional time to establish ovarian follicular waves and develop ovulatory follicles. In addition, fertility is lower in affected cows than in cows with no abnormalities during the periparturient period. Metabolic disturbances and diseases include dystocia, retained placenta, metritis, pyometra, milk fever, ketosis, acidosis, mastitis, laminitis, brucellosis, and tuberculosis. Several studies have demonstrated the relationship between health and reproduction. For example, healthy cows in one study had a shorter interval to first estrus, shorter days to first insemination, shorter days to pregnancy, and fewer services per conception than cows that needed veterinary assistance for postpartum health problems (**Table 2**). Mastitis also has a major effect on reproduction in postpartum dairy cows. Cows that develop clinical mastitis have delayed intervals to first insemination, greater services per conception, and greater days open. A regular herd health program for veterinary care can prevent many deleterious effects of postpartum disease on reproduction.

Ovarian Follicular Cysts (Cysts)

The third fate of follicles during the postpartum period is the development of cysts. Cysts have been classified as anovulatory ovarian follicular structures of at least 2.5 cm in diameter that persist in the absence of a CL for a period of at least 10 days. This definition may no longer be accurate due to the dynamics of follicular growth and the dynamics outlined in previous sections. Nonetheless, the cystic condition is a serious cause of reproductive inefficiency in dairy cattle because cows are infertile as long as the condition persists. It is estimated that 10% of dairy cows develop cysts annually.

Characteristics of Cysts

Follicular dynamics in cows with cysts has similarities to follicular dynamics in normal cows. Development of cysts begins when a cohort of follicles less than 4 mm is recruited to grow beyond 5 mm in diameter. At approximately 7–8 mm in diameter, one follicle (sometimes more than one) is selected for continued growth to become dominant over the other follicles as occurs in normal ovulatory follicles. The growth phase to ovulatory size is similar to ovulatory follicles. However, instead of ovulating, the follicle destined to become a cyst continues to grow for several more days and becomes enlarged and is anovulatory. In some cases, more than one follicle continue growth and codominant or multidominant cysts are formed. The size of the cysts may be slightly less than in the classical definition when more than one cystic structure develops.

Earlier research suggested that cysts persisted for considerable periods of time if left untreated. More recently, studies using ultrasonography or charcoal marking have shown that cysts do not always persist as previously thought. Three fates of cysts have been shown to occur:

1. Persistence, as originally thought. The percentage of cysts that are persistent is approximately 15–20%. Some cysts persist for longer than 60 days, remain dominant, and inhibit follicular growth during this time.
2. Cyst turnover, whereby the original cyst loses dominance, and a new wave of follicular growth is initiated. One (or more) follicle is selected to become dominant from the cohort of new follicles that are recruited, and develops into a new cyst. Cysts that have lost dominance have morphological and endocrine characteristics of atretic follicles. This condition may continue for repeated waves of cyst development, and the anovulatory condition, but not a single cyst, persists. The period of the waves of cyst growth may be similar in length to normal follicular waves, but is, on

Table 2 Effects of problems occurring during lactation on reproductive traits

Item	*Average days to postpartum breeding*	*Average calving interval (days)*	*Average services/ conception*
No problem	86	395	1.8

Anestrus	141	480	2.2
Aborted	80	402	2.4

Data are from 2352 observations in dairy herds (HA Garverick, unpublished data).

the average, twice as long. Cyst turnover is prevalent in most cases (60–65%) of cows with cysts.

3. Turnover with initiation of a new wave of follicular growth whereby the cow self-corrects and ovulates a new dominant follicle. Approximately 20% of cows with cysts self-correct the condition.

Etiology of Cysts

A number of factors including endocrine imbalances, heredity, milk production, and seasonality have been associated with the development of cysts. Endocrine imbalances include various abnormalities of the hypothalamic–hypophyseal–ovarian axis. There is an increase in mean circulating and pulse amplitude secretion of LH during cyst development, and pulse frequency is similar to that observed in a normal follicular phase (**Figure 3**). Both mean concentration and pulse amplitude of LH are nearly twice as high in cows with cysts compared with cows that ovulate. However, there is an absence of the preovulatory LH surge in cows with cysts. Cysts may produce more estradiol than ovulatory follicles, but the LH response to estradiol is absent in cows with cysts. There is no difference in pituitary concentrations of FSH and LH in cows with cysts and cows that ovulate. The concentration of GnRH in the hypothalamus is lower in cows with cysts, but the GnRH content of the median eminence is greater in cows with cysts. Thus, the GnRH content of the median eminence is likely released and caused increased secretion of basal LH.

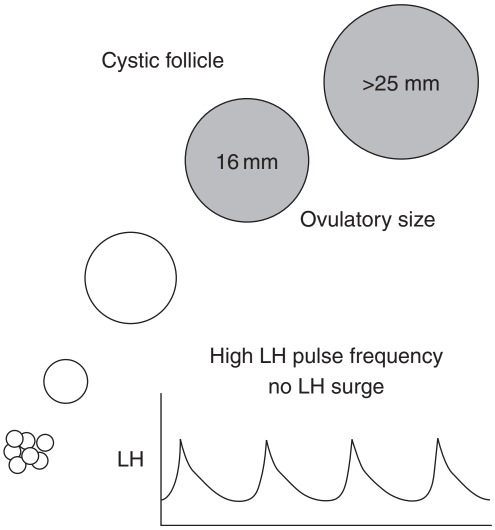

Figure 3 Formation of ovarian follicular cysts in cows. Cysts form when postpartum luteinizing hormone (LH) secretion is highly pulsatile. A large follicle develops on the ovary and secretes estradiol. Estradiol secretion, however, fails to trigger an LH surge and the cow becomes cystic because the follicle does not ovulate.

Heredity has also been associated with cyst development. However, the estimation of heritability has been difficult because of confounding factors such as nutrition, body condition, and milk production. Increased milk production has also been associated with cyst development. However, it is unclear whether increased milk production produced cysts or whether cows produced more milk because they were cystic and were not pregnant for a longer period of time. Season of the year has also been associated with the development of cysts. However, there are reports that did not find a relationship between cysts and the level of milk production or seasonality.

Numerous miscellaneous factors have been linked to cyst development. These include estrogen content of forages, which is consistent with the altered response of the cows with cysts to estradiol as previously mentioned. Abnormal reproductive and metabolic events during the postpartum period have also been linked to development of cysts, suggesting that the increased stress associated with these events contributes to cyst development.

Diagnosis and Treatment of Cysts

Classical diagnosis of cysts was based on behavioral symptoms of intense sexual desire or nymphomania. Cows exhibiting such behavior exhibited estrus for extended periods of time, sometimes with repeated periods between times of no estrual activity. However, it is now clear that most cows with cysts do not exhibit estrous activity (anestrous). Diagnosis of cysts is usually based upon finding a follicular structure of 2.5 cm in diameter or larger following a single examination via manual palpation per rectum or ovarian ultrasonography. While diagnosis based upon the single examination is efficacious for producers, the diagnosis may not be accurate for several reasons. First, size alone is not an absolute criterion because size is influenced by stage of development, which is difficult to know with one examination. Second, there are often large follicles on the ovaries of cows during a normal estrous cycle as previously described. Thus, the dynamic nature of follicular and cyst growth complicates diagnosis. Third, some CLs developing during the first 5–7 days following estrus exhibit characteristics similar to cysts when diagnosis is by manual palpation. Luteal structures during this period are often soft and contain fluid-filled structures that rupture during manual palpation. Diagnosis with ultrasonography greatly reduces this type of diagnostic error.

Cysts are typically treated with GnRH to induce an endogenous LH release, or treated with human chorionic gonadotropin (hCG) that has LH-like activity. In both cases, successful treatment is based upon luteinization of the cystic structure and subsequent production of progesterone in response to the GnRH-induced LH release or the exogenous hCG. Success rates are about 80% with these treatments. Response of the cystic structure is dependent upon its state at treatment. Responding cysts are those that are 'healthy' in that theca and granulosa cells appear morphologically intact and are producing estradiol. More recently, progesterone implants have been used successfully to treat cysts. Treatment with progesterone must raise blood levels of progesterone to high enough levels to mimic luteal phase concentrations. Success of the aforementioned treatments is dependent upon increased concentrations of circulating progesterone that restore the sensitivity of the hypothalamic–pituitary axis to estradiol. With these treatments, concentrations of LH are inhibited, the cyst(s) undergo atresia, and a new follicular wave follows that results in selection of an ovulatory dominant follicle that secretes estradiol. The sensitivity of the hypothalamic–pituitary axis to estradiol is restored and an LH surge and ovulation of the dominant follicle occur.

Conclusion

Initiation of ovulatory ovarian cycles following parturition is a prerequisite for the establishment of pregnancy within an opportune time interval. Following parturition, waves of ovarian follicular growth are usually established within 10–14 days. There are three fates of the first wave dominant follicles. The selected follicle may (1) continue its growth to normal ovulatory size and ovulate, (2) grow to less than ovulatory size, fail to ovulate, and undergo atresia, or (3) surpass ovulatory size and develop into an ovarian follicular cyst. Body condition at calving, negative energy balance, and disease determine the fate of ovarian follicles postpartum (ovulation, anovulation, or cystic) by affecting the endocrinology of the postpartum cow (LH, FSH, and IGF-I secretion).

Estrous Cycles: Seasonal Breeders

S T Willard, Mississippi State University, Mississippi State, MS, USA

Introduction

The effects of seasonal influences on reproduction are directly linked to milk yield, as the production of offspring is required for initiation of lactation, and is important in relation to targeting milk markets. For example, in India and Pakistan, water buffaloes calve primarily between July and December, which can result in excess milk production in the winter months and milk shortages during the summer months. Similarly, dairy sheep producers are particularly cognisant of the effects of seasonality on lambing intervals of ewes and on an ewe's lifetime lactation yield in light of the strict seasonal nature of some sheep breeds used in intensive dairy sheep operations. While an understanding of seasonality is critical from a production standpoint, from an evolutionary perspective seasonal breeding has evolved as an adaptation to ensure a favorable reproductive rate and the survival of offspring in regions with great variations in climatic, nutritional, and/or other adverse environmental conditions. The reasoning behind the evolution of these strategies in the context of agriculturally important livestock species will be explored herein, in addition to the physiological basis for seasonality and how it might be controlled in a production setting. For comparative purposes, the seasonal nature of several multipurpose livestock species will be indicated, with emphasis on those used worldwide for the production of milk and milk by-products.

Strategies and Theories for the Seasonal Regulation of Reproduction

Some species do not exhibit seasonal cycles in reproductive activity (nonseasonal breeders), while others may display 'clusters' of reproductive cycles that occur only during a certain season of the year (seasonal breeders). Of the seasonal breeding species, some exhibit reproductive cycles during the short day lengths (autumn; e.g., sheep and goats), while others exhibit reproductive cycles only during the long day lengths (spring; e.g., mare). Patterns of seasonal breeding range from species that have one period of estrus (receptivity and mating) each year (monoestrus), to species that exhibit a series of estrous cycles limited to a portion of the year (seasonally polyestrus). True seasonal breeding patterns are inherent in some species (e.g., ewe, doe, and mare), while other species may show seasonal patterns due to environmental or other overriding influences. Of these, climatic, nutritional, and behavioral effects on seasonal cycles will be described below. However, one should be cognisant of the fact that seasonality is a coordinated effort in which multiple exogenous (environmental) and endogenous (hormonal) rhythms may be involved in the integration of seasonal reproductive cycles.

Climatic

Climatic events that regulate seasonal reproductive processes encompass primarily the effects of photoperiod and temperature, with climatic variables including drought and precipitation influencing reproduction as related to nutrient availability (nutritional considerations will be described in greater detail below). Of these, photoperiod is seen as a primary mechanism driving the endogenous circannual rhythm that synchronizes mating and birthing seasons. The effects of photoperiodism (photic cues) are translated into reproductive effects via hormonal mediators (e.g., melatonin), which augment or suppress endocrine and neuroendocrine pathways critical to reproductive processes (see 'Endocrine and Neuroendocrine Regulation of Reproduction in Seasonal Breeders'). The influence of photoperiod on the reproductive system was first observed in relation to the timing of puberty for lambs born at different times of the year. Specifically, spring-born lambs attain puberty in about 30 weeks of age, which they reach during the breeding season, while fall-born lambs reach the pubertal age of 30 weeks during the nonbreeding season, and thus do not exhibit reproductive cycles until the following breeding season at nearly 1 year of age. Such dramatic effects illustrate the prevailing and central role that photoperiod plays in the reproductive lives of strict seasonal breeders.

In conjunction with or independently from photoperiod, which changes incrementally during the year, alterations in ambient temperatures (high and low) can contribute to shifts in seasonal breeding activities as well. For dairy cattle bred by natural or artificial means in the southern United States and elsewhere, it has been observed that fertility is lowest in late summer when ambient temperature and humidity are high, and is often followed by a slow recovery time thereafter producing a lag effect into the fall. To this end, heat stress in cattle has been the primary focus of research, which has illustrated how severe thermal stress can suppress reproductive processes, negatively impacting livestock production operations – particularly in dairy cattle. Summer heat stress has been shown to lower semen quality in bulls, alter hormonal secretory patterns, suppress estrous behavior, reduce conception rates, and negatively affect embryo quality and survival. Moreover, heat stress during late gestation can adversely affect fetal growth in cattle and sheep, with summer-born calves and lambs being generally smaller than winter-born calves and lambs, and an increased incidence of stillbirths has been observed in swine.

Low temperatures (i.e., cold stress) at the time of birth also have implications relative to offspring survival (e.g., *Bos indicus* calves are more susceptible to cold stress than *Bos taurus* calves), yet in relation to mating success the effects of cold stress are less well characterized in livestock than the effects of heat stress. This is due to the confounding effects of food intake, which increases during colder periods to facilitate metabolic heat production (i.e., maintenance of thermoneutrality) as part of an adaptive response to low environmental temperatures. Nevertheless, appropriate adaptation periods to low environmental temperatures are required to alleviate both endocrine and exocrine effects on reproductive processes in some breeds. For example, in Brahman bulls translocated to the northern United States, reduced concentrations of testosterone and decreased semen quality have been observed during the winter months (0 to −10 °C).

When considering both heat and cold stress together, it seems reasonable that seasonal breeding strategies would have evolved, in part, to coordinate breeding periods for an increased probability of mating success and postparturient neonatal survival in relation to annual changes in environmental temperatures.

Nutritional

Late pregnancy, birth, and lactation require energy and nutrient demands above and beyond what is required for normal body maintenance. This means that conception must occur months earlier in relation to other environmental cues (e.g., photoperiod) to achieve a birthing season that will coincide with the season of greatest abundance in nutrient quantity and quality. When energy and protein, for example, become limiting, a number of reproductive processes may be affected, resulting in delayed puberty, suppressed estrus and ovulation, reduced conception rates, an increased incidence of fetal resorption, and premature or weak offspring. As evident from these examples, the seasonal suppression of puberty or estrous cycles due to nutritional deficiencies could delay transitions into seasonal breeding periods, while deficiencies later in the year may influence survival of the fetus late in pregnancy or the neonate postpartum. Conversely, an abundance of nutrients may permit animals to exhibit reproductive cycles earlier in the season, and adequate nutritional reserves during pregnancy and lactation would directly benefit offspring survival postpartum. Food in this regard has been described as having a 'proximate' and 'ultimate' action in relation to seasonal breeding. Specifically, the quantity of nutrients available can have an immediate beneficial or detrimental effect on an animal's reproduction (a proximate action), and the fact that the presence of nutrient resources can vary seasonally in an animal's environment is an important factor in the evolution of that animal's reproductive strategy (an ultimate action). The tendency toward seasonal breeding begins to manifest primarily in regions where nutrient availability varies somewhat, with increases in the severity of this variation leading to stricter and stricter breeding and birthing seasons out of an apparent necessity for nutrient resources. This is, of course, superimposed on other climatic events (photoperiod, temperature, precipitation, etc.) that can influence growing seasons and plant vigor.

Social/Behavioral

Reproductive processes can be dramatically affected by social cues relayed from one individual to another of the same or opposite sex. This can occur via pheromones, which are chemical substances liberated from one animal (through urine or other secretions) and received by another (olfactory cues), or through visual or tactile cues associated with complex mating rituals. These behavioral or chemical cues have a priming effect that can alter hormonal secretions (primarily luteinizing hormone (LH) and prolactin from the pituitary) and advance the breeding season. In sheep, this is often referred to as the 'ram effect', as ram exposure can increase LH pulsatility in the ewe and elicit signs of estrus in the female that would not normally be present in the absence of a ram. Furthermore, introduction of a ram into an ewe flock during the transition from anestrus to estrus can in turn result in a high degree of synchrony in first mating. A similar reaction is achieved in wapiti (North American elk) and red deer, in which vocalizations from the stag during the early rut can hasten seasonal reproductive cyclicity in females. While in today's livestock management systems such cues have become less vital from a mating strategy standpoint, for animals in the wild with varying social structures (e.g., dominance hierarchies, single-sex groups) and a need to locate receptive mates, such behavioral cues are critical to mating success and genetic survival. While social interactions are not a singular cause for initiating or terminating seasonal reproductive events in most species, they can greatly augment the degree to which an animal responds to other environmental cues regulating seasonal processes.

Endocrine and Neuroendocrine Regulation of Reproduction in Seasonal Breeders

Seasonal breeders are often referred to as undergoing an annual puberty, in that reproductive cycles must begin anew following a period of anestrus (i.e., no estrus or the absence of heat cycles). The principal mechanism responsible for transitions into and out of periods of sexual activity in strict seasonal breeders is mediated by the retinal-hypothalamo-pituitary pathway (**Figure 1**). Specifically, photic cues detected by the sensory neurons in the retina of the eye are transmitted via the suprachiasmatic nucleus of the hypothalamus to excitatory cervical ganglia that can alter the release of the hormone melatonin from the pineal gland and, in turn, influence hypothalamic gonadotropin-releasing hormone (GnRH) and pituitary LH release. The pineal gland is located posterior to the hypothalamus between the hemispheres of the brain, and increased sympathetic activity induced by darkness increases the secretion rate of its primary hormone, melatonin. Exactly how melatonin acts singularly or in a coordinated fashion with other hormones (e.g., norepinephrine) to influence reproductive processes is still unresolved. Nevertheless, in short-day breeders (e.g., sheep and deer), cyclic activity that occurs during the short photoperiods (longer nights) of fall and winter is characterized by greater melatonin release and an active hypothalamic GnRH neurosecretory system, while the long photoperiods (short nights) of

Figure 1 Integration of environmental cues on endocrine and neuroendocrine pathways regulating seasonal reproduction. A multitude of exogenous environmental factors and endogenous hormonal cues coordinate the seasonal reproductive cycle in short- (e.g., sheep) and long- (e.g., horse) day breeders. Central to seasonal regulation is the role of photoperiod (light:dark cycles), which changes annually (see **Figure 2c**). To this end, photic cues are relayed via the retino-hypothalamo-pituitary pathway using melatonin as a primary regulator of GnRH and LH/FSH release either directly or indirectly by mediating changes in the sensitivity of the hypothalamus and pituitary to the negative feedback effects of gonadal steroids. It has been said that seasonal breeders undergo an annual puberty, with spermatogenesis and estrous cycles beginning anew each breeding season as they make the transition from sexual inactivity into periods of reproductive competence and back again. While strict seasonal breeders are driven principally by photoperiodic cues, other species may exhibit seasonal cycles directed by a variety of climatic, nutritional, and/or behavioral indicators. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

spring and summer are characterized by lower melatonin release, and thus periods of reproductive dormancy. In long-day breeders like the horse, the relationship between melatonin and season remains the same (high during short days and low during long days), but the effects on the reproductive axis are opposite to that seen in short-day breeders (i.e., for the mare, reproductive dormancy during fall and winter and reproductive competence during spring and summer).

The role of melatonin in coordinating the seasonal regulation of reproduction has been demonstrated in studies where melatonin has been administered to short-day breeders during long days (thus, increasing melatonin and mimicking the effects of short days) to induce gonadal recrudescence. In sheep, the switch from the breeding season to anestrus, or vice versa, is associated with marked changes in hypothalamic GnRH pulse frequency, which has downstream effects on pituitary LH release, gonadal steroid hormone production, and gamete development. There is conclusive evidence that changes in photoperiod can specifically alter the communicative relationship between the gonads and higher brain centers. Indeed, during seasonal transitions in and out of the breeding season in response to changes in photoperiod, there are marked changes in the sensitivity of hypothalamus (GnRH release) and pituitary (LH release) to the negative feedback effects of gonadal steroid hormones in both males and females. These coordinated activities influence not only gonadal activity, but also related behavioral processes and secondary sex characteristics.

Opposite to melatonin, pituitary secretion of prolactin is high when melatonin is low (long days) and vice versa. While prolactin has been implicated as being inhibitory to reproductive function in some short-day breeders and induced (reflex) ovulators (i.e., species that require stimulation of the vagina and/or cervix for ovulation to occur), there is strong evidence that fluctuations in prolactin are not related to the seasonality of mating; however, an endogenous rhythm of prolactin is noted in the ram and stag. Changes in prolactin have been linked specifically to secondary seasonal characteristics, such as coat growth and molt in red deer stags, suggesting that seasonal changes in prolactin may be more related to alterations in temperature. This notion is supported by studies of blind bulls and steers that have shown that photoperiod does not affect prolactin secretion, implicating temperature as the dominant environmental cue regulating prolactin. Thus while photoperiod has been described as being central to the regulation of seasonality, multiple factors can positively or negatively affect the sensitivity and integration of the endocrine and neuroendocrine systems in mediating seasonal cycles and seasonal reproductive transitions (**Figure 1**).

Artificial Manipulation of Seasonal Breeders

Advancement or prolongation of the breeding season in seasonal breeders used in livestock production has been desired in some areas to coordinate breeding seasons with other management-related events (e.g., forage availability). An example specific to the equine racing industry is that foals are routinely assigned a universal birth date of 1 January (northern hemisphere) regardless of when they are born, making advancement of the breeding season beneficial to achieve the birth of foals as early in the year as possible. At present, the primary means to alter circannual rhythms in strict seasonal breeders includes manipulation of photoperiod through exposure of animals to alternate light cycles, and the use of pharmacological (hormonal) means. While these methods will be highlighted in more detail, it should be noted that a variety of other management-related alterations have similarly resulted in a dampening of seasonal influences for some species. For example, seasonal fluctuations in libido and semen quality, estrous activity, and conception rates have been overcome in dairy cattle and water buffalo by providing cooling facilities during heat stress. Additionally, other management practices including early weaning (beef cattle and small ruminants) and increased nutrition (e.g., flushing) have also aided in facilitating early returns to estrus to override any seasonal influences on reproductive function. Finally, behavioral influences should also not be overlooked, as the exposure of ewes to a ram prior to the breeding season can induce early cyclicity (the ‘ram effect’).

Artificial Manipulation of Light–Dark Cycles

The artificial manipulation of light–dark cycles is achieved primarily by altering housing strategies. This can be accomplished by blocking natural light from entering stalls or barns for specified periods of time at the beginning and end of each day, or through controlled lighting. In a long-day breeder like the mare, changes in photoperiod to mimic long days (16 h of light:8 h of darkness) during the nonbreeding season (short days) will stimulate reproductive function in anestrous mares. Conversely, periods of seasonal anestrus in the ewe, a short-day breeder, can be altered by changing day length during long days to mimic short days (8 h of light:16 h of darkness). While dairy cattle are not traditionally considered as seasonal breeders, supplemental lighting (16–18 h of light:6–8 h of darkness) has been shown to boost milk production through increased secretion of insulin-like growth factor-1 (IGF-1), which acts on the mammary gland, and concomitant decreases in melatonin secretion. How IGF-1 is regulated in response to reduced concentrations of melatonin when day length increases remains unclear. To this end, the manipulation of photoperiod to alter melatonin release may have numerous implications in relation to the reproductive and lactational abilities of animals sensitive to photoperiodic cues.

Pharmacological Control: Exogenous Melatonin and Other Hormonal Means

Pharmacological control of seasonal breeding has been achieved in a number of species, and has been implemented as part of routine production management strategies in some areas. As described previously, increasing concentrations of melatonin of pineal origin during short days arouse dormant reproductive processes in short-day breeders. Thus melatonin implants have been inserted in ewes for periods of 30–40 days to advance the breeding season for matings in spring or early summer. However, one problem with using these types of manipulations (melatonin and changes in photoperiod) is that animals can become refractory (i.e., temporarily unresponsive) after a period of time to the stimulatory effects of melatonin and light, thus limiting their use. Moreover, use of melatonin for advancement of the breeding season may not be effective in all seasonal breeding species. For example, in the female goat, melatonin administration has been less successful than in sheep in advancing the breeding season. In addition to melatonin, a whole host of other hormones have been utilized to stimulate reproductive activity during the nonbreeding season or as methods for prolonging the breeding season itself. Specifically, hormonal treatments have included equine chorionic gonadotropin (eCG), human chorionic gonadotropin (hCG), crude pituitary extracts, GnRH, progesterone, and prostaglandins. In camels, GnRH treatment can stimulate sexual activity in males during the nonbreeding season, while in other induced ovulators such as the llama and alpaca, hCG and GnRH have been used to induce ovulation outside of normal periods of sexual receptivity. Taking management strategies a step further, combinations of artificial lighting and pharmacological approaches have also been used with some success. For example, in the mare, initiation of a 16-h photoperiod for 60 days prior to treatment with altrenogest (a synthetic progestin) for 12 days followed by the administration of hCG on day 2 of estrus has been reported to be an effective regime for induction of estrus and ovulation in the mare early in the year outside of the normal breeding period. Such lighting and hormonal combinations and other clinical therapies abound for short-day and long-day breeders alike, with the intent to modify periods of sexual activity to meet management constraints, whether environment- (e.g., temperature or forage availability) or industry- (e.g., the equine racing industry) related.

Seasonal Breeding in Domesticated and Semidomesticated Multipurpose (Meat and Dairy) Livestock

While not all of the livestock species described herein are used in typical dairy production operations (e.g., swine), for comparative purposes the seasonal nature of reproductive cycles, whether endogenously generated or due to exogenous environmental cues, will be discussed briefly for each species indicated. As described previously, photoperiod, temperature, and a multitude of other climatic and/or nutritional factors are the driving forces regulating the timing of breeding and birthing seasons in most species.

Domestic Cattle: Temperate (*Bos taurus*) and Tropical (*Bos indicus*)

Cattle are nonseasonal and polyestrous, yet the onset of puberty and postpartum reproduction are often stimulated by exposure to long days. Moreover, seasonal trends emerge in some climates due to adverse environmental conditions. Specifically, heat stress is often implicated as the cause of reduced reproductive performance, particularly in temperate, European-type cattle (*B. taurus*). Summer heat stress conditions can lower semen quality in the bull, reduce fertilization rates, affect embryo quality and viability, and result in an overall decrease in conception rates. Of all temperate breeds, dairy cattle (e.g., Holstein) in particular show marked seasonal fluctuations in reproductive function due to the effects of environmental heat stress and to meet the metabolic demands of lactation. In the southern United States, cows calving in spring and summer have reduced reproductive performance, with milk production depressed for cows that calve in summer and fall. During heat stress, dairy cows exhibit shorter less intense periods of estrus (as much as 6–8 h less) and a reduced frequency of mounting activity than during cooler seasons. These effects contribute to a lower estrus detection rate, an increased number of artificial breeding services per conception, and an overall decrease in conception rates in production dairy operations during the summer months. Nevertheless, through the implementation of housing strategies to offset environmental extremes (e.g., cooling with fans and sprinklers during heat stress), seasonal influences on fertility in cattle can be markedly reduced. In contrast to heat stress, cold stress has not been implicated in causing seasonal depressions in fertility in cattle, with the exception of when tropically adapted cattle (Zebu; *B. indicus*) have been translocated to colder environments without appropriate periods for adaptation. To this end, Zebu cattle exhibit the greatest entrainment to seasonal cycles (primarily temperature-related) than all other breeds, with the frequency of estrus, ovulation, and conception rates being higher during the summer months than during the winter months in equatorial Africa.

Water Buffalo (*Bubalus bubalus*)

Water buffaloes are polyestrous and can breed year-round. However, peaks in calving during the year do occur, which indicates possible seasonal effects on fertility that are most likely the result of temperature, photoperiod, and nutritional interactions. The impact of these effects is seen in buffaloes that calve in winter and spring and do not exhibit postpartum estrous cycles as early as cows that calve in summer and fall. Those calving in winter and spring would be returning to reproductive function during the summer months when high temperatures, increased photoperiods, and elevated prolactin levels might prolong periods of anestrus. Moreover, high temperatures (heat stress) may contribute to reduced sexual activity of male buffaloes during this time. In tropical regions where water buffaloes are maintained, conception rates have been observed to be greatest 2–4 months following the peak in the rainy season. This coincides with cooler temperatures and increasing forage availability.

Yak (*Bos grunniens*)

Yaks are considered seasonally polyestrous in their native environments, although female yak showing only a single estrus in a season, even if mating and conception does not occur, is not uncommon. The driving force affecting the onset and end of the breeding season is primarily climatic factors including forage availability and location (latitude). When ambient temperatures and vegetation increase as the winter thaw progresses, females will show an increase in body condition and weight gain, which can initiate cyclicity. The breeding season begins in June and reaches its peak in July and August (in China and upper Mongolia), when temperatures are highest and forage availability is maximal. Estrous activity decreases in frequency and generally stops around November. As the yak is usually found at high altitude, it has been observed that at lower elevations of 1400 m breeding seasons begin earlier (late May), while at higher elevations of 2700 m breeding seasons tend to begin later (late June).

Sheep (*Ovis aries*) and Goats (*Capra hircus*)

In temperate regions, both sheep and goats are seasonally polyestrous. Seasonality is driven by photoperiodism with increased estrous activity during decreasing day lengths. In tropical regions, sheep and goats tend to breed throughout the year. Nevertheless, even in tropical environments, feed restriction (dry seasons) and high temperatures may cause a suppression of sexual activity, but when rainy seasons resume sexual activity increases. Genetics plays a large role in the breeding seasons of sheep and goats, with some breeds showing longer breeding seasons (sheep: Dorset, Merino, and Rambouillet; goats: Anglo-Nubian) than others with more restrictive breeding seasons (sheep: Southdown, Shropshire, and Hampshire; goats: Toggenburg, Saanen, and French Alpine). Unlike the female, the male is less restrictive with respect to seasonal breeding activity, although sexual activity is greatest in the fall in response to decreasing day length when the secretion of testosterone, testis size, and testicular spermatogenesis increase. As such, melatonin interacts with the neuroendocrine axis mediating the sensitivity of higher brain centers (hypothalamus and pituitary) to the negative feedback effects of steroid hormones in both sheep and goats (see general model depicted in **Figure 1**).

Deer (Cervidae species)

The majority of deer are classified as seasonal breeders that are polyestrous, short-day breeders. Nevertheless, 19 species of the 40 or more existing deer species are found in equatorial regions (between 20° N and 20° S latitude) and exhibit nonseasonal breeding capabilities, although peaks in breeding and fawning seasons differ markedly among tropical deer species – some of which inhabit the same ecosystem. In white-tailed deer (*Odocoileus virginianus*), for example, the distribution of this species extends from 55° N to 18° S latitude, with white-tailed deer in temperate regions breeding strictly seasonally, while those in tropical climates (Caribbean, Central America, and northern part of South America) breeding year-round. In addition to short-day and nonseasonal breeders, one species, Peré David's deer (*Elaphurus davidianus*), has an advanced onset of the breeding season, which begins mid-summer (3–4 months before typical short-day breeders) when day lengths are long, melatonin is low, and prolactin levels are high. Thus, some have referred to the Peré David's deer as a long-day breeder. While photoperiod is the primary factor that mediates seasonal cycles in most deer, an inherent rhythmicity in metabolism, antler and coat (pelage) growth, and hormonal cycles is evident when photoperiods are altered dramatically or eliminated completely. This suggests entrainment of reproductive and metabolic cycles to an endogenous rhythm that is overlaid on the influence of photoperiodic cues. Even in tropical species of deer (e.g., axis deer; *Axis axis*), circannual cycles of antler growth, testis size, and body weights are observed, yet estrous cycles, testicular spermatogenesis, breeding, and fawning occur throughout the year. For comparative purposes, the year-round estrous cycle activity of a strict seasonal breeder

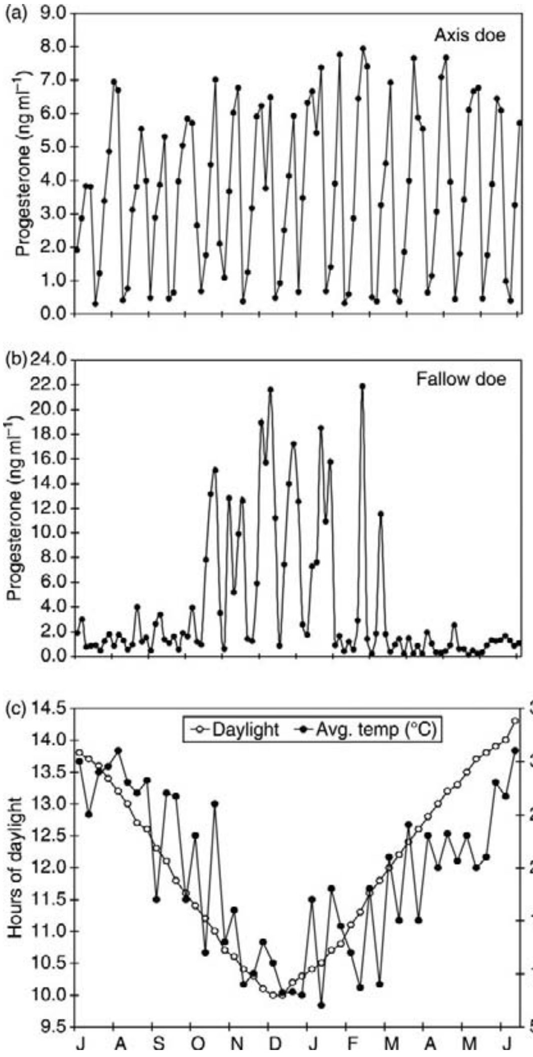

Figure 2 Serum concentrations of progesterone depicting the estrous cycles of nonseasonal (axis deer (a)) and seasonal (fallow deer (b)) species of farmed deer in relation to photoperiod and ambient temperature (c). The axis deer is a tropical deer species that is a nonseasonal breeder and exhibits continuous estrous cycles irrespective of changes in photoperiod (a). Note the presence of ~18 estrous cycles throughout the 346-day sampling period for the axis doe depicted here (serum samples for progesterone analysis were collected twice weekly). In contrast, the seasonally polyestrous fallow doe shown in panel b exhibits only 6–7 estrous cycles annually, which are restricted to the short photoperiods between October and March. Both deer were maintained at the same location at the Texas Agricultural Experiment Station in Overton, Texas (32°16′N; ST Willard and RD Randel, unpublished data).

(e.g., fallow deer (*Dama dama*)) and a nonseasonal breeder (e.g., axis deer) is shown in **Figure 2** for axis and fallow does maintained at the same location in Texas. Irrespective of the nonseasonal nature of some deer species, seasonal peaks in the frequency of breeding and fawning are still noted in tropical deer, and are attributed to climatic and/or nutritional cues to achieve fawning during periods that would favor fawn survival. This is true for all deer, as evidenced by the fact that late-born fawns show lower survival rates due to a shortened lactation (early weaning), low birthweights, and winter death loss, while early-born fawns exhibit similarly low birthweights and may succumb to summer thermal stressors. Thus a window of opportunity exists for fawns born neither too late nor too early, which would favor their survival. For reindeer (*Rangifer tarandus*) in the arctic, highly variable rates of fertility are noted with reproductive success intimately linked to body fat reserves and the timing of births directed toward snow melt and the emergence of new plant growth. As in sheep and goats, reproductive cyclicity in deer is driven by the myriad of hormonal interactions that occur between melatonin, prolactin, GnRH, gonadotropins, and gonadal steroid hormones in response to photoperiodic, metabolic, and/or other exogenous and endogenous cues.

Camel (*Camelus dromedarius*)

Female camels are typically seasonally polyestrous and are induced ovulators. Decreasing day length appears to be the stimulus for reproduction in most regions, although in equatorial locations when adequate rainfall and nutrients are available year-round breeding can occur. It is well documented that by providing sufficient food, nutrition may override the effects of photoperiod and increase sexual receptivity in the female. Male camels also exhibit seasonal sexual activity, with higher concentrations of testosterone and increased spermatogenesis during cooler months. Nevertheless, spermatogenesis can continue throughout the year in the male, reaching a peak during the rutting period. Increased prolactin (hyperprolactinemia) during the nonbreeding season has been suggested as the cause of reduced fertility and sexual activity via prolactin-induced inhibition of gonadotropin (FSH and LH) secretion, although more research in this area is needed.

Llama (*Lama glama*) and Alpaca (*Lama pacos*)

Like camels, llamas and alpacas are induced ovulators that show rhythmic patterns of follicular development and periods of sexual receptivity. In their native highlands of Peru, llamas and alpacas exhibit seasonal sexual cycles from December to March, which are the warmer summer months for this region. However, in these wild settings, males and females are generally together throughout the year, and when females are separated from males in production management settings and pair-mated monthly, they will exhibit sexual activity year-round. Therefore, seasonal breeding can be directly influenced by the continuous contact of females with males, versus when males and females are managed separately. Ovulation rates, fertilization rates, and embryo survival do not appear to be affected by the season in which breeding occurs under these management circumstances. Male llama and alpaca produce fertile ejaculates throughout the year, although the quality of the ejaculate is directly affected by season and nutrient availability, with higher testosterone and greater spermatogenesis during the spring and summer months (the peak breeding periods). The degree to which other environmental cues (visual, olfactory, etc.) may influence reproductive processes in the llama or alpaca is unclear. However, like camels, food availability may directly influence the existence of nonseasonal breeding activity. In North America, llama births are observed throughout the year, reaching a peak during the warmer months of June–November.

Horse (*Equus caballus*)

Mares are seasonally polyestrous, long-day breeders. However, considerable variation exists among breeds and with respect to location (latitude). Some mares exhibit a strict breeding season accompanied by estrus and ovulation, while others may have a defined fertile breeding period preceding and followed by a transitory period in which estrous cycles are present but may not be accompanied by ovulation. Still others may show continuous, year-round periods of estrus and ovulation such as for those mares maintained in equatorial regions. It is well accepted that photoperiod is the primary regulatory mechanism controlling seasonal breeding in the mare as mediated by the hormonal interactions of melatonin, prolactin, GnRH, FSH, LH, and estradiol. Unlike the mare, the stallion does not show as defined a breeding season, with fertile ejaculates capable of being collected throughout the year. Nonetheless, seasonal differences in reaction time, mounting frequency, testis size, semen volume, numbers of spermatozoa, and other semen quality characteristics are observed in the stallion, decreasing during short photoperiods and increasing during long photoperiods.

Swine (*Sus domesticus*)

Swine are polyestrous and nonseasonal. Nevertheless, fertility (mean litter size) declines sharply when photoperiods are long and temperatures become elevated (summer months). In addition to effects on litter size, increased ambient temperatures can cause sperm output and the motility of spermatozoa in the boar to decrease, which undoubtedly contribute to a decrease in fertilization rate and subsequently litter size. Unlike dairy cattle, which show a decrease in the duration of estrus during the hotter summer months, periods of estrus in sows and gilts are longest during summer and shortest in winter. Today, any traces of seasonality in swine breeds have been, for the most part, completely controlled or eliminated due to the enclosed housing environments within which most swine are currently maintained.

Control of Estrous Cycles: Synchronization of Estrus

Z Z Xu, Livestock Improvement Corporation Ltd., Hamilton, New Zealand

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Techniques for synchronizing the onset of estrus in dairy cattle and other species have been available since the 1960s. Research effort to improve the performance of estrus synchronization programs continues to this day and more work is required to make estrus synchronization more acceptable on the farm. The reasons for using estrus control vary between breeds and species and between different farming systems. In dairy cattle, estrus synchronization is often used to aid mating management by improving the efficiency and accuracy of detection of estrus (heat) or by reducing the labor requirement for estrus detection. Estrus synchronization is especially useful in small herds with year-round calving where there may be only one animal in estrus at any given time or in animals, such as nulliparous heifers on pasture, that cannot be easily accessed for estrus detection. Estrus synchronization can also be used to increase the percentage of cattle conceiving within a defined period of time. This is achieved by improving the efficiency and accuracy of estrus detection and by allowing most eligible cattle in a herd to be bred within a few days rather than spread over an entire estrus cycle. Another important usage of estrus synchronization in dairy cattle is to synchronize recipient animals for embryo transfer so that the desired number of recipients at the appropriate stage of the estrous cycle are available. There are other likely benefits from estrus synchronization in dairy cattle, such as facilitating the adoption of treatments or management practices that must be implemented at a specific stage of pregnancy or lactation.

A successful estrus synchronization program should have the following features:

- easy implementation with minimal distress to animals;
- applicability to animals of different physiological status, for example, cyclic versus noncyclic;
- precise onset of estrus to minimize or eliminate estrus detection;
- no detrimental effect on reproductive performance compared with that achieved under the current system;
- cost-effectiveness relative to the objectives to be achieved.

This article discusses the techniques available to synchronize dairy cattle for breeding after detection of estrus. Techniques for synchronizing ovulation so that breeding can be carried out at a fixed time after treatment without estrus detection are discussed elsewhere (*See* **Reproduction, Events and Management**: Control of Estrous Cycles: Synchronization of Ovulation and Insemination). Ovulation synchronization removes the need for estrus detection and is well suited for production systems where accurate estrus detection is difficult and costly. However, a successful ovulation synchronization program usually involves synchronization of follicular wave development, which requires additional treatments with hormones. There may be semen wastage associated with ovulation synchronization because not all treated animals ovulate around the time of artificial insemination (AI).

Principles of Estrus Control

During each bovine estrus cycle, there are characteristic changes in sexual behaviors, follicular development, and the circulating profiles of several reproductive hormones (*see* **Reproduction, Events and Management**: Estrous Cycles: Characteristics). Among all the reproductive hormones, progesterone can be considered as the main ‘orchestrator’ of events during an estrus cycle. During the luteal phase of the estrus cycle when circulating progesterone concentration is high, no estrous behavior or ovulation occurs. The decrease in circulating progesterone concentration after the onset of luteolysis relieves the reproductive system from the negative feedback control of progesterone and, consequently, estrous behavior and ovulation ensue within a few days. Therefore, estrus control mainly involves manipulating the circulating concentrations of progesterone. This can be achieved either by artificially prolonging the luteal phase of the estrus cycle using exogenous progesterone or a synthetic progestogen or by shortening the luteal phase using prostaglandin $F_{2\alpha}$ (PG) or one of its analogues, or by a combination of both mechanisms.

Estrus Control Using Progestogens

For a group of cattle at random stages of the estrus cycle, treatment with progestogen for more than 14 days will produce a synchronized onset of estrus within 2–3 days after cessation of the progestogen treatment. The progestogen treatment prevents cows whose corpora lutea (CLs) undergo spontaneous luteolysis during the treatment period (cows on day 5 or later of the estrus cycle at treatment initiation) from showing estrous behavior and ovulating until after the end of treatment. For animals in the early stage of the estrus cycle (days 0–4), the progestogen treatment either prevents the formation of CLs or shortens the life span of freshly formed CLs.

Early studies on estrus synchronization with progestogens involved daily injection of sufficient amounts of progesterone or the feeding of orally active and highly potent progestogens, such as melengestrol acetate (MGA). The development of progestogen application devices, including the norgestomet ear implant, the progesterone-releasing intravaginal device (PRID), and the controlled internal drug release (CIDR) device, has facilitated the use of progestogens for estrus synchronization in dairy cattle. However, a common adverse effect of estrus synchronization with progestogen alone is the reduction in conception rate at the synchronized estrus. The longer the duration of progestogen treatment, the better the synchrony, but the lower the conception rate. It is now known through studies of follicular dynamics using ultrasonography that the reduction in conception rate at the synchronized estrus is due to the development of persistent dominant follicles. The doses of progestogens administered in these programs, while effective in suppressing estrus and ovulation, are ineffective in suppressing the development of persistent dominant follicles in the absence of a functional CLs. Oocytes from persistent dominant follicles can be fertilized, but the resulting embryos have reduced developmental capability. As a result, estrus synchronization programs using progestogens alone are no longer widely used commercially.

Estrus Control Using Prostaglandin

The luteolytic property of PG and its analogues was discovered in the early 1970s. This was followed by numerous studies on the use of PG for estrus synchronization. Several PG products are licensed for use on dairy cattle and there does not appear to be significant differences among products in their efficacy for estrus synchronization. A single injection of PG will reliably induce regression of the CLs between days 7 and 18 of the estrus cycle. Regression of the CLs results in a drop in circulating progesterone concentration. This allows the normal sequence of physiological and endocrinological events associated with the follicular phase to proceed, leading to estrus and ovulation. However, PG is not effective at all stages of the estrus cycle. It has no consequence if administered after the spontaneous onset of luteolysis. The developing CLs before day 5 of the estrus cycle are not responsive to PG and young CLs (days 5 and 6) are less responsive to PG than mature CLs. Consequently, about two-thirds of cows treated with a single injection of PG can theoretically show estrus over a 3-day period. Estrous response to PG injections can be lower in *Bos indicus* than in *Bos taurus*, which may be related to poor estrus expression in *B. indicus* rather than luteal responsiveness to PG.

Several approaches have been developed to circumvent the problem that not all cows in a group will respond to a single PG treatment (**Figure 1**). The most widely used approach is to administer two injections of PG 11–14 days apart (**Figure 1**, program (1)). This treatment program ensures that all animals are at a stage of the estrus cycle when they are capable of responding to the second PG treatment, irrespective of whether they have responded to the first PG treatment or not. A variation of the above program is to treat all cattle with PG and breed on detection of estrus, followed by retreatment 11 days later of those that have not responded to the first PG (**Figure 1**, program (2)). A third approach is to mate cows for 5–7 days on detection of estrus and then to treat with PG animals that have not been mated (**Figure 1**, program (3)). Another approach is to treat only cows that are identified, using rectal palpation, ultrasonography, or progesterone measurement, to have responsive CLs. This approach is not often used systematically at the herd level because of errors in, and costs associated with, identifying cows with responsive CLs.

Initially, it was hoped that the double-PG program would result in a synchronized onset of estrus that was precise enough for a single fixed-time insemination to achieve an acceptable conception rate. Such a hope has never been realized because the interval from PG injection to onset of estrus is influenced, among other things, by the developmental stage of the dominant follicle at the time of PG treatment. In nonlactating heifers, estrous response rate

within 7 days after the second PG treatment can exceed 90% with a large peak response (up to 60%) between 48 and 72 h. By contrast, estrous response of lactating dairy cows to the double-PG treatment is inconsistent and less precise compared with that of heifers (**Table 1**). The percentage of cows that are noncyclic at the time of PG treatment can affect the estrous response. Stage of the estrus cycle at the time of PG treatment can also affect estrous response, with advanced stages of the luteal phase being associated with increased estrous response rate (**Table 2**). Thus, a 14-day interval between the two PG treatments will result in a higher estrous response rate compared with an 11-day interval due to an increase in the proportion of animals in the middle to late stages of the luteal phase. Progesterone supplementation for 5 days before the second PG injection can affect the pattern of onset of estrus and increase the estrous response rate (**Table 1**). The increase in estrous response rate mainly occurs in cows in the early to middle stages of the luteal phase (**Table 2**).

Many studies have found that conception rate after PG treatment is normal or even improved compared with nonsynchronized animals. Some of the improvement in conception rate could be due to improved estrus detection accuracy in synchronized cows. In herds with high estrus detection efficiency and accuracy, estrus synchronization with PG can reduce conception rate. The reduction in conception rate mainly occurs in cows in the early to middle stages of the estrus cycle at the time of the second PG injection. Therefore, it is not the PG treatment *per se* that reduces conception rate, rather the reduction is probably caused by shortening of the luteal phase, thus reducing the total amount of progesterone the reproductive system is exposed to before ovulation. The reduction in conception rate can be largely eliminated by supplementing progesterone for 5 days before the second PG injection (**Table 2**).

In some countries, PG is the only drug that is licensed for estrus synchronization in lactating dairy cows. Systematic breeding programs based on PG have been developed. Targeted breeding is a systematic breeding program that is advocated by the manufacturer of Lutalyse, Pharmacia-Upjohn (now a division of Pfizer) (**Figure 1**, program (4)). It consists of three PG injections at 14-day intervals. For simplicity of implementation in nonseasonal herds, PG is usually administered on 1 day of the week to all cows that qualify in that week. To get more cows bred early, the first set-up injection of PG could be given to cows that are between 7 and 14 days before the end of the voluntary waiting period. Cows are not mated after the first set-up injection. The set-up injection ensures that cows will be in a stage of the estrus cycle when the CLs are responsive to the second PG injection. The second PG injection is administered 14 days later and cows are mated after detection of estrus. Those that have not been detected in estrus after the second PG treatment are given a third PG injection 14 days later, and the cycle can continue. For the targeted breeding program, a fixed-time insemination is carried out at 80 h after the third PG injection on cows that have not displayed estrus by that time. Alternatively,

Table 2 Effects of stage of the estrous cycle at second PG and progesterone supplementation for 5 days before second PG on ORR (%) and CR (%) of postpartum lactating cows synchronized with two injections of PG 14 days apart

	No_progesterone		*Progesterone*	
Stage of estrous cycle	*ORR*	*CR*	*ORR*	*CR*
Days 5–9	75.9	52.3	86.8[a]	64.8[b]

Days 14–19	93.1	71.3	94.3	71.4

[a] $p < 0.05$ compared with the corresponding value for cows in the no_progesterone group.
[b] $p < 0.1$ compared with the corresponding value for cows in the no_progesterone group.
CR, conception rate; ORR, estrous response rate; PG, prostaglandin $F_{2\alpha}$.
From Xu ZZ, Burton LJ, and Macmillan KL (1997) Reproductive performance of lactating dairy cows following estrus synchronization regimens with $PGF_{2\alpha}$ and progesterone. *Theriogenology* 47: 687–701.

the first PG injection in the targeted breeding program could be given to those cows that have just passed the voluntary waiting period and cows are mated after detection of estrus. This treatment program will be cheaper due to the reduced total number of PG injections, but the interval from calving to first AI will be longer because only two-thirds of the cows can potentially respond to the first PG injection.

Combination Treatment Programs

To improve the precision of synchrony and to reduce the adverse effects on fertility, various treatment programs involving a combination of two or more drugs have been developed. Some of the popular combination programs for synchronizing estrus are discussed here.

Progestogen and Prostaglandin

Progestogen in combination with PG is a widely used combination treatment program for estrus synchronization. It usually involves a short period (commonly 6–8 days) of progestogen treatment with a PG injection 1–2 days before or at the time of termination of the progestogen treatment (**Figure 2**, program (5)). This combination program ensures that, at the time of PG injection, animals either do not have functional CLs or have CLs that are responsive to PG. Most treated animals (85% or more) will show estrous behaviors between 2 and 5 days after the end of treatment. The time and the magnitude of the peak estrous response are affected by when PG is administered relative to the termination of progestogen treatment. If PG is injected 1–2 days before the end of progestogen treatment, peak estrous response occurs on the second day after progestogen treatment, whereas it occurs on the third day if PG is injected at termination of progestogen treatment. Conception rate to inseminations at the synchronized estrus has been reported to be normal or slightly reduced, but the reduction is generally less compared with the situation in which long-term progestogen treatment is used for synchronization. Persistent dominant follicles can still develop in some animals that are in the late stage of the estrus cycle at the start of progestogen treatment.

Another combination program involving progestogen and prostaglandin is to presynchronize animals with a long-term (e.g., 14 days) progestogen treatment, followed by an injection of PG during the late luteal phase of the synchronized cycle (e.g., 17–18 days after the end of the progestogen treatment) (**Figure 2**, program (6)). This program takes advantage of the ability of a long-term progestogen treatment to precisely synchronize estrus and the high estrous response and normal fertility when PG is administered in the late luteal phase (**Table 2**). However, this program requires that progestogen treatment be initiated more than 30 days before the start of breeding when many postpartum cows may have not resumed ovarian cyclicity. Therefore, this program may not be well suited for postpartum lactating dairy cows.

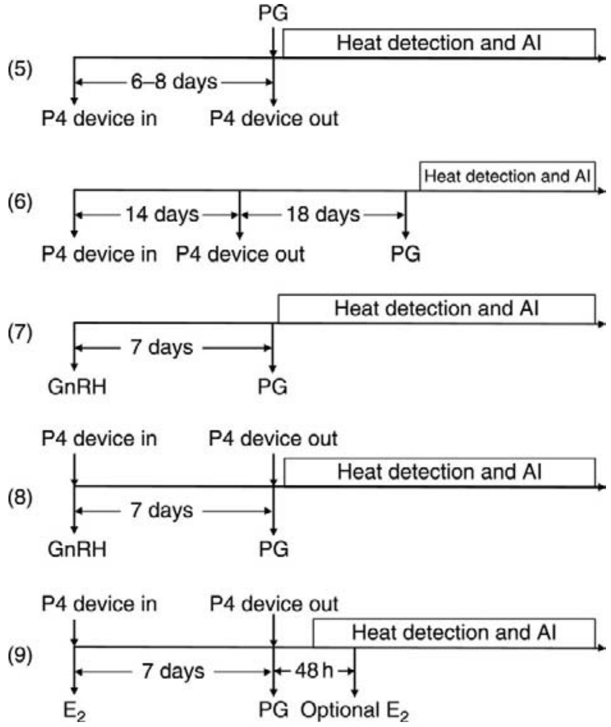

Figure 2 Diagrammatic illustration of the various estrus synchronization programs involving a combination of two or more hormones. PG, prostaglandin $F_{2\alpha}$ or its analogue; GnRH, gonadotropin-releasing hormone; P4, progesterone or synthetic progestogen; E_2, estradiol-17β or its derivatives; AI, artificial insemination.

Estrogen and Progestogen

Studies have shown that an injection of progestogen and estrogen at the start of an estrus synchronization program using progestogen can reduce the duration of progestogen treatment from >14 to 9 days. This has formed the basis for the Synchro-Mate-B (SMB) treatment for estrus synchronization in beef cattle and dairy heifers. The SMB program involves a 9-day treatment with an ear implant containing 6 mg of norgestomet plus an injection of 5 mg of estradiol valerate and 3 mg norgestomet at the time of implant insertion. The injection of estradiol valerate and norgestomet serves two functions. First, the injection causes regression of large antral follicles and initiation of a new follicular wave 4–5 days after treatment so that a newly developed dominant follicle is available for ovulation after the 9-day treatment program. Second, the injection, presumably the estradiol valerate in the injection, causes premature luteolysis of CLs during the treatment period, irrespective of the stage of the estrus cycle at the start of

SMB treatment. Estrogen induces luteolysis by stimulating PG secretion from the uterus. In addition, progestogen treatment during metestrus can also prevent normal CLs development in some animals. Estrous response following SMB treatment is typically greater than 90% and fixed-time insemination between 48 and 54 h after implant removal can achieve acceptable reproductive performance. However, SMB has been withdrawn from the market.

Gonadotropin-Releasing Hormone and Prostaglandin

Studies, mainly in North America, have shown that treatment with gonadotropin-releasing hormone (GnRH) followed 7 days later by PG can be used for estrus synchronization (**Figure 2**, program (7)). The dose of GnRH used in this program is typically half of that recommended for treating follicular cysts. The GnRH treatment induces ovulation of existing dominant follicles and the formation of new or accessory CLs. This prevents most animals in the late luteal and follicular phases of the estrus cycle from showing estrus before PG injection. However, between 5 and 10% of treated cows can still show estrus between the GnRH and PG treatment, thus reducing the effectiveness of this program for estrous synchronization. Nevertheless, some studies have shown similar or improved reproductive performance after this program compared with the double-PG program.

Progestogen, gonadotropin-releasing hormone, and Prostaglandin

Studies in New Zealand and Ireland have investigated synchronization programs that incorporate progesterone treatment between GnRH and PG injections (**Figure 2**, program (8)). A CIDR device is inserted at the time of GnRH injection and removed at PG injection. The progesterone treatment prevents estrus and ovulation before PG injection and may also improve conception rate at the synchronized estrus by increasing circulating progesterone concentrations in cows without a functional CLs. An estrous response rate of greater than 90% has been obtained and the conception rate at the synchronized estrus is similar to that of nonsynchronized herd mates inseminated at detected estrus.

Estrogen, Progestogen, and Prostaglandin

Estrogen has been used at the beginning of combination treatment programs involving progestogen and PG (**Figure 2**, program (9)). The purpose of this estrogen treatment is to regress dominant follicles that are present at the time of estrogen treatment so that freshly developed dominant follicles are ready to ovulate after the program. A gelatin capsule containing 10 mg of estradiol benzoate is developed for intravaginal use together with the CIDR device or PRID. Injection of 5 mg of estradiol-17β or 2 mg of estradiol benzoate has also been found to improve the precision of synchrony and conception rate compared with no estrogen treatment. Estrogen has also been used after the end of progestogen and PG treatment to increase the precision of onset of estrus. An injection of 1 mg of estradiol benzoate 48 h after the end of progesterone and PG treatment can significantly increase the percentage of cows showing estrus between 48 and 72 h (85 vs. 57%).

However, in 2006, the European Union banned the use of estradiol and its derivatives for estrus synchronization in food-producing animals. This has led other countries, such as New Zealand and Australia, to adopt the EU Directive and ban the use of estrogens for estrus synchronization. Consequently, the use of GnRH at the beginning of a progesterone–PG program to increase the precision of onset of estrus and/or after the progesterone–PG program to synchronize ovulation has gained popularity.

Treatment of Noncyclic Cows

In a group of cows eligible for breeding, some may be noncyclic. The problem of noncyclic cows at the start of the breeding season is particularly severe in high-producing dairy cows or in seasonal dairy cows grazing on pasture. Therefore, an effective estrus synchronization program should also be able to induce estrus and ovulation in noncyclic cows.

In New Zealand, a popular program for treating noncyclic cows involves progesterone treatment in the form of an intravaginal CIDR device for 6–7 days, followed by an injection of 1 mg of estradiol benzoate either 24 or 48 h after CIDR removal. An estrous response rate of close to 90% and conception rate of around 35% have been obtained with this treatment program. However, this program does not work for cyclic cows and special effort is therefore needed to separate cyclic from noncyclic cows.

Recent studies have shown that a combination program involving GnRH, progesterone, PG, and estradiol may be used to synchronize all cows in a herd regardless of their cyclic status. Cows are treated with a CIDR device for 7 days, along with GnRH at CIDR insertion and PG at CIDR removal. At 48 h after CIDR removal, 1 mg of estradiol benzoate is injected to cows that have not been detected in estrus by that time. This program has been tested for treating noncyclic cows due to nutritional stress and has been found to result in better estrous response (93 vs. 89%) and conception rate (47 vs. 29%) than the program based on progesterone and estradiol benzoate only. The GnRH and PG used in this program could also be beneficial for treating noncyclic cows due to ovarian cysts and uterine infection.

Following the ban on the use of estrogens in food-producing animals, the available programs for both cyclic and noncyclic cows in New Zealand have been changed to Ovsynch-type programs involving a combination of GnRH and PG, with or without progesterone in the form of the CIDR device. A second GnRH injection around 56 h after PG and fixed-time insemination at 72 h may improve pregnancy rate compared with insemination after detected estrus.

Practical Considerations

Despite the aforementioned advantages from using estrus synchronization, it remains a major challenge to make this technique widely accepted by commercial dairy producers. Costs of drugs and labor for implementing an estrus synchronization program are among the first things considered by dairy farmers when deciding whether to use estrus synchronization. Estrus detection can be more difficult in a large group of synchronized cattle because so many animals are in estrus at the same time and it is difficult to identify those that are in genuine estrus. This problem can be solved by developing synchronization programs that allow fixed-time insemination. Herd managers need to have good organizational skills and some technical knowledge of the program in order to implement a successful estrus synchronization program. Good communication and cooperation among herd managers, veterinarians, and AI technicians are essential. Good record keeping is also important because the use of PG on pregnant animals will lead to abortion.

The Future

The challenge for future research on estrus synchronization will be to increase the estrous response rate, to improve the precision of synchrony, and at the same time to maintain and increase conception rate at the synchronized estrus. A reduction in conception rate at the synchronized estrus is a common feature following most estrus synchronization programs. Although many studies have reported improved reproductive performance after estrus synchronization compared with nonsynchronized control animals, most of this increase is probably due to improvement in the efficiency and accuracy of estrus detection and not due to improved fertility. The objective is to achieve a conception rate that equals the conception rate to inseminations at correctly detected natural estrus or to natural mating. It is likely that achieving this objective will require the use of multiple drugs. Therefore, the other challenge for research is to develop smart drug delivery systems that simplify the implementation of estrus synchronization programs. Furthermore, the development of semen products that allow sperm to survive for several days in the female reproductive tract will eliminate the need for tight synchrony. Finally, the challenge will be even greater to develop estrus synchronization systems that can effectively synchronize the onset of estrus in those animals that return after a synchronized insemination.

Introduction

Intensive genetic selection for milk production without attention to reproductive performance has contributed to an inverse relationship between milk production and reproduction. Inclusion of productive life and daughter pregnancy rate and, more recently, the availability of sire conception rate, as a measure of phenotypic service-sire fertility, appear to have reduced the rate of decline in fertility in the United States. Reproductive management of the lactating dairy cow has been a challenge because of poor expression of estrus and low fertility to insemination at a detected estrus. The duration of estrus is reduced as milk production increases, and the frequency of double ovulations and subsequent occurrence of twins is also increased in cows with high levels of milk production at the time of the breeding period. The high-producing dairy cow of today expresses estrus for approximately 7 h during which time an average of 6.5 standing events take place with an accumulative period of standing of 20 s (i.e., 3 s per standing event).

Pregnancy rate over a 21-day period for the national herd of dairy cows in the United States is approximately 16.2%. The component parts of pregnancy rate are the rate of estrus detection and conception rate. Technology is available for systems to detect estrus accurately, but a major issue is that lactating dairy cows do not display strong symptoms of estrus. Expression of estrus has been affected adversely by high milk production and associated metabolism of hormones, as well as housing facilities (e.g., concrete floors) that reduce the cow's willingness to be sexually active. An additional challenge is the high occurrence of nonovulatory dairy cows that either have reoccurring follicle waves without ovulation or develop ovarian cysts.

A major advance in reproductive management that has addressed how to improve pregnancy rate has been the development of timed artificial insemination (TAI) programs based on the development of systems to control or program optimal development of ovarian follicles, induce ovulation, and develop a corpus luteum (CL) capable of supporting pregnancy. The component pharmaceutical agents available to the dairy industry in many countries for use with dairy cattle are gonadotropin-releasing hormone (GnRH), luteolytic prostaglandins, and intravaginal progesterone (using a controlled intravaginal drug release (CIDR) insert, or similar device). These are pharmaceuticals that mimic the actions of the cow's endogenous hormones, are physiological, and pose no health hazard to the cow. The original TAI protocol is the Ovsynch procedure. This protocol has been in use for approximately 12 years. During this period, both basic and applied research has led to major advancements in optimizing the system. As a consequence, pregnancy responses have increased, the system has been extended to resynchronization of nonpregnant cows, and programs have been developed for TAI in dairy heifers. The dynamics of various cow factors such as body condition score, parity, and health status in the transitional-periparturient period have been shown to influence pregnancy rates in the controlled breeding program. The present objective is to update major advancements that will increase reproductive performance in controlled breeding in dairy cattle.

Lactating Dairy Cattle

It is essential that producers and veterinarians understand the physiological reasons why certain components of the reproductive management program are able to improve reproductive performance or conversely why a misunderstanding of the program can lead to catastrophic pregnancy results. No one reproductive breeding program is practical and economically optimal for all dairy production units due to differences in available facilities, size of the unit, labor that places reproduction as a high priority, and a functionally dynamic record system.

Optimizing Stage of the Estrous Cycle at the Onset of Ovsynch

The original Ovsynch program involved two injections of GnRH administered 7 days before and 48 h after an injection of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), and cows were inseminated 16–20 h after the second injection of GnRH. If TAI in the Ovsynch protocol is performed at the same time as the second GnRH injection, then the protocol is referred to as Co-synch.

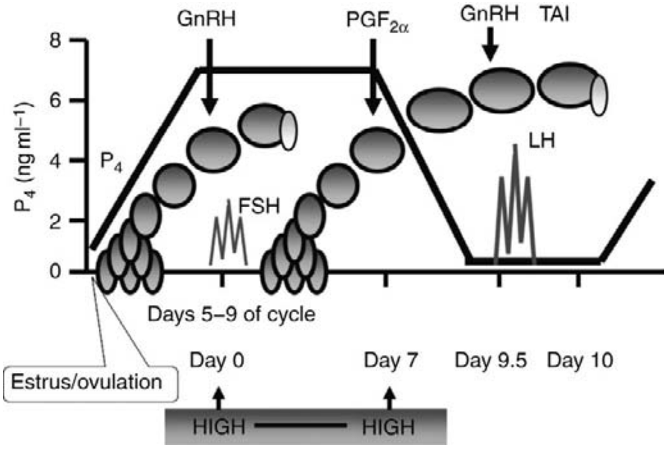

Figure 1 Follicle dynamics and hormonal responses to the Ovsynch protocol. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; PGF$_{2\alpha}$, prostaglandin F$_{2\alpha}$; P$_4$, Progesterone; TAI, timed artificial insemination.

Optimization of stage of the estrous cycle (i.e., days 5–9) at the onset of the Ovsynch protocol is important to achieve a subsequent synchronized ovulation at the second GnRH preceding the TAI (**Figure 1**). Programming the stage of the estrous cycle at the time the Ovsynch protocol is implemented (e.g., days 5–9 of estrous cycle) ensures there is progesterone availability throughout the period between the first injection of GnRH and injection of PGF$_{2\alpha}$, and that there is a CL to respond to the luteolytic injection of PGF$_{2\alpha}$ (**Figure 1**). The continual exposure to progesterone is important for sequentially programming the brain, oviduct, and uterus with the appropriate changes in hormones, receptors, and secretions leading to an induced ovulation, fertilization, and development of an embryo capable of maintaining a pregnancy with minimal embryonic and fetal losses. Programming the start of the Ovsynch protocol to occur between days 5 and 9 of the estrous cycle increases the probability that the first injection of GnRH will induce ovulation of the first wave follicle and recruitment of a new follicle wave (**Figure 1**), which upon induction of ovulation in response to the second GnRH increases the probability of producing a viable oocyte for fertilization and a robust CL. Indeed ovulation of the first follicle wave results in the presence of both the original CL and an accessory CL, induced by the GnRH injection, which are responsive to the injection of PGF$_{2\alpha}$.

The Ovsynch protocol preceded by a PGF$_{2\alpha}$ presynchronization program (Presynch–Ovsynch) has become the nucleus program for reproductive management in the industry. Successful use of such a program is highly dependent upon obtaining good compliance in implementing all component parts of the protocol. The original Presynch–Ovsynch program entailed two injections of PGF$_{2\alpha}$ given 14 days apart with the Ovsynch protocol initiated 12 days after the second injection of PGF$_{2\alpha}$ for presynchronization (**Figure 2**). This system increased pregnancy rates compared to Ovsynch alone for

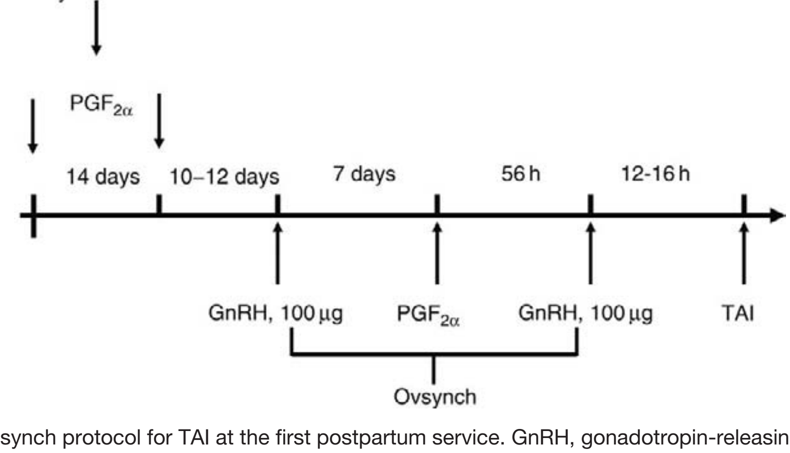

Figure 2 Presynch/Ovsynch protocol for TAI at the first postpartum service. GnRH, gonadotropin-releasing hormone; PGF$_{2\alpha}$, prostaglandin F$_{2\alpha}$; TAI, timed artificial insemination.

AI, artificial insemination; CIDR, controlled intravaginal drug release; GnRH, gonadotropin-releasing hormone.

the reasons outlined above, when the Ovsynch protocol is initiated in early diestrus (**Table 1**). Dairy producers were keen to extend the period when Ovsynch was initiated to a 14-day interval such that four of the five sequential hormonal injections would be given on the same day of week. Field experiences indicate that 60% of detected estruses occur on days 3–6 after the second injection of $PGF_{2\alpha}$ of presynchronization. A recent study indicated that an 11-day interval after presynchronization (i.e., cows would be predominately 5–8 days of the estrous cycle) is better than a 14-day interval to begin the TAI protocol. The overall ovulation rate in response to the first injection of GnRH was greater for an 11-day than a 14-day interval (62 vs. 44.7%). This was attributed to GnRH being given at 11 days when the first wave follicle will ovulate whereas the 14-day interval increased the proportion of cows injected early in the second follicle wave at a time the follicle was developed insufficiently to ovulate in response to GnRH. The latter follicle would continue to develop and be slightly more aged and/or dominant compared to the newly recruited follicle from the day 11 injection interval for GnRH. Indeed pregnancy per TAI was 6.6% greater for the 11-day interval (40.1 vs. 33.5% at day 38 after TAI; **Table 1**). Thus, subtle changes in presynchronization protocols can cause substantial increases in pregnancy rate, and the optimal period to start the Ovsynch protocol is 10–12 days after the second $PGF_{2\alpha}$ injection of presynchronization (**Figure 2**).

Interval from $PGF_{2\alpha}$ to Ovulatory Injection of GnRH and Timing of AI

It has been well documented that cows should be inseminated 8–16 h after the onset of estrus for an optimal conception rate. The preovulatory surge of luteinizing hormone (LH) occurs very close to the onset of estrus with ovulation occurring approximately 28 h after the LH surge. It is important to recognize that the second injection of GnRH of an Ovsynch program is analogous to the onset of estrus since an LH surge is induced immediately. Indeed maximal rate of pregnancies per artificial insemination (AI) was achieved when a timed insemination was made at 16 h after the injection of GnRH. In contrast, percent pregnant to AI was decreased when inseminations were made at the time of GnRH injection or 28 h later. Producers often favor the convenience of carrying out a TAI at the time of GnRH injection (i.e., referred to as a Co-synch program) to reduce the number of times cows need to be held up. Alternatively, some producers prefer to perform TAI on the following day at approximately 24–28 h after the GnRH injection for convenience. Either option likely will reduce percent pregnant to AI. The importance of the correct timing is indicated by a study completed at the University of Wisconsin. All cows were presynchronized with two injections of $PGF_{2\alpha,}$ and the Ovsynch protocol was started 11 days later. The optimal timing program was to inject GnRH 56 h after the injection of $PGF_{2\alpha}$ and inseminate the cows 16 h after the injection of GnRH, which was 72 h after the injection of $PGF_{2\alpha}$ (see **Figure 2**). Percent pregnant to AI was 36.1% compared to Co-synch 48 h (26.7%) and to 72 h (27.3%) programs. The last two programs injected GnRH and TAI concurrently at 48 or 72 h, respectively. Clearly, subtle changes in the timing of the GnRH injection and time of insemination result in substantial differences in percent pregnant to AI responses. If a Co-synch program is to be followed, one needs to understand the physiology of the injection sequence so that functionally active ovarian follicles are at an optimal stage analogous to a follicle in the close periestrus period when GnRH/TAI is performed.

Resynchronization of Nonpregnant Cows Following First Service

A reproductive management challenge following first service is to reinseminate cows that did not conceive as quickly as possible. The same principles to optimize the Presynch–Ovsynch program are applicable to development of a resynchronization program. However, a resynchronization system is somewhat constrained in that programming nonpregnant cows to ovulate must be done in a manner that will not interfere with cows that are pregnant to first service. Thus, accurate identification of nonpregnant and pregnant cows is important, and timing of the diagnosis is dependent upon the technology applied (i.e., rectal palpation at 35–42 days, ultrasound diagnosis at 30–32 days, blood pregnancy test at 27–30 days (measurement of PAG)). To some degree, there is a natural presynchronization of nonpregnant cows because those detected in estrus have a median return to estrus interval of 22 days in which 64.3% show estrus within 17–24 days after first service. Thus, initiation of Ovsynch at 30 days after first service would mean most cows would be at approximately day 8 of the cycle. GnRH injection would induce ovulation of a first wave follicle and initiate recruitment of a new follicular wave under a high progesterone environment. At 37 days after first service, a decision can be made to inject $PGF_{2\alpha}$ in cows diagnosed nonpregnant (e.g., rectal palpation). These cows would then be injected with GnRH and TAI at 56 and 72 h after the $PGF_{2\alpha}$ injection, respectively.

Several days after first service (days 19, 26, and 33) have been examined to begin resynchronization of nonpregnant cows with Ovsynch. Starting resynchronization on day 33 resulted in the highest pregnancy rate for the second service. Ultrasound technology was used for detection of nonpregnant cows at day 26 or day 33 after first service for the day 19–26 and 33 resynchronization groups, respectively. Hypothetically, the timing of GnRH at day 26 would tend to target the majority of cows too early in their follicle wave (i.e., day 4 of the wave) to induce follicle turnover, whereas at day 33 they would be ovulating potential first or second wave follicles and a sustained progesterone environment would be present for cows potentially returning to estrus between 17 and 24 days after first service. Experimental results clearly document that fertility was increased for the day 33 resynchronization group (i.e., 33.7%) compared to the day 19 and 26 groups (27.1 and 26.6%, respectively). The benefit of the day 33 resynchronization on pregnancy per TAI compared to the day 26 resynchronization group was repeated (39.4 vs. 28.6%; **Table 1**) with the benefit most apparent in primiparous cows. In the latter study, insertion of a CIDR insert in cows without a CL improved pregnancy rate per TAI in the multiparous cows to a level comparable to that of primiparous with or without a CL.

An alternative resynchronization strategy is a more conventional system based solely on pregnancy diagnosis per rectal palpation at day 38 (**Figure 3**). In this scenario, an Ovsynch 72 h Co-synch (GnRH, 7 days later PGF, and 72 h later GnRH and TAI) was initiated at day 38 after first service in three groups of nonpregnant cows (Group 1: control, GnRH; Group 2: received a GnRH injection on day 31 at 7 days before pregnancy diagnosis; Group 3: received a CIDR insert on day 38 that was removed at the time of $PGF_{2\alpha}$ injection; **Figure 3**). Pregnancy rate per TAI was greater and tended to be greater for GnRH/Group 2 (33.6%) and Group 3/CIDR (31.3%) cows than Group 1 (24.6%) cows (**Table 1**). It is likely that presynchronization with a single injection of GnRH at day 31 programmed a new follicle wave and increased the occurrence of a CL at the beginning of the Ovsynch 72 h Co-synch protocol. Insertion of a CIDR insert likely improved the synchronization of ovulation associated with the 72 h Co-synch response because it held ovarian follicles from ovulating prematurely in cows that were in late diestrus at the time the Ovsynch 72 h program was started.

It is clear that several alternatives are available for resynchronization of lactating dairy cows. With the acquisition of new technology for a cow side diagnosis of nonpregnant cows early after insemination (e.g., 27, 28, or 30 days), it will be possible to implement even earlier resynchronization systems for TAI within 3 days (e.g., day

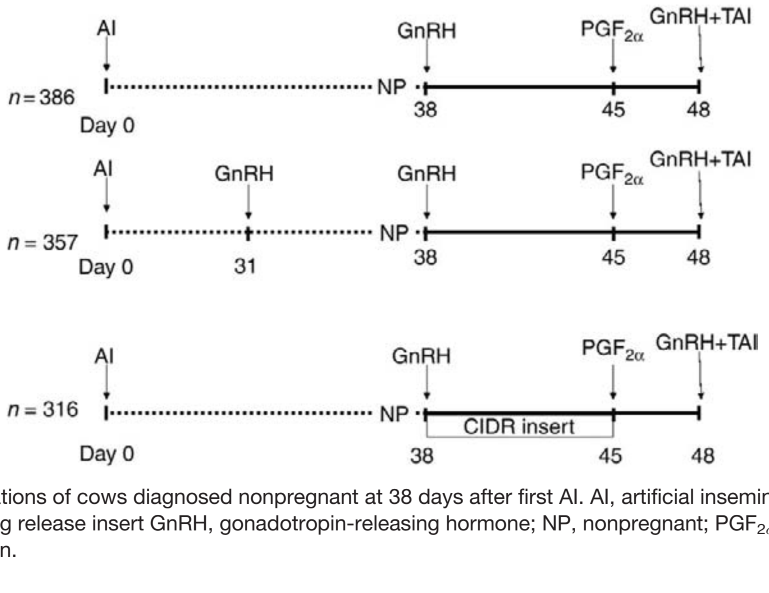

Figure 3 Resynchronizations of cows diagnosed nonpregnant at 38 days after first AI. AI, artificial insemination; CIDR insert, controlled intravaginal drug release insert GnRH, gonadotropin-releasing hormone; NP, nonpregnant; $PGF_{2\alpha}$, prostaglandin $F_{2\alpha}$; TAI, timed artificial insemination.

30, 31, or 33) after the diagnosis of a nonpregnancy. This would offer a reduction in reinsemination interval of 9.5–17 days compared to the promising systems described above.

Timed Artificial Insemination for Dairy Heifers

A major limitation for using AI in dairy replacement heifers is time and effort associated with daily estrus detection. Unfortunately, however, the Ovsynch has resulted in unacceptable pregnancy rates of approximately 38% in dairy heifers (**Table 2**). Compared to lactating cows, heifers have a faster rate of follicular growth and a higher frequency of three wave follicular cycles. Consequently, approximately 57% of the cycle is comprised of times when follicles are unresponsive to the first injection of GnRH. Furthermore, rapid turnover and growth of follicles lead to asynchrony with heifers expressing estrus during different stages of the protocol prior to the second ovulatory injection of GnRH for TAI. Investigators at Ohio State University working with beef cattle deduced that an increase in percent pregnant per TAI could be achieved by insertion of a CIDR insert at the time of GnRH injection and, after 5 days, withdrawing the CIDR insert and injecting $PGF_{2\alpha}$. An extended proestrus period was achieved by allowing a 3-day interval from the time of $PGF_{2\alpha}$ injection to the time of GnRH injection and a concurrent TAI. The entire protocol takes only 8 days to be accomplished. Since the interval from the first GnRH injection and CIDR insertion to $PGF_{2\alpha}$ injection is 5 days, a second injection of $PGF_{2\alpha}$ was given ~12 h after the first $PGF_{2\alpha}$. This program in beef cows resulted in a higher pregnancy rate compared to a 7-day Ovsynch with a CIDR in which the second GnRH and TAI occurred at 60 h. This program has been further modified for use in dairy heifers in which only a single injection of $PGF_{2\alpha}$ is given at the time of CIDR removal (5-day CIDR Co-synch 72 h with one injection of $PGF_{2\alpha}$; **Figure 4**). Pregnancy rates to first and second services at 32 days after TAI were 60.3 and 52.5%, respectively (**Figure 4**). Essentially, 81% (337/416) of the heifers were pregnant after two programmed TAIs following a 5-day CIDR Co-synch 72 h with one injection of $PGF_{2\alpha}$. This is an efficient reproductive management program that successfully synchronizes ovulation for TAI and reduces labor costs associated with estrus detection. Indeed all of the TAI procedures described in **Table 2** incorporated some degree of estrus

detection that is not necessary with the present program. The concept of a 5-day interval between GnRH and $PGF_{2\alpha}$ (i.e., with or without a CIDR insert) and a subsequent 3-day proestrus period (i.e., 72 h Co-synch) warrants investigation in lactating dairy cows.

Conclusion

Tremendous advances have been made in improving milk production, but have in turn resulted in an overall decline in reproductive efficiency for the dairy industry. Problems associated with the cow include inability to properly express estrus and altered hormonal profiles resulting in low conception rates and increased early embryonic death. Coordinated systems of reproductive management offer means to improve herd reproductive performance, and major advances have been made for synchronization of ovulation in both lactating dairy cows and dairy heifers. Such systems are predicated on a greater understanding of the factors controlling follicle development, ovulation, and CL development. The programs as described require the producer, veterinarian, and reproductive management staff to understand the programs and make an effort to obtain a high level of compliance. The platforms used for controlling first service and resynchronized subsequent services in cows that do not conceive provide valuable platforms to implement new technology such as the use of sexed semen, embryo transfer, and cow-side chemical diagnosis of nonpregnant cows. Functional and efficient computer record programs are essential to implement such reproductive management programs. For the research scientist, the reproductive management systems provide the infrastructure to quantify the effects of nutritional, health, and physiological interventions on pregnancy rate. With the advent of new technologies to precisely manipulate reproductive function in lactating dairy cows, dairy producers are presented with a new opportunity. Coordination of management strategies to maximize both milk production and reproductive performance may optimize the economical return of dairy herds, and allow the industry to take complete advantage of the genetic potential to improve milk production through AI.

Mating Management: Detection of Estrus

Introduction

Estrus detection is one of the key components in fertility management programs on dairy farms. Excellent reproductive performance can be defined as the ability to consistently have 90% or more of the cows in a herd conceive and maintain pregnancies in a timely, economically justified manner. On the other hand, low detection rate is strongly associated with poor fertility, long calving interval, intensive replacement of heifers, and reduced genetic progress, resulting in heavy economic losses. Maintaining a consistently high-performing reproductive program requires a substantial investment in management, labor, and other costs, such as semen and pharmaceuticals. The goal of an estrus detection program should be to identify estrus positively and accurately in all cycling cows and to identify all of the cows that are not cycling or are expressing irregular cyclicity. The ultimate goal should be to predict the time of ovulation, thus allowing for insemination that will maximize the opportunity for conception.

Dairy farming is one of the most intensive technologically integrated systems in the world of production agriculture. In general, the market sorts out which technologies offer a competitive advantage and which do not. Most of the aids that have been developed are not reliable or sensitive enough to relieve the farmer from frequent visual observation of the herd. Furthermore, none of the technologies is appropriate for every farm. New approaches are being developed to provide automated systems for estrus detection using remote-sensing technology, but the development of these new tools is in its infancy.

Behavioral Characteristics of Estrus

The expression of estrous behavior is brought about by high systemic concentrations of estradiol-17β produced by the preovulatory follicle, which stimulates behavior coincident with the ovulatory surge of luteinizing hormone. Traditionally, a cow that 'stands' to be mounted is the most definitive behavioral sign of estrus, in particular when reproductive management is based only on artificial insemination (AI). However, 'standing' cannot be the only distinguishing sign of estrus. This is particularly true for silent ovulation (i.e., ovulation without the expression of estrous behavior), which occurs mostly during the postpartum period. Occasionally, pregnant cows exhibit signs of estrus, particularly during middle to late gestation. Also, cows with ovarian follicular cysts may have a hormonal milieu that leads to estrous behavior similar to that of cyclic cows in estrus. Therefore, estrous behaviors other than 'standing' are crucial for accurate identification of estrus coincident with ovulation.

Secondary signs of estrus include attempting to mount other cows, clear mucus discharge from the vulva, swelling and reddening of the vulva from increased blood flow, bellowing, restlessness, trailing other cows, chin resting, sniffing the genitalia of other cows, and lip curling. These signs may serve as clues that cows are near estrus so that they can then be observed more intensely for 'standing' behavior, but cannot be used as a practical predictor of ovulation. Other characteristics are reduction in food intake followed by reduced milk production during estrus, but these are not overt in all animals.

The time of the day and duration of observation are the most important factors for a high detection rate. Traditional management of visual estrus detection is based on a twice-a-day detection regime or observation (20 min each) 3 times a day while taking into account the aforementioned primary and secondary signs of estrous characteristics. Observations are mostly performed in coincidence with each milking. Additional observations are recommended during periods of high activity, such as feeding time or while going to and coming back from the milking parlor. Nevertheless, estrus detection rate in dairy cows is low (<50%) because of limited observation times and the fact that high-yielding dairy cows express shorter duration of estrus.

Automated Systems to Detect Physical Activity

Various approaches have been examined to detect the accurate time of estrus. It includes monitoring of electrical resistance, vaginal and core body temperatures, and progesterone level in plasma or milk, but none of them have yet been implemented in practice. Determination of the onset of estrus is only possible with continuous monitoring for behavioral activity. Based on this concept, few techniques have been developed. The ideal aid should provide continuous surveillance (24 h day^{-1}) of cows, and accurate and automatic identification of the cows in estrus.

Time-Lapse Video Recording

Video recording allows continuous monitoring of behavioral activity. Investigations revealed that cows spent considerably more time walking when in estrus, and less time resting and eating, than when they were not in estrus. Studies with advanced video equipment tested the hourly distribution of onset of estrus. Pooled 6-h intervals demonstrated that the highest frequency of onset of estrus occurs at 1200–1800 and 0600–1200 h in primiparous and multiparous groups, respectively. For a large herd, more cameras are needed because of the resolution of the equipment. Recognition of cows can sometimes be problematic. In addition, the time needed to watch video tapes makes this method not very practical. Time-lapse video recording is mostly used for research rather than for estrus detection in farms.

Pedometer

A pedometer is an electronic device attached to the cow's leg or its neck collar, which measures cow activity (number of steps) in a 24-h day. The potentially useful field application of pedometry is based on the recognition that female mammals display a predictable increase in physical activity when in estrus. Guernsey cows equipped with mechanically activated pedometers were characterized as exhibiting 218% higher physical activity during estrus than during late diestrus and proestrus or during metestrus. Similarly, pedometer has been found to be a practical tool for estrus detection in dairy cows with an average 393% increase in activity at the time of estrus, or approximately 4 times the activity of cows not in estrus when housed in a freestall barn.

Individual cows differ significantly in the amount of activity expressed under the same conditions. A modified pedometer was designed to internally compare the activity change during a specific time interval to the five previous morning or afternoon activity recordings. This modification was implemented to account for the individual activity. **Figure 1** represents a typical activity graph for a complete lactation.

The aim of most reported applications of pedometers was to improve the rates of estrus detection. It was claimed that 70–80% of cows in estrus are detected by pedometer measurements. Pedometry systems that in addition to efficient and accurate estrus identification allow identification of its onset would increase the usefulness of such technology in animal breeding. However, most current pedometry systems do not use real-time data transfer, thus requiring the activity information to be retrieved by an interrogation device. Since retrieval of activity measurements can be performed 2 or 3 times daily, usually at milking, the effectiveness of determining the timing of insemination is not optimal.

An active technology for estrus identification and activity measurements in dairy cows and buffalo was

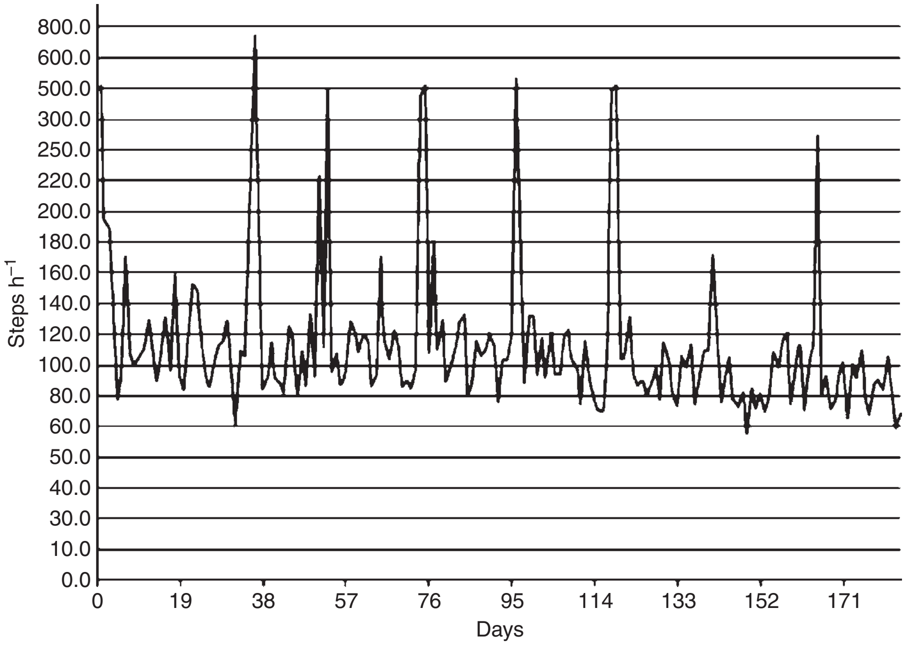

Figure 1 Typical activity graph for the first 175 days of lactation. Reproduced with permission from Nebel RL, Altemose DL, Munkittrick TW, Sprecher DJ, and McGilliard ML (1989) Comparisons of eight on-farm milk progesterone tests. *Theriogenology* 31: 753–764.

developed in the late 1990s and is already being successfully operated (SCR Engineers Ltd., Israel). The technology is based on an integrated neck tag that includes an acceleration sensor, microprocessor, and memory, which enable the recording of a general activity index, which is stored separately in the tag's memory for every 2-h period. This separate recording enables monitoring the cow's activity on a time axis with great accuracy regardless of the time intervals between tag readings. The tag can store data for up to 24 h. The identification unit ('Heatime') is based on an infrared communication method that enables reliable communication. A recent study reported reliability of estrus detection in Holstein heifers with 100% efficiency and 83% accuracy at 1.4 times the threshold value for a 7-day reference period by using a novel radiotelemetric leg pedometer (Gyuho, Comtec, Miyazaki, Japan). The pedometer, powered by a replaceable lithium battery, automatically counted the number of signals generated in 1-h intervals using a pendulum switch (MK-060; Yamasa Tokei, Japan) and temporarily stored the data, which were then read by telemetric receiver (reading ability of 150 m distance) and transferred to a desktop computer.

Pedometry systems that allow prediction of ovulation in addition to efficient and accurate estrus identification will increase the usefulness of such technologies in animal breeding. A study examining the relationship between estrous behavioral parameters, pedometer recordings, and time of ovulation revealed that the increase in the number of steps preceding ovulation, as recorded by the pedometer, rather than other behavioral signs of estrus, could be used to detect estrus and to predict time of ovulation fairly accurately. Cows were equipped with pedometers (Nedap Agri B.V., Groenlo, The Netherlands) that stored number of steps in a 2-h period. Ovaries were examined rectally using an ultrasound scanner. The average interval between onset of pedometer estrus and ovulation was 29.3 ± 3.9 h and ovulation occurred 19.4 ± 4.4 h after the end of pedometer estrus. The interval between onset of pedometer estrus and time of ovulation did not differ between primiparous and multiparous cows. However, the interval between end of pedometer estrus and time of ovulation was shorter for primiparous cows (16.9 ± 3.0 h) than for multiparous cows (20.6 ± 4.5 h), most likely due to the longer duration of estrus in the former. Since the optimal time of AI was found to be 24–12 h before ovulation, based on the above data, inseminations should be performed 5–17 h after the onset of increased activity. Despite the large variation in times from pedometer estrus to ovulation, the pedometer appears to be a promising tool for practical prediction of ovulation as long as the threshold for increased activity is based on the cows' individual activity patterns, and hence could be a tool for improving fertilization rate.

The growing use of computerized dairy management systems and the accurate recording of cow activity by the pedometer system have created new opportunities for the use of cow locomotors as a means of improving the management of both beef and dairy herds. This approach was recently developed by a group of Israeli scientists. Data from serial independent field studies demonstrated that activity data provided by a pedometer system (S.A.E. Tzacham Afikim®, Israel) can serve as a predictor of health problems or stress. Significant differences between pedometric activity of sick and healthy cows were reported in the same herd. It was found that during ketosis, left displaced abomasums, and digestive disorders, walking activity declined several days before the decline in milk production or diagnosis by the herd practitioner. This approach is highly relevant for the early detection of lameness. Clinical lameness causes considerable financial losses for the dairy farm, mostly due to decreased production and delayed estrus and conception. Examination of the pedometer's efficacy at predicting lameness earlier than the appearance of its clinical signs revealed that 46% of the lame cows showed a reduction in pedometric activity (5% or more compared to the average activity recorded through the previous 10 days), 7–10 days prior to the appearance of clinical signs. Given the vast opportunities to improve management routines via the detection of behavior variables, a new behavior sensor has been recently developed by S.A.E. (Tzacham Afikim®), which, in addition to activity (number of steps) for estrus detection, also measures cumulative lying time and lying bouts. For example, this sensor enables the identification of behavioral changes that could indicate calving within 24 h.

Pressure-Sensing Radiotelemetric System

Radiofrequency data communications is the base technology employed by the commercially available pressure-sensing radiotelemetric HeatWatch® system (DDx Inc., Denver, CO, USA) shown in **Figure 2**. A radiotelemetric device attached to each cow consists of a miniaturized radiowave transmitter, powered by a lithium 3-V battery and linked to a pressure sensor enclosed in a hard plastic case that is 5.3 × 8.1 cm and 1.8 cm in height. Each device is secured in a water-resistant pouch, attached to a saddle-shaped nylon mesh patch that is glued with contact-type adhesive to the hair caudal to the sacral region. Activation of the pressure sensor by weight of a mounting herdmate for a minimum of 2 s produces a radiowave transmission (0.4 km range). Transmitted data consist of sensor identification, date (month, day, and year), time (hour and minute), and duration of sensor activation (seconds). Transmitted signals are sent to a microcomputer via a fixed radio antenna. The remote signal receiver should

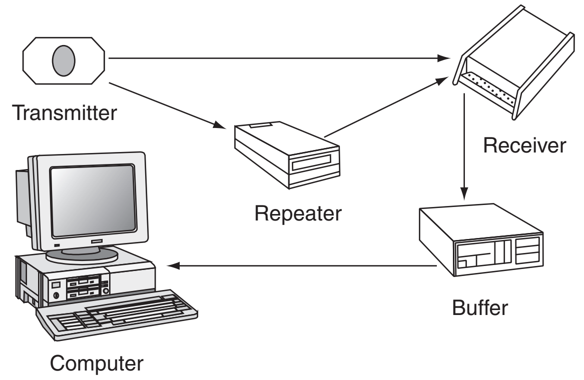

Figure 2 Configuration of the radiotelemetric HeatWatch® system.

be centrally located on each farm to maximize transmission area and situated to minimize transmission interference. Transmitted data from a remote receiver are chronologically stored in a buffer external to the microcomputer and transferred to the microcomputer upon software request. The software generates both fixed management reports and individual cow files, which can be viewed or printed.

Using the radiotelemetric system to monitor mounting activity and ultrasonography to determine the time of ovulation, a significant positive relationship between duration of estrus and time of ovulation was reported. A prolonged duration of mounting activity was associated with an extended interval from first mount to ovulation. However, this relationship existed over a relatively brief time interval (25 ± 34 h); therefore, differences in the duration of estrus would have limited importance in the timing of AI and did not have a significant effect on conception rate.

Duration of estrus, defined as the time interval from first to last standing event recorded by the radiotelemetric system, averaged 7.1 ± 5.4 h for 2055 estrous periods. The duration of estrus varies greatly not only among cows in the same herd but also among different studies (**Table 1**). Differences in age, herd size, management conditions, frequency of observation, and definition of onset of estrus may account for most of the variation in the duration of estrus among studies.

Factors That Affect Estrous Behavior

Most of the older studies report a mean duration of estrus around 18 h; however, recent reports indicate a decrease in 'standing heat', to as low as 37% with shorter periods of around 13 h and, in some cases, as short as 4 h. While not clear enough, various physiological or management factors and health-related problems should also be taken into account.

High Milk Yield

An increased level of milk production has been reported to inversely affect the duration and intensity of estrus and has been related to decreased estradiol concentration in the serum. Since estrogen acts by inducing estrus, both reduced estradiol production and metabolic clearance of estradiol related to high production could account for the inverse correlation between milk level and physical expression of estrus.

Postpartum Period

The postpartum period is critical for efficient reproduction. The occurrence of silent ovulation during the postpartum period is common for the first ovulation following calving. Without progesterone priming, ovulation will occur without clearly expressed behavior. Silent estrus is also related to the extent and duration of negative energy balance and loss of body condition during the transition period or approximately the first 30 days postpartum. Documentation of silent ovulation has been based on endocrine assay and visual observation, including video recording, combined with additional information provided by techniques such as rectal palpation, the use of marker animals, animal activity, and milk–temperature measurements. A recent study using radiotelemetry (HeatWatch® System) that allowed continuous monitoring of cow mounting activity to identify mount acceptance by estral animals and frequent blood collection for progesterone analysis characterized 22% of all ovulations during the postpartum period as being silent ovulations. If visual observations for the detection of

Table 1 Characteristics of estrus and conception rates (least square means ± standard error) for Holstein and Jersey cows and heifers continuously monitored by a rump-mounted pressure-sensitive radiotelemetric system

	Estrous periods (n)	*Standing events (n)*	*Estrous duration (h)*	*Conception rate (%)*
Cows				
Holstein	845	8.8 ± 1.7	7.2 ± 0.31	47 ± 1.5
Jersey	410	123 ± 1.4	8.8 ± 0.37	53 ± 1.1
Helfers				
Holstein	355	23.6 ± 1.3	10.7 ± 0.39	66 ± 1.11
Jersey	166	38.8 ± 1.2	125 ± 0.51	56 ± 0.9

estrus were the only criteria for determination, 62% of all ovulations during the postpartum period would have been classified as silent ovulations. However, many ovulations were associated with fewer mounts accepted by the estral cow and were of shorter duration than mounts accepted at the time of subsequent ovulation.

Circadian Rhythm

Conflicting data concerning diurnal and nocturnal estral activities are found in the literature. While the factors underlying these discrepancies are probably complex, direct or indirect effects on estral expression may be predominant. If estral activities are light-mediated, then suppression of estrus expression would be expected during the nocturnal period. Using the radiotelemetric system to monitor mounting activity in pasture-fed cows, the onset of estrus and total mounting activity were found to be equally distributed throughout the day when grouped into 6-h periods. However, individual hourly variation did occur, with the greatest number of first mounts or onset of estrus occurring between 1200 and 1500 and between 2100 and 2300 h. Total mounting activity did not parallel the hourly distribution of onset of estrus and was more evenly distributed throughout the day, despite a trend toward more mounting activity in the afternoon.

Management Problems

The simultaneous presence of other animals in estrus affords the opportunity of sharing estrous behavior. As a consequence, behavioral signs of estrus involving interactions between cows, such as standing heat, are affected by the number of cows in estrus at any given time. Total herd size as well as milking herd size is an important factor in mating management. A minimum of two cows near or at estrus is required to identify clear estrous behavior. Having few cows in estrus might have an amplifying effect on mounting activity. Small herds are characterized by a low number of mounts per cow in estrus and lack of standing activity, most likely due to the absence of cow–cow interactions.

When housed in comfort stalls, cows were about 2.76 times more active during estrus, indicating that the type of housing influences the magnitude of the change in physical activity. The type of floor can also influence mounting behavior. For example, slippery, wet, or concrete floors are not conducive to mounting, while a dirt floor or thick straw bedding is preferred. Studies in heifers have shown that detection indices by pedometer systems (Gyuho, Comtec, Miyazaki, Japan) were influenced by the location of pedometer attachment (neck or leg) and rearing condition (grazing, paddock, tie stole) with a high value for leg pedometer in paddock rearing condition.

Seasonal variation in ambient temperature, photoperiod, and humidity can influence estrous behavior. Heat stress lengthens the estrous cycle and decreases the duration and the intensity of estrus. Estrus can be 20–30% longer in temperate or moderate climates than in very hot or cold weather. Combinations of different detection systems, including modern cooling systems, have been reported as a better strategy than the use of a single system in order to increase estrus detection and conception rates. When more than one system was used, a higher conception rate was obtained under summer conditions. Therefore, this strategy should be included in dairy herd management programs.

It should be noted, however, that stresses other than heat stress can promote a decline in normal forms of estrous behavior. Different daily activities such as walking to the milking parlor, cleaning the resting area, or number of feedings can also affect estrous behavior. Physical discomfort or social stress caused by moving cows from their original groups can result in altered behavior and production performance.

Estrus Detection and Prediction of Ovulation and Time of Insemination

Several studies have examined the optimal time for insemination relative to the onset of estrus. In one study, each of 17 farms selected a different interval to inseminate cows identified in estrus during the previous 24 h. Pregnancy status was determined by data for return to

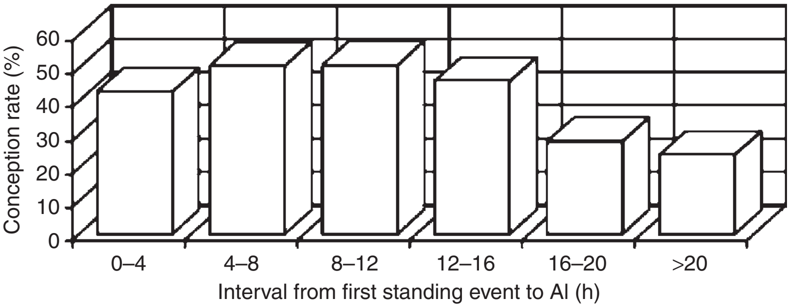

Figure 3 Percentage of pregnant cows by 4-h intervals relative to timing of artificial insemination (AI) from first standing event detected by the radiotelemetric HeatWatch® system across 17 herds and 2661 inseminations.

estrus and palpation of the uterus 35–75 days following insemination. The bar graph shown in **Figure 3** represents the proportion of pregnant cows for each 4-h interval from first standing event to insemination. Inseminations performed between 4 and 12 h following onset of estrus achieved a conception rate of approximately 50 versus 30% for inseminations performed after 16 h from onset (**Figure 3**). From previous studies, near-optimal conception rates would be expected for cows submitted for insemination 12–18 h after detection of estrus. Mathematical modeling to predict the optimal time for AI using activity pedometers and visual signs of estrus estimated 11.8 h from onset as the optimal time for AI, which coincides with the approximate midpoint of the 5 ± 16 h optimum using the HeatWatch® System.

Since the chance of fertilization strongly depends on the interval from insemination to ovulation, it is reasonable that insemination time be based on time of ovulation rather than detection of estrus. Pedometer activity systems and pressure sensing to monitor mounting activity appear to be promising tools for predicting ovulation and hence could serve for the improvement of fertilization rate. Use of these systems showed that ovulation takes place 22–32 h after the first increase in activity. Since the optimal insemination time is 24–12 h before ovulation, the optimal time of insemination becomes 4 ± 17 h after the increase in locomotive activity or 0–12 h following the first standing event associated with the onset of estrous behavior.

Conclusion

Remote-sensing systems for the detection of estrus are expected to be more efficient but not necessarily more accurate than visual observation. Differences in housing and environmental conditions, in addition to labor, cost, and efficacy, have resulted in variable acceptance of remote-sensing technologies. Detection efficiency and accuracy can be improved by the simultaneous use of more than one technology. Combining technologies for simultaneous measurements of several physiological events associated specifically with the onset of estrus and ovulation time should provide more accurate predictions of the optimal time for insemination. Ultimately, herd management must interpret the information gathered by these technologies and judge whether and when to inseminate the identified cows based on visual inspection.

Introduction

Artificial insemination (AI) of cattle represents the most successful sophisticated program of animal breeding ever implemented to improve the quality, productivity, and reproductive health of dairy cattle and other farm animals. This article, in conjunction with other articles on AI (*see* **Gamete and Embryo Technology**: Artificial Insemination), provides an overview of the advanced technology developed, the facilities and management required, and the genetic improvement in cattle as a result of the use of AI during the past half century. Other species are considered briefly. Recent advances in genomics, computerized mating programs, gender sorting of semen, and cloning relevant to AI programs are considered.

Components of a Successful Artificial Insemination Program

The key to any successful program is capable, well-trained, and dedicated people. Expertise represented by the array of people in AI encompasses geneticists to select bulls, expert bull handlers, semen collectors and laboratory technicians, highly trained field staff, skilled inseminators, and superior farm managers. All require appropriate facilities and equipment to conduct a high-quality program. The two major factors responsible for the success of AI are (1) improved reproductive health, particularly through the control of venereal diseases, and (2) genetic improvement in productivity and a reduction in lethal genes.

All of the components of AI and their relationship can be quantified by two simple equations. A sire's genetic contribution will depend upon its genetic superiority and the number of progeny produced:

$$\text{genetic impact per sire} = (\text{genetic superiority of the sire}) \times (\text{number of progeny per sire}) \quad (1)$$

The physiology and management that impact on the number of progeny produced per sire are represented by the equation

$$\text{number of progey per sire per year} = \frac{(\text{number of sperm harvested per sire})}{(\text{number of sperm inseminated per cow})} \times (\text{fraction of the semen used for insemination}) \times (\text{fertility : \% of inseminations producing progeny}) \quad (2)$$

All of the improvements in harvesting sperm from the bull, preserving sperm with minimal loss, and skillfully placing the right number of sperm in the well-managed cow at the proper time will affect the number of progeny.

Landmarks in the Development of Artificial Insemination Facilities

Early in the development of AI for livestock breeding, facilities were very limited, with a modified existing barn to house bulls, an area equipped to serve as a simple laboratory, and a semen collection chute, often outdoors. Originally, developed around a liquid semen program, regionally sited bull studs were needed. Following the introduction of semen cryopreservation, nationally sited centers were developed. With sophisticated facilities allowing assured health surveillance, international trade became possible. Semen cryopreservation required special equipment for processing, packaging, storing, and transportation of semen. The equipment developed for bull sperm provides the basis for the worldwide cryopreservation of biologics today (*see* **Gamete and Embryo Technology**: Artificial Insemination). Modern facilities that were better, larger, and more expensive emerged. Many small bull studs were merged for efficiency, as climate-controlled bull barns, herd health surveillance and isolation facilities, special semen collection areas, animal clinic areas, and modern laboratory facilities were built by consolidated larger AI organizations. Today in the field, supervisors and reproductive specialists help AI technicians and herdsmen to manage the on-farm AI program.

Frozen Semen in the Field

Equipment and techniques were developed for handling semen stored in liquid nitrogen at −196 °C in the laboratory and moving it safely to the field for each inseminator's storage unit. Today, inseminating technicians are given special training to handle frozen semen into and out of the liquid nitrogen tank, and to retrieve the proper breeding unit for insemination without exposing the remaining units in storage. Proper handling of frozen semen and maintenance of an unbroken chain of cryogenic temperature (less than −130 °C) are important. Otherwise, carefully prepared high-quality sperm could be damaged with resultant lowering of fertility. Proper thaw and insemination methods are discussed later in this article. Inseminations today are performed by both professional inseminators and herdsmen who buy semen from a producer. As herd size has increased, many on-farm inseminators have gained proficiency by inseminating several hundred cows, one or more times.

Farm Facilities and Detection of Estrus

Upon adoption of AI, a very important task faced by dairy farmers is accurate detection of estrus, so that cows could be inseminated at the proper time. Extensive efforts are made to ensure that all users of AI implement sound programs for estrus detection. This includes proper identification of each animal (highly visible cow ID), turning out cows in stanchions, and watching of cows for estrus for about 30 min each morning and evening. Some herdsmen manage this program better than others. Many aids for detection of estrus have been developed. Several will be listed here because poor detection of estrus is the largest single cause of prolonged, uneconomic calving intervals (*see* **Reproduction, Events and Management**: Mating Management: Detection of Estrus).

Estrus detection aids include using surgically altered bulls that could not mate with animals, but could mount and roll colored paint on the rump of animals that stood when they were mounted. Alternatively, a colored crayon or especially brittle paint could be used to stripe the tail-head of any animals due to be inseminated. This stripe is smudged or the paint broken up when that cow is mounted. Different types of pressure-sensitive patches, which are easily attached to the rump, were developed that become more visible when pressed hard by a mounting animal. One version uses small digital radio transmitters incorporating a pressure switch in the tailhead patch. The transmitter monitors mounting activity and transmits the data (cow ID, date and time of mount, duration of the mount) to the herd computer. Electronic probes to measure changes in electrical resistance of cervical mucus are also effective in revealing changes at estrus. Pedometers of various types record walking activity of the animal, indicated on a mechanical component of the pedometer. More advanced types transmit activity electronically, along with the cow identification, to a receiver.

To develop effective estrus detection programs and evaluate their efficiency, it was necessary to monitor the estrous cycle of cows. This became possible with the discovery that the cyclic hormone progesterone could be measured in milk. The milk progesterone followed a similar pattern as blood progesterone, so simply collecting small samples of milk 2 or 3 times per week for progesterone determination permitted the cyclic activity of each cow to be tracked. In addition, this monitoring enabled one to determine missed heats, plus cows that were inseminated at the wrong stage of the estrous cycle or when pregnant. Studies in Israel and at Cornell University have shown that the use of some of these technological aids, plus training of the farm managers and the inseminators, can minimize mating at the incorrect time, and thereby maintain an optimal calving interval. Heifers often are housed in open areas with bulls. However, they should be managed to use AI because more genetic progress is made when they are inseminated with conventional or sexed semen from genetically superior bulls.

Procedures for Artificial Insemination

Effective care needs to be taken to prevent temperature fluctuations of thawed semen, abrupt cooling of semen (cold shock), and semen or supplies from sun exposure or warming beyond body temperature. Loading the AI gun should take place in a protected area, free of extreme temperatures and close to the cryostorage unit. All AI should be completed within 15 min of straw thawing. The number of straws thawed at one time is dependent on the quantity that can be used within 15 min. In large herds, teams of inseminators work together to prepare AI guns, and perform AI.

Unless specified otherwise, semen should be 'warm-water thawed'. Some organizations produce semen as straws processed by alternative methods that permit straws to be 'pocket thawed' as well as 'warm-water thawed'. Upon retrieval from the cryostorage unit, straws that require warm-water thawing are thawed in water (~0.5 l) in an insulated vessel at 33–35 °C for a minimum of 40 s. A maximum of four straws at a time can be thawed in the vessel. This prevents the water temperature from cooling to temperatures below specifications. Straws should be agitated slightly to ensure uniform thawing.

Straws that are 'pocket thawed' are immediately placed in a folded paper towel for protection following retrieval from the cryostorage unit. After this preparation, straw and towel are placed into a thermally protected pocket. A minimum of 2–3 min of thawing time within the pocket is provided before preparing the AI guns. For retrieval of multiple straws, straws are placed into separate towels to ensure uniform thawing. Straw forceps should be used at all times to prevent contact between bare fingers and the straw.

If needed, the temperature of the AI gun is tempered by friction and prior placement within the inseminator's coveralls. Before sliding the thawed straw into the barrel of the AI gun, the temperature should be checked by touch, as a subjective method to avoid temperature extremes. The loaded gun is covered with a paper towel for insulation while cutting the straw end. A sheath is slid over the loaded gun and is secured. The loaded gun is then placed within a clean breeding glove, providing an added layer of thermal protection, and is finally tucked inside the coveralls.

The following is a conventional rectovaginal insemination procedure. Generally, the left arm, covered with a disposable glove and lubricated with mineral oil, enters the rectum. Through the thin tract layers, the cervix is located and grasped. Folded paper toweling is used to spread the vulva, allowing clean entrance of the gun into the vestibule of the vagina. Care is taken to gently manipulate the cervical rings of the lumen over the end of the gun until the gun tip reaches just past the anterior cervical ring. Location of the gun tip in the uterine body is determined with an extremely light touch through the uterine body wall. When satisfied with the position, the outside end of the AI gun is braced on the opposing arm and the plunger is pushed to deliver semen to the uterine body in 3–5 s. The gun tip is not extended past the internal uterine bifurcation to avoid the possibility of any injury to the uterine mucosal tissue. Cows that have been bred once, but then exhibit estrus behavior again should be rebred with caution as an abortion can be initiated in a pregnant female. Therefore, the AI gun should be passed completely through the cervix only if the tract is felt to be typical for a female in normal estrus.

Use of Computerized Mating Programs in Artificial Insemination

In dairies that utilize computerized mating programs, each cow in a herd is examined and scored in a linear trait evaluation format. Cows are compared to their contemporaries for each trait and the differences are weighted by the heritability of the specific trait. Deviations from contemporaries are adjusted for the herd's genetic level. Pedigree information is also included. When a mating is planned, the cow's complete phenotypic evaluation linear score is viewed and from computer files of sire information, potential mating sires are selected, emphasizing corrections to worst faults for maximum genetic progress.

A very important benefit of using computerized mating program is that it is possible to control and restrict the level of inbreeding in the herd. A mating program will ensure that no member of a three-generation pedigree is duplicated in the mating. This is expected to maintain inbreeding below 6.25%. Furthermore, mating programs can be set up so that embryo losses that result from harmful gene interactions can be avoided. Cattle that carry the same lethal recessive gene should not be mated.

Artificial Insemination in Estrus-synchronized Cattle

Several programs have been developed to synchronize estrus and ovulation so that a group of cows can be inseminated at a fixed time. These programs involve the injection of prostaglandin F2α or analogues to regress the corpus luteum (the source of progesterone), and an injection of gonadotropin-releasing hormone (GnRH) to stimulate ovulation (*see* **Reproduction, Events and Management**: Control of Estrous Cycles: Synchronization of Estrus; Control of Estrous Cycles: Synchronization of Ovulation and Insemination).

In viewing 2008–09 data (500 000+ inseminations) from a company providing extensive professional AI service in US herds, AI to synchronized cattle approximates 27% of total inseminations; however, in many herds, AI to synchronized cattle accounts for 80% of inseminations. Of these AIs, Cosynch and Ovsynch accounted for 25 and 75%, respectively. Differences in fertility (as unadjusted nonreturn rate means) between the two synchronization protocols were essentially zero. An inspection of adjusted fertility rates revealed that AI to synchronized cattle approaches, but does not equal, AI to nonsynchronized cattle (−1.5% for probability of conception). There is an interaction of bulls and synchronization. That is, while bulls can be ranked with respect to overall fertility, bulls will rerank in a different order when semen is used on synchronized cattle.

Use and Efficiency of Artificial Insemination in the United States

The changes in dairy cow numbers and the use of AI in the United States are summarized in **Table 1**. Milk production per cow has tripled since 1925 while the number of cows has been reduced by two-thirds. Consequently, the many fewer cows today produce as much milk nationally as was produced in 1925. This production meets demands as milk consumption per capita has decreased.

Table 1 Dairy and beef cow numbers and the percentage inseminated artificially in the United States

	Dairy cows[a]		*Beef cows*	
Year	*Number*	*Artificially inseminated (%)*	*Number*	*Artificially inseminated (%)*
1925	25 000 000	0	10 000 000	0
1950	21 500 000	12	15 000 000	<1
1975	12 000 000	57	45 000 000	4
2000	9 000 000	65	34 000 000	10

[a] Dairy cow numbers do not include heifers; a lower percentage of heifers is inseminated artificially. Data indicate trends only, as precise data are not available for all time periods, particularly with many inseminations by on-farm personnel not reported.

This massive increase in the efficiency of milk production, with fewer cows and 99% fewer bulls used through AI, has saved 25 million tonnes of maize otherwise needed for feed. Along with other improvements in management, it has allowed many producers to become so efficient that they have survived the increased costs of doing business.

Economic and organizational efficiencies have resulted in the reduction of the number of AI organizations worldwide. In the United States, there were about 100 AI organizations in the 1940s. Most of these organizations have merged or closed. Today, six AI organizations supply most of the semen for dairy cattle AI.

Extent of Artificial Insemination Worldwide

In **Table 1** it is shown that about 65% of the cows in the United States are enrolled in an AI program. In many European countries, use of AI is as high as, or higher than, 65%. In Czechoslovakia and Hungary, more than 90% of the dairy cows are artificially inseminated, and in Denmark, Israel, and Japan the proportion of cows impregnated by AI is essentially 100%. The various countries comprising the former USSR also use AI extensively.

Most countries rely essentially 100% on frozen semen for cattle. Countries with large dairy cow populations are listed in **Table 2**. In New Zealand, a majority of cows are inseminated during 2–3 months so that cows will calve and initiate lactation during the excellent pasture season. During this short time, mostly liquid semen is used to meet demands, with 2 000 000 sperm per cow giving acceptable fertility. This permits a few top sires to be scheduled to meet the market demands at low costs of semen processing. Frozen semen is banked at other times, with 20 000 000 sperm per breeding unit, providing more than is necessary to compensate for freezing damage.

Sire and Selection Programs and Genetic Progress

The modern progeny test system as a useful genetic program for identifying superior sires for extensive use in AI was developed simultaneously by Henderson at Cornell and by Rendel and Robertson in Scotland. A young bull for progeny testing is produced by inseminating a genetically elite dam with semen from an elite sire. The young bull enters the stud through its isolation facility, enters the production herd, matures and produces semen for progeny testing at about 12–15 months. This semen is used in AI to produce daughters, whose subsequent records for production traits contribute to the production proof of the bull. Bulls being progeny tested are returned to service with a progeny test proof at about 4–5 years of age.

The genetic progress, along with levels of milk production, is illustrated in **Figure 1**. Little genetic progress was made before 1955, but by then a few bulls proven in AI through the progeny testing scheme outlined above were available. Progress has been rapid since 1975 when many tested bulls were available. There is no indication yet that a peak is being reached.

Effect of Genomic Evaluations on Artificial Insemination Utilization

Genomic information in cattle is increasing rapidly, aided partly by cross-species homologies. Geneticists working with cooperating AI companies used DNA derived from a pooled frozen library of semen from generations of dairy bulls and the resulting daughters' milk records. They identified DNA segments associated with phenotypic traits, and this genomics approach, with the application of microarray identification of single nucleotide polymorphisms (SNPs), marker-assisted selection, and other reproductive technologies, has increased the intensity of selection and shortened generation intervals with more

Table 2 Use of frozen semen in countries reporting ≥1 500 000 cows artificially inseminated

Country[a]	*Number of dairy and beef cows artificially inseminated*	*Use of frozen semen (%)*	*Number of sperm per cow* $(\times 10^6)$[b]
Australia	1 600 000	100	20
Brazil	2 860 000	100	40
Canada	1 500 000	100	15
China	10 000 000	100	
France	4 800 000	90	20
Germany	5 600 000	98	15
Italy	2 450 000	100	18
Japan	1 600 000	99	20
Korea	1 600 000	94	30
Netherlands	1 650 000	100	20
New Zealand	3 800 000	37[b]	20
Spain	1 800 000	95	30
United Kingdom	2 600 000	100	20
United States	10 500 000	100	20

[a] Data from the former USSR were not available, but historically it has been a leader in numbers.

[b] For bulls in high demand, the insemination dose may be reduced to 10 million sperm, and with the liquid semen program (63%) in New Zealand only 2 million sperm are used per insemination.

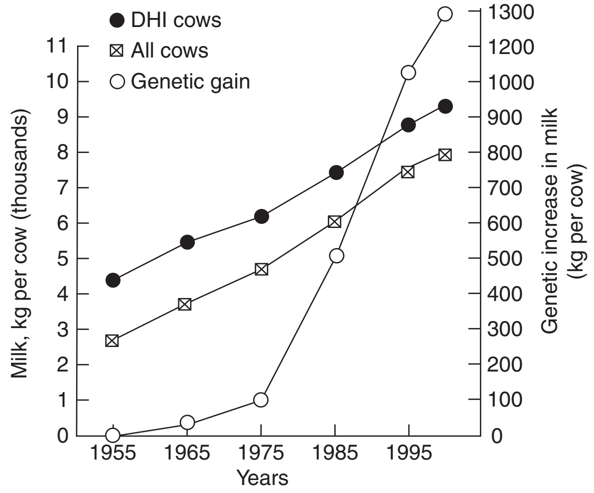

Figure 1 Changes in milk production per cow in all herds and those on test in dairy herd improvement (DHI) in the United States, along with the estimated genetic improvement, primarily as a result of superior sires used in AI.

rapid progress in genetics (*see* **Genetics**: Selection: Concepts). Positive identification of a variety of alleles present in newborn animals will assist in selecting those with the greatest promise for transmission of genes associated with desired traits.

In the United States, more than 30 000 cattle, primarily Holsteins, have been genotyped since December 2007 for important production traits such as milk, fat, protein, somatic cell score (SCS), and daughter pregnancy rate (DPR). While genomic evaluations have a lower reliability, many outstanding bulls have been identified with genomic evaluations, reflecting several years of added genetic progress. In 2009, young Holstein bulls with genomic-only evaluations began to be utilized for breeding purposes. Due to lower reliability, the pattern of AI usage is changing to limit the amount of semen used from an individual bull and to utilize semen from much larger groups of bulls. In 2009, a large proportion of semen being utilized for AI in the United States is from bulls with genomic-only evaluations.

Selection and Mating Based upon Multiple Traits

Selection of Mating Sires Based on Production-Associated Evaluations

Much information is collected on sires proven in AI in addition to the milk, butterfat, and protein production of their daughters. Daughters are checked for traits such as body size, leg conformation, mammary gland size, udder support and teat placement, and milking speed. This information is published so that those who wish to select semen from sires that produce daughters with particular strengths besides high milk yield can do so. Bulls that produce small calves are identified, and may be selected to minimize calving difficulties when small heifers are inseminated. The broad scope of possibilities among frozen semen available from many bulls through AI gives the producers almost limitless opportunities to plan a program that meets individual desires. However, when selection is made for more than one trait, the genetic gain for each trait is reduced. The most profitable program for commercial dairy producers is to put major emphasis on milk yield.

Selection of Mating Sires Based on Fertility-Associated Evaluations

Fertility of the bull is important, as high reproductive efficiency is a major factor in the success of the dairy enterprise. Bulls with low fertility are in limited demand, even when genetic merit is high. Semen from low-fertility bulls is seldom used to inseminate repeat breeder cows. AI companies with large numbers of professional inseminator staff can utilize breeding receipt and farm records to provide sophisticated fertility evaluations. For many companies, it is more difficult to obtain such records as the proportion of semen sales directly to farms has grown. National evaluations for sire fertility exist in many countries. From the USDA's use of milk test records, estimations of sire fertility, as sire conception rate (SCR), are available. SCR results are based on confirmed pregnancies. Important factors that are adjusted include year, herd differences, parity, service number, location, season, milk yield, and sire age. Selection of a mating sire based on its DPR is also possible. A calculated DPR includes calving interval and days open in the calculation. Predicted transmitting abilities (PTAs) for cow fertility traits have high reliabilities only after hundreds of daughters are recorded.

Advanced Reproductive Technologies in Artificial Insemination

Multiple Ovulation and Embryo Transfer

Multiple ovulation and embryo transfer (MOET) herds are an important source (oocytes, sperm) for elite genetics used in cattle AI. With the introduction of genomic evaluations, newborn cattle of either gender produced in MOET herds are quickly evaluated for their genomic estimated production superiority. While conventional AI provides genetic material from superior males, MOET provides a greater influx of genes into the population from superior females.

A genetic evaluation based on MOET-derived cattle is possible. Full brother–sister embryos are produced and transferred. As full brothers and sisters are born at the same time, full sisters can be raised in a sib test to provide contemporary production information for the sires. This decreases the generation interval compared with the progeny test system, although the comparative information is a little less reliable than the progeny test. By harvesting oocytes from juvenile females and fertilizing them *in vitro* to produce embryos, the generation interval can be further reduced (*see* **Gamete and Embryo Technology**: Multiple Ovulation and Embryo Transfer). With MOET programs, animals are usually raised in a central facility. This makes it possible to record multiple production information and related traits. For example, body and udder conformation and milking speed can be recorded. Such a facility could also use sexed sperm to produce embryos of the desired sex by *in vitro* fertilization.

Embryos produced by any method can presently be sexed and in the future can be tested with DNA analysis, allowing genomic evaluation (*see* **Gamete and Embryo Technology**: Sexed Offspring). Also, embryos can be split quite easily with 50% more progeny per donor cow. All these techniques can be combined, and each one adds a small increment to the rate of genetic progress. However, the greatest single component of genetic gain is the use of AI-proven sires.

Artificial Insemination with Sexed (Gender-Sorted) Semen

The ability to use sexed semen has been an important development in AI. With ample replacement cattle now available, it is viewed as allowing the dairy herds to obtain their heifers from their best maternal lines, increase calving ease, close their herds if desired for biosecurity (growing from within the herd), and provide an ability to absorb increased culling rates, allowing disposal of problem cows. Sexed semen, however, is expected to have a lower fertility rate (*see* **Gamete and Embryo Technology**: Sexed Offspring). For this reason, best results are obtained when breeding heifers exhibiting standing heat. Research is ongoing on whether sorted semen can be economically used in cows. Two types of products are available for AI: 90% gender purity and 75% gender purity. While sorting purity can be achieved for either gender, in the dairy industry it is overwhelmingly desired toward producing female offspring.

In 2008, 14% of all USDA-AIPL reported heifer breedings in the United States were with sexed semen AI. During the period from 2006 to 2008, AI with conventional semen in heifers and cows achieved a 56 and 30% conception rate, respectively, while AI with sexed semen achieved 39 and 25%, respectively. In viewing current US data gathered in large commercial herds (188 700+ total professional AIs), AI with sexed semen accounted for 16% of AI and in some herds 100% of heifers are bred with sorted semen. In these herds, use of sorted semen, after adjustments for interactions, was found to reduce the probability of conception by 12.7%. Bulls ranked by overall AI fertility may rerank differently when their semen is sorted.

Cloned Sires in Artificial Insemination

Currently, there are a few cases where semen for AI is currently being processed from sires produced as clones from deceased genetically evaluated individuals. The genetic evaluation of the original sire is utilized as the evaluation for the clone. Currently, cloning is inefficient and expensive. If bulls with rare or unique genes are selected and cloned, the resulting clones can be used to inexpensively disseminate desired genes by AI. Tissue appropriate as a source of cloning could be preserved by cryopreservation for use in cloning.

Artificial Insemination in Beef Cattle and Buffaloes

AI and embryo transfer played an important role following limited importation of several European breeds of beef cattle into North America. In some breeds, AI usage was as high as 75% initially, but with expansion it has decreased. The overall estimated usage of AI is shown in **Table 1**.

Beef bulls produce approximately the same number of sperm as dairy bulls. The management of beef sires is similar to that of dairy sires, but owners should not let beef bulls get fat, as sperm output and quality are depressed. Testis size and quality should be measured on all sires. The quality of frozen beef semen varies more than the quality of semen from dairy bulls, probably because much of the frozen beef semen is custom collected, with less culling of bulls for semen quality.

The major management difference between dairy and beef is in management of the females. Beef cows and heifers for AI must be confined. Animals should be in good condition. Cows suckling calves, and with poor body condition, have low pregnancy rates. High pregnancy rates in beef cattle are much more important than in dairy cattle, as females with no progeny contribute nothing economically to the beef enterprise.

Buffaloes are a major source of meat, milk, and work in many Asian countries where 95% of the world's buffaloes exist. Leading countries include India, Pakistan, China, Nepal, and Thailand. Significant numbers are also found in Romania, Egypt, and Italy (*see* **Animals that Produce Dairy Foods**: Water Buffalo). Reliable statistics on the percentages of AI use and results are not available.

Use of Artificial Insemination in Species other than Cattle

A summary of the technical feasibility of using AI in several species is given in **Table 3**. The fastest growing use of AI is in swine. Sows are usually confined; they are easily inseminated. Large breeding and production farms can capitalize on inseminating many more sows with semen from superior boars than through natural mating. In China, 10 000 000 sows are inseminated annually, with an estimated 50 000 000 inseminated worldwide. With liquid semen, pregnancy rates and litter sizes are normal. Freezing boar sperm depresses fertility.

The poultry industry also depends essentially 100% upon AI in the industrial breeding flocks to produce hatching eggs for turkeys, broilers, and egg-laying hens. Semen is easily collected. Many caged females per male can be inseminated rapidly with fresh semen once a week with high fertility. This permits selection of the best males to produce the next generation of poultry.

Tens of millions of sheep and goats are artificially inseminated worldwide, particularly in Russia, Bulgaria, Romania, China, several other Asian countries, and South America. In western Europe, France is the leading country, where 850 000 sheep are inseminated with liquid semen and 580 000 goats with frozen semen. In Australia, 200 000 ewes are artificially inseminated, particularly in flocks producing rams for sale. The number inseminated

Table 3 Technical feasibility of using AI in species other than cattle

	Fertility of semen		
Species[a]	*Liquid*	*Frozen*	*Any limitations*
Sheep	Good	Poor[b]	Problem with large ranges. Low value per ewe, so AI costs must be very low
Goats	Good	Fair	Detection of estrus in small herds. Insemination is more difficult. Lack of available semen
Swine	Good	Fair	Supply of liquid semen and rapid transportation is required. Improved detection of estrus in gilts. Cost per sow must be kept low, but this is competitive
Horses	Good	Fair	Long estrus. Multiple inseminations needed. Frozen semen conception rates are reduced. Breed restrictions
Turkeys, chickens	Good	Poor	No limitation in breeding flocks. Use of fresh semen is the method of choice

[a] Note that cattle have an advantage over other species in number of progeny possible per tested sire per year: cattle, 50 000; sheep and goats, 5000; swine, 2000; horses, 750. The successful development of a frozen semen bank is especially advantageous in seasonal breeders such as sheep, goats, and horses.

[b] Frozen semen can be used successfully provided a laparoscope is used with intrauterine inseminations.

AI, artificial insemination.

with frozen semen has been limited by low fertility, unless intrauterine insemination with the aid of a laparoscope is used.

Investigation of AI in the early 1900s was directed toward the horse, but declined as the horse populations decreased on farms. In the United States, horse AI has increased to about 300 000 mares inseminated annually, as several breed associations have revised breed codes to permit registration of foals produced by AI. Lighting is often used to alter the seasonal breeding of mares.

The smallest animals where AI is used extensively are laboratory rabbits and foxes. The latter are raised for the fur trade in northern Europe. Deer farming is extensive in a few countries. There are many examples of selective AI used for endangered species in zoos where few males are available, or if females refuse to accept the male.

Mating Management: Fertility

M G Diskin, Teagasc, Animal & Grassland Research and Innovation Centre, Mellows Campus, County Galway, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

In dairy cows, reproduction has two major functions: to induce the onset of lactation and to provide replacement animals for the current generation of cows. Consequently, reproductive efficiency is a major factor affecting production and economic efficiency. Over the past four decades, milk yield per cow has increased significantly through genetic selection and improved management. Not withstanding these improvements, there has been a steady decline in reproductive performance of dairy cows coincident with the improvement in yield. The focus of this article is to review the components that determine reproductive efficiency of dairy cows, and to investigate how best to use the new information that has emerged over the last few decades to improve the reproductive management of a herd and consequently its production efficiency.

Reproductive Targets

Although it is frequently argued that milk production efficiency is at its highest when cows reproduce once every 365 days, the optimal reproduction function that maximizes profit is dependent on numerous factors, including production system, level of milk production, milk prices, and feed cost, among others. Consequently, it is impossible to give a set of specific targets applicable to all systems of production. However, the three measures presented in the following section (see also **Table 1**) are useful as initial measures of reproductive performance in seasonal and all-year-round calving herds. Using only one measure of reproductive efficiency can be misleading and can mask other important inefficiencies.

Components of Reproductive Efficiency

Even though there are numerous factors that affect the reproductive performance of individual cows and consequently herd reproductive performance, these factors can be categorized under the following three broad headings:

1. The interval from calving to resumption of ovulation and regular estrous cycles
2. Estrous detection efficiency and submission rate
3. Conception rate following service

The Interval from Calving to Resumption of Ovulation and Regular Estrous Cycles

Generally, about 80% of dairy cows will have ovulated within 28 days of calving and about 10% of cows will not have commenced ovulation by 42 days postcalving. In dairy cows, the main cause of anestrum is prolonged negative energy balance (NEB), which results in low LH pulse frequency, decreased concentration of insulin-like growth factor-I (IGF-I), low estradiol production, and ultimately the failure of the dominant follicle (DF) to ovulate.

The number of ovulatory estrous cycles preceding insemination has been shown to beneficially influence subsequent conception rate. Consequently, it is desirable that dairy cows resume ovulation in the first 4 weeks after calving. Following delivery of the calf and fetal membranes, there is a decline in the plasma concentrations of progesterone and estradiol and a corresponding removal of the negative feedback effects of these steroids, particularly estradiol, on gonadotropin synthesis and secretion. Follicle-stimulating hormone (FSH) secretion commences during the first week postpartum, and this stimulates the commencement of ovarian follicle growth and the appearance of a DF on the ovary at about days 12–16 postpartum. The fate of this follicle in terms of whether it ovulates or undergoes atresia appears to be related to whether it produces estradiol, which in turn appears to be associated with exposure to an adequate LH pulse frequency and concentration of IGF-I.

NEB in early lactation does not affect the follicle population or the timing of recommencement of DF growth but does affect the ovulatory fate of the first DF. However, energy balance (EB) in early lactation, rather than milk yield *per se*, appears to be the more important factor affecting resumption of ovulation postcalving, and dry matter intake (DMI) is a more important determinant of EB than milk yield. Positive association between EB in early lactation and the interval from calving to resumption of estrous cycles has been recorded. There is increasing evidence that IGF-I is a potential mediator of nutritional effects on fertility. Increased plasma concentrations of IGF-I during the first 2 weeks postpartum are associated with early resumption of ovulation. It has been demonstrated that feeding dairy cows an insulin-promoting diet increases plasma concentrations of insulin and also shortens the interval from calving to first postpartum

Table 1 Targets for seasonal and all-year-round calving herds

Variable	*Seasonal calving herds*	*All-year-round calving herds*
Calving interval	365 days	<420
Culling for infertility	<5%	<10%
Compactness of calving	80% calved in 60 days	NA

ovulation in both high- and low-genetic merit dairy cows. Insulin is a potent stimulator of follicle differentiation and steroidogenesis, promotes DF differentiation, and enhances responsiveness to LH and in turn increases estradiol secretion leading to a preovulatory LH surge and ultimately the ovulation of the DF. NEB also causes a decrease in circulating concentrations of IGF-binding proteins (IGFBPs). Because the IGFBPs transport and increase the half-life of IGFs, low blood concentrations of IGFBPs brought about by NEB would therefore limit the availability of IGFs to target cells in the follicle and hence limit their ability to synergize with pituitary gonadotropins to stimulate cell proliferation and steroidogenesis and ultimately ovulation (**Figure 1**).

An objective with dairy cows in early lactation is to achieve a high DMI, as this would be expected not only to hasten the onset of estrous cycles postcalving but also to increase conception rates (see later) and shorten calving-to-conception intervals. Increasing dietary intake is restricted by the requirement for inclusion of fiber in the diet to maintain rumen function as well as by the variability in voluntary feed intake by cows during this period.

Improving Heat Detection

The single most important factor affecting heat detection efficiency is the ability of those responsible for checking for heat to fully understand the signs of heat and their commitment to heat detection for as long as is planned to use artificial insemination (AI). About 10% of the reasons for failure to detect heats can be attributed to cow problems, and 90%, to 'management' problems. The latter

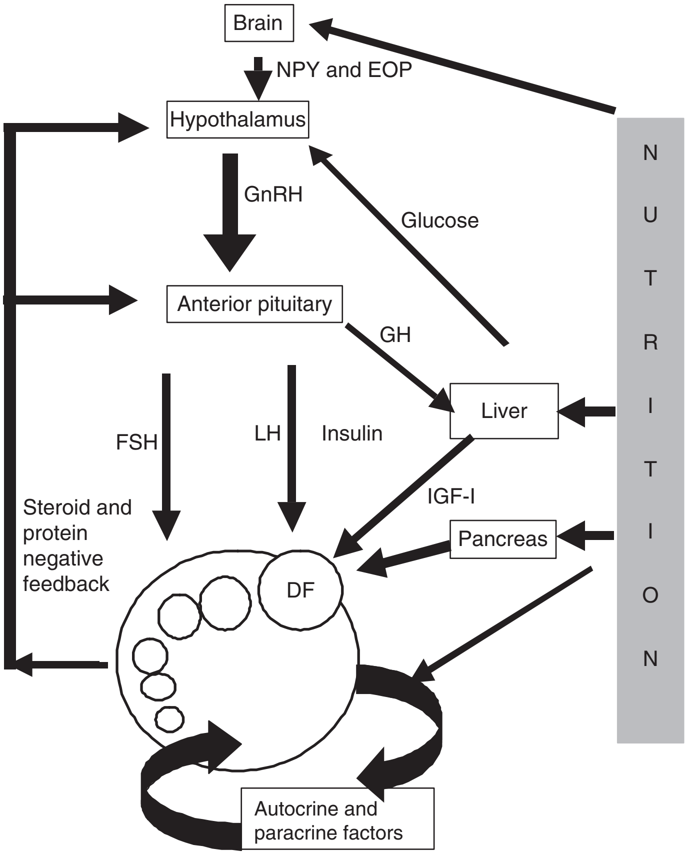

Figure 1 Possible mechanisms by which nutrition could affect ovarian follicular function. EOP, endogenous opioid peptides; NPY, neuropeptide Y. Reproduced with permission from Diskin MG, Mackey DR, Roche JF, and Sreenan JM (2003) Effects of nutrition and metabolic status on circulating hormones and ovarian follicle development in cattle. *Animal Reproduction Science* 78: 345–370.

would include too few observations per day for checking for heat activity, too little time spent observing the cows, and/or observing the cows at the wrong time or in the wrong place, such as feeding time or in the collecting yard at milking time. Another major reason for failure to detect heat is that those involved in heat detection do not understand the signs of heat.

Records

Individual animal records are an essential part of good breeding management. All animals must be clearly and permanently identified by one of several methods, such as plastic ear tags, neckbands, or freeze branding. Whichever system is preferred, it is essential that the animal number be clearly legible from a reasonable distance. Breeding records should include (1) animal number, (2) calving date, and other information relevant to calving, (3) prebreeding heat dates, (4) first and repeat service dates, sire used on each date, and inseminator code, (5) date and result of pregnancy diagnosis, and (6) date of expected calving. Good records are not only part of good farm management practice, but also the first essential step in all infertility investigations.

Monitoring submission rate

Submission rate is calculated as the proportion of cows calved at the beginning of the breeding season that are intended for rebreeding and submitted for insemination. A submission rate of at least 80% of the eligible cows during a 21-day period is desirable. Submission rate, which is easily calculated, is an excellent measure of heat detection rate and should be calculated at the end of the first 21-day period of the breeding season. A submission rate of less than 80% indicates a problem with heat detection, and diagnosis of this problem at an early stage allows corrective action to be taken before much of the breeding period has elapsed.

Technological Aids to Improve Heat Detection

The low to moderate heat detection efficiencies achieved on most farms reflect the difficulty of detecting heat in cows. Consequently, it has been and is the goal of many animal science programs to develop more objective systems to overcome some of the problems of heat detection. An ideal system for detecting estrus should have the following characteristics: (1) continuous surveillance of the cow; (2) accurate and automatic identification of the cow in estrus; (3) operation for the productive lifetime of the cow; (4) minimal labor requirements; and (5) high accuracy and efficiency (95%) for identifying the appropriate physiological events that correlate with estrus or ovulation or both. A number of aids and technologies, inexpensive or expensive, are available to meet some, but not all, of these criteria. In any case, use of the various technologies to identify the symptoms associated with estrus, ovulation, or both will require the judgment of the herd management, based on common husbandry experience, to verify whether or not the cow seems to be in estrus.

Tail-painting

Research from a number of laboratories has shown that applying paint or chalk to the tailhead of cows is effective in indicating standing activity. When such tail-painted cows are mounted from the rear some or all of the chalk or paint is rubbed off indicating that the painted cows possibly stood in estrus while being mounted by a herd mate. When combined with early-morning and late-evening observations, checks for paint loss at milking times should result in a heat detection rate of close to 90%.

Vasectomized bulls with chin ball marking harness

Active vasectomized teaser or detector bulls are useful in identifying cows either coming into or on heat. Vasectomy should be carried out 40–60 days prior to introduction to the herd. Many small- to medium-size dairy herds in Ireland are now finding that teaser bulls are particularly useful after the first 3 weeks of the breeding season when fewer cows are in heat each day and when the level of heat-related activity in the herd is reduced as more cows become pregnant. However, considerable variation in libido exists among bulls, and they require the same management as full bulls without conferring any of the advantages. As an alternative to vasectomized bulls, cows or heifers treated with testosterone or estradiol can be useful in detecting cows in estrus.

Pressure-activated heat mount detectors

These devices, including the ones marketed as Kamars, Bovine Beacon, and Mate Master, are affixed to the tailhead of the cow and change color when pressure is applied by the weight of the mounting animal. Reported efficiencies of heat detection using such heat mount detectors vary from 56 to 94%, whereas the accuracy of heat detection is reported to vary from 36 to 80%. The relatively low accuracy of heat detection, combined with the difficulties in keeping the devices affixed to the tailhead, limits the potential of this approach.

Pedometers

Estrus in cattle is accompanied by increased physical activity. Cows in heat do 2–4 times more walking than a nonestrous cow. Pedometers can be attached to the leg of the cow to measure the amount of her activity over a unit time-span. Early pedometer-aided heat detection systems operated with a reported heat detection efficiency of 60–100% and with an accuracy in the range of 22–100%. The low level of accuracy was related to a high proportion of false-positives and to technical problems that led to breakage, malfunction, or loss of the pedometers. New improved pedometric technology has now led to improved information storage systems; improved analytical capabilities to allow comparison of current with previous physical activity; incorporation of internal power supply to operate the electronics; and the development of self-contained devices to interrogate the pedometers in milking parlor and relay and store the information in a personal computer. Some systems have an inbuilt alert system, such as a bleeper or flashing light, which alerts the farmer when a cow is deemed to be in heat. A number of pedometric systems are commercially available in the United States and Europe. Even though scientific information on their operating efficiencies is not yet available, these systems would appear to have significant commercial potential particularly when cows are housed.

Radiotelemetric devices

The primary sign of heat is standing to be mounted. A number of research laboratories have attempted to develop pressure-sensitive devices that measure such standing activity. Such a system (HeatWatch II; CowChips Manalapan, NJ, USA) is currently commercially available in the United States and in a number of other countries. This system involves the location of a pressure-sensitive battery-powered transmitter on the cow's tailhead, which, when activated by the mounting cow, emits a radio signal, which is picked up by either a receiver or a repeater and relayed to a buffer and ultimately to a personal computer where the information is digitized and stored. The time, date, and duration of each mount along with the identity of each cow are recorded. From this information, the time of heat onset is calculated. The HeatWatch software generates management reports and individual cow reports that can be viewed or printed. HeatWatch classifies a standing heat as a cow having three standing events in a 4-h period. A cow with fewer standing events is recorded as a 'suspect heat', and such a cow should be checked for secondary signs of heat prior to deciding to inseminate her. Periodically during the day, the farmer checks the computer for a listing of the cows in heat. The data available suggest that HeatWatch operates with both an efficiency and an accuracy of almost 100% in detecting cows in heat.

Heat detection patches

Recently, a number of scratch card type patches have come on the market, including Estrus Alert® and ESTROTECT™. These are affixed to the cow's tailhead. Friction from mounting activity rubs off the silver coating to reveal a bright-colored patch underneath. These devices show significant potential to improve submission rates in dairy herds.

The consistent drawbacks with all of these systems that require the fixing of a device such as a kamar, beacon, or transponder to the tailhead of a cow are the significant amount of effort required to maintain the devices on the cows and the high loss rates. Similarly, tail-paint or chalking must be reapplied to cows at 7–10 day intervals – again requiring handling and time.

Conception Rate

This is the third major factor affecting reproductive efficiency. The main factors implicated in causing conception failure or embryo death are normally categorized as those of genetic, physiological, endocrine, and environmental origin.

Fertilization rate and early embryo loss rates in Cattle

Based on published data, there is little evidence to suggest that fertilization rates are likely to be different in the modern high-producing cow as compared with lower-producing cows or heifers particularly under temperate climatic conditions. When adequate numbers of spermatozoa are used from bulls of high fertility and cows are correctly inseminated during or shortly after the end of standing estrus, fertilization rates approaching 90% should be expected. Although fertilization rate is apparently similar in high- and moderate-producing cows and is unlikely to be affected by whether the cows are on pasture or high-input total mixed ration (TMR) diets, the average calving rate to a single service, nevertheless, is significantly lower in high-producing cows than in either low-producing cows or heifers. An embryonic and fetal mortality rate (excluding fertilization failure) of ~40% is calculated for moderate-producing cows based on a fertilization rate of 90% and an average calving rate of ~55%, with an estimated 70–80% of the loss being sustained between day 8 and 16 after insemination. The comparative figure for high-producing dairy cows, based on a fertilization rate of 90% and a calving rate of 40%, would be 56%.

Pattern of early embryo loss

Based on published literature, there is some evidence that the pattern of early embryo death in the modern high-producing cow may be different from that observed in heifers and lower-yielding dairy cows. The extent of early embryo loss appears to be larger in the modern high-producing dairy cows, with a much higher proportion of the embryos dying before day 7 following insemination. The expected outcome of 100 inseminations of British-Friesian and Holstein-Friesian cows is summarized in **Figure 2**. Because fertilization rate is close to 100%, conception failure is almost synonymous with embryo and fetal loss.

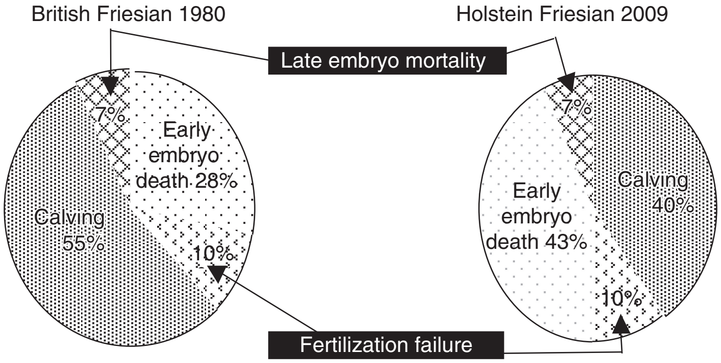

Figure 2 Reproductive outcomes in British-Friesian vs. Holstein-Friesian cows.

With the advent of ultrasound scanning, it has been comparatively easier to accurately establish the extent and timing of late embryo/fetal mortality. A recent study by the Teagasc laboratory, Galway, Ireland, quantified the extent and pattern of embryo/fetal loss from days 28 to 84 of gestation in 1046 lactating dairy cows and 162 dairy heifers managed on pasture-based systems of milk production. The overall embryo/fetal loss rates between days 28 and 84 of gestation were similar for cows (7.2%) producing on average 7247 kg of milk and heifers (6.1%), and the pattern of loss over this period was also similar for cows and heifers. Almost half (47.5%) of the total recorded loss occurred between days 28 and 42 of gestation. There was no significant association between the level of milk production or milk energy output measured up to day 120 of lactation, milk fat concentration, milk protein concentration, or milk lactose concentration and the late embryo/fetal loss rate. The extent and pattern of embryo/fetal loss were not related to either the cow's or the cow sire's genetic merit. The author does acknowledge that the extent of late embryo/fetal mortality recorded in the Irish pasture-based studies is much lower than that reported for some US-based studies. However, a clear explanation for the reported differences is not apparent but may be related to the level of milk production, ambient temperature, and/or the breeding of cows following various Ovsynch-based protocols in the United States.

Progesterone during the cycle immediately prior to insemination and embryo survival rate

Data from a recent study conducted by the Teagasc laboratory, Galway, Ireland, clearly show that there is a positive linear association between the concentrations of progesterone on the day of PGF-2α-induced luteolysis and the subsequent embryo survival rate (**Figure 3**).

Following a literature review, it was concluded that the most probable effect of low concentrations of progesterone in the cycle preceding estrus on subsequent embryo survival rate is preterm oocyte maturation, which subsequently compromises its ability to continue normal embryo development after its fertilization.

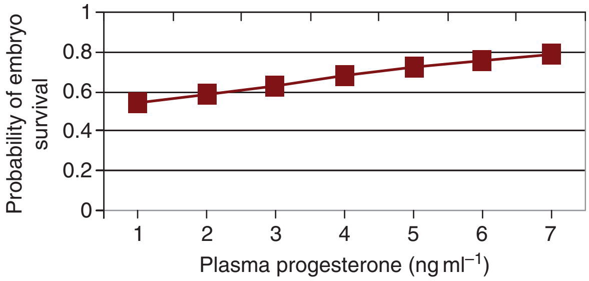

Figure 3 Relationship between plasma concentrations of progesterone on day of induced luteolysis and subsequent embryo survival rate.

Post insemination progesterone and embryo survival rate

Recent studies by the Teagasc laboratory, Galway, Ireland, that have employed logistic regression techniques to model the relationship between the binomially distributed dependent variable (conception/embryo survival rate; yes or no) and the continuously distributed independent variable (progesterone) have established a relationship between circulating progesterone and embryo survival rate. In a study by Stronge *et al.* (**Figure 4**) there was a positive linear relationship between milk concentrations of progesterone on days 5, 6, and 7 post insemination and the embryo survival rate, and a quadratic relationship between the rate of change in concentrations of progesterone between days 4 and 7 and the embryo survival rate. Further analysis of this data set reveals that 75, 72, and 56% of dairy cows had concentrations of progesterone that were optimal for conception on days 5, 6, and 7 post insemination, respectively. There is evidence that progesterone supplementation of dairy cows having low endogenous

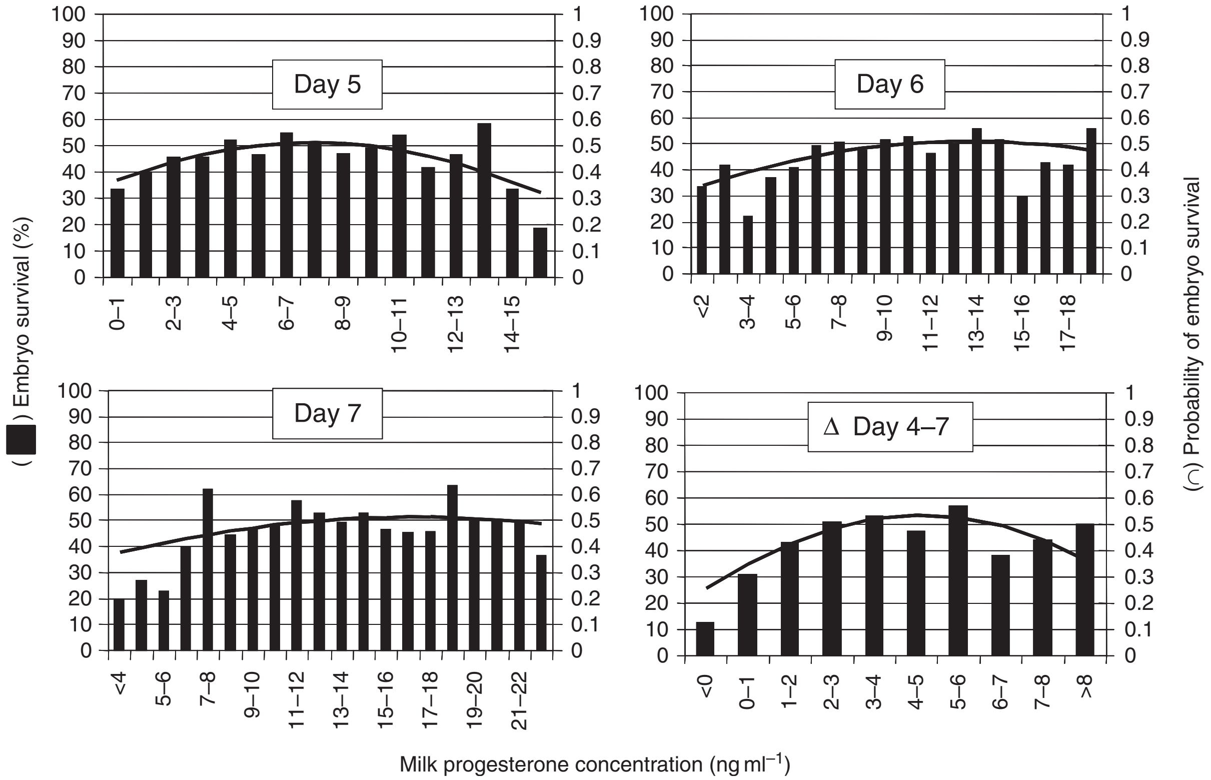

Figure 4 Relationship between milk concentrations of progesterone on day 5, 6, and 7 after AI and subsequent embryo survival rate in lactating dairy cows. Reproduced with permission from Stronge AJH, Sreenan JM, Diskin MG, Mee JF, Kenny DA, and Morris DG (2005) Post-insemination milk progesterone concentration and embryo survival in dairy cows. *Theriogenology* 64: 1212–1224.

concentrations of progesterone, and consequently at risk of suffering embryo death, will have improved embryo survival rates.

A series of studies with dairy cows at the University of Wisconsin have shown that peripheral concentrations of both progesterone and estradiol are lowered by increased plane of feed intake owing to increased metabolic clearance rate (MCR) of the steroids, which is related to liver blood flow (LBF). From these studies, it would appear that LBF is elevated in high-producing lactating dairy cows and this in turn would result in a lowering of peripheral concentrations of progesterone thus increasing the risk of embryo death. The reduced progesterone effect may retard the growth and development rate of the embryo by hampering uterine secretion of proteins and growth factors essential for early embryo development. Interferon-τ, the embryonic signal required for the maintenance of the corpus luteum and the estalishment of pregnancy, has also been shown to be positively correlated with progesterone. Uterine expression of the mRNA for progesterone receptor and estradiol receptor and of the retinol-binding protein mRNA are all sensitive to changes in peripheral concentrations of progesterone during the first week after AI.

Nutrition–Energy Balance

Over the past three decades, intensive genetic selection for milk yield has increased the differences between feed intake potential and milk yield potential. This has resulted in dairy cows that have a greater predisposition for mobilizing body reserves and for NEB. It is also clear that even under optimal grazing conditions total DMI is lower than when cows are fed maize-based TMR diets. A pasture DMI of ~3.4–3.6% of body weight has been recorded for early-lactation cows grazing high-quality pasture compared to 3.9–4.2% of body weight for cows fed a nutritionally balanced TMR. From this, it is clear that under optimal grazing conditions the actual DMI of cows is significantly lower than the cows' potential intake, and this is likely to have implications for EB status and subsequent fertility in early lactation, particularly for cows with a high genetic potential for milk production.

Energy balance during the early postpartum period and subsequent conception rate

The relationships between EB, DMI, and peripheral concentrations of IGF-I measured during the first 28 days of lactation and subsequent conception rate have recently been explored in a number of Teagasc studies. All three variables were positively associated with first-service

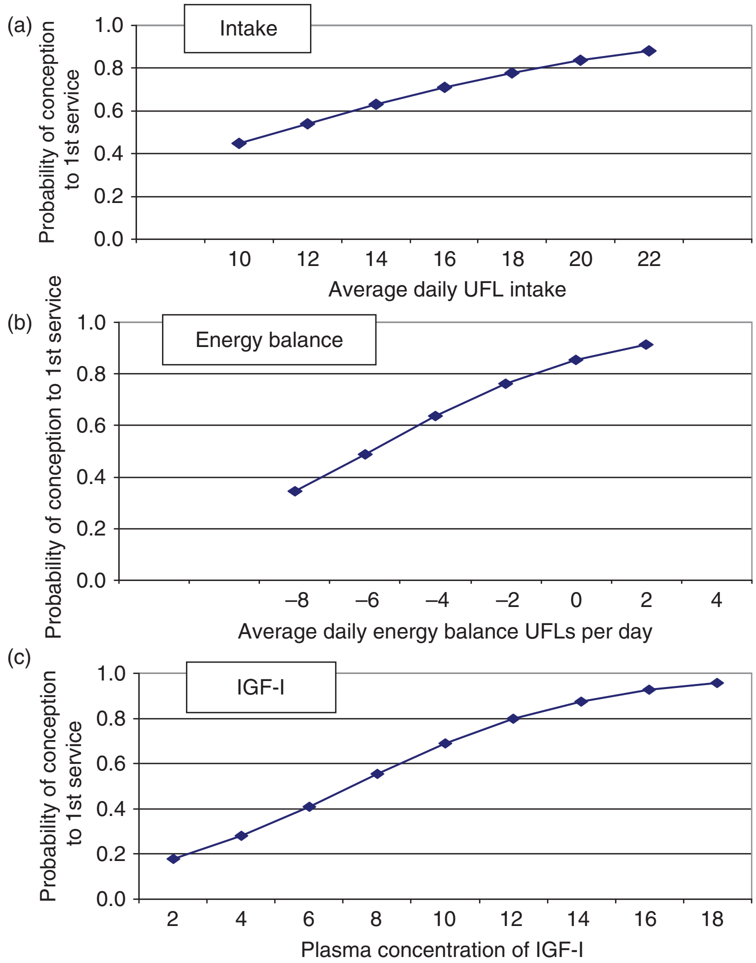

Figure 5 Relationships between (a) average daily intake (UFL day^{-1}), (b) average daily EB (UFL day^{-1}), and (c) plasma concentration of IGF-I during the first 28 days of lactation and probability of conception rate to first service in dairy cows. Reproduced with permission from Patton J, Kenny DA, Mee JF, *et al*. (2006) Effect of milking frequency and diet on milk production, energy balance, and reproduction in dairy cows. *Journal of Dairy Science* 89: 1478–1487.

conception rate, and the results are presented in **Figure 5**. This is a particularly interesting observation and suggests that there may be long-term carryover effects of nutrition/EB on conception rate. It has also been hypothesized that follicles exposed to adverse conditions such as a negative EB during their initial stages of growth would have impaired development resulting in the production of inferior quality oocytes and dysfunctional corpora lutea. The results of this study strongly emphasize the importance of maximizing feed intake and minimizing NEB in the immediate postcalving period.

Energy balance at around the time of insemination and subsequent conception rate

It is clear that DMI is lower for cows grazing pastures than for cows fed maize-based TMR diets. Supplementation of dairy cows at pasture with concentrates increases the total DMI, but its effects on conception rate are equivocal. Following a review of a number of experiments that examined the effects of supplementation on conception rate, Diskin *et al.* (2008) concluded that supplementation had little effect on conception rate but that withdrawal of the supplementation during the breeding period may be counterproductive to conception rate. Only a small proportion of the additional feed intake achieved by concentrate supplementation is partitioned toward an improvement in EB, with >80% supporting increased milk production. This clearly highlights the difficulty that improving the EB of the modern dairy cow presents at this stage of lactation when grazed grass is the predominant component of the diet. Based on the Wisconsin study, it is reasonable to hypothesize that the increased milk production resulting from concentrate supplementation may well be associated with a further increase in hepatic blood flow resulting in increased metabolism of progesterone and consequently in lowering of the peripheral concentrations of progesterone, thus predisposing cows to greater risk of embryo death.

Effect of sudden reductions in feed intake on conception rate

Studies by the Teagasc laboratory, Galway, Ireland, show that sudden reductions in DMI at around the time of insemination adversely affect embryo survival in heifers. When energy intake was reduced from a high level of twice their maintenance requirement to 0.8 times maintenance for 2 weeks immediately after AI, embryo survival rate in heifers was consistently <40%. When heifers were either provided with a constant level of feed intake or changed from a low to a higher level of feed intake, embryo survival was consistently high at 65–71%. In one study where heifers were used, there was no indication of any association between energy intake and systemic progesterone concentration.

Unlike the situation in sheep and pigs, there was no change in systemic progesterone following either an increase or a reduction in energy intake. Changes in progesterone metabolism may have been balanced by changes in progesterone production.

Protein nutrition and conception rate

Dairy cows at pasture frequently ingest high quantities of protein, often with a high proportion of the ingested protein being rapidly degradable in the rumen. The effects of high intakes of crude protein on conception rate are equivocal. For example, US data have shown that high-protein intake reduces uterine pH, which has been hypothesized to have a detrimental effect on either the gametes or the developing embryo. High-protein diets elevate plasma urea nitrogen (PUN) levels. PUN in excess of $19\,\mathrm{mg\,dl^{-1}}$ has been associated with a 20% depression in conception rate in dairy cows. However, in an extensive range of studies by the Teagasc laboratory, Galway, Ireland, using beef heifers in positive EB, no effect of a high crude-protein intake on conception in heifers was recorded, irrespective of whether the crude protein was derived from highly nitrogen-fertilized grazed grass or from added urea to a silage-based diet. Furthermore, a retrospective analysis of the data failed to record any association between peripheral concentrations of urea and embryo survival, notwithstanding peripheral concentrations of urea having been elevated up to $25\,\mathrm{mmol\,l^{-1}}$. It is concluded that elevated peripheral concentrations of urea *per se* are not detrimental to embryo survival. However, it needs to be clarified whether the observed adverse effects of urea on embryo survival are dependent on the energy status of the animal.

Insemination technique

The reported effects of the site of placement of semen within the uterus on conception rate are equivocal. In a recent study by the Teagasc laboratory, Galway, Ireland, involving 3546 dairy cows in 51 herds and 8 inseminators, Diskin *et al.* (2005) recorded a significant effect ($P < 0.02$) of insemination site and inseminator on conception rate. For some inseminators, there was a significant increase (up to + percentage points) on conception rates following cornual insemination, whereas for others there was no effect. A retrospective analysis of all the data showed that there was an inverse relationship between the improvement in conception rate and conception rate following uterine body insemination. The largest improvements in conception rates were recorded by inseminators with the lowest conception rate following body insemination. These results suggest that conception rates could be improved for individual inseminators by adopting the practice of placing half of the inseminate beyond the curvature of each uterine horn as opposed to body insemination, which is the normal practice. It is clear from many studies that placement of the inseminate in the cervix results in significantly lower conception rates. Therefore, it is critical to at least ensure that the inseminate is placed in uterine body, and for skilled and experienced inseminators, it would appear beneficial to place half of the inseminate in each uterine horn.

Time of insemination

Results from a recent large-scale study that utilized the HeatWatch system to detect the onset of standing heat concluded that conception rates were optimum when dairy cows were inseminated 4–16 h after heat onset. Insemination later than 16 h after heat onset results in significantly lower conception rates. However, in most instances the time of heat onset is not accurately determined, and in such situations once-daily AI for cows observed in standing heat is equally effective as inseminating cows in accordance with the long-established a.m.–p.m. guidelines.

Calving difficulty

Calving difficulty, besides affecting calf and cow mortality and the milk yield, also decreases cow rebreeding performance. Teagasc data clearly show that as the severity of calving difficulty increases, conception rate to the first and to all services combined also decreases (**Figure 6**). This reduction in conception rate is owing to the abnormalities directly arising from calving difficulty, including delayed uterine involution and increased uterine infection, damage to the reproductive tract, and the development of uterine and ovarian adhesions. Furthermore, the interval to first heat is often extended after a difficult calving. For optimal reproductive performance, calving difficulty must be minimized.

Two factors that greatly influence the incidence of calving difficulty are the age of the cow and the breed of the sire. The incidence of calving difficulty is 4–8 times higher in first-calving heifers than in mature cows and about twice as high in second calvers as in mature cows. The breed of the sire and indeed the individual sire within a breed should be carefully selected for use on

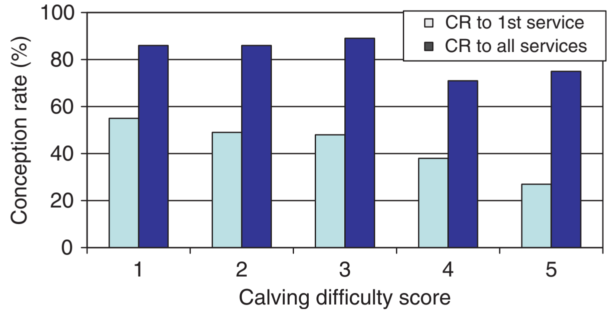

Figure 6 Relationship between calving difficulty score and conception rate to first services and to all services combined. Difficulty ranges from score 1 (unassisted birth) to score 5 (severe difficulty requiring mechanical extraction of the calf).

heifers and on young cows to minimize the risk of calving difficulty and therefore of subsequent infertility.

In some countries, there is a practice of breeding late-calving dairy cows to beef sires. The combined effect of the longer gestation and the increased incidence of calving difficulty makes it even more difficult to achieve a 365-day calving interval in such cows. The wisdom of this practice, especially if the objective is to optimize reproductive performance, is therefore questionable.

Bull fertility

Bull reproductive performance is influenced by several factors including testicular development, semen quality, libido, mating ability, and physical soundness. On farms using natural service, the level of bull fertility can have a major impact on pregnancy rate and calving spread. Published data suggest that up to 5% of bulls in natural service may be completely infertile and that a further 30% may be subfertile. Unfortunately, if a bull is infertile, it is not usually discovered until at least one repeat interval has elapsed since joining the herd.

Although a veterinary examination combined with a semen evaluation 1 month before the start of the breeding season will help to identify the majority of infertile bulls, it will not identify subfertile bulls. Furthermore, it should be realized that a bull may not remain fertile for all of his working life or even throughout a single mating season. For example, a bull that is ill with a raised temperature for a number of days may have a period of temporary infertility ~40–60 days later. Similarly, injury to the penis, sheath, or prepuce, though not necessarily affecting mounting behavior, can prevent mating. Therefore, the bull should be observed regularly for serving ability, and all mating dates recorded. Such recording will help identify infertile or subfertile bulls at an early stage.

AI versus natural service

AI is often criticized on the grounds that conception rate is lower than when following natural service. Apparent improvement in conception rate often arises following the introduction of a bull. This apparent improvement is likely to be because of cows being mated at a longer postpartum interval and/or because of inaccuracies in heat detection being eliminated. Where heat detection is accurate, and when insemination is timed and carried out correctly, conception rate is similar following either AI or natural service.

Relative Importance of Heat Detection Efficiency and Conception Rate

Once estrous cycles have resumed postcalving, then it is the product of heat detection efficiency and conception rate that determines the overall herd reproductive efficiency (**Table 2**).

The clear message from **Table 2** is that low or relatively low conception rates can be compensated for by improving heat detection efficiency. Practical and easily adoptable technologies are available to improved heat detection efficiency.

Conclusion

It is well established that reproductive performance is critically important, particularly in seasonally calving herds, to maintain compact calving close to the onset of the grazing season. Even though the modern high-genetic merit Holstein-type dairy cow selected solely for milk production is biologically more efficient at converting forage, irrespective of source, to milk, their sustainability in predominately pasture-based systems of production is questionable given their low fertility. Therefore, it is important to develop appropriate supplementation strategies, probably beginning before parturition, to improve fertility in dairy cows on pasture-based systems of production. In the medium to long term it should be possible to develop more balanced breeding strategies with greater emphasis on fertility- and feed intake-related traits, which are critically important to pasture-based systems of milk

Table 2 The effect of different heat detection (submission) and conception rates on the percentage of the herd that is pregnant at 90 days after onset of breeding season

		Conception rate (%)			
		60	*50*	*40*	*30*
Heat detection rate (%)	*90*	96	91	83	71
	70	89	82	73	61
	50	76	68	59	48
	40	67	59	50	40

production. It is clear that sufficient genetic variability exists within the Holstein breed for important fertility and feed intake traits. Alternatively, strains of cows derived from more balanced breeding objectives, such as the New Zealand Friesian, or alternative dairy breeds such as the Jersey or Norwegian Red could also be utilized in such production systems.

It is now becoming increasingly clear that EB during the immediate postcalving period affects both the onset of estrous cycles postcalving and the subsequent conception rates. Development of feeding strategies that increase intake without proportionally increasing milk yield, thereby improving EB, is important. Paying more attention to other factors that are predominately under management control, particularly heat detection, can significantly offset some consequences of inherently low fertility traits that exist with the modern dairy cow. Improving heat detection efficiency by 12–15% has the equivalent effect of increasing conception rate by 10 percentage points. Based on numerous published reports, it can be concluded that there is scope in most herds to improve heat detection efficiency by at least 15 percentage points by adopting well-described practices. Conception rate is affected by a range of both cow and management-related factors. Producers should ensure that cows presented for insemination are in heat and are properly inseminated with high-fertility semen. Sudden reductions in feed intake during the breeding season should be avoided.

Introduction

Milk, like all consumable products obtained from domestic animals, is acquired through exploitation of reproductive processes. Therefore, dairying will be efficient only if females regularly produce offspring. Both sexes must be involved for the initiation of pregnancy but, with the ejaculation of viable spermatozoa into either a natural or artificial vagina, the male's role is finished. In contrast, the female's role has just begun. The mammalian embryo is referred to as a zygote from fertilization through the early cleavage divisions, a morula when a spherical cluster of cells has formed, and a blastocyst once it consists of a hollow sphere and the two cell lineages that will give rise to the embryo proper and the placental membranes. Once organs have formed, the developing offspring is referred to as a fetus. At any stage, it can be referred to as a conceptus, the product of conception. For the purposes of this article, these terms may be used interchangeably.

As gestation progresses, the maternal systems are modified to provide an environment that supports development. The process includes remodeling of uterine structure and function to provide nutrients for growth plus suppression of maternal immune responses so that the potentially antigenic conceptus is not rejected. The following text deals with the establishment, progression, duration, and detection of pregnancy. Although most of the world's milk comes from *Bos taurus* or *Bos indicus* cows, information on other species used for dairying will be included when available.

In the Beginning

Preattachment Development: Zygote to Expanded Blastocyst

Embryos pass through the first few cleavage stages as they travel down the oviduct. All development up to the mid-blastocyst stage occurs while the embryo is confined within its zona pellucida (**Figures 1**(**a**)–**1**(**d**)). Because zona-enclosed embryos do not grow larger, as the number of blastomeres doubles at each cleavage their individual size is halved. In cattle, sheep, and goats, embryos enter the uterus 3–5 days after fertilization, typically at the 8- to 16-cell stage.

In the sheep, if two oocytes are released from the same ovary and no ovulation occurs from the other ovary, one embryo commonly migrates down the ipsilateral horn of the uterus, passes through the uterine body, and develops in the contralateral horn (i.e., on the opposite side). In contrast, migration between uterine horns in cattle is rare. If there are two ovulations from the same ovary, both embryos will remain and develop in the adjacent uterine horn. It was thought that uterine capacity might be limiting, such that twins gestated in separate horns would be more likely to survive to term. However, studies have found this to be a problem only with nulliparous heifers. Twinning in cattle, regardless of uterine position, is associated with substantially higher rates of calf mortality, dystocia, and metabolic problems. An additional problem associated with twins in cattle is the possible fusion between the placental membranes of the two conceptuses. This situation leads to exchange of cells and signaling molecules between fetuses. If one fetus is male and the other female, the male will be normal but the female will have abnormal sexual differentiation. Most heifer calves that develop as cotwins with males become sterile freemartins characterized by apparently female external genitalia with variable asexual or phenotypically male internal genitalia. Although some aspects of this centuries-old phenomenon remain a mystery, studies of freemartins in cattle have made fundamental contributions to our understanding of sexual differentiation and immunology. In fact, the groundbreaking work by Medawar (cowinner of Nobel Prize, 1960) on naturally acquired immunological tolerance was initiated by studying transplantation reactions in freemartins.

Soon after entering the uterus, the embryo passes through the morula and to the blastocyst stage (**Figures 1**(**e**) and **1**(**f**)). Fluid accumulates between some of the cells and these spaces unite to form the blastocoel, a fluid-filled cavity. A cluster of cells give rise to the inner cell mass, which will form the embryo proper, while the remainder surrounding the cavity form the trophectoderm, the precursor of the placental membranes. Embryos

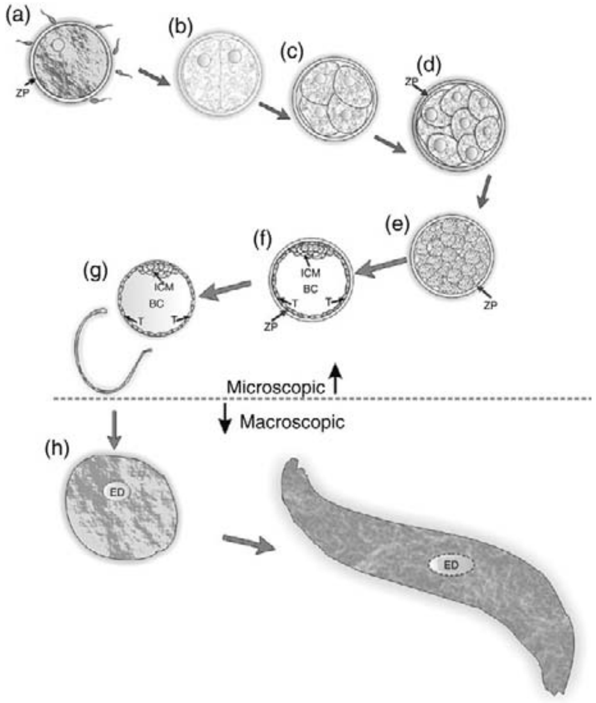

Figure 1 Development of the conceptus from fertilization to elongation of the chorionic vesicle. (a) Fertilization, the union of spermatozoon and oocyte to form the zygote or embryo; ZP, zona pellucida. (b) First cleavage, occurring about 24 h after fertilization, producing an embryo with two cells or blastomeres still contained within the zona pellucida. (c) Second cleavage, usually within 12 h of first cleavage, producing four blastomeres. (d) Third cleavage, within a few more hours, resulting in eight blastomeres within the zona pellucida. (Blastomere division is not synchronized exactly, so zygotes with intermediate numbers may be observed.) (e) Subsequent cleavages produce the morula with 16–64 blastomeres, still within the zona pellucida. (f) Continued cleavage results in a blastocyst with a distinct inner cell mass (ICM) and a layer of trophectodermal cells (T) surrounding a fluid-filled central blastocoelomic cavity (BC). (g) Outward pressure from the growing blastocyst ruptures the zona pellucida (hatching), so the conceptus can now increase in size. (h) The conceptus grows rapidly into and through the spherical blastocyst stage. At this time, it is a fluid-filled sac with a distinct embryonic disc (ED) on the surface. (i) In most ungulate species, the spherical blastocyst elongates quickly into a filamentous form that grows to fill much of the uterine lumen. The embryonic disc remains as a distinct spot on the surface of this chorionic vesicle. It is the trophectoderm or outer cell layer that interacts with the endometrium to form the placenta.

intended for transfer are typically collected from the uterus at the morula or blastocyst stage.

Early in the second week of gestation, the zona pellucida ruptures and the blastocyst is freed or hatched (**Figure 1**(**g**)). Cell division continues and, since the blastocyst is no longer confined within the zona, it can now increase in size. By 10 days, the inner cell mass forms an embryonic disc located as a discrete structure at the surface of a hollow sphere (**Figure 1**(**h**)). The original cells forming the inner cell mass and trophectoderm constitute the ectoderm, the first of the three primary germ layers. A sheet of flattened cells, the endoderm, proliferates from the inner cell mass during the second week of gestation and develops into a single cell layer closely associated with the inner surface of the trophectoderm. This proliferation progresses until the endoderm lines the entire inner surface, forming a two-layered or bilaminar membrane surrounding the blastocoel. Shortly after the bilaminar blastocyst forms, further differentiation within the inner cell mass initiates production of mesodermal cells beneath the disc. The mesoderm or the third germ layer proliferates and spreads between the ectodermal and endodermal cells resulting in a trilaminar blastocyst. During subsequent development, the three germ layers interact to produce tissues and organs within the developing embryo/fetus plus the various embryonic membranes.

The hatched blastocysts of domestic ruminants remain in the spherical stage (**Figure 1**(**h**)) for several days. The trophectoderm, which has now become the outer embryonic membrane or chorion, extends to form an oval shape and quickly stretches into an elongated, sausage casing-like, filamentous structure (**Figure 1**(**i**)). Much of this initial increase in length is accomplished through cellular remodeling into greatly stretched configurations rather than by cell proliferation. The embryonic disc begins to develop a neural fold and somites, giving rise to a primitive embryo that is enveloped by an infolding of the rapidly growing membranes. Late in the second or third week of gestation, the filamentous blastocyst, also called a chorionic vesicle, assumes a fixed position within the uterus, stretches to a substantial length, and begins to fuse with the uterine lining.

Formation of Embryonic Membranes

As a blastocyst elongates and the embryo forms, several other membranes develop. A yolk sac grows out from the middle section of the embryo and proliferates within the chorionic vesicle. The yolk sac quickly develops an extensive vascular bed and extends toward, but never reaches, the chorionic tips. Both the chorion and yolk sac synthesize peptides, proteins, and steroid hormones, some of which serve as signals from the conceptus to the dam, coordinating maternal responses to embryonic requirements. In addition, the yolk sac produces the first embryonic blood cells and serum proteins. The primordial germ cells, which subsequently migrate to the genital ridge and transform this region into a gonad, also originate in the yolk sac. Once the liver and other organs develop and assume their functions, the yolk sac regresses.

Another embryonic membrane, the allantois, develops from the hind region of the embryo late in the third week of gestation. It begins as a small sac but soon becomes filled with fluid and expands. In most species, the allantois displaces the yolk sac and, within a few days, lines most of the chorionic vesicle. The allantoic and chorionic membranes fuse to form the chorioallantois. This combined membrane rapidly develops an extensive blood vascular system that is connected directly with the embryonic circulation via the umbilical cord. In most mammals, the chorioallantoic membrane constitutes the outermost layer of the embryo/fetal unit that attaches to the uterine lining forming the placenta.

As the yolk sac and allantois are developing, the differentiating embryonic disc sinks below the surface of the chorionic vesicle. The embryo is then surrounded or enveloped by infolding chorion that fuses in the middle to form a separate sac, the amnion. This compartment is also filled with fluid and intimately surrounds the embryo/fetus to provide a stable physical environment for growth and a cushion against mechanical shock. Embryos implant in the distal third of the ipsilateral uterine horn, and the chorionic vesicle expands into the contralateral horn. In camelid species, embryos tend to implant in the left horn even though ovulation can occur on either side, with membranes expanding into the opposite horn.

Development of the Fetus

As the embryonic membranes organize, the ectodermal, mesodermal, and endodermal components of the inner cell mass differentiate and begin forming specific organs. Early in gestation, the embryonic disc region organizes through the primitive streak, neural fold, and somite stages. Around the time when placental attachment commences, the heart forms and vascularization of the embryo and associated membranes begins. At this stage, a head and body region become recognizable but bear little resemblance to the final product. The individual organs, limb buds, and other features appear within a very few weeks, heralding the transition from an embryo to a fetus.

During the initial stages of development, there is almost no increase in uterine size. Once the attachment of the chorion to the uterine epithelium is well under way, fluids begin to accumulate in the chorioallantoic and amniotic space and the uterus enlarges (**Figures 2(a)** and **2(b)**). It is this fluid that accounts for much of the increase in size through midgestation. In the later stages, growth of the fetus accelerates so that by term it will account for about half of the total conceptus-uterine weight. In late gestation, the fetal fluids probably account for another quarter, with the placenta and uterus constituting the remainder.

Nutrition of the Conceptus

Mammalian oocytes have sufficient stores of yolk material to provide nutrients to support embryonic development through the first few cleavage divisions. However, once cell numbers begin to increase through the morula and blastocyst stages, the embryo must obtain and metabolize materials from the mother. There are two possible ways for the embryo to obtain nutrients. First, material secreted by the epithelial lining of the endometrium (inner layer of uterus) is absorbed by the outer surface of the chorionic vesicle. This mode of transfer, known as histotrophic (histiotrophic) nutrition, is carried out by a uterine lining of tall, columnar cells loosely associated with the fetally derived layer. Uptake is facilitated by areolae, which are pockets of columnar trophoblast cells overlying

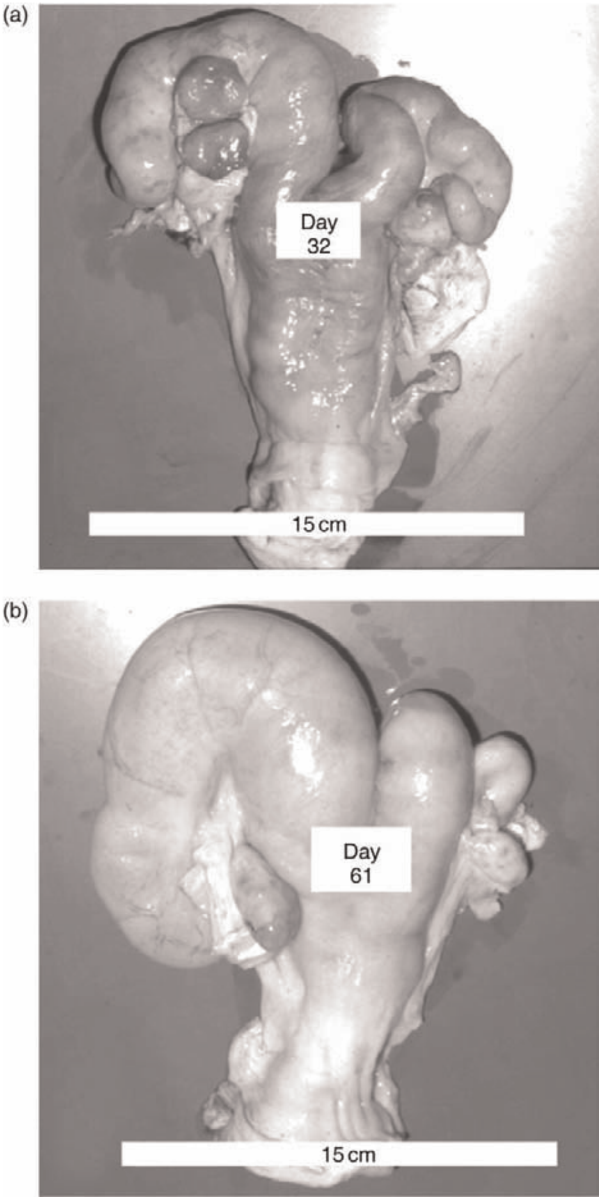

Figure 2 (a) Bovine uterus, day 32 of gestation. The embryo/fetus is located near the middle of the slightly enlarged left (ipsilateral) uterine horn. The right (contralateral) horn is just beginning to enlarge. The corpus luteum on the left ovary is cut open. (b) Bovine uterus, day 61 of gestation. The fetus is located in the substantially enlarged left uterine horn. By this stage, the contralateral horn is also obviously distended.

the mouths of uterine glands. In the second route, material diffuses between maternal and fetal circulations through various tissue layers. This mode of nutrient transfer, hemotrophic nutrition, requires a well-vascularized fetal layer and a thinning of the layers separating maternal and fetal vasculature. The placenta provides this situation.

All mammalian embryos are dependent on histotrophic nutrition up to the blastocyst stage. These stages are considered to be anaerobic, such that embryos require a supply of nutrients but minimal levels of oxygen. Subsequently, the relative importance of histotrophic nutrition and the timing of the switch to hemotrophic nutrition are highly variable among species. In humans, the period of histotrophic exchange is believed to be very brief, since the embryo invades and implants within the uterus quickly (10 days after fertilization) and the placenta is formed relatively early in pregnancy. In contrast, in all ungulates (hoofed animals), attachment to the uterus is delayed and the placenta is formed later in gestation. Because histotrophic transfer is important throughout the entire gestation, conceptuses in ungulate species typically undergo considerable expansion prior to attachment to occupy a larger surface area of the uterus.

Placentation

In all mammals, placentation begins when the embryonic vesicle assumes a fixed position within the uterus (apposition), followed by adhesion between chorion and uterine epithelium and the interdigitation of finger-like projections (microvilli) that develop on apposed maternal and embryonic cells. In many mammalian species, attachment is followed by destruction of uterine epithelium, and invasion of endometrium by embryonic cells (e.g., true implantation). However, placentation in ungulates is characterized by simple attachment to the uterine epithelium with little or no destruction of maternal tissues. In essence, the ungulate placenta forms as a result of interaction between the outermost membrane of the embryonic vesicle, the chorion, and the epithelial lining of the uterus. Attachment begins on days 18–19 in cows and goats, and on days 14–15 in sheep. The intimate association between chorion and endometrium constitutes the mature placenta in camelids.

In true ruminants (e.g., cattle, goats, sheep), the most obvious features of the placenta are placentomes, which consist of caruncles – raised round or oval areas on the inner uterine lining – interacting with cotyledonary areas of the chorioallantoic membrane (**Figure 3**(**a**)). Individual caruncles are composed of dense connective tissue covered by simple columnar epithelium. A distinctive feature of the caruncular endometrium is its lack of glands; the openings of uterine glands are found only on the intercaruncular surface. Although caruncles do not come into play until pregnancy, they begin to develop during fetal life, and are easily visible in the inner surface of a prepubertal calf uterus (**Figure 3**(**b**)). The number of caruncles is highly variable both between and within species, with estimates of 70–142 in cows, 160–180 in goats, and 60–150 in sheep.

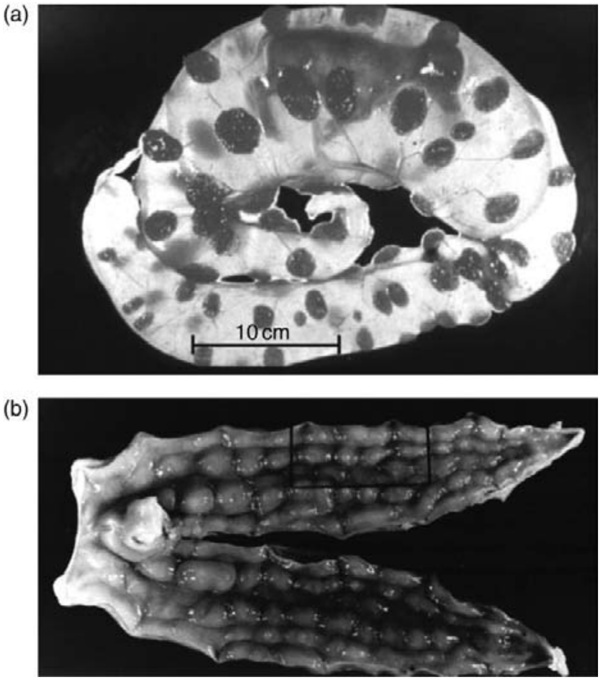

Figure 3 (a) Bovine fetus within the placental membranes showing conspicuous cotyledons at the surface. Note that the largest cotyledons are nearest to the fetus. The gestational age is approximately 6.5 months. (b) Inner endometrial surface of the uterus from a 6-month-old calf. Note the four rows of caruncles in each uterine horn. Modified with permission from Atkinson BA, King GJ, and Amoroso EC (1984) Development of the caruncular and intercaruncular regions in the bovine endometrium. *Biology of Reproduction* 30: 765, Figure 2(a).

In both intercaruncular and caruncular regions, apposition and subsequent attachment of the chorion and uterine epithelium commence near the embryonic disc. The union of maternal and fetal surfaces is consolidated by ridging or folding of the interface, which follows almost immediately after attachment begins. In the cow, physical union between these tissues extends over the entire mucosa by day 27. Attachment at placentomes is reinforced by the penetration of chorionic villi into crypts that form within the endometrium (~day 33 in the cow). The folding of the maternal–fetal interface together with the progressive branching of the villi and deepening of the maternal crypts provide a vast surface area for exchange.

The placentomes are such obvious features that the ruminant placenta is classified as a cotyledonary placenta. This terminology infers that definitive placentation involves only the placentomes. However, interplacentomal regions are also involved in exchange. Indeed, placentomal and interplacentomal regions are specialized for hemotrophic and histotrophic nutrition, respectively. The caruncles, with their thin, closely applied covering of trophoblast and extensive vascular bed, are well suited for hemotrophic exchange of gases and small molecules.

The glandular interplacentomal regions with their areolar-gland complexes are well suited for histotrophic transfer, and are believed to be primarily involved in the exchange of large molecules. Histotrophic nutrition is of greater significance in ungulates than in any other placental group.

Gestation Length

The duration of gestation in mammals is controlled almost entirely by genotype with major differences between species and minor variations among breeds or strains. The age of the dam, sex of the fetus, or season of birth may have slight effects, but these are small in comparison to the interspecies variation. The ranges of gestation lengths for various domestic animals used for milk production are given in **Table 1**.

In cattle, birth weight is correlated positively with gestation length since the longer a fetus remains *in utero*, the larger it grows. Also, the heavier male calves are usually carried slightly longer than female calves. Equine gestation length is somewhat longer and more variable than that in the ruminant dairy animals. The interval for mares may range from just over 300 days to almost 1 year, but most parturitions probably occur from 330 to 350 days. The differences between breeds and season of foaling are significant. Gestation is longer than normal in mares carrying mules. With the wide ranges reported for the various camelids, one might question how accurately mating was recorded or whether a number of offspring were born prematurely.

Table 1 Gestation lengths for species of animals that might be used for dairying

Species	*Gestation length (days)*
Cow – *Bos taurus*	278–290
Cow – *Bos indicus*	285–295
Water buffalo – *Bubalus bubalis*	302–317
Goat – *Capra hircus*	142–154
Sheep – *Ovis aries*	143–153
Horse – *Equus caballus*	330–350
Arabian camel – *Camelus dromedarius*	345–395
Asian camel – *Camelus bactrianus*	370–440
Llama – *Lama guanicoë glama*	320–345
Alpaca – *Lama guanicoë pacos*	325–366
Reindeer – *Rangifer tarandus*	210–240
Yak – *Bos grunniens*	250–270

Pregnancy Diagnosis

The main hurdles to successful pregnancy are breeding the female to a fertile male when she is in estrus, conception, and the resulting conceptus attaching to the uterus and developing a placenta. The majority of pregnancy failures are early in gestation (first 2 months in cattle). Thus, mating even during estrus is not a guarantee that females will complete gestation. Because of this uncertainty, managers of both intensive and extensive livestock production units may seek assurance that mated or male-exposed animals are truly pregnant.

The ideal pregnancy test would be sensitive enough to detect pregnancy early to allow timely rebreeding of the animal. It would be specific, in that it correctly distinguishes nonpregnant from pregnant animals. Pregnancy tests should be inexpensive and simple to conduct under field conditions. The procedure itself should have no negative impact on pregnancy, involving minimal physical manipulation of the pregnant uterus or stress to the pregnant female. At this point, the pregnancy test for dairy animals that meets all these criteria does not exist. An example of an ideal indicator is the chorionic gonadotropin of higher primates (e.g., human chorionic gonadotropin (hCG) in humans), which can be measured in blood and urine as early as 1 week after conception. Unfortunately, analogous molecules have not yet been identified in dairy species.

Detecting Nonpregnancy by Return to Estrus

Although the occasional cow may show weak estrus-like signs during pregnancy, female domestic animals rarely exhibit any signs of sexual behavior at one cycle interval after a fertile mating. Thus, for animals mated on known dates, demonstration of sexual receptivity when the next estrus is due indicates no conception from the previous service. Conversely, the absence of sexual behavior is a strong evidence for pregnancy. When hand mating is practiced, cows, ewes, or does can be tested with males just before and during the period when the next cycle should occur. Animals that show estrus can then be remated or treated hormonally. However, one caveat is that in many dairy herds relying on visual observation of estrus for mating via artificial insemination, estrus detection efficiency may be less than 50%. In such cases, a presumptive diagnosis of pregnancy based on missed estrus cannot be very accurate.

Direct Methods of Pregnancy Detection

Ballottement

The increasing size of fetal membranes and associated fluids within the uterus eventually produce abdominal distension. The physical enlargement usually becomes obvious during the later stages of gestation and is too late to be of much practical use for management decisions. Palpation of the firm fetal mass through the body wall may be attempted in ewes or does accustomed to being handled enough to relax their abdominal muscles. In cows, it is frequently possible to detect the presence of mid- or late gestation fetuses by ballottement. The open palm or fist is placed against the right flank just above the stifle joint, pressed firmly into the body wall with a short rapid movement, and then held in this position. The pressure wave produced by this movement shifts the fetus within its fluid-filled sac away, then back toward the hand. Once the fetal mass reaches a substantial size, it can be detected as a rebounding bump. Right horn pregnancies are easily detected by ballottement during the last trimester. However, the presence of the rumen between the uterus and left flank often hides fetuses developing on that side. In some instances, left-horn pregnancies may be detected by right-side ballottement.

Rectal palpation

Rectal palpation is an extremely useful procedure for pregnancy diagnosis in larger animals such as cattle. The bovine rectum is quite distensible and elastic allowing considerable mobility by the palpating arm and thus complete examination of the reproductive tract. Very early pregnancies can be diagnosed by detecting the very slight bulge of the embryo within its amnion before any obvious swelling of the gravid horn occurs. It is also possible to detect twins by this method. In the fifth or sixth week of gestation, the bovine conceptus enlarges within the uterus and the embryonic membranes thicken, so they can be felt through the uterine wall. The tactile sensation generated as the uterine wall is gently released between thumb and fingers provides the membrane slip test for pregnancy. Later, actual placentomes and fetal parts may be palpated. Around midgestation, the weight of the fetus and placental fluids pull the uterus forward into the abdominal cavity, so it cannot be reached by palpation. At this stage, it is still possible to diagnose pregnancy through examination of the middle uterine arteries and detection of the characteristic fremitus or dynamically vibrating pulse to the gravid uterine horn. By late gestation, the limbs and head are again within reach.

Although learning to diagnose pregnancy by rectal examination is not beyond the ability of most people, some expert instruction and considerable practice is necessary to develop this skill. Careless or rough handling, particularly in early gestation, can induce abortions. Thus, the procedure should be left to experienced professionals and even they must be very careful when examining animals before 50 days.

Ultrasonography

Several types of ultrasound units are commercially available for pregnancy diagnosis. The most sophisticated and accurate are real-time B-mode ultrasound models equipped with rectal or surface probes. Although these units are relatively expensive, ultrasound examinations are an integral part of reproductive management programs for a substantial number of dairy practitioners. Experienced technicians can detect pregnancy in cows by the third or fourth week of gestation. Some herd health programs also include a follow-up examination a few weeks later to determine fetal sex. Simpler Doppler or amplitude-depth (A-mode) ultrasound units are also available. The Doppler principle is based on detection of movement – blood flow in uterine or umbilical arteries, fetal heartbeat. A-mode ultrasound detects a fluid-filled uterus, which can occur in situations other than pregnancy. Although these less expensive units cannot be used as early in gestation, or with the same accuracy, as real-time units, they can be reliable in experienced hands.

Reports on the reliability of ultrasound for early pregnancy diagnosis in sheep and goats are variable. Using rectal probes in research settings, pregnancy in sheep and goats can be consistently diagnosed by days 20–25. However, in the field, it is generally recommended to scan after day 45 and even later (70–90 days) for information about number of fetuses. While the sensitivity and accuracy of ultrasound methods in all species vary with the skill level of the technician and type of equipment, the results in goats and sheep are influenced by additional factors such as animal position (for rectal) and whether wool is shaved (abdominal probes in sheep). Although rectal probes have the advantage of earlier detection, they may result in rectal damage in small ruminants.

Indirect Methods of Pregnancy Detection

Indirect methods for pregnancy diagnosis are based on measurements of substances in blood or milk. Antibody-based methods, either radioimmunoassays (RIAs) or enzyme-linked immunosorbent assays (ELISAs), have been developed for detection of these molecules. Because RIA uses radioactively labeled tracers that require expensive detection equipment, the emphasis is now on development of ELISAs that are based on changes in color.

Despite many decades of research, options for early pregnancy markers in dairy ruminants are still limited. Elevated concentration of progesterone, a steroid hormone produced by the ovaries, in blood or milk at the time of next expected estrus is the best established biochemical test for pregnancy in dairy animals. Unfortunately, progesterone levels are elevated during both the luteal phase of the nonpregnant cycle and pregnancy, so this test must be interpreted carefully. A more recently developed biochemical test is based on concentrations of pregnancy-associated glycoproteins (PAGs) in maternal blood. Although the functions of PAGs in pregnancy are not clear, the fact that they are produced by the placenta suggests that they would make an ideal marker for pregnancy. The limitations of these two approaches will be discussed in more detail below.

Milk progesterone concentrations as indicators of nonpregnancy

There are a number of variations but generally milk samples are collected from cows 20–24 days after service. In concept this same method is available in goats and sheep, but blood rather than milk is often used. If the female is pregnant, progesterone concentrations should be elevated. In contrast, luteolysis will occur in cows that were serviced without conception and progesterone concentrations should be very low. The test is very accurate for nonpregnancy but not so reliable for a positive diagnosis. For example, if a female is inseminated not at estrus but during the luteal phase and a sample taken 3 weeks later, she will be in her next luteal phase and could be incorrectly identified as pregnant. An animal with a prolonged luteal phase would also produce a false-positive result. With careful interpretation, milk progesterone tests are a valuable management aid for herdsmen with good estrus detection practices. Researchers in Denmark have developed a mathematical model capable of processing raw progesterone values from milk collected by a robotic milking system into a palatable form, providing the biological interpretation. These innovations, particularly when combined with in-line measurement technology, will be of great interest to operators of large herds.

Pregnancy-associated glycoproteins in plasma as indicators of pregnancy

The PAGs, including pregnancy-specific protein B (PSPB), are a large family of glycoproteins produced by binucleate cells within the chorion of the ruminant placenta. These unusual cells, which constitute up to 20% of the trophectodermal cells, are present only during pregnancy. However, detectable levels of PAGs have been reported in a proportion of virgin heifers, unbred cows, and even bulls, suggesting an alternate source. For this reason, the cutoff value to discriminate between pregnant and nonpregnant animals must be carefully considered. Another drawback of PAGs is that, typical of heavily glycosylated proteins, they have a long half-life in the circulation. Plasma concentrations rise to very high levels in dairy cows during the last few days of gestation, which carry over into the postpartum period. Residual levels of PAGs that would be considered diagnostic of pregnancy can still be detected up to 3 months postpartum, which limits the use of PAGs for early pregnancy detection. A third drawback of PAGs is that they are not secreted into milk to any appreciable extent, which necessitates collection of a blood sample.

Development of assays for pregnancy-associated glycoproteins

RIAs utilizing antisera from rabbits immunized with purified or semipurified preparations of bovine cotyledons have been described in the scientific literature beginning in the late 1980s. These assays have also been used to detect PAGs in sheep and goats, using bovine standards and tracer. More recently, RIAs using antisera raised against preparations of ovine and caprine placentomes have been developed. Curiously, when used for screening of cattle, these heterologous RIAs measured higher concentrations than homologous assays using all bovine reagents. Indeed, an RIA using a mixture of rabbit antisera produced with cow, sheep, and goat PAGs as immunogens found greater differences in PAG concentrations in pregnant versus nonpregnant cattle.

ELISAs do not require expensive detection equipment or radioactivity, and can be modified to provide qualitative 'cow-side' kits for on-farm use. A test based on an ELISA developed at the University of Idaho has been commercially available since 2005 (BioPRYN™, BioTracking, Moscow, ID, USA). This test requires that a blood sample be sent to a testing lab. A 'sandwich' type of ELISA has been developed at the University of Missouri, Columbia, using a mixture of monoclonal antibodies to trap PAG in the wells and a polyclonal antiserum to detect the bound PAG. The goal was to develop an assay that detected the PAG subset that was expressed during early pregnancy rather than the late gestation forms that persist into the postpartum period. The ELISA outperformed the RIAs in this regard, with the vast majority of cows with undetectable levels by 8 weeks postpartum. A cow-side version of this test is currently under development and may eventually be available for commercial use.

One of the challenges in developing these assays is that PAGs are a diverse family of molecules rather than a single molecule. As gestation progresses, differentially glycosylated forms of particular PAGs and even different PAG molecules are expressed. Detection of these different forms is highly dependent on the assay system. PAG secretion may even be affected by parity and level of milk production. Developing robust immunological assays for these molecules clearly presents a different challenge than for a molecule like progesterone, which is biologically identical across all mammals.

Management Considerations in Development of Pregnancy Diagnosis Strategies

Features of currently available methods for early pregnancy diagnosis in cattle, goats, and sheep are summarized in **Table 2**. However, dairy producers must recognize that there is one inherent problem that will continue to be associated with even the most reliable pregnancy test. No matter how accurate the procedure, the results are valid only for the time the sample was

Table 2 Methods for early pregnancy diagnosis in common dairy ruminants

Method	*Species*	*Stage*	*Comments*
Nonreturn to estrus	Cow Goat Sheep	Days 20–24 Days 20–24 Days 16–19	Best to assess nonpregnancy; requires knowledge of breeding dates and behavioral observation
Progesterone (milk or blood)	Cow Goat Sheep	Days 20–24 Days 20–24 Days 16–19	Best to assess nonpregnancy; requires knowledge of breeding dates
Rectal palpation	Cow	After day 35[a]	Some risk to developing fetus; requires considerable expertise
Ultrasound	Cow, rectal Goat and sheep, rectal Abdominal	After day 28 After day 25 After day 35	Use of rectal probes in small ruminants is associated with risk of rectal damage; thus, animal restraint system must be factored into decision to use this approach
PAG/PSPB (blood)	Cow Goat and sheep	After day 30 After day 24	At present, no animal-side test available, so samples must be shipped to testing laboratory

[a] Pregnancy can be diagnosed in heifers as early as days 28–30, but rectal palpation at this early stage is not recommended due to the risk of damage of the very fragile conceptus.

PAG, pregnancy-associated glycoprotein; PSPB, pregnancy-specific protein B.

collected or the physical examination was conducted. A substantial number of pregnancies are lost during the first trimester, so any early pregnancy diagnosis should be reconfirmed at a later date. False positives in early assessments and early embryo losses will be detected at a follow-up check. But false negatives (animals incorrectly identified as nonpregnant) are potentially disastrous, in that prostaglandins used to induce estrus for rebreeding would cause abortion in pregnant animals.

Physiology

Pregnancy is a key event in the life of a dairy animal because the hormonal processes that are played out during this period include those that prepare the mammary gland for lactation following parturition. Indeed, perturbations in the placenta, the source of many mammogenic hormones, can conceivably lead to a reduction in the magnitude of milk synthesis in the subsequent lactation. For pregnancy to succeed, the conceptus must be able to successfully progress through a series of preprogrammed developmental steps that transform it from an undifferentiated one-cell organism into a neonatal animal capable of life outside of the womb. Accordingly, the maternal system must be made to serve the nutritional, immunological, and physiological needs of the conceptus. Not surprisingly, then, there is a close coordination of maternal and conceptus physiology that is achieved by the exchange of information between mother and offspring through chemical signals.

The complexity of pregnancy makes it susceptible to failure and the newly formed conceptus has only a fair chance of completing development. In many populations of lactating dairy cows, especially those that are intensively managed for high milk production, only about 15–30% of cows that are inseminated carry a fetus to term. Pregnancy failure is most prevalent early in development but can occur throughout gestation (**Figure 1**). Historical data indicate that pregnancy rate per conception in dairy cattle declined through the last 30–40 years or so of the twentieth century in most developed countries. The reasons for this decline are unclear but likely include the consequences of increased milk yield, changes in animal housing, and increased inbreeding. Understanding the physiology of the processes involved in pregnancy, then, offers the opportunity to increase reproductive function and improve the efficiency of milk production.

Unfortunately, a diverse and not always coherent system has arisen for naming organisms during the period of prenatal life. In this article, the term conceptus will be used to refer to all of the products of conception (the embryo or fetus and its associated extraembryonic membranes). Until differentiation of placental tissues, the term embryo can be considered analogous to conceptus. Thereafter, embryo refers to the part of the conceptus that will give rise to the neonate. Once the embryo has undergone sufficient differentiation to be reasonably identifiable as a member of the species, it is referred to as a fetus. This transition, which is somewhat arbitrary, occurs at about day 45 of gestation in cattle and day 34 in sheep.

Preimplantation Period

Pregnancy is initiated at the moment of conception when the newly ovulated oocyte is fertilized by one of the spermatozoa resident in the oviduct following mating. The early preimplantation embryo is distinct from most other cells in that the embryonic genome is largely repressed for the first several cleavage divisions. Rather, the embryo relies on mRNA formed during oocyte growth for direction of the bulk of protein synthesis. In the cow and sheep, major activation of the embryonic genome occurs at the 8- to 16-cell stage. There is limited transcription before these stages, however, and heat shock can induce transcription of genes for heat shock protein 70 as early as the two-cell stage. Activation of the embryonic genome is initiated following the loss of maternally derived mRNA, which is in turn caused by the loss of proteins such as MSY2 that mask mRNA.

A schematic illustration of events in early pregnancy is presented in **Figure 2** (*see* **Reproduction, Events and Management**: Pregnancy: Characteristics). Early stages of development involve a series of cleavage divisions whereby cell number of the embryo increases while size of individual cells (called blastomeres) decreases. Early cells of the embryo are totipotent – a new individual can be derived from a single blastomere appropriately transferred to an empty zona pellucida (the protein coat surrounding the embryo). Differentiation of the preimplantation embryo is first initiated at the morula stage of development (5–6 days after ovulation in cattle and 3–4 days in sheep), which is characterized by a loss in the ability to view individual cell membranes. Morulae are formed through a process called compaction in which embryonic size decreases somewhat and cells become more tightly associated. The underlying basis for compaction is the formation of intercellular junctional complexes between blastomeres at the basolateral regions of the cells. These tight junctions limit fluid movement between cells and lead to the polarization of blastomeres into apical

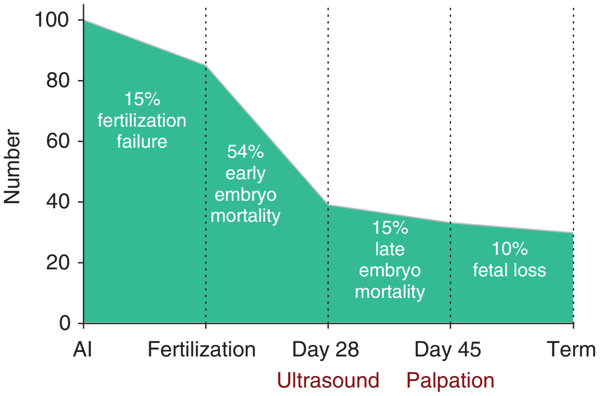

Figure 1 Pregnancy loss throughout gestation in a hypothetical herd of 100 lactating dairy cows with a calving rate of 30%. The *y*-axis represents the number of cows. Note that fertilization occurs only in about 85% of inseminated cows. Following fertilization, large numbers of embryos die before pregnancy diagnosis by ultrasound at day 28. Other losses occur between days 28 and 45 (about 15% of pregnancies), when pregnancy is diagnosed by rectal palpation, and day 45 and term (about 10% of pregnancies present at day 45). AI, artificial insemination. The figure is reproduced with permission from Hansen PJ (2007) Hidden factors affecting fertility. *WCDS Advances in Dairy Technology* 19: 339–349.

regions in contact with the external environment of the embryo and basolateral regions located near the interior of the embryo. The blastocyst is formed from the morula when fluid accumulates in the embryo to form a blastocoelic cavity. Embryos progress from the morula stage to the blastocyst stage at about days 6–8 after ovulation in cattle and days 6–7 in sheep. At the same time, two distinct cell layers can be identified – the trophectoderm, which subsequently gives rise to the extraembryonic membranes, and the inner cell mass, which gives rise to the fetus. Two processes have been implicated in the formation of the blastocoel (**Figure 3**). The outer layer of blastomeres develop Na^+/K^+ ATPase pumps on the basolateral surface that use movement of ions to direct water into the interior of the embryo. In addition, water channel molecules called aquaporins allow direct movement of water across blastomeres.

Emergence of the blastocyst from the zona pellucida follows blastocyst formation. This process, called hatching (at about days 9–10 postovulation in cattle and days 7–8 in sheep), is caused by a combination of proteinases from the

Days after mating

Figure 2 Schematic diagram of events during early pregnancy in the sheep. Events in the cow are similar except that timing relative to days after mating differs slightly. For example, interferon-τ (IFN-τ) secretion starts between days 15 and 17 of pregnancy and the earliest attachments to the uterus are at day 18 of pregnancy. In the bottom panel, progesterone concentrations are represented by blue lines. CL, corpus luteum; ZP, zona pellucida. The figure is reproduced with permission from Spencer TE, Johnson GA, Bazer FW, Burghardt RC, and Palmarini M (2007) Pregnancy recognition and conceptus implantation in domestic ruminants: Roles of progesterone, interferons and endogenous retroviruses. *Reproduction, Fertility and Development* 19: 65–78. Figure 3 Blastocoel formation in embryos. Formation of a central, fluid-filled cavity is a central event in development, which results in morphological differentiation of the embryo into inner cell mass (from which the fetus will arise) and trophectoderm (from which the extraembryonic membranes arise). Two processes have been implicated in the formation of the blastocoel. The first involves pumping of sodium. The outer layer of blastomeres develop Na^+/K^+ ATPase pumps on the basolateral surface of the cell membrane that pump sodium out of the cell. Other specialized proteins on the apical side of the cell allow sodium to enter the cell and remove potassium that is pumped into the cell. Water flows between cells and into the central cavity of the embryo to maintain osmolarity. The second process involves channel proteins called aquaporins that allow direct movement of water across blastomeres. These proteins are present on the apical and basolateral surfaces of the plasma membrane of trophectoderm cells.

embryo and uterine environment as well as the physical forces applied to the zona pellucida as the blastocoel undergoes periodic contractions and expansions. The process of expansion and contraction is dependent upon embryonic synthesis of prostaglandin E_2. Hatching is followed by a process initiated at about day 14 or 15 in cows and day 11 in sheep whereby the trophoblast rapidly expands to transform the embryo into a long filamentous structure. Expansion is rapid – while the day 13 cow embryo is 3 mm in diameter, it reaches a size of 25 cm by day 17 and begins to grow into the opposite uterine horn by day 18. The regulation of the process of trophoblast expansion, which is caused largely by increased cell division, is unknown. However, it is likely that the process requires a uterine signal since the process cannot be mimicked *in vitro*. One purpose of elongation is to ensure that the conceptus covers much of the endometrium so that secretory molecules regulating endometrial function (particularly those for inhibition of prostaglandin synthesis) are distributed widely throughout the uterine horn in which the embryo resides.

Ruminant embryos spend a considerable period of time (16 and 18 days in sheep and cattle, respectively) unattached to the epithelial lining of the reproductive tract. Before attachment, the embryo is dependent upon secretions from the oviduct and endometrium for nutritional support. The embryo has only a limited ability to utilize glucose as an energy source before compaction and glucose utilization can potentially be inhibitory to embryo development. During this period, pyruvate, lactate, and amino acids are the primary energy source. Many specific amino acids are present in high concentration in the oviduct and these not only serve as an energy source but also help regulate osmotic pressure and pH in the embryo and inhibit deleterious actions of glucose. Beginning at compaction, which represents the first major energy-expensive event in development, glucose uptake increases and glucose becomes the preferred energy substrate.

As is apparent from the successful development of embryos produced by *in vitro* fertilization, there is no absolute requirement of the embryo for macromolecules specific to the reproductive tract environment. However, *in vitro*-produced embryos have aberrant biochemical and molecular properties compared to embryos produced *in vivo* and it is likely that macromolecules in oviductal and uterine fluid regulate early embryonic development.

Many of the components of oviductal and uterine fluid are derived from transudation from the blood. In addition, both the oviduct and endometrium secrete specific molecules into the lumen of the reproductive tract. Secretion of many of these locally produced factors is under the control of progesterone or estrogen. Some molecules, such as oviductal secretory protein-1 and osteopontin, may play a role in fertilization. Many are regulatory molecules that mediate the complex communication between the cells of the reproductive tract and embryo. For example, growth factors and other regulatory molecules produced by cells of the oviduct and endometrium include insulin-like growth factors I and II, basic fibroblast growth factor (bFGF), activin, and leukemia-inhibitory factor. Similarly, the embryo produces epidermal growth factor and transforming growth factor-α. The reproductive tract also produces proteinase inhibitors such as plasminogen activator inhibitor-1 and tissue inhibitor of metalloproteinase-1 (TIMP-1) that likely prevent degradation of the lining of the female reproductive tract by embryonic proteinases and thereby block implantation of the embryo into the underlying stroma.

Most embryonic mortality occurs during the preimplantation period, that is, before day 20 of pregnancy (see **Figure 1**). Numerous causes of embryonic loss have been identified. These include chromosomal abnormalities, inheritance of specific alleles causing embryonic or fetal death (e.g., allelic variants in fibroblast growth factor 2, STAT5A, and uridine-5′-monophosphate in cattle), reduced progesterone concentrations or premature luteolysis in the dam, and defects in the process of development (e.g., inadequate trophoblast development and reduced secretion of interferon-τ). Oocytes damaged during follicular development can give rise to embryos with reduced developmental competence. Environmental influences that increase embryonic mortality include provision of feed with high levels of rumen-degradable protein, various microbial or viral diseases, and heat stress.

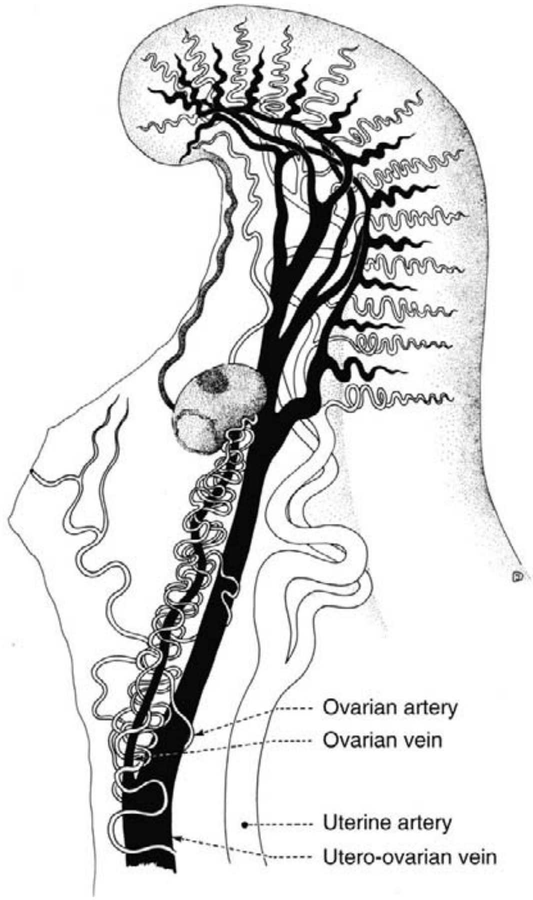

Figure 4 Arrangement of the uterine and ovarian vasculature of the sheep. Note that the utero-ovarian vein, which carries blood draining the uterus, is in very close apposition to the highly coiled ovarian artery carrying blood to the ovary. The close anatomical relationship of these two vessels facilitates the countercurrent movement of prostaglandin $F_{2\alpha}$ from the uterus to the ovary during luteolysis. Figure reproduced with permission from Flood PF (1991) The development of the conceptus and its relationship to the uterus. In: Cupps PT (ed.) *Reproduction in Domestic Animals*, 4th edn., pp. 315–360. San Diego, CA: Academic Press.

Maintenance of the Corpus Luteum

Among the changes in maternal physiological function necessary for the maintenance of the corpus luteum is the rescue of the corpus luteum from luteolysis. In the absence of pregnancy, the corpus luteum regresses beginning around days 15–16 in cattle and days 13–14 in sheep as a result of release of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) produced by endometrial epithelial cells. Prostaglandin is rapidly metabolized in the lung and other organs; the prostaglandin responsible for luteolysis arrives at the corpus luteum via a local pathway involving movement out of the utero-ovarian vein and into the closely apposed ovarian artery (**Figure 4**). Some prostaglandin may also reach the ovary through the lymphatic system. $PGF_{2\alpha}$ causes luteolysis by stimulating local luteal synthesis of cytokines, endothelin-1, and nitric oxide, which in turn initiate functional (loss of progesterone secretion) and structural luteolysis (loss of luteal cells by apoptosis). Endothelin-1, for example, decreases progesterone production by luteal cells while stimulating additional luteal production of $PGF_{2\alpha}$.

As shown in **Figure 5**, the embryo blocks luteolysis by inhibiting $PGF_{2\alpha}$ synthesis. The embryo first acts to inhibit luteolysis between days 15 and 17 of pregnancy in cow and days 12 and 14 in sheep. Removal of the embryo before this time does not affect luteal life span but the life span of the corpus luteum is extended if the embryo is removed afterward. The most important of the antiluteolytic signals produced by the embryo, at least during the initial rescue of the corpus luteum, is a molecule called interferon-τ. This molecule is a member of the class I interferon family, which also includes

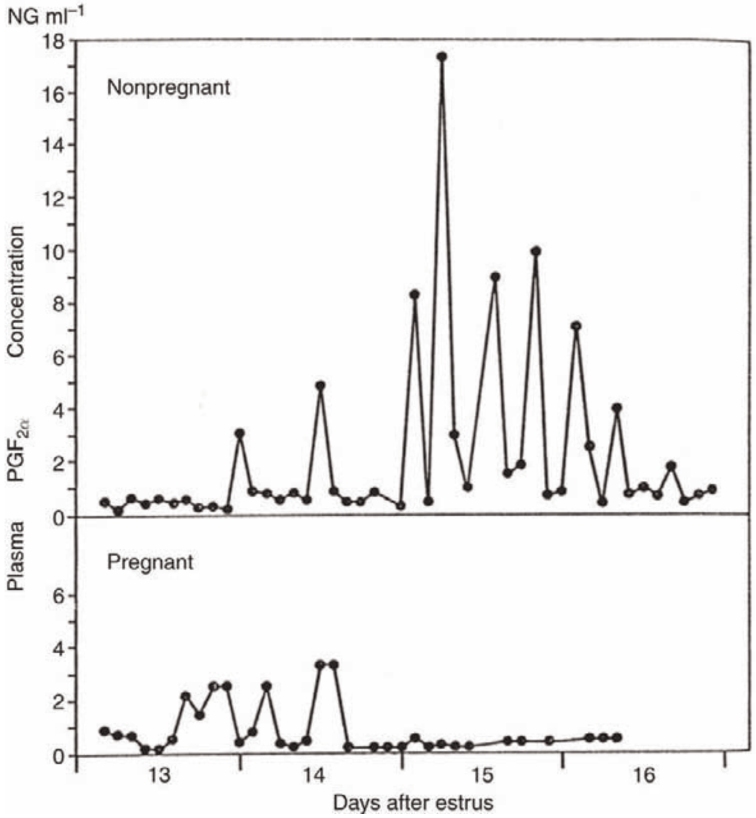

Figure 5 Concentrations of prostaglandin F$_{2\alpha}$ in utero-ovarian plasma of nonpregnant and pregnant ewes during the time of expected luteolysis. Note the large pulses of prostaglandin F$_{2\alpha}$ in the nonpregnant ewe that are responsible for luteolysis. These pulses are attenuated in the pregnant ewe. Figure is reproduced from Barcikowski B, Carlson JC, Wilson L, and McCracken JA (1974) The effect of endogenous and exogenous estradiol-17β on the release of prostaglandin F2α from the ovine uterus. *Endocrinology* 95: 1340–1349 with permission of the Endocrine Society.

interferon-α, β, and ω. Interferon-τ arose in evolution in ruminants via gene duplication about 36 million years ago. While interferon-τ is similar in many ways to other class I interferons (including binding to class I interferon receptor, signal transduction, antiviral, and immunosuppressive activity), it differs from these interferons in the fact that gene expression is under the control of a trophoblast-specific promoter and expression is not strongly induced by virus.

The pattern of expression of interferon-τ gene is distinct. The protein can be detected in low amounts when the embryo undergoes blastocyst formation. There is then a massive upregulation of gene expression coincident with impending luteolysis so that interferon-τ becomes the major secretory product of the conceptus from around days 15–20 in cattle and days 13–17 in the sheep. Gene expression is then rapidly turned off so that secretion is low by 25 days in cows and 21 days in sheep.

Interferon-τ acts on endometrial epithelial cells to inhibit PGF$_{2\alpha}$ secretion. Proposed mechanisms by which interferon-τ inhibits prostaglandin secretion are illustrated in **Figure 6**. Endometrial PGF$_{2\alpha}$ synthesis is caused by oxytocin-induced activation of cyclooxygenase-2, the rate-limiting step in the conversion of arachidonic acid to PGF$_{2\alpha}$. Responsiveness of the endometrium to oxytocin is dependent upon estradiol-induced synthesis of oxytocin receptors. There is evidence to suggest that interferon-τ acts to inhibit expression of oxytocin receptor gene. Inhibition of oxytocin receptors may be due to inhibition of gene expression of estrogen receptors to make the endometrium unresponsive to estradiol induction of oxytocin receptors. This seems to be the case for sheep. In the cow, oxytocin receptors can be inhibited independent of the changes in estrogen receptor. In addition, interferon-τ increases the fatty acid linoleic acid, at least in cattle, and this molecule acts as an inhibitor of cyclooxygenase.

The corpus luteum also becomes more resistant to destruction by PGF$_{2\alpha}$ in early pregnancy. This could be due to interferon-τ because small amounts of the molecule leave the uterus, due to the actions of another prostaglandin, PGE$_2$, that is produced by uterine endometrium, or due to another unknown molecule. Later in pregnancy, some unidentified molecule is important for

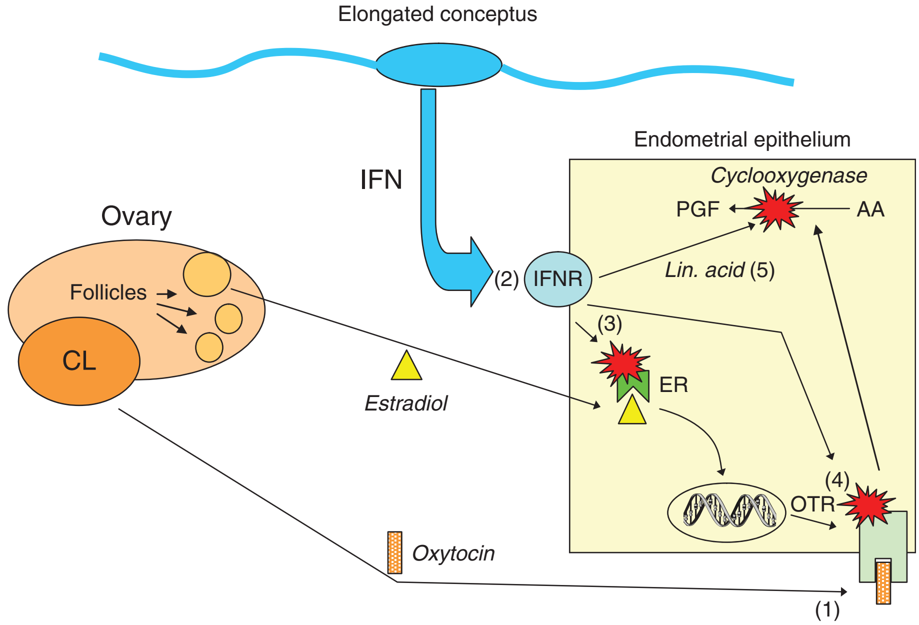

Figure 6 Proposed mechanism by which interferon-τ (IFN-τ) inhibits estradiol- and oxytocin-driven induction of luteolytic prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) release from endometrium. Luteolytic pulses of $PGF_{2\alpha}$ are driven by the release of oxytocin from the corpus luteum (CL) and hypothalamus (1). Oxytocin acts through receptors (OTR) that are synthesized under the control of estradiol to activate the synthesis of $PGF_{2\alpha}$ from arachidonic acid (AA) by cyclooxygenase. IFN-τ acts through binding to its receptor (IFNR) (2) to cause several changes that lead to inhibition of $PGF_{2\alpha}$ synthesis. Foremost is a reduction in the synthesis of OTR, caused by inhibition of the estrogen receptor (ER) (3), as in the sheep, or by direct inhibition (4), as occurs in the cow. The reduction in OTR makes the endometrium unresponsive to oxytocin. In addition, IFN-τ increases intracellular concentrations of linoleic acid (Lin. acid), at least in the cow, and this fatty acid acts to inhibit cyclooxygenase (5).

luteal maintenance. This is so because administration of interferon-τ to nonpregnant animals extends luteal life span for a limited time that is much shorter than the period during which the corpus luteum of pregnancy persists. For example, intrauterine infusion of interferon-τ extended interestrous interval from an average of 23 days in controls to 32 days in cattle and from 16 days to 32 days in sheep.

Role of Progesterone

While progesterone is indispensable for pregnancy in all mammals, the major sources of progesterone vary between species. In both cattle and sheep, progesterone is produced by the placenta, especially the fetal cotyledon. In cattle, however, placental secretion of progesterone is low for most of pregnancy, possibly because of the presence of an endogenous inhibitor of steroidogenesis. Removal of the corpus luteum before day 200 of pregnancy leads to pregnancy loss. Placental progesterone synthesis rises at the end of pregnancy. Pregnancy can continue if the corpus luteum is removed after day 200 although premature parturition is common. In the sheep, in contrast, the placenta becomes a sufficient source of progesterone earlier in pregnancy, by day 50 of gestation.

Progesterone maintains pregnancy by exerting a variety of actions on the uterus. One target is the myometrium – progesterone maintains the quiescence of this muscular layer of the uterus by causing hyperpolarization of myometrial cells. *In vitro*, progesterone causes increased proliferation of endometrial stromal cells in cattle without affecting epithelial cells. *In vivo*, however, progesterone causes some increase in the proliferation of luminal endometrial epithelial cells in sheep. It is likely that progesterone's effects on the epithelium are mediated by growth factors such as hepatocyte growth factor that are secreted by the stroma.

Progesterone increases expression of multiple genes in the endometrial lining of the uterus. Use of DNA microarray technology has led to the identification of 140 genes whose expression is higher during the luteal phase of the estrous cycle. Some progesterone-induced genes encode for proteins involved in conceptus nutrition. For example, retinol binding protein, which binds retinol and presumably transports it to the conceptus, is a progesterone-induced endometrial secretory protein in cattle. It is also likely that the actions of progesterone are required for attachment of the conceptus to the endometrium and for subsequent placentation. Among the genes induced in the endometrium by progesterone is osteopontin, which is a glycoprotein component of the extracellular matrix that promotes cell–cell attachment by binding to cell surface integrins. Osteopontin may have an important role in mediating attachment of the trophoblast to the maternal endometrium. Other genes induced by progesterone regulate angiogenesis to increase vascular blood supply to the placenta. Among the genes identified as being upregulated during the luteal phase in cattle were several involved in angiogenesis including angiotensinogen, hypoxia-inducible factor 2-α, and ephrin-A1.

Exogenous administration of progesterone early in pregnancy hastens the growth of the embryo. Certain cases of infertility may be due to inadequate progesterone secretion because correlations have been made in cattle between the concentrations of progesterone in the blood early in pregnancy (days 4–5) and embryo development, amounts of interferon-τ in the uterus at day 16 of pregnancy, and pregnancy rate following insemination. The lactating dairy cow, which represents an infertile animal type, often experiences reduced circulating concentrations of ovarian steroids.

Placental Function

Placentation is a gradual process in ruminants (*see* **Reproduction, Events and Management**: Pregnancy: Characteristics). Invasion of trophoblast cells into the uterine endometrium is limited and the basement membrane of the luminal epithelium of the endometrium remains intact. Attachment to the endometrium is a gradual process that starts with apposition of conceptus and endometrium, adhesion of the two tissues mediated by interdigitation of microvilli, invasion of trophoblast binucleate cells into the endometrial epithelium, and fusion of binucleate cells with endometrial epithelial cells to form a syncytium. In the cow, the first attachments are seen at day 18 and binucleate cell invasion is initiated at ∼day 20. In sheep, the conceptus is adhered to the endometrium by day 16. The adhesion process is facilitated by cell adhesion molecules on the surface of the trophoblast (e.g., integrin) and molecules secreted by the endometrium such as galectin 15 and osteopontin.

The anatomy of the definitive placenta, which has differentiated by about day 37 of pregnancy in the cow and day 30 in the sheep, is described elsewhere (*see* **Reproduction, Events and Management**: Pregnancy: Characteristics). Most growth in the placenta is completed by midgestation. Growth occurs at a much slower rate after this time in cattle and ceases in sheep. The placenta serves as the sole organ for chemical exchange between fetus and mother. All of the water, oxygen, and nutrients necessary to support life and growth of the developing fetus move through the placenta. In addition, the placenta serves as the organ by which fetal waste products including carbon dioxide and by-products of metabolism are removed to the mother for eventual elimination via the maternal respiratory, renal, and digestive systems. In addition to its transport role in fetal respiration, nutrition, and electrolyte balance, the placenta is also an endocrine organ. The hormones it produces alter maternal function to support pregnancy, lead to development of the mammary gland in anticipation of parturition, and participate in the process leading to parturition. Other regulatory molecules secreted by the placenta probably act locally on the uterus to optimize maternal function during pregnancy.

The mechanism for transport across the placenta varies depending upon the specific chemical. Some molecules such as oxygen, carbon dioxide, free fatty acids, and some electrolytes passively diffuse across the placenta. The glucose transports GLUT1 and GLUT3 are involved in the transport of glucose. Amino acids are also actively transported a cross the placenta. Fatty acids are poorly transported across the ruminant placenta. As a result, despite being major sources of energy for the adult, fatty acids contribute in only a minor way to the energy needs of the fetus. Movement of some other molecules poorly soluble in water is facilitated by carrier molecules secreted by uterine glands. For example, retinol is carried by retinol binding protein and iron by transferrin.

Most of the chemical exchange between mother and fetus occurs at the placentomes, which are formed from the union of specialized protrusions of the chorioallantois called cotyledons with corresponding structures on the maternal endometrium called caruncles (*see* **Reproduction, Events and Management**: Pregnancy: Characteristics). As a result, about 94% of fetal blood flowing to the sheep placenta is distributed to the cotyledons and 84% of maternal blood distributed to the uterus is distributed to the caruncles. Nonetheless, some placental exchange occurs in the interplacentomal regions also. In this region, there is a close contact between maternal and fetal epithelia. Moreover, maternal endometrial glands are in the interplacentomal regions and their secretions are released into the fetal–maternal interface.

Placental efficiency can be estimated by determining the mass of fetal tissue that a given unit of placenta can support. By this measure, the ruminant placenta is a relatively efficient organ. The ratio of fetal to placental tissue is 13:1 in cattle and 10:1 in sheep and goats. In contrast, each gram of human placenta can support only about 6 g of fetus. The efficiency of the placenta is due largely to the architecture of the maternal blood vessels supplying the placenta relative to the fetal vessels. In ruminants, maternal and fetal blood vessels are arranged so that most blood flow is in a countercurrent or cross-current direction (**Figure 7**).

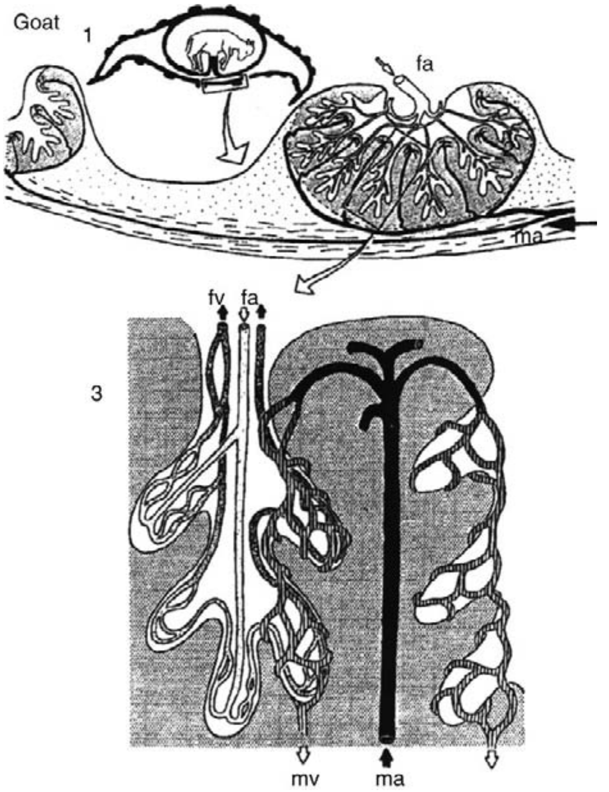

Figure 7 Overview of the ruminant placenta. The placenta of the ruminant is characterized by an outer placental membrane formed from the fusion of the chorion and allantois (1). Knob-like projections of the chorion called cotyledons fuse with complementary structures on the maternal endometrium called caruncles to form placentomes. A single placentome is shown in (2) where fetal tissue is white and maternal tissue is stippled. Note the chorionic villi that project into the crypts in the maternal caruncles. As shown in (3), fetal vessels in chorionic villi are in close apposition to the corresponding maternal vessels in the caruncular septa. Basket-like maternal capillaries surround fetal venous capillaries. This arrangement of vessels allows for very efficient exchange of materials between mother and fetus because the pattern of flow is crosscurrent and countercurrent. fa, fetal artery; ma, maternal artery; mv, maternal vein. The figure, which was modified from Leiser R, Krebs C, Ebert B, and Dantzer V (1997) Placental vascular corrosion cast studies: A comparison between ruminants and humans. *Microscopy Research and Technique* 38: 76–87 and is reproduced with the permission of the publisher, is based on an earlier figure from Dantzer V, Leiser R, Kaufmann P, and Luckhardt M (1988) Comparative morphological aspects of placental vascularization. *Trophoblast Research* 3: 221–244.

Placental blood flow increases during pregnancy to match the increased demands of the fetus. Increased blood flow is due to vasodilation and angiogenesis. During late pregnancy, endothelial cells in the uterine artery increase synthesis of two vasodilators, prostacyclin and nitric oxide. Angiogenesis is at least in part regulated by growth factors such as vascular endothelial growth factor (VEGF) and bFGF produced by the placenta. These molecules, as well as others such as angiotensin II, also likely contribute to vasodilation by participating in the regulation of synthesis of prostacyclin and nitric oxide.

The placenta is an endocrine organ that produces hormones whose synthesis occurs uniquely in the placenta as well as those also produced by other organs. Among the former is placental lactogen, which is a member of the prolactin/growth hormone family. Synthesis occurs by the binucleate cells that migrate from the trophoblast into the uterine endometrium. Concentrations of placental lactogen in the blood increase as gestation progresses. Placental lactogen is believed to play two roles – increase mammary development in anticipation of the birth of the neonate and act as a metabolic hormone to redirect maternal metabolism to provide nutrients for the fetus.

The role of the placenta in progesterone production has already been noted. In addition, the ruminant placenta produces estrogens, androgens, and prostaglandins in increasing amounts toward late pregnancy. Estrone synthesis predominates over estradiol-17β synthesis and most of the circulating estrogens exist in conjugated, inactive form (e.g., estrone sulfate). Estrogen plays at least two roles during late pregnancy. With progesterone, estrogen stimulates growth of the mammary gland. Estrogen also plays a role in parturition by counteracting the effect of progesterone on uterine contractility (causing depolarization of myometrial cells so that the uterine capacity for contractions is increased) and by acting on the fetus to increase adrenocorticotropin, the hormone that acts as the central regulator of the timing of parturition. Unlike some species, ruminant placentas do not produce a chorionic gonadotropin or relaxin.

Another secretory product of the placenta is a group of proteins called the pregnancy-associated glycoproteins (PAGs). These proteins, which are members of the aspartic proteinase family, are very unusual in that they are encoded by a large number of genes (perhaps as many as 100). Some PAGs are produced predominately in binucleate cells, while others are produced throughout the chorionic epithelium. It is not clear whether the PAGs are hormones or what function they serve during pregnancy. However, PAG genes have undergone rapid evolution, suggesting that they play an important role in pregnancy. Radioimmunoassay of PAGs (originally called pregnancy-specific protein B) has been utilized as the basis for a pregnancy test in cattle. The long half-life of PAGs in the blood after parturition has limited the usefulness of PAG-based pregnancy tests, however.

Maternal stress can lead to a disruption in placental function and compromised fetal development. Since hormones produced by the placenta are involved in mammogenesis, disruptions in placental function can conceivably alter subsequent milk yield. One example is heat stress, which causes a redistribution of blood from the internal organs (including the placenta) to the skin to

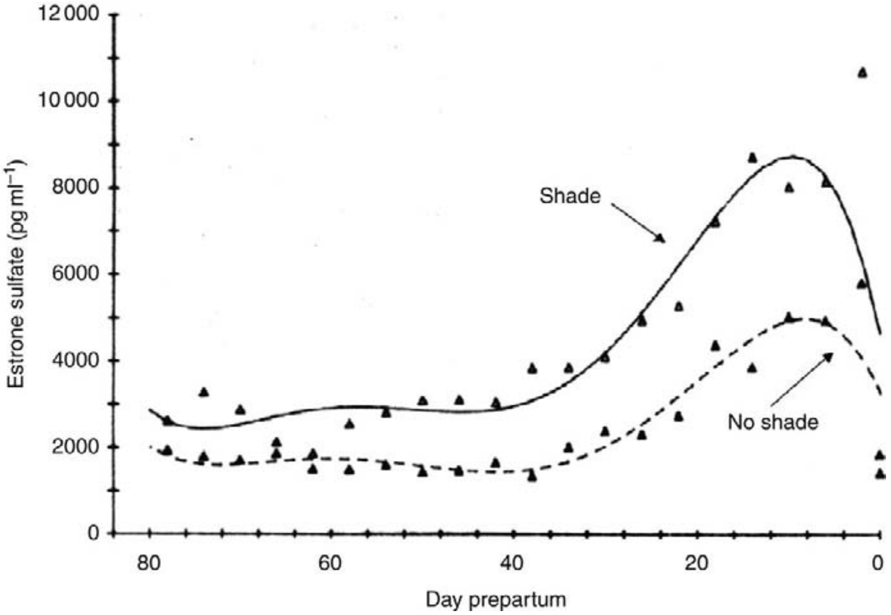

Figure 8 Effect of heat stress on plasma concentrations of estrone sulfate in pregnant cows. Cows during the summer in Florida were housed with or without shade. Note the reduction in estrone sulfate concentrations in cows housed without shade. This reduction represents reduced secretion of estrone sulfate from the placenta. The figure, which is reproduced with the permission of the publisher, was modified slightly from Collier RJ, Doelger SG, Head HH, Thatcher WW, and Wilcox CJ (1982) Effects of heat stress during pregnancy on maternal hormone concentrations, calf birth weight and postpartum milk yield of Holstein cows. *Journal of Animal Science* 54: 309–319.

increase heat loss to the environment. The resultant decrease in placental perfusion leads to depressed placental growth accompanied by reduced fetal growth and placental hormone secretion (see **Figure 8**). There is evidence in cattle that failure to cool cows during late parturition can compromise subsequent milk yield. Undernutrition can also have complex effects on placental function. The placenta can adjust somewhat to a reduction in circulating glucose concentrations by increasing the synthesis of glucose transporter GLUT3. However, severe glucose deficiency can lead to reduced placental uptake of glucose and fetal growth retardation. In fat ewes, underfeeding during early and mid-pregnancy can actually lead to increased placental growth while overfeeding during the same period can sometimes reduce placental growth. Nutritional deprivation during fetal life can also have consequences such as altered cardiovascular function that persist into adult life.

Immunology of Pregnancy

The conceptus inherits transplantation antigens from its father that could potentially lead to activation of tissue rejection responses against the conceptus by the mother. However, fetal gene expression in the placenta is altered to minimize the antigenicity of the tissue that is in direct contact with maternal tissues. Tissue graft rejection responses are typically mounted by the host against two classes of proteins called major histocompatibility complex (MHC) antigens. The expression of MHC antigens on the trophoblast is limited. This absence of antigenicity on the placental surface is likely a major cause of survival of the conceptus as a foreign tissue. In sheep, both class I and class II MHC are absent from the surface of the placenta. The same is true in cattle except that there is some expression of MHC class I antigen on the interplacentomal parts of the chorionic epithelium, especially during late pregnancy. Most of these trophoblast MHC class I molecules represent 'nonclassical' MHC proteins that have limited genetic polymorphism and which may regulate populations of lymphocytes called natural killer cells that ordinarily kill cells not expressing MHC class I molecules.

The conceptus and uterus secrete molecules that regulate the function of maternal lymphocytes. Early in pregnancy, interferon-τ secreted by the trophoblast of the cow and sheep causes upregulation of a host of immune response genes in the endometrium. Later in pregnancy, molecules that inhibit immune responses predominate. Progesterone is one of the major systemic regulatory molecules produced during pregnancy and it regulates uterine immune function. In fact, progesterone can promote survival of skin grafts and xenografts in the sheep uterus. Progesterone can directly inhibit lymphocyte function at micromolar concentrations. However, it is likely that concentrations of progesterone at the fetal–maternal interface do not reach these high concentrations until after placental progesterone synthesis becomes sufficient to maintain pregnancy (i.e., day 50 of gestation in sheep and day 200 in cattle). Rather, it is believed that progesterone regulates uterine immune function primarily by inducing endometrial secretion of molecules that block lymphocyte proliferation. In the ewe, this activity has been ascribed to a progesterone-induced protein of the serpin superfamily of serine protease inhibitors called ovine uterine serpin (also called SERPINA14).

Despite the prevalence of immunosuppressive molecules in the uterine environment, some leukocyte populations accumulate in the endometrium during pregnancy and may become activated to play roles in immune regulation, placental growth, parturition, or host defense against uterine pathogens. One such population of cells is the macrophage. Another, at least in the sheep, is a type of lymphocyte called the $\gamma\delta$-T lymphocyte. These granulated cells, which increase in both number and granularity after about day 50 of pregnancy, have been identified as $\gamma\delta$-T lymphocytes. The cells express perforin and may function as lytic cells to facilitate parturition or to lyse virally infected cells. They may also secrete cytokines that promote placental growth. There is some limited evidence that expulsion of the placenta is facilitated if the mother and conceptus have dissimilar MHC class I haplotypes. Perhaps, macrophages, $\gamma\delta$-T cells, or other leukocyte populations are involved in the placental expulsion process.

Introduction

Parturition in animals, after a normal gestation, is a unique physiological process that signifies the termination of pregnancy and the beginning of extrauterine life of the newborn (neonate). Once parturition is initiated, it must proceed to completion and, as such, is difficult to interrupt or delay. It is a timed event that requires the fetus to have attained a stage of maturity that will enable it to survive extrauterine life. Parturition involves the orchestration of a complex series of physiological events that require the rotation of the fetus into the birth position, which is accompanied by a cascade of endocrine changes that terminates with a successful delivery. When the fetus is in the birth position, the temporal alignment of these endocrine changes is paramount in determining the timing of delivery. Although many of the hormonal cues as well as physiological and anatomical changes that precede delivery are similar among domestic animals, each species seems to have developed its own temporal relationship among events that govern parturition. A great deal of research has been undertaken over the past 25 years, particularly on the endocrine parameters of the fetal hypothalamic–pituitary–adrenal (HPA) axis and endocrine contribution of the fetal membranes, to understand better the mechanisms associated with parturition in humans and domestic animals alike. With the exception of the mouse, the sheep has been the most popular animal model of study and data from this model have contributed significantly to this field of reproductive biology. Parturition in domestic animals is initiated by the fetus but can be postponed temporarily, as in the case of the mare, when disturbed. Feeding can also alter the exact timing of delivery in sheep and cattle. It is now very apparent that both the mother and the fetus contribute significantly to the events associated with parturition and the importance of their individual contributions will be addressed in this article.

Duration of Pregnancy

In the western hemisphere the most common dairy breeds of cattle are of European origin. However, other domestic animals, including the goat, sheep and, to a lesser degree, the horse, are used for the harvesting of milk for production of dairy products. Observations of these domestic breeds have shown that duration of gestation is genetically determined (*see* **Reproduction, Events and Management**: Pregnancy: Characteristics). However, factors that can modify length of gestation include age and parity of the dam, sex and size, normality and abnormality, and genotype of the fetus, twinning (in cow and mare) and an array of environmental factors (**Figure 1**).

The average duration of pregnancy in dairy breeds of cattle is approximately 280 days but there are considerable differences between breeds (**Table 1**). The yak, although not a common species, is an important related species of cattle found in the harsher climates of Asia where it is used as a source of meat and milk. In this species, duration of pregnancy is much shorter (258 days) and this is reflected in the lower birth weight of calves (bull and heifer calves, 14.2 and 12.9 kg, respectively). The camel, an important beast of burden and source of meat and milk in desert environments, displays species variation in duration of gestation. The African dromedary has a gestation length of 385 days (~13 months) while the Bactrian camel has a gestation length ranging from 370 to 440 days. There is also a breed-dependent difference in the duration of pregnancy in the horse (pony, light and draft breeds, 330–345 days), sheep (domestic breeds, 144–152 days) and goat (domestic breeds, 145–151 days). Genotype is apparent when cows are crossed with certain breeds of sires.

Crossbreeding may result in an increase in length of gestation. Embryo transfer studies have clearly established that the breed of the embryo determines length of gestation (i.e. embryos from breeds with shorter gestation transferred to recipients with longer gestation and vice versa). Gender has also been cited as a factor, with bull calves having a slightly longer gestation (1–2 days) than heifers of the same breed. Size and/or weight of calf may contribute to a longer gestation (**Table 1**), a factor that may be influenced by season and/or level of nutrition of the dam. Twinning is thought to occur in 1–2% of cattle and is more frequently observed in multiparous or older cows. In sheep, the genotype of the fetus accounts for approximately two-thirds of the variation in length of gestation; male lambs and singletons are carried longer and gestation lengths increase with age of the dam.

Presentation of Fetus in Birth Position

As parturition approaches, the fetus must rotate into the birth position. For most of gestation, the fetus usually rests on its back with its feet directed upward. After rotation into the birth position, the fetus rests on its abdomen or thorax with its nose resting between the forefeet as they extend toward the uterine aspect of the cervix (**Figure 2**). Correct positioning of the fetus allows for parturition to proceed more easily while malpresentation of the fetus predisposes to a complicated delivery that may, in severe cases, lead to the loss of both fetus and dam. This is true for the cow, sheep, horse and goat. Abnormal presentation of the fetus occurs in 5% of dairy cows and is observed more frequently with twin pregnancies. Such abnormal presentations may range from one leg to both legs and/or head reflected back to severe breech positions, including tail presentation toward the uterine aspect of the cervix (**Figure 3**).

Fetal Hypothalamic–Pituitary–Adrenal Axis

The initiation of parturition is associated with a spontaneous increase in activity of the fetal HPA, and is completed by a complex interaction of endocrine, neural and mechanical events. The discovery in the 1960s that hypophysectomy of the fetal sheep abolished initiation of parturition in the ewe demonstrated that the fetus played a fundamental role in the process of parturition. Since it is essential that the fetus is born at a time when it is capable of surviving extrauterine life, it is fitting that it plays a role in determining the time of parturition. It is now well established that the fetus initiates parturition and that together the fetal and maternal endocrine environments orchestrate the process of delivery. What drives the activation and maturation of the peripartuerient fetal HPA axis is unclear. Several lines of evidence have suggested that the increase in activity is a programmed event, and that the rapid growth of

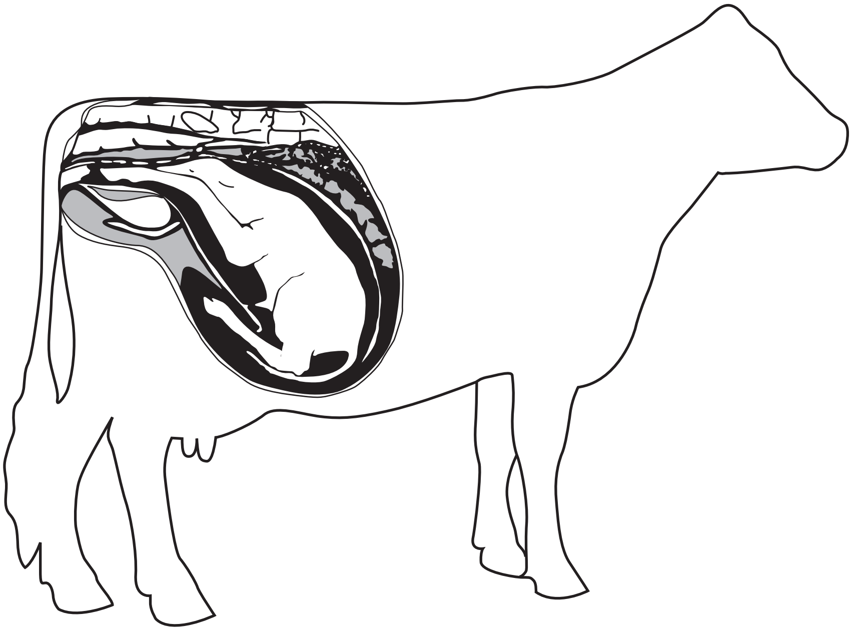

Figure 2 Normal birth position in cows assumed before labor. After rotation into the birth position, the fetus rests on its abdomen or thorax with its nose resting between its forefeet as they extend forward toward the uterine aspect of the cervix. The horse, sheep and goat adopt a similar birth position. (Adapted from Salisbury GW, Van Demark NL and Lodge JR (1978) *Physiology of Reproduction and Artificial Insemination in Cattle*, 2nd edn, San Francisco: WH Freeman.)

the fetus in the final weeks of gestation causes the release of endocrine signals from the placenta, leading to the maturation of key organ systems in the fetus, including the HPA axis, and terminating with delivery (**Figure 4**).

Research data suggest that the increase in fetal HPA axis activity at the end of gestation is associated with the increased secretion of estrogen by the placenta. Chronic increases in estradiol and androstenedione, another placental hormone, can advance the day of parturition in the sheep and other species. Others have promoted the hypothesis that release of prostaglandin E_2 (PGE_2) by the placenta facilitates the maturation of the HPA axis, resulting in increased secretion of adrenal corticotrophic hormone (ACTH) and cortisol. The rapid growth of the fetus toward the end of gestation is thought to be a genetically programmed event stimulating both fetal and maternal sources of PGE_2 that facilitate the maturation of the fetus and preparation of the mother for delivery. In the latter stages of gestation, the pituitary source of ACTH is from corticotrophic-releasing hormone (CRH)-sensitive cells that act on the adrenals via type II receptors to increase fetal cortisol production. Placental PGE_2 overrides the negative-feedback effects of cortisol on CRH release, thus enhancing fetal adrenal cortisol production. Cortisol enhances prostaglandin endoperoxide H synthase-2 (PGHS-2) expression, leading to an increase in PGE_2 production that in turn promotes C17α hydroxylase and cytochrome P-450$_{c17}$ enzyme activity in the placenta. This elevated enzyme activity increases the amount of C19 steroids for conversion to estrogen, resulting in increased contraction-associated protein (CAP) gene expression (oxytocin and prostaglandin receptors, Na^+ and Ca^{2+} ion channels, gap junction protein connexin-43). The functional expression of these CAP genes leads to increased spontaneous activity of the myometrium and enhanced responsiveness to oxytocin and prostaglandin. In addition to these changes, the coincidental increase in the estrogen-to-progesterone ratio promotes production of both oxytocin and prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$). The increase in estrogen synthesis toward the end of pregnancy is a common phenomenon among mammalian species but strategies associated with its production may vary.

In the bovine, parturition is initiated by endocrine changes originating from the fetus when it reaches a critical size and stage of maturation. The fetal adrenals become increasingly responsive to ACTH secreted by the fetal pituitary. In turn, there is a corresponding increase in the rate of cortisol secretion from the fetal adrenals that induces placental trophoblast 17α-hydroxylase and 17,20-lyase activity. This activity increases the metabolism of progesterone to estrogen, thereby increasing the maternal estrogen-to-progesterone ratio. During pregnancy, progesterone maintains the quiescent state of the uterus that facilitates the growth and development of the fetus. In the cow, the onset of

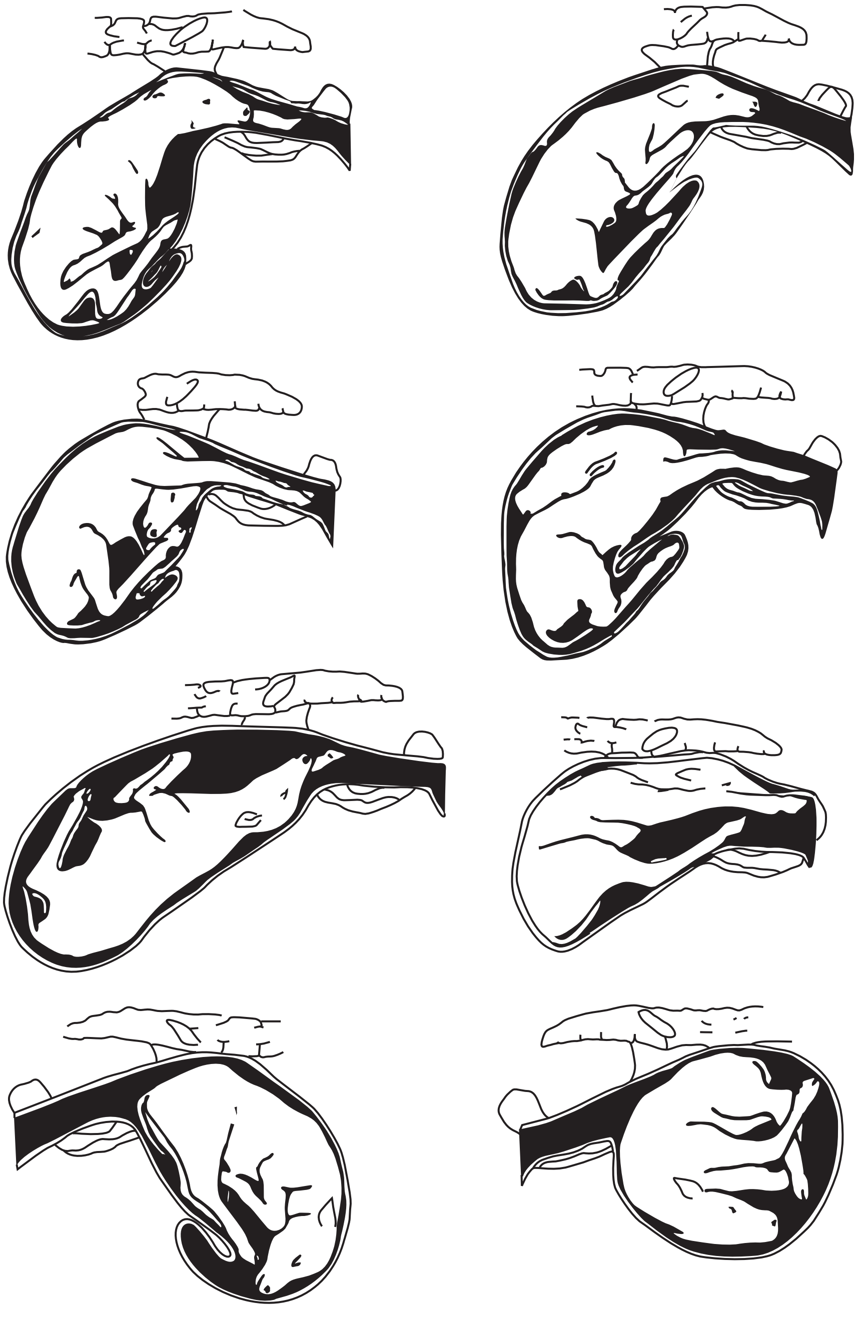

Figure 3 Diagrammatic representation of abnormal birth positions that may be observed in cattle. (Adapted from US Department of Agriculture (1942) *Diseases of Cattle*.)

labor is associated with a switch from a state of progesterone domination to one of enhanced estrogen influence. The decline in circulating progesterone, often referred to as progesterone 'withdrawal', together with elevated circulating concentrations of estrogen, stimulates increased prostaglandin production, formation of myometrial gap junctions, sensitization of the uterus to uterotonic agents (prostaglandins, oxytocin), cervical ripening and the commencement of labor. Cortisol is thought to increase prostaglandin synthesis during labor primarily due to an increase in PGHS-2 (inducible cyclooxygenase, COX-2 gene product) expression and function in uterine and intrauterine tissue. The activity of prostaglandin endoperoxidase synthase in the placenta (cotyledons) increases and mirrors the changes in ACTH concentrations seen in fetal plasma at this time. The prostaglandin cascade is also activated by proinflammatory cytokines (i.e. interleukin-1β) and these effects are modulated by antiinflammatory cytokines (i.e. interleukin-10). Oxytocin, a potent

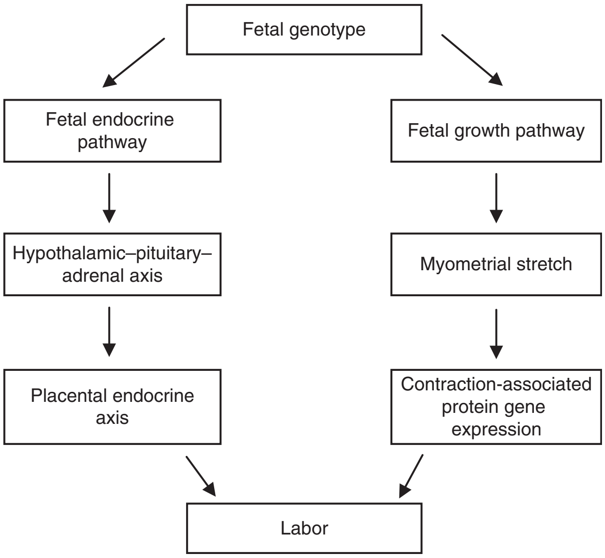

Figure 4 Schematic representation of factors associated with the onset of events involved in labor in domestic animals.

uterotonic stimulant, is expressed in intrauterine tissue in late pregnancy and stimulates myometrial contractility and fetal expulsion.

Maternal Endocrine Changes and Myometrial Activity

Progesterone is the primary hormone responsible for the maintenance of pregnancy. In the pig, goat and cow the presence of functional corpora lutea is essential for the production of progesterone and pregnancy maintenance, while in the ewe and the horse the placenta is the primary source after the luteoplacental shift has occurred. This shift in source of progesterone is completed by approximately day 55 and day 150 of pregnancy in the ewe and mare, respectively. Removal of the ovaries before this date will terminate the pregnancy.

Parturition cannot proceed without uterine contraction. At term, there is a dramatic increase in uterine myometrial activity. This activity is facilitated by spontaneous changes in the secretion of estrogen and progesterone at the end of gestation. During pregnancy, progesterone maintains uterine quiescence by hyperpolarizing the myometrial smooth muscle cells. As the rate of production and concentrations of estrogens increases relative to progestagens, the myometrial cells begin to depolarize and increase in contractile activity. This activity is augmented by the release of prostaglandins. In most mammalian species, the increase in estrogen toward the end of gestation seems to be a common theme and the placenta seems to be the source of the estrogen responsible for the increased myometrial activity. However, the strategy in the production of estrogen differs among species. At the end of gestation, the sheep placenta, under the influence of increased fetal cortisol levels, acquires the ability to induce 17α -hydroxylase enzyme activity, which enables the synthesis of placental estrogen. Thus, the maturation of the fetal HPA axis is critical for the initiation of parturition in ruminants.

In the horse, the source of estrogen is the fetoplacental unit because the equine placenta alone does not possess an inducible 17α-hydroxylase enzyme system. In this instance, the steroid precursors, for example, dihydroepiandrosterone (DHEA), necessary for estrogen synthesis, are derived from the fetal horse gonads. Gonadectomy of the fetal horse results in the interruption of initiation of parturition in this species. Humans and other primates are similar to the horse in that estrogen synthesis is also dependent on a functional fetal–placental unit. However, the source of steroid precursors (i.e. DHEA) is the fetal adrenals since the placenta in these species lacks the cytochrome $P\text{-}450_{C17}$ enzyme system to produce estrogen from cholesterol.

Parturition depends on the coordinated rhythmic contraction of the uterine smooth muscle (myometrium) and on involuntary contraction of abdominal muscles. Throughout most of pregnancy the myometrium is nonexcitable and relatively unresponsive to uterotonic agents (prostaglandins, oxytocin). This relative quiescent state of the uterus is due to progesterone or the progesterone 'block'. Under the influence of progesterone, myometrial activity and coordination of contractions and responsiveness to uterotonic agents are diminished. However, the onset of labor is linked to a transformation in the pattern of contractile activity of the myometrium. The myometrium becomes highly responsive to prostaglandins (PGE_2 and $PGF_{2\alpha}$) and oxytocin once the progesterone block has been removed. This increased capacity of the myometrium to develop contractions is referred to as myometrial activation, and once activated it can respond to paracrine and endocrine stimulation from increasing concentrations of uterotonic agents. This concomitant activation and stimulation enable the myometrium to generate intense, high-amplitude and high-frequency contractions that are necessary to dilate the cervix and facilitate fetal expulsion. Also, fetal growth leading to increased tension on the uterine wall and stretching of the myometrium can augment CAP gene expression. It has been suggested that two parallel pathways are initiated by signals within uterine tissues that lead to the development of intense and synchronous myometrial contractions that facilitate dilation of the cervix and accommodate delivery of the fetus (**Figure 5**).

During pregnancy and in the face of elevated progesterone, fetal growth stimulates myometrial stretch and hypertrophy which in turn reduces myometrial tension. At term, the increase in the estrogen-to-progesterone ratio terminates the uterine growth response, while increased fetal growth enhances myometrial tension, CAP gene expression and initiation of labor. The rise in estrogen not only increases myometrial activity but also enhances the synthesis and release of prostaglandins and oxytocin during labor. Myometrial smooth muscle contraction is dependent on an increase in intracellular free calcium, which causes formation of a calcium–calmodulin complex. This complex binds to and activates myosin kinase to interact with actin to cause contraction of the smooth muscle fibers. Oxytocin and $PGF_{2\alpha}$ influence smooth muscle activity by regulating intracellular concentrations of Ca^{2+}. Prostaglandins increase free calcium by liberating Ca^{2+} from intracellular binding sites while oxytocin has a direct effect on the rate of Ca^{2+} influx and also lowers the threshold for initiation of action potential activity. Oxytocin is not effective on myometrial activity until uterine receptors are expressed. This is an estrogen-dependent event in sheep. Similar patterns of myometrial activity exist before parturition in the sheep, goat and cow. Recent information also suggests that the fetal membranes in the sheep and human contribute to the enzyme pathways that facilitate and promote endocrine (prostaglandin) synthesis at parturition.

Figure 5 Proposed scheme for the initiation of parturition. E:P, estrogen-to-progesterone ratio. At term, the uterine environment switches from a progesterone-dominated to an estrogen-dominated environment. The consequence of this shift is the activation of parallel pathways that involve a complex series of molecular, cellular and biochemical events within uterine tissues terminating with the expulsion of the fetus and fetal membranes. (Adapted from Lye SJ (1996) Initiation of parturition. *Animal Reproduction Science* 42: 495–503.)

Progesterone may regulate myometrial activity by downregulating the synthesis of oxytocin receptors, prostaglandin receptors and gap junction proteins, as well as inhibiting pituitary oxytocin release and suppressing prostaglandin production. Progesterone blocks high-amplitude myometrial cell contractions but low-amplitude, high-frequency contractions persist during pregnancy. However, there are other endocrine factors that regulate myometrial activity. For example, relaxin, a small polypeptide hormone, is capable of inhibiting spontaneous myometrial contractions. Although a bovine relaxin gene and protein have not been identified, there is immunohistochemical evidence for the presence of the protein hormone in the corpora lutea of pregnant cows but little or no activity was found in the placenta. Heterologous radioimmunoassay studies have detected relaxin in plasma of pregnant cows between days 5 and 1 prepartum and this therefore suggests a role for relaxin in preparation of the birth canal for delivery, as in other domestic species. A relaxin-like factor (RLF) gene and protein is expressed by the bovine corpus luteum of pregnancy; however, its role in the corpus luteum is unclear. Moreover, the identification of a third relaxin gene in the human (H3) and the mouse (M3) may prove to be the active relaxin gene in the bovine, although such a gene has yet to be identified in this species. Whether similar expression of RLF and/or a third relaxin gene occurs in the bovine placenta has yet to be determined, and implicating a role during delivery for RLF protein would be speculative. A recent but all-important discovery in the relaxin field is the activation of orphan receptors (heterotrimeric guanine nucleotide-binding protein (G-protein)-coupled receptors) by relaxin via an adenosine 3′,5′-monophosphate-dependent pathway. This discovery will undoubtedly lead to new studies that will enhance our understanding of the role relaxin plays in parturition. Other inhibitory uterotonins, including prostacyclin and nitric oxide, have an inhibitory effect similar to relaxin. Progesterone, in association with relaxin, nitric oxide and prostacyclin, suppresses spontaneous and stimulated myometrial activity, thus preventing the spontaneous expulsion of the fetus.

In summary, parturition is thought to be a linear biochemical and physiological process beginning with fetal maturation, leading to an increase in fetal cortisol, which initiates synthesis and release of uterotonic agents that intensify uterine myometrial contractile activity, leading to delivery. The endocrine events associated with the periparturient period are complex, and summarized in **Figures 5** and **6**. Enhanced myometrial activity and delivery at term result from the dual activity of increased uterine activation as characterized by increased connexin-43 (gap junction proteins), oxytocin and prostaglandin receptor expression, along with increased concentrations of oxytocin and prostaglandins.

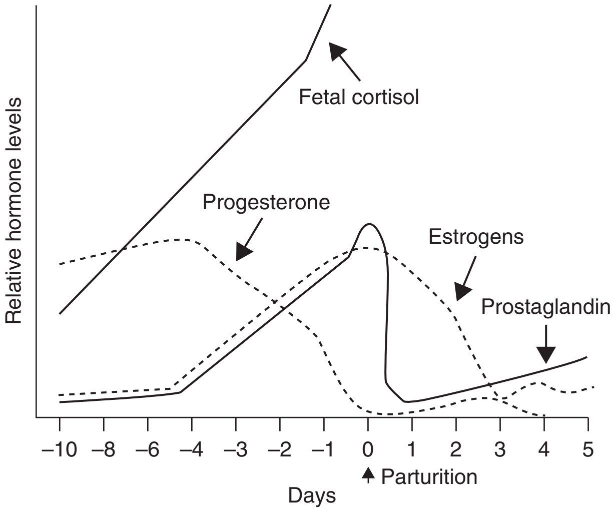

Figure 6 Relative hormone profiles in the cow during the periparturient period. (Adapted from Senger PL (1997) *Pathways to Pregnancy and Parturition*, p. 243. Pullman: Current Conceptions.)

Cervical Ripening and Expulsion of the Fetus

During pregnancy in mammals, the cervix is a relatively firm and inextensible structure that protects the fetus from the external environment and prevents spontaneous delivery. This firmness is due to the highly organized arrangement of collagen fibers in dense parallel bands. As term approaches, the cervix begins to soften and the collagen fibers become dispersed and randomly oriented within an increased proteoglycan extracelluar matrix, accompanied by an increase in the uptake of water. Remodelling of cervical tissue is necessary in order to accommodate normal expulsion of the fetus and fetal membranes at term. This softening or remodeling and increased distensibility of the cervix are regulated hormonally. Several hormones, including estrogen, relaxin, prostaglandin and oxytocin, have been implicated in the stimulation of cervical distensibility. Unlike in the mare and ewe, the ovaries of the cow are essential for the latter stages of pregnancy maintenance and thus may be the primary source of hormones for initiating cervical ripening. Relaxin is an important hormone of pregnancy in many species and is known to facilitate tissue remodelling of the reproductive tract, including the cervix. The effects of relaxin on cervical ripening are particularly important in the mare and the sow since failure of relaxin to facilitate these events can result in increased incidence of dystocia and stillbirths, as is the case in the pig. Interestingly, the placenta is the source of relaxin during pregnancy in the mare, while the corpora lutea of pregnancy are the principal source in the sow. Although the evidence of a bovine relaxin is sketchy, there are sufficient physiological data to support the presence of such a hormone in this species. The biochemistry of cervical ripening is a complex process that involves the upregulation of proteolytic factors such as matrix metalloproteinases and the corresponding tissue inhibitors of matrix metalloproteinases. Also, the increased expression of gap junction proteins (connexin-26, -32 and -43) is thought to be important in this process. Connexins are gap junction proteins that belong to an evolutionarily conserved, multigene family of channel-forming proteins which are important for cell–cell communication and are hormonally regulated.

In cattle, the ratio of fetal birth weight to maternal weight is high (approximately 11% and may be higher when crossbreeding is practiced), and the pelvic cavity expands rapidly during the last 4 days prepartum to facilitate delivery of the calf. Little is known concerning secretion of relaxin in the cow; however, there is reason to suspect that relaxin may loosen the pelvic ligaments and facilitate softening of the cervix. Treatment of cows with highly purified porcine relaxin a week before their due date resulted in a rapid increase in pelvic height and width similar to the elevation of the tail head seen in prepartum cows. When porcine relaxin was placed in the cervical os of beef heifers 5–7 days before the anticipated day of delivery, a premature increase in the dilation of the cervix occurred within 8–12 h of relaxin treatment. In addition, this relaxin-induced cervical ripening was observed to reduce the incidence of dystocia in the treated heifers. In general, little is known about the hormonal regulation of cervical ripening or distensibility in cattle at parturition. Most of our knowledge of the changes that occur in the cervix before delivery is derived from studies performed in pigs and rodents.

Stages of Labor

Labor has been described as occurring in three stages; great variations in the duration of these stages exists among species (**Table 2**). Stage I involves the initiation of labor by the fetus and the resultant dilation of the cervix. Uterine contractions begin to occur in a more rhythmic fashion and continue until the cervix is fully dilated and continuous with the vagina. This period is accompanied by increased restlessness of the dam accompanied by elevated body temperature, pulse and respiratory rates. This is more evident in the horse where the mare may break out in a sweat. Changes in the fetal position and posture will also occur at this stage.

Stage II is associated with fetal expulsion. During this stage of labor the dam may assume recumbency and commence straining, which results in the rupture of the allantochorion and release of chorionic fluid from the vulva. Moments later, the amnion appears as a whitish fluid-filled bag at the vulva. This is followed by the appearance of the forelimbs and nose of the fetus and is accompanied by strong uterine and abdominal contractions. The expulsion and delivery of the fetus follow rupture of the amnion. This stage of labour is the shortest and is associated with the commencement of strong uterine and abdominal contractions and completion of cervical dilation. The cervix remains in a dilated state until the termination of the delivery of the fetus. In sheep and goats, twin births are usually more rapid than single births, but the interval between the delivery of twins may vary from minutes to a couple of hours.

Stage III is the final stage of labor and is associated with the expulsion of the fetal membranes. During this stage of labor the uterine contractions begin to decrease in frequency and amplitude. For successful expulsion of the placenta to occur, loosening of the chorionic villi from the maternal endometrial crypts must take place. The spasmodic contraction of the uterine wall, which abates following the inversion and expulsion of the fetal membranes, facilitates this process. However, the interval between birth of the fetus and expulsion of the fetal membranes varies among species. In the horse, the placenta is shed within 30–60 min after delivery compared to the 6–12 h it typically takes in the cow (**Table 2**).

Table 2 Average duration of the three stages of labor in different domestic species

	Stages of labor (h)		
Animal	*I: Dilation of cervix*	*II: Expulsion of fetus(es)*	*III: Expulsion of fetal membranes*
Cow, buffalo	2–6	0.5–1.0	6–12
Ewe	2–6	0.5–2	0.5–8

Complications (Dystocia and Retained Placentas)

Complications associated with parturition can impact negatively on postpartum cows in terms of their reproductive efficiency and milk productivity (*see* **Reproduction, Events and Management**: Estrous Cycles: Postpartum Cyclicity; Pregnancy: Periparturient disorders). Dystocia and retained placenta are the most common problems associated with parturition in dairy cattle and are probably linked to a number of interrelated variables. Dystocia is defined as prolonged or difficult delivery and can be due to either fetal or maternal abnormalities. Fetal dystocia refers to an abnormality of the fetus that may lead to incorrect birth positioning while maternal dystocia refers to abnormality of or physical problem of the mother. Such abnormalities of the mother may include poor pelvic confirmation, incomplete ripening of the cervical canal and immaturity. The most common causes of dystocia in cattle include the incompatibility of size of the fetus and the mother's pelvis and the malpresentation, position or posture of the fetus *in utero*. In beef cattle, size and birth weight of calves have been determined to be the most common factor contributing to dystocia. Very large calves also tend to have higher perinatal mortality. Other factors that contribute to dystocia are uterine inertia, uterine torsion and failure of the cervix to dilate.

In primiparous or first-calf heifers, stricture of the vulva can also be problematic and may lead to dystocia and stillbirth. In addition, the economic need to place heifers into the milking parlor at an earlier age has led to the practice of breeding heifers at under 15 months of age, increasing the risk of dystocia in first-calf heifers. In the yak, the incidence of dystocia is low (3.3%) and twinning is rare (0.5%). In high-yielding dairy cows, reduced blood calcium concentrations at time of parturition can be problematic and increase the risk of dystocia in these animals. This condition is associated with milk fever and the incidence is on the rise as dairy producers genetically select for high-yielding cows. Milk fever is a metabolic disorder of calcium homeostasis and decreased blood calcium reduces the availability of Ca^{2+} for uterine smooth muscle contraction and, in so doing, increases the risk of a difficult delivery and/or retained placenta (*see* **Diseases of Dairy Animals**: Non-Infectious Diseases: Milk Fever). Feeding anionic salts to near-term cows, which mobilizes bone reservoirs of calcium, thereby elevating blood Ca^{2+} concentrations and availability for uterine muscle tissue, can alleviate this condition. Treatment with opiate antagonists (e.g. naloxone) in low doses has recently been shown to be a safe method to offset the adverse effects of milk fever in cows and thus reduce muscular complications at delivery (dystocia and retained placenta).

Dystocia in horses is also a serious problem and if proper assistance is not given can put both the mare and foal at risk. The incidence of dystocia in horses is breed-dependent, with a rate of 4% in light breeds (thoroughbred, standardbred, walking horse, saddle horse) but increases to 8% in pony breeds (Shetlands, Connemara), with an incidence of 10% in the heavy draft breeds (Shire, Belgian). The causes of dystocia in horses are many but the most common appear to be reflected head and neck and/or forelimbs when the foal is in anterior presentation. Other contributing factors include deformed limbs, oversized fetus and hydrocephalus, being more frequently observed in pony breeds.

Dystocia may also affect the future reproductive performance of the cow and is often associated with a delayed postpartum estrus, extended calving interval and an overall reduction in fertility (*see* **Reproduction, Events and Management**: Estrous Cycles: Postpartum Cyclicity). Implementation of two simple rules of thumb may help reduce the incidence of dystocia and resulting stillbirths in a herd. The first is to avoid breeding young heifers when below their optimum breeding weight (**Table 3**) and the second is to take advantage of the selection of easy-calving bulls that have been identified by breed associations to inseminate heifers. Dairy heifers should attain at least 60% of the mature adult body weight for the breed before being mated. European and Israeli dairy producers have taken advantage of genetic information provided by their dairy breed associations on control of dystocia due to feto-pelvic incompatibility, resulting in approximately a 60% and 40% reduction in the incidence of dystocia and stillbirths, respectively. The bottom line is to select carefully ease-of-calving sires, giving due consideration to maternal traits to avoid producing progeny that may be small of stature as adults and thus confound the dystocia problem. It is important to remember the genetic (breed) and environmental (size, pelvic dimensions, uterine environment) factors that the dam contributes to a pregnancy and the impact they have at delivery. Studies have shown that fetal genotype is the primary factor controlling birth weight in crossbred breeding, but that the maternal uterine environment (size, number of placentomes) could promote or markedly limit the full genetic growth potential of the calf *in utero.*

Implications of hormonal imbalances have been correlated with dystocia. Scientists have looked at blood concentrations of prolactin, progesterone and the various estrogens (estrone, estradiol-17α and -17β) for an endocrine association with the incidence of dystocia in dairy cows. Estrogen concentrations were markedly depressed in animals experiencing dystocia but in most cases there seemed to be an accompanying anatomical incompatibility. The possibility of other endocrine factors known to be important in parturition, including adrenal corticosteroids, uterine prostaglandins, oxytocin and relaxin release, cannot be overlooked.

Placental dystocia refers to the retention or difficult delivery of the placenta and is more commonly referred to as retained placenta or retention of fetal membranes. It is the failure of the chorionic villi (cotyledons) to separate from the caruncles of the uterine endometrial wall and be expelled within a specific timeframe (**Table 2**). A placenta is usually classified as retained if the cow has not shed the placenta within 24 h of delivery. Retained placentas increase the risk of uterine infections (metritis), predispose the cow to toxemia, diminish milk production and markedly reduce the reproductive efficiency of the animal (*see* **Reproduction, Events and Management**: Estrous Cycles: Postpartum Cyclicity). The incidence of retained placentas in cattle is thought to be 5–15% of the deliveries in healthy herds. In herds where the incidence runs higher than 15%, there is usually an underlying cause contributing to the problem. For example, poor nutrition and lack of essential micronutrients such as vitamin A or selenium can cause a higher than normal incidence of retained placentas in a herd. Also, cases of retained placentas are more frequent after difficult deliveries, induction of parturition, premature deliveries and twins; first-calf heifers are at higher risk than multiparous cows. This may be true in cases where the calving age of heifers is less than 24 months. Retained placenta in the horse is regarded as the most common postpartum problem and may be associated with the failure to shed part or all of the allantochorionic membranes with or without the amniotic membrane. The time it takes to pass the placenta in this species is critical. Although varying times have been given, failure of a mare to pass the placenta within 2 h postpartum is regarded as a retained placenta. As in the cow, failure to shed the placenta is associated with failure of the microvilli (microcotyledons) to separate from the endometrial crypts. Failure to pass the placenta in a timely manner usually predisposes the animal to uterine infection and increases the potential for poor postpartum reproductive efficiency. This is especially problematic in horses and dairy cows.

Introduction

The majority of diseases that affect dairy cows occur during the peripartum time, which is defined as parturition, initiation of lactation and the early postpartum period. Parturition and the onset of lactation impose tremendous physiological challenges that may predispose the dairy cow to physiological and infectious disorders. These disorders include parturient paresis (milk fever), calving difficulty (dystocia), retained fetal membranes (fetal membranes retained beyond 24h postpartum), metritis (infection and infammation of the uterus), fatty liver (pathological 2310 PREGNANCY/ Periparturient Disorders fat accumulation of the liver), ketosis (excessive ketone body production) and displacement of abomasum (displacement of the abomasum to the left side of the abdominal cavity). These disorders result in signifcant economic losses to dairy producers by reducing reproductive performance and milk yield during the subsequent lactation, cost of treatments and culling.

Dynamics of the Dry Period

When dairy cows are 7 months pregnant milking should be discontinued to allow them a 2 month rest period (dry period). The dry period allows lacteal tissue involution and regeneration, which prepares cows for the next lactation. It is generally perceived that during the dry period, the pregnant nonlactating dairy cow is in a quiescent metabolic state. This is an incorrect assumption since the late pregnant cow undergoes a series of complex metabolic changes as parturition approaches. These changes are related to growth of the calf, reduction of feed intake during the end of gestation and the initiation of lactation. Collectively, these events increase the energy and calcium demands during parturition and the initi-ation of lactation. If difficulties occur in making the necessary peripartal energy and calcium adjustments, metabolic disorders such as fatty liver, ketosis and parturient paresis may occur (**Figure 1**).

Fetal Growth

Fetal growth occurs exponentially, with over 60% of total fetal growth occurring during the last 2 months of gestation. Maximal growth occurs during the last 6-8 weeks of gestation. This fetal and placental growth results in a nutritional burden of pregnancy to the cow during the dry period. Therefore, inadequate nutrition at this time can result in loss of maternal body reserves in order to sustain fetal and placental development. These losses in body reserves or fat mobilization cause an increase in blood of certain type of fats, called plasma nonesterifed fatty acids (NEFA), which predispose the cow to hepatic fat accumulation or fatty liver.

Parturition

Parturition occurs as a result of a complex series of hormonal changes in the dam that are initiated by the fetus (**Figure 1**). When the size of the fetus reaches a certain relation to the mother's size, corticoidal hormones increase gradually from 3 weeks to 4 days prepartum. This increase in fetal corticoidal hormones during the last month of gestation is responsible for the conversion of placental progesterone and pregnenolone to estrogenic hormones. One week prepartum, in response to the increase in estrogen production, a fatty acid hormone, prostaglandin F2a is released from the uterus. This increase in prostaglandin results in lysis of the corpus luteum of pregnancy and is accompanied by a decline in luteal progesterone. Similar hormonal changes, are also common in other domesticated species and in women.

Lactation

Initiation of lactation occurs in concert with the hormones that are involved in the initiation of parturition, which are: an increase in estrogen, a reduction in progesterone and an increase in corticoids. Alteration in these hormones also induces changes in a series of other regulatory hormones (thyroid hormones, insulin, glucagon, growth hormone,

placental lactogen, prolactin) that promote the production of glucose and ketone bodies and the mobilization of fatty acids. These complex hormonal and metabolic alterations shift the priorities of the cow from tissue and fetal gain to mammary development and copious milk production.

Feed Intake

Feed intake decreases 5 to 7 days prior to parturition. This reduction can reach up to 30% under normal feeding management practices. Depression of feed intake before parturition has been considered a major factor in the development of the fatty liver complex. Accumulation of fat in the liver occurs during periods of elevated fat mobilization, especially in cows with excessive fat body reserves at parturition. During the last 2 weeks prepartum, NEFA increases twofold in blood. This increase in plasma NEFA concentration prepartum has been attributed to excessive fat mobilization that provides energy for the growing fetus/maternal tissues, during the period of feed intake depression and the endocrine events associated with parturition.

Energy Status, Body Condition Score and Reproductive Performance

Dairy cows reach peak milk production around 8 to 10 weeks post calving. However, feed intake increases slowly after parturition lagging 2 weeks behind the peak of milk production. This lag explains the adipose reserve mobilization experienced by cows, with a typical weight loss during the first one-third of lactation. Because energy output (milk yield) exceeds energy intake via feed consumption, dairy cows undergo a period of negative energy balance in early lactation (**Figure 2**). Any periparturient disorder that predisposes the cow to reduce feed consumption will exacerbate

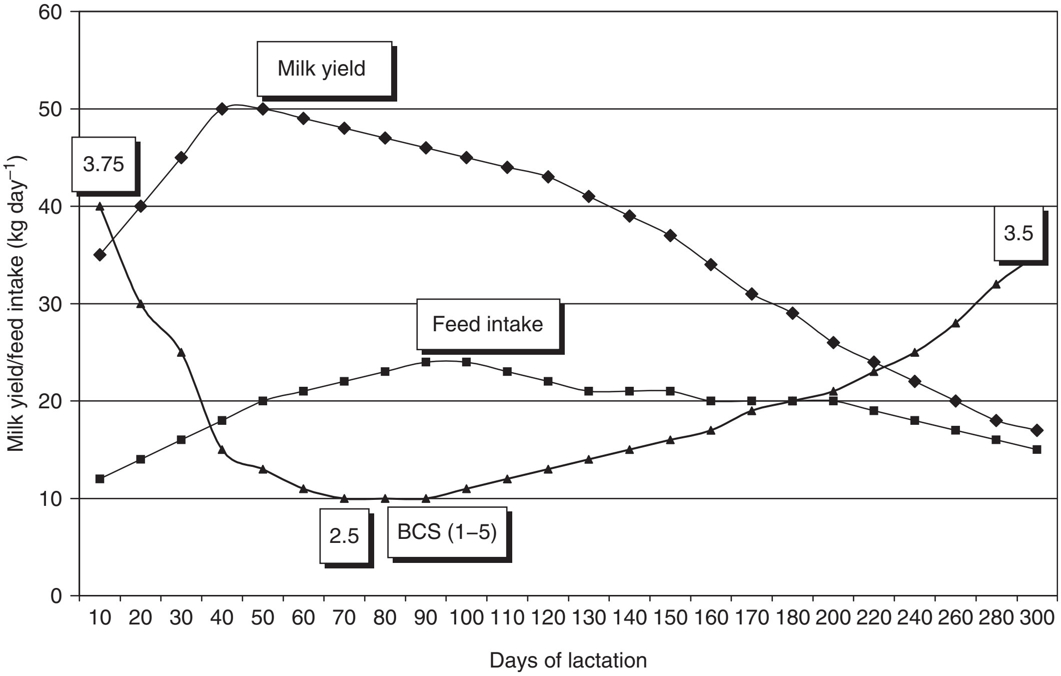

Figure 2 Milk production, feed intake and body condition score (BCS) in a typical dairy lactating cow.

the negative energy status already present during the postpartum period.

The energy status of the postpartum cow has an effect on integrated reproductive activity during early lactation. Cows losing weight may experience a delay in the resumption of cyclicity. A return toward a positive energy status appears to be important in the initiation of cyclicity. The marked deficit in early energy status for the anestrus cow exerts a negative carryover effect on conception.

Body reserves can be measured through a visual evaluation of different anatomical points of the cow. This methodology called body condition scoring (BCS) has been validated through different studies using scales from 1 to 5 or 1 to 9, being 1 a very thin cow and 5 or 9 a very fat cow. Body condition score has been related with the magnitude and severity of negative energy balance. Cows that lose more than 0.5 to 1.0 BCS (scale 1-5) during the frst 60 days postpartum have been shown to have lower conception rates to first insemination. A score of 3.25 to 3.75 at calving is recommended with no more than a 0.5 point loss of body condition during the frst 60 days postpartum (**Table 1**).

Table 1 Target body condition scores (BCS scale 1-5)

Stage	*Ideal BCS*	*Range*
Dry-off (around 7 month of pregnancy	3.5	3.25–3.75
Calving	3.5	3.25–3.75
Early lactation	3	2.5–3.25
Mid-lactation	3.25	2.75–3.25
Late lactation	3.5	3.0–3.5
Growing Heifers	3	2.75–3.25
Heifers at calving	3.5	3.25–3.5

Cows that are overconditioned at calving (>3.75) experience less feed intake, more fat mobilization and are at high risk of experiencing calving-related disorders. Consequently, BCS should be monitored specially during the last one-third of lactation and the dry period. Losses of more than 0.25 units should be avoided during the entire dry period. Changing body condition through dietary manipulations requires some strategic planning and careful consideration. Underconditioned cows (thin animals) should be allowed to recover condition during the late lactation period because during this time lactating cows are more efficient in restoring body condition than during the dry period. In addition, the dry period may be too short to fully recover condition needed prior to calving. Cows should not lose weight during the dry period, as the cow must gain 0.45 to 0.68 kg day-1 simply to meet the needs of the rapidly developing fetus.

Periparturient Disorders Milk Fever (Parturient Paresis)

During calving or shortly thereafter, the fall of calcium levels in blood (hypocalcemia) is inevitable in the dairy cow and is characterized by a blood calcium concentration

<1.88 mmol l-1(<7.5 mg dl-1). Hypocalcemia develops as a result of the sudden drain of calcium to colostrum at the onset of lactation, resulting in a tremendous challenge to cows' ability to maintain normal calcium levels. At parturition, 30 g or more of calcium must be replenished into the calcium pool each day to maintain the normal calcium levels. Clinical hypocalcemia or milk fever develops when blood calcium concentration is below 7.5 mg dl-1. A cow affected with milk fever may present with nervousness, staggering but usually becomes recumbent and is unable to rise (paresis). If blood calcium concentration is not restored quickly death occurs. Ten to fifty percent of cows may develop low calcium levels without symptoms of milk fever (subclinical hypocalcemia) up to 10 days postpartum. Hypocalcemia may affect organs that have smooth muscle function such as the uterus, rumen and the abomasum. Hypocalcemia is a significant risk factor for calving difficulty, retained fetal membranes, metritis, uterine eversion or prolapse, displacement of abomasum and clinical ketosis. These disorders have been associated with no estrus or heat expression (anestrus), cyst in the ovaries and metritis, which negatively affect the reproductive performance of dairy cows.

Retained Fetal Membranes (Retained Placenta)

Retained fetal membranes (RFM) is defined as the lack of detachment of fetal membranes (cotyledons) from the maternal membranes (caruncles) within the first 12-24 h after calving. The incidence of retained fetal membranes may range from 1.3% to 39.2%. The cost of a case of RFM ranges between US$106 and $285. Some risk factors for RFM are hypocalcemia, calving difficulty, parity, abnormal gestation length, season and sire of the calf. Retained fetal membranes have been the major factor predisposing cattle to metritis. About 20-25% of cows affected by RFM may develop moderate to severe metritis.

Metritis (Puerperal Metritis, Toxic Metritis)

Metritis (infection of the uterus) is one of the most frequent disorders affecting dairy cows during the postpartum period. Metritis is a major cause of economic losses to the cattle industry. The condition is characterized by an abnormal uterine discharge, with local or systemic symptomatology. Systemic or toxic metritis is characterized by a foul-smelling, watery uterine discharge usually accompanied by a severe drop in milk production and a fever, and it may be life threatening. The total cost to producers for each lactating dairy cow with a uterine infection has been estimated in US$106. Some predisposing factors for metritis are calving difficulty, retained fetal membranes, twins or stillbirths, fat cows at calving and metabolic disorders.

Ketosis and Liver Fat Accumulation (Fatty Liver)

Ketosis is defined as a metabolic disorder characterized by high levels of ketone bodies (-OH-butyrate, acetoacetate and acetone) affecting dairy cows in the period from parturition to 6 weeks postpartum. There are two types of ketosis, primary or secondary. A cow with primary clinical ketosis has a decreased appetite and elevated serum, milk, urine or breath ketones in the absence of another concurrent disease. Ketosis may be clinical or subclinical. Subclinical ketosis is defined as a preclinical stage characterized by an elevated ketone body level but not clinical signs, such as loss of appetite, hard feces, or dullness; however reproductive responses might be affected. The incidence of ketosis may range from 1.3% to 18.3%. Economic losses from ketosis have been estimated to total approximately US$145 per case.

Feed intake starts to decrease precipitously, and the reduction could reach as high as 30% on day 1 or 2 before calving and does not recover until 1 to 2 days after calving. Glucose availability is an important factor in the pathogenesis of clinical ketosis and liver fat accumulation. When glucose availability is low, ketone bodies formation occurs; when glucose is high, fat deposition is favored. Elevation of plasma fatty acids starts prior to feed intake depression, on day 5 before parturition. Liver fat infiltration does not occur until the concentration of plasma fatty acids are maximized on day 1 after calving. Liver fat accumulation can occur very rapidly. Within 48 h, hepatic fat levels can rise up to 25%, under conditions of extreme fat mobilization.

Left Displacement of Abomasum (LDA)

In left displacement of the abomasum, the abomasum slides under the rumen and dorsally along the left body wall. The result is a partial impairment of abomasal outflow, leading to abomasal gas accumulation, electrolyte pooling with subsequent systemic alterations, and depressed gastrointestinal motility and appetite. Left displacement of abomasum occurs most commonly 2 weeks prepartum to 8 weeks postpartum.

The incidence of LDA may range between 0.3% and 6.3%. This digestive disorder may occur in cows from first lactation and later. Cows with displacement of the abomasum experience severe losses of milk yield and body weight. They are more likely to have another disease than healthy

Table 2 Summary of periparturient disorders in dairy cattle

Disorder	*Incidence (%)*	*Risk factors*	*Cost per case*	*Prevention*
Hypocalcemia	0.03–22	• Parity • Milk yield • Breed	$335	Acidic (Anionic) diets prepartum
Retained fetal membranes (RFM)	1.3–39.2	• Parity Hypocalcemia • Calving difficulty • Twins	$285	Adequate feeding and obstetrical management
Metritis	2.2–37.3	• Hypocalcemia • RFM • Calving difficulty • Ketosis	$106	Avoiding predisposing factors Adequate treatments for RFM
Ketosis	1.3–18.3	• Hypocalcemia • RFM • Displacement of abomasum • Parity • Metritis • Mastitis • Milk Yield • Fat cows	$145	Avoiding risk factors Good feeding management
Displacement of abomasum	0.3–6.3	• Ketosis • RFM • Metritis • Mastitis • Hypocalcemia	$340	Good feeding management Avoiding risk factors

cows and thus are more likely to be culled than normal cows. Left displacement of abomasum is a multifactorial disease. Hypocalcemia, calving difficulty, ketosis, excessive body condition score at calving and incorrect feeding management practices are risk factors for displacement of abomasum. Prevention and Management of Periparturient Disorders

The most common periparturient disorders of dairy cattle are summarized in **Table 2**. Prevention of these disorders is best accomplished by providing a well-balanced diet to prepartum cows. Enhancing calcium availability during the time of parturition is crucial in preventing milk fever. This may be achieved by feeding a diet low in potassium and selecting feedstuffs with higher chlorine and sulfur contents (anionic diets). These diets induce a mild metabolic acidosis, which increases calcium levels in blood. Thus, the effectiveness of these diets can be tested monitoring the acidity of urine (urine pH). Too much acidity or alkalinity of the urine indicates that the cows are not responding to the anionic diets. Furthermore, prevention of hypocalcemia with oral calcium products have been recommended. These products are administered near calving, as supportive therapy in the management of clinical hypocalcemia in cattle. The most common oral products are calcium chloride and calcium propionate. However, under adequate management of acid diets and low incidence of hypocalcemia, oral products as prevention may not be necessary. Intravenous calcium products are only recommended for treatment purposes.

In order to prevent liver fat accumulation and ketosis, the key is to minimize the increase in fat mobilization from adipose tissue as parturition approaches. This can be accomplished by ensuring that the ration contains the required amount of energy and maintenance of maximum feed intake during the prepartum period (**Table 3**). Vitamins and minerals should be fed to dry cows at the

National Research Council recommendations as shown in **Table 4**.

Good feeding management not only includes the formulation of the diet, but also feed trough space in order to allow maximal feed intake per cow, adequate shade and good quality water and a comfortable environment where cows can lie down. Cows during the prepartum period need to adapt to the new diet, when the cow commences lactation. This challenge requires gradual changes through the prepartum until the early postpartum period and is the art of feeding transition cows.

Conclusions

During the postpartum period dairy cows are at a higher risk of developing metabolic diseases that impair milk production and reproductive performance. Many of these diseases are a result of improper nutritional management during the dry period. Because dry cows do not contribute to the economics of the dairy farm, many producers ignore these animals and their nutritional needs are compromised. We have to convince producers that the dry period is a preparatory phase for the next lactation, and that dry cows must be considered an investment for the next lactation.

RHEOLOGY OF LIQUID AND SEMI-SOLID MILK PRODUCTS

O J McCarthy, Massey University, Palmerston North, New Zealand

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The rheological behavior of milk is, in a general sense, typical of a semi-dilute emulsion/suspension. However, the complex composition and microstructure of milk result in complexities in behavior not exhibited by simple systems of this kind. These complexities become more pronounced when milk is subjected to such treatments as concentration (of fat or of total solids), fractionation, homogenization, heating, renneting, and acidification during its conversion to dairy products.

In this article, quantitative descriptions (mathematical models) of the rheological properties of milk, cream, concentrated milks and creams, sweetened condensed milk, ice cream mix, yogurts, buttermilk, and fresh cheeses are presented. The models are of three kinds: those that relate rheological behavior to composition and microstructure, those that quantify objective properties related to texture (texture itself must be measured subjectively), and phenomenological models useful for process engineering design and other technological purposes.

Milks and Creams

The rheological behavior of milk and cream is in accord with that of emulsions and suspensions in general. Milk and cream can exhibit Newtonian or non-Newtonian behavior depending on composition, temperature, prior treatment, and measurement conditions.

Fresh skim milk, whole milk, and cream can for almost all practical purposes be treated as Newtonian liquids under the following conditions: fat content <40% (w/w), temperature >40 °C (milk fat completely molten; no cold agglutination of fat globules), and moderate to high shear rates. Rheological behavior is completely characterized by a temperature-dependent coefficient of viscosity, defined by Newton's law of viscosity:

$$\tau = \eta\ \dot{\gamma}\ \text{(Pa)} \qquad [1]$$

where τ is the shear stress (Pa), $\dot{\gamma}$ is the shear rate (s^{-1}), and η is the coefficient of viscosity (Pa s). The term 'coefficient of viscosity' strictly denotes the proportionality constant in eqn [1]. The term 'viscosity' is a more general one, meaning the extent to which a fluid resists being sheared. The distinction between the two is irrelevant for Newtonian liquids, though not for non-Newtonian liquids.

Representative values, at 20 °C, of the coefficient of viscosity of whole milk and fractions derived therefrom, measured under conditions where Newtonian behavior exists, are given in **Table 1**.

Several points can be made on the basis of these data. First, lactose, the major low-molecular-weight milk component, and even the whey proteins influence viscosity to a relatively small extent. Second, the fat content has a major influence. Third, the (micellar) casein content has by far the greatest influence. The viscosity and the rheological behavior of milk (and the semi-liquid products made from it) depend largely upon the state and concentration of the fat and casein, and thus on factors that affect these.

The viscosity of whole and skim milk, for conditions under which Newtonian behavior occurs, can be modeled with Eilers's semi-empirical equation:

$$\eta = \eta_0 \left(1 + \frac{1.25\Sigma(\phi_i)}{1 - \Sigma(\phi_i)/\phi_{\max}}\right)^2 \qquad [2]$$

where η is the coefficient of viscosity of the milk product (Pa s); η_0 is the coefficient of viscosity of the portion of the product consisting of water and low-molecular-weight substances other than lactose (Pa s); ϕ_i is the volume fraction of a dispersed component with a particle size at least an order of magnitude greater than the size of the water molecule; $\Sigma(\phi_i) = \phi_{\text{fat}} + \phi_{\text{cas}} + \phi_{\text{wp}} + \phi_{\text{L}}$, where fat represents milk fat, cas is casein, wp whey proteins, and L lactose; and $\phi_{\max}$ is the assumed value of $\Sigma(\phi_i)$ for maximum packing of all dispersed particles; $\phi_{\max}$ depends on the overall size distribution of the dispersed particles and on particle shapes (though not on particle size *per se*).

The volume fraction of an individual component is given by

$$\phi_i = V_i c_{v,i} \qquad [3]$$

where V_i is the voluminosity of component i ($m^3\,kg^{-1}$ of dry component) and $c_{v,i}$ is the volume concentration of the component in the product ($kg\,m^{-3}$ of product). Representative values of voluminosity are given in **Table 2**. Voluminosity and volume fraction pertain to

hydrodynamic volume, and thus account for particle shape and water of hydration as well as volume *per se.*

Equation [2], for $\Sigma(\phi_i) \rightarrow 0$, reduces to Einstein's equation for the viscosity of a very dilute solution of hard spheres:

$$\eta = \eta_0(1 + 2.5\phi) \qquad [4]$$

Einstein's equation assumes no particle–particle interaction; Eilers's equation accounts for both the presence of the dispersed phase(s) and the hydrodynamic interaction between particles during flow. Eilers's equation does not, however, account for mutual attraction/repulsion between particles.

Eilers developed his equation at a time when viscometric techniques were too unsophisticated to detect non-Newtonian behavior at low shear rates. The equation is useful for predicting the effects on viscosity of variations in the composition and concentration of milks and creams. Viscosity increases with %TS (total solids), but, for a given %TS, is inversely related to %fat content (F) because of the lower voluminosity of fat when compared with that of casein in particular. When $\Sigma(\phi_i)$ exceeds 0.6 (which corresponds to $\eta/\eta_0 \approx 10$), viscosity increases steeply with $\Sigma(\phi_i)$, and the rheological behavior becomes non-Newtonian.

The volume fraction of the casein (ϕ_{cas}) in milk is the main determinant of $\Sigma(\phi_i)$, and thus of viscosity. Large differences in viscosity between different lots of milk are almost certainly attributable to differences in ϕ_{cas}, which depends, in turn, upon such factors as the concentration of colloidal calcium phosphate, Ca^{2+} activity, and pH. The viscosity of milk and cream increases with age owing partly to changes in ionic equilibria. The viscosity of milk increases slightly with increasing pH, perhaps owing to swelling of the casein micelles. Conversely, a small decrease in pH reduces viscosity, whereas a large decrease causes micelle aggregation.

Temperature and Thermal History

Viscosity is inversely related to temperature *per se.* Cooling of milk results in an increase in viscosity, which is partly the result of an increase in η_0 and partly the result of a sharp increase in V_{cas} and thus in ϕ_{cas}. Furthermore, some caseins, especially β-casein, dissociate from the micelles at low temperatures; this contributes to an increase in viscosity because dissociated proteins have higher hydrodynamic volumes.

Heating of skim milk or whole milk to 65 °C, followed by rapid cooling, results in a temporary decrease in viscosity (measured at a lower temperature) because of the increased association of β-casein with the micelles that would have occurred at the higher temperature; viscosity recovers exponentially with time as some β-casein gradually dissociates again at the lower temperature.

Warming of milk to temperatures above ambient causes viscosity to decrease, because η_0 decreases and ϕ_{cas} decreases moderately. The change in ϕ_{cas} is reflected by a decrease in the ratio $\eta_{\text{skim}}/\eta_{\text{whey}}$ when temperature is increased from 5 to 30 °C. The decrease is less marked at temperatures >30 °C.

During dynamic heating and cooling (e.g., 15 ↔ 80 °C), the viscosity of milk can vary depending on both temperature and temperature history; plots of viscosity versus temperature can display hysteresis. The hysteretic pattern for fresh milk itself depends on temperature history, and this effect is attributable to the reversible melting and crystallization behavior of the milk triglycerides. Different hysteretic patterns are found with aged milk; these are considered to reflect the decreases in the heat stability of proteins with age.

The viscosity of whole milk increases with age. The rate of increase is inversely related to the temperature of measurement. Pasteurization, a relatively mild heat treatment, results in no noticeable change in the rheological properties of whole milk.

Non-Newtonian Behavior

Non-Newtonian behavior manifests itself in raw whole milks and creams under conditions that favor cold agglutination of fat globules (temperatures of <40 °C and low shear rate). Shear thinning is the predominant rheological behavior. Aggregates of fat globules contain trapped interstitial plasma, and thus together have a high effective volume fraction, especially at low shear rates. As shear rate is increased, shearing forces cause aggregates to become more regular in shape or to break down. The volume fraction and consequently the apparent viscosity then decrease. Apparent viscosity, which is thus shear rate dependent, is defined

$$\eta_{\mathrm{app}} = \frac{\tau}{\dot{\gamma}} \qquad [5]$$

As shearing forces become larger compared with the attractive forces holding the globules together, successive increases in shear rate have smaller and smaller effects on apparent viscosity. At sufficiently high shear rates, the behavior becomes Newtonian. At high fat contents, non-Newtonian behavior is more pronounced and persists to higher shear rates.

At very low shear rates ($\dot{\gamma} \leq 30\,\mathrm{s}^{-1}$), at ambient temperature, the shear rate dependence of the viscosity of model emulsions made by mixing pasteurized cream with pasteurized skim milk is due only to the skim milk. Skim milk exhibits shear-thinning behavior at shear rates $<250\,\mathrm{s}^{-1}$ and temperatures $<30\,°\mathrm{C}$.

Lower temperatures enhance cold agglutination. This increases both the apparent viscosity and the non-Newtonian behavior, the latter persisting to higher shear rates. Separation of milk at temperatures $\geq 40\,°\mathrm{C}$ gives cream in which cold agglutination is largely reduced owing to the loss of agglutinin to the skim milk. Conversely, cold separation enhances cold agglutination. Thus, the separation conditions influence the rheology of cream. Cold agglutination in raw cream, and the presence of homogenization clusters in homogenized cream, can result in time-dependent shear thinning (called thixotropy if recovery of viscosity occurs on resting after shearing).

The apparent viscosity of raw milk at infinite shear rate ($\eta_{\dot{\gamma}=\infty}$), at temperatures $<40\,°\mathrm{C}$, can be related to ϕ_{fat} by the following equation:

$$\eta_{\dot{\gamma}=\infty} = \eta_{\mathrm{skim}}(1 + 3.25\phi_{\mathrm{fat}}) \qquad [6]$$

Evaluation of apparent viscosity at $\dot{\gamma} = \infty$, by extrapolation, allows the effects of fat content to be separated from the effects of shear rate.

The Cross equation, which relates apparent viscosity to shear rate, has been found to describe exactly the pseudoplastic nature of raw cream:

$$\eta_{\mathrm{app}} = \eta_{\dot{\gamma}=\infty} + \frac{\eta_{\dot{\gamma}=0} - \eta_{\dot{\gamma}=\infty}}{1 + b\dot{\gamma}^{m}} \qquad [7]$$

where η_{app} is the apparent viscosity at $\dot{\gamma}\,\mathrm{s}^{-1}$; $\eta_{\dot{\gamma}=0}$ is the apparent viscosity at $\dot{\gamma} = 0$, found by extrapolation; and b and m are constants. The factors $\eta_{\dot{\gamma}=0}$, $\eta_{\dot{\gamma}=\infty}$, b, and m are each dependent on temperature and fat content. The applicability of the Cross equation implies that a state of equilibrium exists during flow between the size and number of fat globule aggregates and shear rate.

Shear thickening can be observed in high-fat creams; shearing induces partial coalescence of globules, thereby increasing the effective ϕ_{fat} by entrapment of plasma. Cream is viscoelastic; its rheological behavior may be represented by the generalized Maxwell body (a mechanical analog), the relaxation time of which is nearly independent of fat content. Cream, a concentrated emulsion, can in fact exhibit most of the possible types of non-Newtonian behavior depending on conditions and treatment. The viscosity of milks and creams depends on technological treatments as well as on composition, concentration, and shear rate.

Effects of Technological Treatments

Homogenization

Homogenization of milk and cream results in an increase in viscosity measured at high shear rates. The increase is inversely related to fat globule size. At low shear rates and ambient temperature, the viscosity of homogenized milk is lower than that of raw milk. This is possibly a consequence of the destruction of agglutinin by homogenization. Homogenization of cream reduces deviation from Newtonian behavior, possibly for the same reason.

Heat treatment, renneting, acidification

The effects of heat treatment, renneting, and acidification on the viscosity of milk, under conditions where coagulation has not (yet) occurred, can be modeled using the so-called adhesive hard sphere (AHS) theory.

It has been shown that skim milk behaves rheologically as a semi-dilute colloidal suspension of hard spheres, the casein micelles, in a medium comprising all of the other milk components. For such a suspension, the viscosity (strictly speaking the coefficient of viscosity at $\dot{\gamma} \rightarrow 0$) is given by the following theoretical equation (which is a modification of Einstein's equation [4]):

$$\eta = \eta_0(1 + 2.5\phi + k_{\mathrm{H}}\phi^2) \qquad [8]$$

where k_{H} (the Huggins constant) accounts for hydrodynamic interactions. For $\phi \leq 0.2$ (semi-dilute dispersion), in the absence of mutual attraction/repulsion between the micelles (nonadhesive hard spheres), k_{H} is equal to 5.913. Viscosity is then given by

$$\eta = \eta_0(1 + 2.5\phi + 5.913\phi^2) \qquad [9]$$

Untreated skim milk closely follows this equation.

A series development of the semi-empirical Eilers's equation (with $\phi_{\mathrm{max}} = 0.74$) gives a similar expression:

$$\eta = \eta_0(1 + 2.5\phi + 4.94\phi^2 + 8.78\phi^3 + \cdots) \qquad [10]$$

Both eqn [9] and eqn [10] reduce to Einstein's equation when ϕ is small enough to preclude interactions of any kind between the suspended spheres.

The Huggins constant is given by the following equation:

$$k_{\mathrm{H}} = 5.913 + \frac{1.9}{\tau_{\mathrm{B}}} \qquad [11]$$

where τ_{B} is the Baxter interaction parameter, which is a measure of adhesive interactions between the spheres (stickiness). It is related to the second osmotic virial coefficient, B_2, a property of the casein micelle suspension:

$$\frac{B_2}{V_{\mathrm{HS}}} = 4 - \frac{1}{\tau_{\mathrm{B}}} \qquad [12]$$

where V_{HS} (=$4/3\pi a^2$) is the volume of a hard sphere of radius *a*.

For nonadhesive hard spheres (no mutual attraction) $\tau_{\mathrm{B}} = +\infty$, and $k_{\mathrm{H}} = \mathrm{constant} = 5.913$, as indicated above (eqn [9]). When mutual attraction does exist (adhesive hard spheres), τ_{B} has a positive finite value. Then, $k_{\mathrm{H}} > 5.913$, and viscosity has a value larger than that predicted by eqn [9]. The adhesive hard-sphere theory is embodied in eqns [8], [11], and [12].

Heat treatment of skim milk severe enough to cause denaturation of β-lactoglobulin and its subsequent association with the casein micelles results in an increase in ϕ and a decrease in τ_{B}, the latter change indicating the development of mutual attraction between the casein micelles. This results in a viscosity increase larger than that predicted by either eqn [9] or eqn [10].

A computer-based model utilizing both the AHS theory and the denaturation kinetics of β-lactoglobulin has been developed that allows the prediction of the viscosity of skim milk resulting from any combination of heating temperature and heating time. The model shows that viscosity not only depends on the extent of denaturation of β-lactoglobulin but, for a given denaturation, also is higher for a higher heating temperature or a higher heating rate.

The addition of chymosin to milk at the start of renneting initiates two sequential changes. First, there is a fall in viscosity caused by the enzyme cutting κ-casein hairs from the surfaces of the casein micelles, with a consequent reduction in ϕ_{cas}. Second, the loss of the stabilizing κ-casein layer causes the micelles to become mutually attractive (adhesive hard spheres). This leads to an increasingly rapid rise in viscosity, which eventually culminates in micelle flocculation. These two effects together are qualitatively and quantitatively modeled well by the AHS theory. The theory can be used to predict coagulation time, defined as the time, after chymosin addition, at which the viscosity recovers its initial value after its temporary fall.

Acidification of milk, for example, that resulting from starter bacterial activity during yogurt manufacture, causes micelle flocculation (eventually leading to coagulation) owing to a loss of the steric stabilization of micelles. Loss of stabilization is due to the loss of the extended conformation of the κ-casein hairs on the micelle surfaces, and their eventual collapse. The AHS theory accurately quantifies the relationship between viscosity (increasing) and pH (decreasing) during acidification.

The AHS theory has been applied mainly to normal skim milk. The effects of other variables such as fat content and calcium concentration on the applicability of the theory are apparently yet to be investigated.

Storage

The viscosity of ultra-high temperature (UHT) sterilized milk can increase gradually during storage. This phenomenon, age thickening, can eventually lead to gelation. It is thought to be the result of the gradual release, from the casein micelles, of β-lactoglobulin–κ-casein complexes formed during the high-temperature heat treatment, and the subsequent cross-linking of the complexes to form a gel network.

Technologically Useful Relationships for Predicting the Rheological Properties of Milks and Creams

Successful attempts have been made to establish empirical relationships useful for technological and engineering purposes between the viscosity of Newtonian-fluid milk products and their temperature and composition. A number of these relationships, the development of which ignored any observed (slight) non-Newtonian behavior, are given in **Table 3**.

In the case of non-Newtonian milks and creams, phenomenological relationships between shear stress and shear rate have been developed for practical purposes. (These contrast with expressions for viscosity at zero shear rate, which are valuable for relating rheological behavior to structure and composition in a fundamental way.)

The shear-thinning behavior of raw whole milk in the shear-rate range 1–1500 s^{-1} can be modeled well by the power-law (Ostwald–de Waele) equation:

$$\tau = k\dot{\gamma}^{n} \qquad [13]$$

Typical values of *k* and *n* for raw milk (3.35% fat) at 25 °C are 6.14×10^{-3} Pa s and 0.798, respectively. Rheological behavior becomes essentially Newtonian at shear rates $>800\ \mathrm{s}^{-1}$.

The shear-thinning behaviors of pasteurized skim milk, whole milk, and cream at low shear rates and

η and η_0 = viscosity in mPa s, θ = temperature in °C, %*TS* = % total solids, *F* = % fat, and *P* = % protein.

temperatures <40 °C, can be modeled satisfactorily by the Bingham equation:

$$\tau = \eta_{\mathrm{pl}}\dot{\gamma} + \tau_0 \qquad [14]$$

Values of η_{pl} (the plastic viscosity) for skim milk and whole milk (3.5% fat) at 25 °C are 1.53×10^{-3} and 1.81×10^{-3} Pa s, respectively. The corresponding values of τ_0 (the yield stress) are 1.98×10^{-2} and 4.6×10^{-2} Pa. For cream of 38% fat, at 25 °C, the values of η_{pl} and τ_0 are 9.44×10^{-3} Pa s and 0.381 Pa, respectively.

Raw cream of 60% fat has been found to obey the Bingham equation at constant temperature in the range 15–80 °C. When subjected to dynamic heating and cooling in this temperature range, the rheological behavior of the same cream is modeled better by the power-law equation [13]. The values of *k* and *n* at a given temperature depends on thermal history, a phenomenon attributed to the interaction between heating/cooling rates and the rates of melting and crystallization of milk triacylglycerols.

Cream of 40–55% fat, at 5–20 °C, has been shown to obey the Herschel–Bulkley equation:

$$\tau = k\dot{\gamma}^n + \tau_0 \qquad [15]$$

This equation is a generalized form of the Bingham equation [14]. Values of *n* have not been reported. (The power-law equation [13] and Newton's equation [1], as well as the Bingham equation, are special cases of eqn [15].)

As stated above, the Cross equation [7] accurately models the shear dependence of the apparent viscosity of cream.The numerical values of the parameters in these phenomenological equations depend on composition, concentration, and temperature.

Non-Newtonian Behavior in Concentrated Milks and Creams

When milk is concentrated by heat evaporation or by membrane processes (ultrafiltration, reverse osmosis), $\Sigma(\phi_i)$ increases because of the concentration effect *per se* and because particle–particle interactions (especially micelle–micelle interactions) increase owing to smaller interparticle distances. These interactions lead to aggregate formation. The effects of aggregate formation on rheological behavior are essentially the same as the effects of concentrating only the fat globules, as in cream: apparent viscosity increases; shear thinning becomes more pronounced; and deviation from Newtonian behavior persists to higher shear rates. Time-dependent shear thinning appears at a sufficiently high concentration or after a sufficiently long storage time (at concentrations and temperatures above certain minima) during which structure development occurs. Such structure development, and the consequent steady viscosity increase, is known as age thickening.

Rheologically, there are no fundamental differences between concentrates produced by heat, by reverse osmosis, or by ultrafiltration, or between whole milk and cream concentrates on the one hand and skim milk concentrates on the other. Rather, the differences are of degree. For given conditions, non-Newtonian behavior tends to appear at lower %TS in ultrafiltration skim milk concentrates than in evaporated skim milk (because of the preferential concentration of proteins in the former), and at lower %TS in skim milk concentrates than in whole milk concentrates (because the proportion of protein in the dry solids is higher in the former). For the same reasons, viscosity at a given %TS is higher in ultrafiltration skim milk concentrates than in evaporated skim milk, and in skim milk concentrates than in whole milk concentrates.

The viscosity of any concentrate under given conditions of %TS, shear rate, temperature, dry solids composition, time after preparation, and other variables such as preheat treatment and pH is directly related to $\Sigma(\phi_i)$. This is discussed first below. Then, phenomenological relationships that have been found useful in describing the non-Newtonian behavior of concentrates as a function of shear rate are reviewed. Last, the phenomenological description of age thickening is presented.

Dependence of concentrate viscosity on total volume fraction

It has been shown that the apparent viscosity (at a specified shear rate) of heat-concentrated whole and skim milks is weakly related to %TS but closely related to total volume fraction calculated by

$$\Sigma(\phi_i) = \phi_{\text{cas}} + \phi_{\text{nwp}} + \phi_{\text{dwp}} + \phi_{\text{fat}} \qquad [16]$$

where ϕ_{nwp} and ϕ_{dwp} are the volume fractions of native and denatured whey proteins, respectively; the effect on the whey proteins of preheating the milk prior to concentrating is thus automatically taken into account.

Volume fractions (ϕ_i) of individual components were calculated by

$$\phi_i = \phi_{i,\text{ milk}} \times \frac{\text{TS}_{\text{conc}}}{\text{TS}_{\text{milk}}} \times \frac{\rho_{\text{conc}}}{\rho_{\text{milk}}} \qquad [17]$$

where ρ is the density (kg m^{-3}) and the subscripts 'milk' and 'conc' refer to the milk prior to evaporation and the concentrated milk, respectively.

Concentrates are shear thinning; $\eta_{\text{app},\dot{\gamma}=\infty}$ of freshly prepared heat concentrates (no age thickening) is closely predicted by Eilers's equation [2]. ϕ_{max} in the equation, for heat concentrated skim milk, has been shown to be 0.79, by extrapolation of heat gelation time versus ϕ_{protein} curves to gelation time = 0. The same value has been found to be satisfactory for whole milk concentrates.

η_{o} in Eilers's equation may be calculated for heat-evaporated and reverse-osmosis milks by

$$\eta_0 = \eta_{\text{water}} + (\Delta\eta_s + \Delta\eta_{\text{L}s})\left(\frac{(\%\text{TS})_{\text{conc}}}{(\%\text{TS})_{\text{unconc}}}\right) \qquad [18]$$

$\Delta\eta_s = \eta_{\text{water + salts}} - \eta_{\text{water}} = 0.02\ \eta_{\text{water}}$ and $\Delta\eta_{\text{Ls}} = \eta_{\text{water + 5\%lactose}} - \eta_{\text{water}}$. For ultrafiltration concentrated milks, $\eta_0 = \eta_{\text{permeate}}$. Temperature dependence of viscosity can be allowed for by evaluating $\Delta\eta_{\text{s}}$, $\Delta\eta_{\text{Ls}}$, and η_{permeate} at the required temperature using literature data or direct measurement.

The apparent viscosity, the rate of age thickening, and the degree of shear thinning of milk concentrates made by evaporation all increase with both time and %TS. At elevated holding temperatures, for example, 50 °C, even $\eta_{\dot{\gamma}=0}$ increases slightly with holding time (at a given %TS), suggesting a permanent change in concentrate structure that cannot be reversed by shearing.

The change in the apparent viscosity with time during age thickening can be predicted by a modified Eilers's equation:

$$\eta_{\text{app}} = \eta_0\left(1 + \frac{1.25\Sigma(\phi_i)(1 + t.k_{\Sigma(\phi_i)}/\Sigma(\phi_i))}{1 - \Sigma(\phi_i)(1 + t.k_{\Sigma(\phi_i)}/\Sigma(\phi_i))\phi_{\text{max}})}\right)^2 \qquad [19]$$

where t is the time, $\Sigma(\phi_i) = \Sigma(\phi_i)$ at t = 0, and $k_{\Sigma(\phi_i)} = \text{d}(\Sigma(\phi_i))/\text{d}t$. For a given shear rate and temperature, $k_{\Sigma(\phi_i)}/\Sigma(\phi_i)$, the so-called shear-thickening constant, is independent of %TS. The rate of age thickening is somewhat lower for whole milk concentrates than for skim milk concentrates because the fat in the former, while contributing to the overall volume fraction, is inert with respect to the age-thickening process.

Phenomenological rheological relationships for concentrated milks and creams

As %TS increases, the rheological behavior of freshly prepared milk concentrates changes from Newtonian to time-independent shear thinning to time-dependent shear thinning.

Under conditions where time dependence is absent, flow behavior changes, as %TS is increased, from Newtonian (eqn [1]) to shear thinning with no yield stress (power-law behavior; eqn [13]) to shear thinning with a yield stress (Bingham plastic behavior (eqn [14]) or Herschel–Bulkley behavior (eqn [15])).

In fact, because (as pointed out above) the Newtonian, power-law, and Bingham equations are all special cases of the Herschel–Bulkley equation, this last equation can be said to describe adequately the flow curves of time-independent milk concentrates and the instantaneous flow curves of time-dependent concentrates, under all conditions of temperature, shear rate, and other variables. When τ_0 = zero and $n = 1$ in the Herschel–Bulkley equation, $k = \eta$, the Newtonian coefficient of viscosity.

For a given type of concentrate, the constants n and k of the power-law equation [13] tend to be inversely related to one another in ways that are independent of %TS, temperature, and other factors. This reflects the fact that structure development in concentrates that results in greater deviation from Newtonian behavior (lower n) also results in increased viscosity (higher k).

The constant k can often be related directly to $\Sigma(\phi_i)$. For example, a unique direct relationship between $\log_{10} k$ (at

20 °C) and concentrate $\Sigma(\phi_i)$ has been demonstrated for ultrafiltration whole milk and cream concentrates. This relationship is linear up to $\Sigma(\phi_i) = 0.5$, and also linear, but with a higher slope, for $\Sigma(\phi_i) > 0.5$. For $\Sigma(\phi_i) < 0.5$, concentrates are Newtonian and the relationship is

$$\log_{10} k = \log\eta = 3.82\Sigma(\phi_i) - 3.35 \qquad [20]$$

where the units of k and η are Pa s^n and Pa s (i.e., $n = 1$), respectively.

Shear-thinning behavior exists at $\Sigma(\phi_i) > 0.5$. This critical value of ϕ is close to the theoretical maximum value of 0.52 that could exist in an ideal monodisperse suspension in which the suspended particles are in contact with one another but able to move in straight lines in the direction of flow. The dependence of k (at 20 °C) on $\Sigma(\phi_i)$ at $\phi > 0.5$ is higher than that expressed by eqn [20] and has been found to be

$$\log_{10} k = 10.15\Sigma(\phi_i) - 6.51 \qquad [21]$$

Fresh skim milk heat concentrated 6.22-fold was found to obey the Bingham equation [14]. Yield stress was found to be proportional to $(\phi_{\text{cas}})^{4.1}$ at $\phi_{\text{cas}} > 0.3$. The value of the exponent is close to the value of 3.85 exhibited by weakly flocculated latex suspensions, implying that concentrated milks are themselves weakly flocculated suspensions.

Phenomenological description of time-dependent behavior

Milk concentrates can exhibit two forms of time-dependent rheological behavior: time-dependent shear thinning (a decrease in viscosity with time at constant shear rate) and age thickening (an increase in viscosity with storage time). These can be directly related: age thickening is caused by gradual structure development, which at a certain point starts to result in time-dependent shear-thinning behavior – the result of the time-dependent breakdown of the developed structure when the age-thickened concentrate is sheared.

When concentrates age thicken, the Herschel–Bulkley equation *per se* or the Bingham equation has been found to describe adequately the instantaneous flow curves.

The rate of viscosity increase during age thickening can be quantified in terms of the rate of evolution with time of the flow equation constants or the rate of increase with time in apparent viscosity, which at a given time is a function of these constants.

Sweetened Condensed Milk and *Dulce De Leche*

Sweetened condensed milk (SCM) is essentially a high-viscosity suspension of lactose crystals, fat globules, casein, and whey proteins in a saturated solution of lactose and sucrose. Its rheological behavior is complex.

SCM exhibits age thickening, which occurs faster at higher storage temperatures. The structure development is thought to involve not only casein micelles but also the whey proteins (especially if these have suffered a high degree of denaturation during milk preheating) and the fat globules. The viscosity and the rate of age thickening of recombined SCM are significantly influenced by the conditions used during milk powder manufacture.

SCM exhibits time-dependent shear thinning. Recovery of structure (and consequently of viscosity) at ambient temperatures is highly retarded by the still-high viscosity that exists after shearing.

The rheological properties of shear-thinned SCM can be characterized by the power-law equation [13] or the Herschel–Bulkley equation [15], depending on composition and processing conditions. Deviation from Newtonian behavior is slight immediately after manufacture, but increases with time during storage.

The viscoelastic properties of SCM have been described by means of a generalized Maxwell model that incorporates yield stresses.

Dulce de leche is an Argentinean dairy product similar to SCM in composition but with even more complex rheological properties. There are three types: standard, low calorie, and confectionery. The last contains a hydrocolloid thickener. Like SCM, *dulce de leche* is a time-dependent shear-thinning material. The properties of shear-thinned samples can be modeled by the power-law equation [13], the Herschel–Bulkley equation [15] or the Casson equation, depending mainly on composition. The Casson equation is

$$\sqrt{\tau} = \sqrt{\eta_{\text{Ca}}}\sqrt{\dot{\gamma}} + \sqrt{\tau_{0,\,\text{Ca}}} \qquad [22]$$

where η_{Ca} and $\tau_{0,\,\text{Ca}}$ are the Casson viscosity and the Casson yield stress, respectively.

The Herschel–Bulkley and the Casson equations appear to be equally useful models for samples that possess a yield stress.

Dulce de leche, like SCM, is viscoelastic, as indicated by the stress overshoot that occurs just after the start of a constant shear rate experiment. Thereafter, the shear stress declines with time as the structure is broken down by shear. The entire shear stress–time data can be modeled well with a generalized form of the Bird–Leider equation:

$$\tau = k\dot{\gamma}^n\left[1 + (b\dot{\gamma}t - 1)\sum_{j=1}^{j} w_j \exp\left(-\frac{t}{\delta_j n}\right)\right] \qquad [23]$$

where k and n are the power-law equation constants, b and δ are fitting parameters that model the time dependence, and w_j is a weighting factor. At long times, this equation converges to the power-law equation [13], which describes the equilibrium flow behavior of many foods.

At times post the maximum (overshoot) stress, the decay of shear stress during shear thinning can be modeled with the Weltman equation:

$$\tau = A - B\ln t \qquad [24]$$

where A is the maximum (overshoot) shear stress, B is the coefficient of time-dependent breakdown, and t is the time.

Oscillatory rheometric frequency sweep measurements, at strains within the linear elastic region, of the dynamic elastic modulus G' and the loss modulus G'' (where $G' + iG'' = G^*$, the complex elastic modulus) reveal differences in structural characteristics among the three types of *dulce de leche*. The behavior of all three approaches that of concentrated solutions, especially when presheared. The confectionery type, when unsheared, possesses characteristics intermediate between those of a concentrated solution and a gel, and may thus be termed a weak gel.

Ice Cream Mix

Unfrozen ice cream mix is a dispersion of milk fat and vegetable fat in an aqueous phase containing non-fat milk solids, carbohydrate sweeteners, and a stabilizer (usually a hydrocolloid). The mix commonly contains, in addition, an added emulsifier. The total fat concentration is about 10% (w/w). Ice cream mix is thus essentially a dilute oil-in-water emulsion and in this respect is similar to cream. However, viscosity and rheological behavior are more variable, as they depend on both mix formulation and processing conditions.

Ice cream mixes are time-dependent shear-thinning liquids that can exhibit significant viscosity recovery after subjection to high shear. Shear thinning and viscosity recovery can be attributed partly to deflocculation and flocculation, respectively, of fat globules (to the surfaces of which the micellar casein is attached) and to changes with time in the crystalline state of the fat.

Age thickening of unsheared mix has been attributed to progressive flocculation of fat globules.

Mixes exhibit viscoelastic behavior typical of weak gels, the gel network being the result of interactions involving fat globules, and the proteins and polysaccharides present in the aqueous continuous phase.

Ice cream mix flow curves can generally be described adequately by the power-law equation [13]. The values of the constants k and n in the equation are largely influenced by the presence, type, and concentration of the hydrocolloid stabilizer and by processing treatments such as homogenization.

Melted ice cream has a much weaker structure, and consequently a lower viscosity and a lower extent of deviation from Newtonian behavior, than had the original mix. This is a consequence of the continuation, on melting, of the fat globule coalescence that takes place during the initial stages of whipping and freezing. The rheological properties of the melt are important with respect to the subjective assessment of ice cream on the palate.

Yogurt

Two basic types of yogurt are made commercially: set yogurt and stirred yogurt. Yogurt rheology is complex. Yogurt exhibits viscoelastic behavior (especially the set type) and highly time-dependent shear thinning in flow. The rheological behavior of the final product depends on the concentration, composition, and pretreatment of the milk (especially heat treatment), starter culture and incubation conditions, and post-incubation shearing (stirred type). Measurement of rheological properties is useful in objectively investigating, characterizing, and predicting the effects of these variables on the nature of the final product, especially its texture.

Heat Treatment

The development of desirable final rheological properties is highly dependent on there being sufficient interaction between, and flocculation of, the casein micelles during incubation, so that a satisfactory coagulum forms; heat treatment of the milk must be severe enough to cause extensive denaturation of β-lactoglobulin, some denaturation of α-lactalbumin, and the interaction of both of these whey proteins with the micelles. The effect of heat treatment depends on whether it is carried out before or after homogenization.

Fermentation

Though acid production by the starter microorganisms is the main cause of micelle flocculation and consequent structure development, the starter strain can be chosen to influence the rheological properties. In particular, strains that produce exopolysaccharides can be used to increase yogurt viscosity and decrease susceptibility to syneresis. Final rheological properties are dependent both on strain and on incubation conditions (time and temperature).

Post-Fermentation Shearing

The rheological properties of stirred yogurt are greatly influenced by the shearing to which the yogurt is subjected during post-fermentation stirring, cooling, and packaging. The shear history and consequent structure breakdown are related directly to equipment geometry and to process conditions such as temperature and flow rate. The final product is a strongly shear thinning, viscous liquid.

Solid-like and Viscoelastic Behavior

The solid-like behavior of yogurt (especially set yogurt) can be determined very simply by measuring the force required to push a probe into the product under standard conditions. The method is empirical, but simple, rapid, and inexpensive. The result obtained is some function of the elastic, viscous, and breakdown properties of the product. The results can be correlated to texture, and can be used to investigate the relative effects of changes in processing conditions.

Objective measurements of the texture-related rheological properties of set-type yogurts can be made using the technique of texture profile analysis, which involves force–distance measurements during compression/decompression tests in suitable rheometers. When measurements are to be made on intact yogurt gels in well-defined rheometer geometries, either during or at the end of fermentation, the fermentation process must, of course, be carried out in the rheometer itself.

Fundamental viscoelastic properties of both set and stirred yogurts have been determined using dynamic oscillatory rheometry and stress relaxation measurements. The mechanical spectra (dynamic elastic moduli versus frequency) of the set and the stirred yogurts are similar, with the moduli of the former being 8–10 times higher than those of the latter.

In one study (of a stirred yogurt) dynamic measurements showed that at low strain ($\gamma < 3\%$) linear viscoelastic behavior existed: the rigidity modulus G' and the loss modulus G'' were constant and independent of strain. For $3\% < \gamma < 32\%$, there existed a non-linear region where G' started to decrease but G'' remained fairly constant, indicating a partial breakdown of the elastic structure. At $\gamma = 32\%$, G'' became larger than G', indicating a change from a predominantly solid-like to a predominantly liquid-like behavior. For $\gamma > 32\%$, G'' became increasingly larger than G' as the strain was increased. Pre-shearing and then resting resulted in the same behavior, but the values of the moduli in the linear region were ~20% lower, indicating a temporary or perhaps permanent loss of structure. Within the linear region, values of G' measured dynamically were in good agreement with the values of the relaxation modulus measured in stress relaxation experiments. (Critical values of strain such as those given above would be expected to vary with yogurt and the method of measurement.)

Flow Behavior

Rheological behavior in continuous shear can be determined either by empirical tests, in which no attempt is made to generate fundamental shear stress–shear rate data, or by tests in which such data are generated and then modeled phenomenologically.

The rheological characterization of a yogurt by means of a standardized empirical measurement (e.g., the apparent viscosity at a specified spindle rotational speed in a rotary viscometer, or the area of the hysteresis loop on a plot of torque versus rotational speed obtained with the same type of viscometer) can be useful when the manufacturing process itself is highly standardized; in such a process the rheological character of the final product may be predictable from a simple measurement of this kind.

Stirred yogurt, in particular, is amenable to more fundamental characterization by means of experiments, usually in rotary viscometers, in which instrument-independent values of shear stress and shear rate can be measured. Three approaches are commonly used: the generation of hysteresis loops by increasing and then decreasing the applied shear rate; the measurement of the shear stress as a function of time at constant shear rate; and the measurement of the effect on viscosity of time and shear rate at constant shear stress.

Flow curves and hysteresis loops

Hysteresis in up–down flow curves is a consequence of the highly time-dependent shear-thinning behavior of yogurt. As the recovery of viscosity (i.e., of shear damaged structure) on post-shear resting is usually slight, this behavior has been called ‘irreversible thixotropy’.

Individual flow curves (up, down, or equilibrium) have been modeled with the power-law equation [13], the Bingham equation [14], the Herschel–Bulkley equation [15], and the Casson equation [22].

The Herschel–Bulkley equation has been found particularly useful for characterizing yogurt flow curves. However, one comparative study found that over the complete range of shear rates involved, the following hyperbolic relationship, inspired by the well-known Michaelis–Menten equation, modeled flow curves more accurately:

$$\tau = \frac{Q\dot{\gamma}}{(R + \dot{\gamma})} + \tau_0 \qquad [25]$$

$(Q + \tau_0)$ is the hypothetical asymptotic value of shear stress, τ, at infinite shear rate, and R is the shear rate at $\tau = \tau_0 + Q/2$.

Values of the parameters in these phenomenological models are highly dependent on the experimental procedure used to obtain the up–down flow curves, as is the area enclosed by the curves. This area is proportional to the degree of time-dependent behavior.

The modeling of thixotropic loops can be useful in product formulation. For example, it is found that the addition of pectin to stirred yogurt increases both viscosity and shear stability, whereas the addition of fruit concentrate increases viscosity in a less shear-stable way. Rheological measurements allow rheological properties to be manipulated purposely by the addition of these two ingredients in appropriate proportions.

Constant shear rate experiments

If the initial viscosity of a yogurt (the viscosity at zero time of shearing) can be modeled by a phenomenological equation such as the power-law or the Herschel–Bulkley equation, the decay of shear stress (and thus apparent viscosity) with time at constant shear rate can be modeled by incorporating into the equation a time-dependent structure parameter, λ. The Herschel–Bulkley equation, for example, is then written as

$$\tau = \lambda(k\dot{\gamma}^n + \tau_0) \qquad [26]$$

The value of λ ranges from unity at the start of shearing ($\lambda_0 = 1$, corresponding to $\eta_{\text{app, 0}}$) to an equilibrium value, λ_e, after prolonged shearing that is less than unity and corresponds to an equilibrium viscosity, $\eta_{\text{app, e}}$.

The rate of change of λ with time is given by the following *b*th-order kinetic equation:

$$-\frac{\mathrm{d}\lambda}{\mathrm{d}t} = K(\lambda - \lambda_e)^b \mathit{for}\lambda > \lambda_e \qquad [27]$$

where

$$K = a\dot{\gamma}^d \qquad [28]$$

K is a rate constant, and *b*, *a*, and *d* are empirical constants.

A definition of λ is obtained by combining eqns [5] and [26]:

$$\lambda = \frac{\eta_{\text{app}}\dot{\gamma}}{(\tau_0 + k\dot{\gamma}^n)} \qquad [29]$$

At equilibrium,

$$\lambda_e = \frac{\eta_{\text{app, e}}\dot{\gamma}}{(\tau_0 + k\dot{\gamma}^n)} \qquad [30]$$

By integrating eqn [27] and incorporating the definitions represented by eqns [26], [29], and [30], the dependence of apparent viscosity on time at constant shear rate can be expressed as

$$\begin{aligned}\eta = \Big\{ &\left[\eta_{\text{app, 0}} - \left(\tau_0\dot{\gamma}^{-1} + k\dot{\gamma}^{n-1}\right)\right]^{1-b} \\ &- Kt(1-b)\left(\tau_0\dot{\gamma}^{-1} + k\dot{\gamma}^{n-1}\right)^{1-b}\Big\}^{1/(1-b)} \\ &+ \left(\tau_0\dot{\gamma}^{-1} + k\dot{\gamma}^{n-1}\right) \qquad [31]\end{aligned}$$

Analogous equations have been developed for yogurt by starting with the power law or with an exponential model modified as in eqn [26]:

$$\tau = \lambda k\dot{\gamma}^n \qquad [32]$$

$$\tau = \lambda\left(\tau_0 + \dot{\gamma}\sum_{p=1}^{\infty}\eta_{\text{app}, p}\exp(-t_p\dot{\gamma})\right) \qquad [33]$$

In a study of a commercial stirred yogurt, the decrease in shear stress with time at constant shear rate was modeled in a somewhat different way by means of the Weltman equation [24], modified as follows:

$$\tau = A - B\left[\log\left(\frac{t}{t_{\max}}\right)\right] \quad \text{for } t \geq t_{\max} \qquad [34]$$

where $t_{\max}$ is the time (e.g., 12 s from the start of a 60 min shearing time) at which τ is at a maximum (the overshoot shear stress); thus $A = \tau_{\max}$. The value of τ at zero time, which cannot be expressed by eqn [34], is obtained by a separate linear graphical procedure. This initial shear stress and the parameters *A* and *B* in eqn [34] are quantitatively related to shear rate and temperature.

Equation [31] and its analogs, and eqn [34], are currently the best quantitative descriptions of the time-dependent shear-thinning properties of both stirred and set yogurts.

The Cross equation [7] has been used successfully to model the shear rate dependence of the equilibrium apparent viscosity of yogurt. It has been shown that a vane viscometer gives the same results as that of a bob-in-cup viscometer. An advantage of the former instrument is that it enables measurements to be carried out on yogurt containing fruit pieces.

After fermentation, yogurt must be transported to filling equipment and dispensed into the final containers. The effects of pumping yogurt through pipework and filling heads on the viscosity of the final filled product, which is closely related to texture, can be predicted by a procedure based on straightforward rheological measurements made under controlled shear rate conditions that simulate process conditions. By measuring changes in apparent viscosity over a sequence of shear rates consistent with those existing in different stages of the real process – shear rates being applied for periods of time consistent with yogurt residence times in these stages – the end-of-process viscosity can be predicted. The extent of structural recovery in the filled containers can also be predicted by simple oscillatory tests conducted on the unsheared and sheared yogurt.

Constant shear stress experiments

Processing effects can be predicted by an alternative approach, as follows. The time-dependent shear thinning of yogurt can be described by means of a plot of shear rate against time at constant shear stress (measurements being made using a controlled-stress rheometer). The typical plot shows a steep slope initially, which then decreases with time to a constant positive non-zero value. It has been shown, for yogurt that has been sheared (e.g., in processing and filling operations post-fermentation), that the straight line part of the plot can be predicted from the straight-line part of a similar plot determined for an unsheared (unprocessed) sample. This is done by offsetting the latter plot in a negative time direction by a period that can be related to the work done on the yogurt per unit volume during processing. This approach, which allows prediction of the effect of process handling on the rheological properties of the yogurt as packaged, was demonstrated to be accurate in the case where the 'process' was flow through a straight round pipe (a relatively simple system). It can in principle be applied to (more complex) real processing systems that are amenable to the fluid mechanical analysis required.

Cultured Buttermilk

An Irish study showed that eqn [31] could be used to model the time dependence, at 5 °C, of cultured buttermilk made directly from skim milk. In this particular case, it was found that $b=2$ in eqn [27], and that the dependence of K in the equation on shear rate was relatively slight. The latter finding allowed eqn [27] to be integrated, using an average value of K, to give an equation for shear stress in terms of only shear rate and time:

$$\tau = \left[\lambda_e + \frac{1}{(1/\lambda_0\,\lambda_e) + K\ \ t}\right](\tau_0 + k\dot{\gamma}^n) \qquad [35]$$

Numerical values of the variables in eqn [35], for the particular buttermilk investigated, were as follows:

$$\tau = \left[0.449 + \frac{1}{1.815 + 0.0051t}\right]\left(0.4 + 1.362\dot{\gamma}^{0.385}\right) \qquad [36]$$

An American study found that both 'modern' cultured buttermilk (made directly from low-fat milk, as in the Irish study) and 'traditional' cultured buttermilk (made from cultured cream) were time independent at 25 °C and could be characterized rheologically by the power-law equation [13]; at 10 °C, the modern buttermilk exhibited time-dependent behavior.

It is appropriate to mention here that eqn [31] (with $b=2$) has been found to describe adequately the time-dependent shear thinning of a thickened cream (containing 35% fat, and gelatin as stabilizer). Clearly, this approach to modeling such behavior is especially useful for dairy products.

Fresh Cheeses

Low-total solids fresh cheeses have structures similar to that of stirred yogurt. However, the wider ranges of composition and processing technique lead to a correspondingly wider variation in rheological behavior.

Some are shear thinning, but time independent. Flow curves can be modeled by the power-law equation [13], or by the following expression for apparent viscosity:

$$\log\ \eta_{\text{app}} = \log\ \eta_{\theta=\infty,1} + B\log\dot{\gamma} + \frac{E}{RT} \qquad [37]$$

where $\eta_{\theta=\infty,1}$ is the hypothetical apparent viscosity (Pa s) at a temperature (θ °C) of infinity and a shearing time of 1 s; E is the activation energy of flow (J mol^{-1}), R is the gas constant (8.314 J K^{-1} mol^{-1}), T is the absolute temperature (K), and B is a constant.

Some fresh cheeses exhibit time-dependent shear thinning. For a constant D the fall in apparent viscosity with time at constant shear rate has been modeled by the following equation:

$$\log\ \eta_{\text{app}} = \log\ \eta_{\theta=\infty,1} + \frac{E}{RT} + D\log t \qquad [38]$$

For such cheeses at 1 °C, the relationship between apparent viscosity and time in experiments where the shear rate was oscillated linearly between 0 and 4.5 s^{-1} at a frequency of 0.05 Hz has been modeled for the shear rate range 1–4.5 s^{-1} by the equation

$$\eta_{\text{app}} = \frac{1}{\dot{\gamma}}\left[\tau_{t=\infty} + (\tau_{t=} - \tau_{t=\infty})\ \exp\left(-\frac{t}{P}\right)\right] \qquad [39]$$

where P is the time required for η_{app} to become equal to $(1/\dot{\gamma})\ (\tau_{t=\infty} + (\tau_{t=0} - \tau_{t=\infty})/\text{e})$.

At any given time, the phenomenological relationship between shear stress and shear rate could be modeled well by the Bingham equation [14] for shear rates between 1 and 4.5 s^{-1}. Over the whole shear rate range of 0–4.5 s^{-1} the data could be modeled by the power law equation [13] or the Herschel–Bulkley equation [15] or the Casson equation [22]. The power law was the poorest (though still reasonably good) model. The best model was found to be a modified Bingham equation:

$$\tau = \tau_0 + \eta_{\text{pl}}\dot{\gamma} - \frac{C}{\dot{\gamma} - \dot{\gamma}_0} \qquad [40]$$

$C/\dot{\gamma}$ is the difference between the shear stress value calculated using the Bingham equation and the value found by fitting the experimental results with eqn [40]. $C/\dot{\gamma}_0$ is the value of $C/\dot{\gamma}$ at $\dot{\gamma} = 0$. (The unit of C is Pa s^{-1}.)

Fresh cheeses are viscoelastic. Such behavior can be investigated conveniently by measuring the dynamic rigidity and loss moduli (G' and G'', respectively) using oscillatory rheometry. Such measurements indicate, for example, that a soft cheese similar to Mozzarella behaves in a way typical of a weak viscoelastic gel. In contrast, for double cream cheese, the frequency dependence of G' suggests viscoelastic behavior dominated by a network, whereas the frequency dependence of G'' is similar to that observed for a nonchemically cross-linked polymer. Measurement of the dynamic moduli is a sensitive way of investigating and interpreting the effects of making changes to cheese milk composition and cheesemaking conditions.

The Bird–Leider equation (see eqn [23]) has been found to model the combined viscoelastic and time-dependent properties of whipped cream cheese, but only moderately well; this is perhaps owing to the absence of yield stress as a variable in this equation, which is one of the limitations of the equation. In spite of this, the equation has been found to be satisfactory for modeling the sensory property 'thickness' of whipped cream cheese when shear rate in the equation is replaced by an expression for shear rate in the mouth that incorporates thickness and other relevant variables.

It has been possible to model the stress relaxation properties of commercial fresh cheeses using the Avrami equation:

$$\tau = \tau_{t=0} - (\tau_{t=0} - \tau_{t=\infty})\exp\left[-\left(\frac{t}{R_1}\right)^n\right] \qquad [41]$$

where n = exponent of time and R_1 = relaxation time after 1 s of stress relaxation.

The time-dependent shear thinning, at constant shear rate, of spreadable cheeses made from whole milk pre-concentrated by ultrafiltration has been modeled by eqn [31] with $b = 2$. At a given shear rate, the constant K in eqn [31] changed from one value (K') during the early part of the shearing time to a lower value (K''),which then stayed constant during the remainder of the shearing time. K' decreased with increasing shear rate. K'' was about half the value of K'. These findings may be evidence for macroscopic shear-induced breakdown initially, followed by slower breakdown at a finer structural level.

Empirical rheological measurements made by uniaxially compressing or penetrating the cheese sample can give data of practical usefulness.

Conclusion

In spite of the complexity of milk and the semi-solid products made from it, there has been considerable success in quantitatively elucidating the interrelationships between rheological properties and microstructure, and in providing quantitative descriptions of rheological behavior useful in dairy process design and control.

These is no doubt that future advances in rheology theory, in computing, and, perhaps especially, in the sophistication of rheometers will lead to a deeper understanding.

RISK ANALYSIS

C Heggum, Danish Agricultural and Food Council, Aarhus C, Denmark

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Risk analysis is a formalized scientifically based approach that is recognized by the World Trade Organization as a tool for addressing food safety issues and which shall establish food safety regulations. When carried out correctly, risk analysis provides a tool for the identification, assessment, management, and communication of risk.

In the area of food safety, risk analysis approaches have been applied for many years to assess and manage chemical food hazards (e.g., food additives, veterinary drugs, and pesticides). More recently, risk analysis techniques have been established for addressing microbiological food risks.

The application of risk analysis techniques is an emerging discipline. This article attempts to provide an overview of the concept of risk analysis, the individual steps of risk analysis, and the application of risk analysis.

Purpose and Role

Traditionally, the approach to food safety control, both by the food industry and by public authorities, has been technical, *ad hoc*, and mainly reactive, based upon utilization of experience obtained from many years of exposure to various hazards, taking into account local practices, traditions, and technological possibilities. This approach has proven to be insufficient to ensure public health and fair international trade in foods.

Analyses of major food safety problems that have occurred through the last decades demonstrate that these are, most of the time, the consequence of organizational deficiencies, reflecting defective global organizations for controlling food safety.

Risk analysis provides an opportunity to address these organizational difficulties by systematic integration of scientific understanding of the risks involved and the legitimization of decisions taken.

The rationale for utilizing a formal risk analysis approach is multiple:

1. To assist in the control of the multiple foodborne risks in a proactive and cost-effective way.
   The multiplicity of food safety comprises
   a. potential microbiological foodborne risks (for instance, from 'classical' salmonellosis to emerging pathologies due to protozoa or viruses);
   b. chemical/toxicological risks, such as naturally and environmentally occurring toxicants and residues of chemicals and drugs used;
   c. newly emerging areas of concern, such as allergenicity, antimicrobial resistance, genetic engineering, and nanotechnology.
2. To support national food safety regulation by providing a sound, science-based, systematic and target-focused tool that secondarily facilitates fair international trade. The Sanitary and Phytosanitary (SPS) Agreement of the World Trade Organization has established the tenet that "members shall assure that their sanitary and phytosanitary measures are based on an assessment, as appropriate to the circumstances, of the risk to human, animal or plant life or health, taking into account risk assessment techniques developed by relevant international organizations" (Article 5.1). Codex Alimentarius has established international principles and guidelines for risk analysis.
3. To address the increase in the social unacceptability of food risks.

As food becomes objectively safer, the remaining and occasional risks are even less tolerated by the public at large, a trend that is enhanced by the general public feeling increasingly alien to food safety control activities (decisions are perceived to be mainly the affair of the food industry and/or the public agencies having jurisdiction).

The application of the risk analysis concept has, however, also some disadvantages when used to support national food legislation. Many legislative measures are multifunctional as they address public health issues as well as other issues such as wholesomeness/suitability of foods, environmental protection, and basic animal welfare. Therefore, the challenge for legislators is to achieve sufficient transparency in the objective(s) of reasoning for any such measure to avoid confusion.

Risk analysis is usually described as a process consisting of three elements: risk assessment, risk management, and risk communication. It is a decision-oriented process and making decisions is a managerial activity (**Box 1**).

Box 1 Hazards and risks

The meaning of the terms hazards and risks is often confused. This is due mainly to translation problems as, in many languages, these terms are directly translated into the same word.

Although often synonymous in everyday life, they have taken different meanings in the technical language used in risk analysis.

A hazard is a biological, chemical, or physical agent in, or a condition of, food with the potential to cause an adverse health effect (Codex Alimentarius).

A risk is the function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard in food (Codex Alimentarius). In more common words, a risk is the likelihood and severity of a failure causing deaths or illnesses among consumers.

For instance, the probability of humans being affected by the survival of a pathogenic microorganism during pasteurization is the risk while the microorganism itself is the hazard.

Risk analysis should not be confused with the similar term hazard analysis, the latter constituting the assessment steps of the hazard analysis and critical control point (HACCP) system. Although hazard analysis contains some of the same steps as does risk analysis, it is principally limited to a single type of food from a single processing line (or from the specific food chain it has been following). Hazard analyses of two processing lines/food chains are independent and may result in different outcomes (HACCP plans), as the objective is to ensure the safety of the specific food lots resulting from the specific process. Risk analysis is principally broader in scope, typically addressing one or more food types (e.g., a whole food category) from multiple manufacturers/food chains, the objective being to protect the health of the population.

Risk Assessment

Risk assessment is the scientific part of risk analysis that is initiated and commissioned by risk managers. The purpose is to estimate the severity and likelihood of harm from exposure to a certain hazard by furnishing all scientific data relevant for the evaluation. The output might, for example, be an estimate of the annual rate of illness per 100 000 inhabitants or an estimate of the rate of human illness per eating occurrence.

The scientific data needed are both qualitative and quantitative. They concern the nature and sources of the hazard, how it affects human health, and how it behaves under various conditions. In addition, scientifically based information on the potential exposure of humans is needed.

The risk assessment process comprises four steps: hazard identification, exposure assessment, hazard characterization, and risk characterization. The information is passed to the risk managers to assist them in continuing the risk management process.

Codex Alimentarius has established general principles for the conduct of risk assessments.

Hazard Identification

Hazard identification is predominately a qualitative process, the purpose of which is to identify the hazards of concern associated with food.

Hazards can be identified from relevant data sources. Information on hazards can be obtained from scientific literature, from databases such as those in the food industry and government agencies, and through expert elicitation/consultation. Relevant information includes data in areas such as clinical studies, epidemiological studies and surveillance, laboratory animal studies, investigations of the characteristics of the hazards, the interaction between hazards and their environment through the food chain, and studies on analogous hazards and situations.

Exposure Assessment

The purpose of exposure assessment is to obtain a quantitative assessment of the actual or anticipated human exposure to a food hazard. It is normally based upon realistic exposure scenarios, including the potential extent of food contamination, and on actual dietary information. Susceptible and high-risk population groups with regard to acute, chronic (including long-term), cumulative, and/or combined adverse health effects should also be brought into consideration.

Typical factors considered include the following:

1. the frequency and level of contamination of food over time, which are influenced by
   a. the characteristics of the hazard,
   b. the nature/ecology of the food,
   c. the initial contamination of the raw material,
   d. the level of process controls,
   e. the methods of processing, packaging, distribution, and storage of the foods,
2. patterns of consumption, which relate to socioeconomic and cultural backgrounds, ethnicity, seasonality, age differences (population demographics), regional differences, and consumer preferences and behavior.

In practice, exposure assessment of foods can be qualitatively categorized according to (1) the likelihood that the foodstuff will or will not be contaminated at its source and (2) whether or not the level of the hazards in the food can increase over time, taking into account the potential for abusive handling.

Hazard Characterization

The purpose of hazard characterization is to provide a qualitative or quantitative description of the severity and duration of adverse effects that may result from the ingestion of contaminated food. The level of the hazard that causes an adverse health effect (dose–response assessment) should be estimated if such data are obtainable.

Several important factors that are considered in hazard characterization relate both to the hazard itself and to the human host.

Factors related to the hazard:

- potential of the hazard to replicate;
- virulence and infectivity of the hazard;
- impact of interactions between the host and the environment;
- potential for transfer of genetic material (e.g., antibiotic resistance, virulence factors);
- potential for spread through secondary and tertiary transmission;
- incubation period (clinical symptoms can be delayed substantially following exposure);
- potential for changed pathogenicity due to the attributes of a food, for example, fat content.

Factors related to the host:

- genetic factors;
- increased susceptibility due to the breakdown of physiological barriers;
- individual host susceptibility characteristics such as age, health and medication status, concurrent infections, immune status, and previous exposure history;
- population characteristics such as population immunity and population behavior, and persistence of the organism in the population.

Risk Characterization

Risk characterization represents the integration of the results of hazard identification, hazard characterization, and exposure assessment, the purpose being to provide qualitative or quantitative estimates of the likelihood and severity of the adverse effects, which could occur in a given population. The data may permit only a qualitative estimate of risk.

The degree of confidence in the final estimation of risk depends on the variability, uncertainty, and assumptions made in all previous steps.

Variability represents heterogeneity within biological systems and populations, while uncertainty represents a lack of precise knowledge associated either with the data themselves or with the choice of model. Variability and uncertainty arise at all steps of the risk assessment process:

- Hazard identification, where uncertainty or variability may arise because of (1) misclassification of the agent, (2) the potential unreliability of the screening method used to identify the hazard, or (3) problems in extrapolating the information provided by the screening test for predicting human hazards.
- Hazard characterization, where uncertainty and variability arise when extrapolating from high to low doses and from one species to another and when considering varying sensitivities within human populations. When models are used, additional uncertainty as to whether they represent actual biological processes is introduced. For instance, the transfer of data from animal studies into estimates relating to humans involves uncertainties. For this reason, a 100-fold safety factor is often applied to account for likely inter-species differences in susceptibility.
- Exposure assessment, where many uncertainties arise due to the lack of detailed data on, for example, the level of the agent in food products and the frequency, duration, and magnitude of human intake of food products, and changes in the concentration of the chemical or microbiological agent during storage, processing, and preparation of the food product. There is also a great deal of variability in dietary habits.
- Risk characterization, where uncertainty and variability arise because of the uncertainties and variability involved in its constituent steps and in the model used for constructing the distribution of individual or population risk.

Risk Assessment of Chemical Hazards

Chemical risk assessment in one form or another has been applied to the evaluation of various chemical hazards in foods for many years. Assessment of food additives and that of contaminants fundamentally differ because food additives, which are generally of low toxicity, are deliberately added to food, whereas contaminants are unavoidable and generally demonstrate greater potential toxicity. Food additives can be controlled easily, while the elimination of contaminants from foods incurs cost, such as reduction in food availability and/or affordability.

JECFA (Joint FAO/WHO Expert Committee on Food Additives) and JMPR (Joint FAO/WHO Meeting on Pesticide Residues) carry out risk assessments of the following substances:

- food additives, resulting in the establishment of acceptable daily intakes (ADIs);
- food contaminants and naturally occurring toxicants, resulting in the establishment of provisional maximum tolerable daily intakes (PMTDIs) or provisional maximum tolerable weekly intakes (PMTWIs) where no observed effect can be identified; in other cases, other outcomes are provided;
- veterinary drug residues, leading to the establishment of ADIs and, taking into account good practices, the establishment of maximum residue levels (MRLs) in target animal tissues, milk, and egg;

- pesticide residues, resulting in the establishment of ADIs and acute reference doses and, taking into account good practices, the establishment of MRLs in foods.

The approach is somewhat different from risk assessment, but does have the advantage of preventing problems associated with deciding on an acceptable level of risk.

The acceptable or tolerable intake is an indication of both the magnitude and the duration of acceptable intake. The ADI usually represents an acceptable average daily intake for the life span of an individual. Tolerable intakes for contaminants should be compared with intake surveys of appropriate duration. In cases where no threshold is thought to exist, such as aflatoxins, JECFA does not allocate tolerable intake values but recommends that the level of contaminant in food be reduced to as low as reasonably achievable (ALARA). The ALARA level is regarded as the concentration of a substance that cannot be eliminated from a food without having to discard that food or severely compromising the availability of major food supplies.

Microbiological Risk Assessment

The risk assessment process was originally developed for chemicals. Extending the practice to microbial pathogens poses significant difficulties. Therefore, most microbial risk assessments currently have a qualitative base. However, in recent years, the interest in qualitative approaches to microbial food safety has increased dramatically and quantitative models for specific pathogen/food combinations are developed in many circles.

One difficulty relates to the fact that microbial pathogens can multiply as food moves from the farm to the table, making intake assessment very difficult. In addition, many data gaps exist, limiting the precision necessary for quantitative risk assessments. For example, little information is available to accurately estimate the relationship between the quantity of a biological agent and the frequency and magnitude of adverse human health effects, particularly for susceptible populations.

Microbial pathogens multiply and die, and the biological interactions are complex. The contamination levels of the raw material entering the food chain dictate the character of the initial microflora, but this can be modified markedly by subsequent events. Additionally, there are marked differences in the virulence and pathogenicity of animal and environmental strains for humans, and the individual interactions of host and pathogen are very variable.

Factors to consider for exposure assessment include the frequency and level of contamination of raw materials, possibilities of post- and cross-contamination, and the level of contamination of the food during the shelf life of the product. The characteristics of the pathogenic agent, the microbiological ecology of the food, the level of basic hygiene, the level of sanitation and process controls, and the methods of processing, packaging, distribution, and storage of the foods impact these factors.

Microbial pathogen levels may be kept low, for example, by proper time/temperature controls during food processing, but they can increase substantially with abuse conditions. Therefore, exposure assessment should include different scenarios describing the pathways from production to consumption and should be constructed to predict the range of possible exposures.

Construction of scenario trees for all steps from production and processing through to intended end-uses of a food describes the pathway for exposure, and targeted research is often required to accumulate appropriate microbiological data. Predictive modeling plays an important role in this respect. Unfortunately, dose–response data to service the hazard characterization component are currently very limited.

Because of the wide variability inherent in much microbial data, Monte Carlo simulation modeling is being used increasingly to generate probabilistic risk estimates that are biologically realistic.

FAO and WHO have recently established an expert body system, similar to JECFA and JMPR, the tasks of which are to carry out microbiological risk assessments.

Physical Risk Assessment

Risk assessment of physical hazards can be achieved readily. The characteristics of the hazards do not usually change once they have been introduced to the food, and adverse health effects can usually be subjected to simple ranking systems to generate estimates of risk.

Risk Management

Risk management is a continuing process and constitutes the managerial and political part of risk analysis. It concerns the transfer of the results of risk assessment into actions in accordance with established political priorities. Risk management sets priorities, commissions risk assessments, and implements, monitors, and reviews the chosen strategies and options.

The risk management process comprises four steps: risk evaluation, risk management options assessment, implementation, and monitoring and review.

Risk Evaluation

The initial part of the risk management process sets the stage for risk assessment, and evaluates the outcome of the risk assessment process, which should result in a risk estimate.

Risk profiling

A risk profile is developed when a new food safety problem has been identified or if surveillance information shows an unacceptable increase/level of a disease or a hazard. The food safety problem and its context are described briefly, including the size and nature of the problem, available data, type of foods involved, main sources, the values expected to be placed at risk (e.g., human health, economic concerns), stakeholders perceptions, distribution of risks and benefits, and what immediate action(s) may be necessary, including whether a risk assessment should be carried out.

Goal setting/acceptable level of protection

To guide the rest of the decision-making process, the goals for the risk management activity need to be identified as early as possible. However, the results of a subsequent risk assessment process and subsequent steps of risk management may identify needs to modify or redefine the goals. One management goal can be to establish relevant risk-based metrics such as food safety objectives (FSOs) and performance objectives (POs).

Any goal should be related to the acceptable level of protection – defined by the SPS Agreement as the level of protection deemed appropriate by the member state to protect human life within its territory and could, for instance, be expressed as the acceptable number of cases of a particular foodborne disease per million inhabitants. Usually, when no significant food-related public health problem exists, the acceptable level of protection is the level obtained from the sanitary measures already practiced.

Decisions on acceptable levels of protection should be determined primarily by human health considerations, but other factors may legitimately be taken into account, for example, technological feasibility and economic/political/social concerns (**Box 2**).

Different approaches to acceptable levels include

- ‘zero-risk’ policies, for example, *de minimus*, ADI;
- risk-balancing policies, for example, cost–benefit, ALARA;
- risk threshold policies, for example, specified levels of risk deemed acceptable;
- risk comparison policies, for example, comparison between sources, precedence;
- procedural approaches, for example, negotiation, consensus building.

Risk assessment policy

Risk assessment policy setting serves to protect the essential scientific independence and integrity of the risk assessment. It provides guidelines for value judgments and policy choices that may be needed at specific decision points in the risk assessment process and addresses how to ensure transparency, clarity, and consistency in outcome and how to deal with uncertainties (e.g., application of safety factors) (**Box 3**).

Box 2 The SPS Agreement

The key point in the Sanitary and Phytosanitary (SPS) Agreement is that any sanitary measure has to be based on science. A government cannot restrict trade or maintain a restriction against scientific evidence. Science can, of course, be misused. Therefore, the Agreement also specifies that the scientific approach applicable is the scientific assessment principles and evaluation procedures established by international organizations such as Codex Alimentarius.

The SPS Agreement stipulates government’s rights to decide what they regard as the appropriate level of protection, or in other words, the right to decide on the acceptable level of risk that should be valid on their territory. Therefore, the level of protection may differ between countries, but it shall be determined using harmonized risk analysis procedures. Therefore, the importance of transparency in the risk assessments carried out is obvious. A government must be able to show which factors it has considered and what have been the results of its consideration. This is to ensure that potential differences between the regulations of two countries (e.g., differing maximum limits) are not due to differences in scientific evidence but only due to differences in the politically decided acceptance levels.

Box 3 Examples of risk assessment policies at specific decision points in chemical risk assessment

- Reliance on animal models to establish potential human effects.
- Using body weight scaling for inter-species comparison.
- Assuming that absorption in animals is approximately the same.
- Using a 100-fold safety factor to account for likely inter- and intraspecies differences in susceptibility, with guidelines for deviations that are permitted in specified situations.

Commissioning of risk assessments

Commissioning of the risk assessment process is a risk management activity that aims at ensuring that the needs of the risk managers are addressed and that resources are used in the most effective way. Typically, it includes clear statements of purpose and scope of the assessment addressing the risk management goals.

Consideration of the result of risk assessment

When the results of the risk assessment are available, a risk estimate is established. Risk estimates should take into account variability, uncertainties, and assumptions made during the risk assessment process.

Risk Management Options Assessment

Risk management option assessment typically includes four steps:

- identification of available management options;
- selection of the preferred management option, including consideration of an appropriate level of protection (ALOP; see above);
- evaluation of the impact of the preferred management option on other factors;
- final management decision targeted at appropriate stages throughout the food chain.

Identification of available options

Risk management options include consideration of all general and hazard-specific measures.

General risk management measures

- developing or encouraging the development of good agricultural practices (GAPs), good veterinary practices (GVPs), good hygienic practices (GHPs), and good manufacturing practices (GMPs);
- developing, or encouraging the development of, guidelines for the establishment of hazard analysis and critical control point (HACCP) systems, and establishing public inspection schemes and audit procedures;
- setting up approval and certification procedures;
- promulgating awareness and developing educational and training programs for consumers and industry.

Measures targeted at the individual commodities/hazards

- setting risk-based targets for benchmarking purposes, for example, FSOs (or POs at the end of shelf life) for a particular food safety hazard, leaving flexibility to the industry to select appropriate control measures to meet the target;
- setting maximum limits (e.g., MRLs, microbiological criteria) in support of testing procedures intended to determine the presence (or levels) of specific hazards;
- establishing specific control measures required to be used by industries that do not have the means to establish appropriate measures themselves or that adopt such control measures;
- tailoring frequencies of testing and monitoring for each commodity/hazard;
- requiring export/import certificates.

Selection of options

The SPS Agreement states that sanitary measures must not be more trade restrictive than required to achieve the ALOP, taking into account technical and economic feasibility (Article 5.6). A measure would be more trade restrictive than required if another equivalent and reasonably achievable measure is significantly less restrictive.

The outcome of the risk management process for a specific hazard will differ in various societies, due to natural or cultural differences. Such difference can be scientifically justified, for instance in relation to the exposure situations in different countries. Differences from the contaminant levels recommended by Codex Alimentarius may, for instance, be justified where the average body weight differs and where relatively little average consumption permits higher threshold levels in a particular food.

Also, the prevalence of various foodborne pathogens in the food chain and variation in foodborne disease patterns may justify different risk management outcome.

In selecting the preferred option, the consequences of impact on other factors should be estimated, such as

- impact on consumption patterns (e.g., nutritional consequences of restricting food availability),
- possible introduction of substitute risks (i.e., increasing another risk by reducing a risk, for instance increasing microbial risks when not allowing a preservative),
- impact on public acceptability of measures that intervene in cultural patterns and traditions (e.g., requiring that cheeses be made from pasteurized milk).

Examples of socioeconomic and technological factors may be taken into account and these could, for instance, result in the best management option being

- control at the source rather than later in the food chain,
- regulation through detailed GMP rules rather than, for example, mandatory HACCP systems,
- food safety verification through end product testing rather than reliance on HACCP systems (for instance, where the origin of the food is unknown),
- reliance on labeling, the effectiveness of which has been subject to validation.

Use of risk-based targets

An important element in risk management is the responsibility of competent authorities to specify the level of control that food businesses should achieve, typically in the form of food safety metrics, such as microbiological criteria (for analytical testing purposes), process criteria (e.g., pasteurization temperature), and product criteria (e.g., water content of milk powder). New metrics have been developed by Codex Alimentarius (see **Box 4**), which are related more directly to public health outcomes through risk assessment processes.

FSOs assist in making the ALOP operational, that is, by translating the health risk into food-related targets that can be used readily by food business operations to design their food safety management systems appropriate to location and role within the particular food chain. Conceptually, the FSOs can be viewed as the consumers'

Box 4 The three new risk-based food safety targets

- Food safety objective (FSO), defined as the maximum frequency and/or concentration of a hazard in a food at the time of consumption that provides or contributes to the appropriate level of protection (ALOP).
- Performance objective (PO), defined as the maximum frequency and/or concentration of a hazard in a food at a specified step in the food chain before the time of consumption that provides or contributes to an FSO or ALOP, as applicable.
- Performance criterion is the effect in the frequency and/or concentration of a hazard in a food that must be achieved by the application of one or more control measures to provide or contribute to a PO or an FSO.

maximum level of exposure to a hazard that achieves the ALOP. As such, FSOs articulate the overall performances expected of a food chain in order to reach a stated or implied public health goal.

POs assist in making the FSOs operational throughout a particular food chain. A PO is a means by which a particular control measure combination can be shown to contribute to achieving an FSO. The PO describes the expected outcome of the food chain up to the point of its application.

A performance criterion (PC) is an expression of the target change in the frequency and/or concentration of a hazard in a food that must be obtained by the application of one or more control measures. PC can be expressed, for instance, in terms of a desired reduction (or acceptable increase) in the concentration of a hazard in the course of a particular control measure.

Equivalence

Differences in food safety programs inevitably exist between countries. Therefore, determination of the equivalence in the sanitary measures applied in importing and exporting countries is becoming a priority issue in the international trade. The SPS Agreement requires that sanitary measures of other countries are accepted as equivalent, even if they differ from their own or others, if the exporting country objectively demonstrates that its measures achieve the ALOP established by the importing country (Article 4.1).

The quantitatively expressed risk-based metrics, FSOs and POs, are also intended to be applied as a means to demonstrate whether different processing lines, plants, or food chains can achieve equivalent outcomes.

Risk Communication

Risk communication is the third component of risk analysis, and is a central and integral part of effective food safety management.

Every stage of risk management should rely on an exchange of information and opinions about risk between risk managers, risk assessors, and all other stakeholders concerned about or affected by the problem and the risk management decision. Risk communication and involvement of stakeholders are crucial for open, transparent, and effective decisions. Communication of correct and updated risk assessment information to the food manufacturers is also crucial for obtaining correct hazard analyses and designs of HACCP programs.

Risk communication aids in considering the different, and at times conflicting, interpretations about the nature and magnitude of the risk; it offers an opportunity to bridge gaps in understanding, language, values, and perceptions; it ensures that public values are considered; it generates better accepted and more readily implemented risk management decisions. In brief, it supports democratic decision making. Poor risk communication will almost always increase conflict and distrust over risk management decisions.

Introduction

Basic pest control in the dairy processing plant is an essential prerequisite for a food safety program. Unfortunately, many processors have never established a systematic, organized pest control program. This article outlines the pests of concern and steps that the dairy processors can take to start a pest control program. All dairy processing facilities, regardless of size, must maintain a hygienic facility, and this requires a sanitation program. One section of the sanitation program should address the exclusion/control of pests: rodents, birds, and invertebrates. Current good manufacturing practices (cGMPs) specified in the Code of Federal Regulations (CFR) clearly state that pests cannot be present in the food-processing environment. To prevent infestation, the processor must take a proactive approach to stopping these pests from threatening the safety and quality of the product.

The pest control program is both a stand-alone program and a prerequisite program under hazard analysis and critical control points (HACCP). Most small food plants must decide whether to maintain a pest control program themselves or contract the program to a pest control company. There are positive and negative aspects of each approach. **Table 1** illustrates key differences between plant operated programs and contract pest control programs.

Many small dairy processing facilities hire a pest control company because the processor lacks the personnel and expertise to run such a program. Such pest control contractors must be reputable and have proper training and experience. A pest control contractor must provide records and reports to the processor, verifying that the program is effective and operating successfully. This verification is usually done through visual inspection for pests and/or evidence of pests in the plant or product. The processor must maintain these records with the plant's hazard analysis records to prove that the contracted pest control program is effective. The verification records should include evidence of contractor training and certification to apply pesticides in a food manufacturing environment.

Many processors choose to develop and maintain a pest control program themselves. An effective program can be developed in-house if the processor understands how to control pests. The program should consist of several written sections and include the following items:

1. *Pest control procedures*: The activities performed to control each type of pest. The written procedures should be detailed and include frequency of action.
2. *Recordkeeping*: The documentation of each performed activity. The records must be accurate, up-to-date, and include inspection for evidence of pests in each plant area.
3. *Responsible individuals*: The person(s) who are responsible for performing pest control procedures and recordkeeping and the supervisor who is responsible for signing off on reviewed records.
4. *Deviation*: Evidence of a pest problem is a subjective determination that requires expertise. For example, periodically finding a cockroach under a waste bin may be accepted as evidence of a possible problem, while finding many cockroaches would be a deviation, that is, when an allowable limit has been exceeded.
5. *Corrective measures*: Written action steps in the plan that will be performed if there is a deviation from the pest control program. Often, they may include increasing control procedures, retraining of employees, cleaning up the area, and other measures.
6. *Verification and validation*: Written scientific evidence that the procedures are effective in controlling pests. This material is often available from chemical, trap, and pest control equipment makers. Also, verification is documentation of visual inspection for evidence of pests.

Common Pests in Dairy Plants and Ways to Control Them

Potential pests in the dairy plant range in size from mammals and birds down to barely visible invertebrates. While problems can arise from almost any animal seeking to take advantage of the food available, including stray dogs and cats, the most common sources of pests are discussed below.

Rodents

Rodents include rats and mice. They must be controlled in and around a food plant because they carry and transmit disease and because they can cause significant economic loss by damaging food containers, contaminating food with their droppings, and consuming food. Two

Table 1 Major differences between internal and external pest control programs

	Plant operated program	*Contracted program*
Upfront costLower	Higher	
Processor time commitment	High – at least one dedicated employee	Minimal – need to periodically meet the contractor
Pest control expertise	Usually low	High
Recordkeeping	Plant supported	Contractor maintained
Equipment and chemicals	Plant must obtain	Contractor provided
Validation materials	Processor obtains/develops	Contractor provided
Overall benefits	Must be evaluated by the processor, taking into account all the factors necessary to develop and maintain the program	

major species of rats are found in and around human habitation: the gray or Norway rat (*Rattus norvegicus*) and the black or roof rat (*Rattus rattus*). The house mouse (*Mus musculus domesticus*) is the common mouse species prevalent around human population in the United States and Europe. Both rats and mice reproduce rapidly, with rats having 20 offspring per year and mice up to 35 young per year. Both mammals are primarily nocturnal, but they leave behind several signs of infestation. Signs of rodents are as follows:

1. *Droppings*: Fecal matter is a sign of the presence of rodents, and the quantity can indicate the extent of infestation.
2. *Visual sightings*: Seeing rats or mice often indicates a serious and probably well-established infestation, but most experts believe that visual sightings are the least reliable indicators.
3. *Noises:* Shrill squeaks, gnawing sounds, and scurrying sounds could be caused by rodents.
4. *Smudge marks*: Rodents emit oily lipid material from their fur and leave greasy smudges at entry points and frequent travel paths. Rat smudge marks are often more noticeable than those left by mice.
5. *Tracks*: Coating the area around suspected entry points and travel ways with talc, chalk, or flour can detect tracks and tail marks to identify locations for bait station or trap placement.
6. *Gnawing*: Both rats and mice chew and gnaw materials, which is a sure sign of the presence of rodents. Rats and mice are known to gnaw the insulation of electrical wires, causing fire hazards. Mice are known to cause extensive damage to insulation materials.
7. *Urine stains*: Both rats and mice leave urine stains, which can be detected with long-wavelength UV light as a yellow-to-blue fluorescent spot.

Elimination of harborage is the most effective way to control rodents. This includes removing all general clutter from the food plant and storage areas to eliminate rodent hiding places. Maintain an open, well-kept perimeter around the processing plant to discourage rodent activity; a bare concrete or bitumen surface is ideal. Next, food and water sources must be eliminated. This would include environmental management to reduce or eliminate free water and food sources. Third, rodents must be denied entry into the food plant. This would include filling all structural cracks, screening fan and vent openings, and installing drain covers to prevent rodent entry. It has been shown that a mouse can squeeze through a 6 mm gap, for instance under a poorly fitting door. Mice and black rats are also exceptional climbers, which means openings should be located and closed at all levels in the facility.

Next, a physical control system should be included. Physical control systems would include strategically placed poisons, glue boards, bait boxes, ultrasonic devices, and traps, described in more detail below.

1. *Toxic baits and concentrates*: Primary types are the anticoagulant baits; they are relatively safe to use, inexpensive, and effective. Single- and multidose anticoagulant products are available, as are products with active ingredients other than anticoagulants. Prebaiting with similar nonpoisonous bait may be effective if the rodents exhibit bait shyness. Regular rotation of brands and formulations of baits may also deter bait shyness. Poisons may be administered in bait blocks, liquid baits, pelletized baits, or treated grain.
2. *Toxic tracking powders*: Tracking powders are designed to kill the rodents when they groom themselves. These powders are placed along rodent travel ways or in burrows.
3. *Trapping*: Traps are a safe and effective method of eradication, especially for mice and roof rats. Rodents, especially rats, can become trap shy. Glue traps are also effective, and they may trap cockroaches as well.
4. *Ultrasonic devices*: There is controversy about the effectiveness of using ultrasounds (above 30 000 Hz) to repel rodents. Some devices alter the wavelength and direction of sound, and most are somewhat effective when placed at openings to food plants. Most rodents become used to ultrasonic devices on exposure.

Rodenticides can be used in food-processing plants when placed in secure/tamper-proof stations and restricted to areas where food is not processed (warehouse, storage and service spaces, utility rooms/closets, offices, etc.).

Normally, three perimeters are established for physical control measures. First, bait stations are positioned at the perimeter of the processing plant fence. Second, the outside wall of the plant should be spotted with bait boxes placed directly against the wall, with entry holes to the boxes parallel to the wall. Boxes should be locked and chained to prevent tampering. Finally, a third perimeter of traps inside the plant should be concentrated at areas of high rodent density and near entrances to the plant. All bait stations should be numbered and inspected once each week. Traps should be inspected daily. The density of bait placements may need to be adjusted upward during the fall when a large number of rodents seek winter harborage inside buildings. Norway rats most often build their nests below ground and may be effectively controlled by baits placed directly in their burrows, if that can be done without risk of exposure to nontarget animals or tampering. Roof rats present special control problems since they typically nest in overhead areas. Solid and liquid baits should be placed in attics or above drop ceilings. Block baits or traps should be attached to rafters, joists, and sills in open overhead spaces.

Birds

Several species of birds harbor disease and pose a risk to food plant hygiene. The most common species involved are pigeons (*Columba livia*), sparrows (*Passer domesticus*), and starlings (*Sturnus vulgaris*).

Birds pose a threat to the food processor by carrying disease-causing microorganisms, by contaminating product areas with excreta and feathers, or by carrying external parasites such as mites. The most common microorganisms spread by birds are *Salmonella* spp. Up to 50% of house sparrows were found to contain these microorganisms. *Campylobacter jejuni* has also been commonly isolated from wild birds.

The best and most effective means of controlling birds is to eliminate nesting and feeding sites on the building(s) and in the vicinity. This includes initial construction of window, door, and ledge areas to prevent roosting and nesting. Birds are difficult to eradicate once they frequent a dairy. Once a bird problem develops, an effort should be made to scare and deter birds from roosting areas.

There are a number of common bird repellent methods:

1. *Scaring devices*: Decoys of natural predators, such as owls and hawks, have been used to scare birds but often become ineffective after birds learn to ignore them.
2. *Sticky pastes*: Pastes can be applied to roosting areas to entangle birds and frighten them away.
3. *Electrical wires*: Wires that emit a shock to roosting birds can be effective but are difficult to maintain and costly to operate.
4. *Netting*: Placing netting or chicken wire over nesting sites such as trusses on a loading dock can be very effective. This has been used extensively to prevent pigeons from roosting on older commercial buildings where there are plenty of wide ledges, and on monuments and federal buildings in Washington, DC.
5. *Entry barriers*: Devices designed to block entry to a building, such as automatic doors, vertical plastic strips, and even high-velocity air curtains, are available. A double barrier system is often needed as some birds, for example, robins, can learn to get around strips by hitching a lift on a forklift truck.
6. *Needle strips*: Needle strips are applied to ledges, rooflines, and other roosting points. They have been shown to be very effective if installed correctly.

Traps can effectively remove bird pests. Starlings are the most easily trapped bird pests. Traps can become expensive, because they must be examined regularly so that accidentally trapped nontarget species are not destroyed. (Bats, for instance, are very heavily protected under European law.)

Baiting and poisoning of birds is debatable, and highly contentious. This method is usually a last resort when other means of control have failed. Poisons are indiscriminate, having the potential to harm desirable species of birds as well as pest birds. It is recommended that only professional pest control applicators use toxicants for bird pests. Several chemical control agents are commercially available, and Avitrol is one of the most commonly used chemical. There is a fumigant formulation that is available for use in warehouse areas. As with all chemicals, one should follow the manufacturer's instructions on application and use.

Insects

Insects are the most common source of invertebrate infestation problems and may be divided into those that essentially crawl, for example, cockroaches, and those whose adult forms normally fly.

Cockroaches

There is no insect, other than the housefly, that is more easily recognized and detested than the cockroach. Cockroaches have been shown to transmit diseases including those caused by pathogenic foodborne bacteria such as *Salmonella* spp., *Vibrio cholerae*, and *Staphylococcus aureus* by carrying these in their gut and also on the exterior surface of the body.

Each species has specific habitat preferences, although any species could be found in a food plant building. A good way to detect cockroaches is to enter a darkened production or storage area, turn on the lights, and quickly look for cockroaches scurrying back into hiding. Cockroaches may also be found by inspecting inside the electrical junction boxes, receptacles, and control panels, or by looking behind objects and in floor drains. Glue traps are often a good monitoring device; some come equipped with a pheromone attractant. The use of flushing gases (a number of pyrethroid aerosol products are very good for this purpose) is a common method of driving them out in the open. These materials are so highly repellent that a single squirt into a suspect crack or crevice can cause the cockroaches to come out into the light. Also, look for droppings and egg cases, which indicate their presence.

Control of cockroaches starts with the elimination of debris (especially cardboard boxes that could harbor the insects or their egg cases) and elimination of their harborage. This is done by sealing and filling cracks and crevices and maintaining a sealed, smooth surface throughout the plant in production and nonproduction areas. Seal junction boxes and trunking, receptacles, and control panels. Seal openings around conduits and pipes where they pass through walls and ceilings. Inspect shipments (packaging, ingredients, etc.) and reject infested shipments. Chemical control requires that European Community (EC)- or United States Environmental Protection Agency (USEPA)-permitted insecticides be used in the food plant. These products are generally formulated as sprays, aerosols, or dusts. Dry powders and dusts, such as boric acid and insecticide powders, take advantage of the cockroaches' habit of preening themselves. It is important to understand that no pesticide can be used in a food-processing plant unless the statutory authority, for example, the EC or EPA, has approved such use.

Flying insects

The most common flying insects are the housefly and fruit fly. A single housefly has been estimated to carry up to 3.6 million bacteria. Flies transmit disease by spending part of their life in direct contact with or in close contact with fecal matter or decaying material. Flies must liquefy their food before ingestion, so they secrete salvia (often called vomitus) onto surfaces. Flyspecks are dried vomitus and fecal material. The movement of flies from unwholesome sources to fresh food products, processing equipment, and other surfaces provides many opportunities to transmit disease-causing bacteria. The common housefly is a known carrier of diseases and pathogens, including *Listeria* spp. and *Salmonella* spp. It has been estimated that in a 6-month period, a pair of houseflies and their offspring would total 191 000 000 000 000 000 000 if all survived.

Removal and elimination of breeding sites is a key to fly control. This primarily involves avoiding the availability of garbage. Garbage must be kept away from doors in sealed/enclosed containers and removed frequently; in addition, waste disposal areas must be regularly cleaned and properly maintained. Next, flies must be excluded from entering the food-processing facility. This includes using air curtains (air screens) and/or doors that close automatically.

Electrocution traps with blue fluorescent light traps are effective in reducing flying insects, including flies. One drawback of these electrocution traps is that they can literally cause the fly to explode, throwing an aerosol of fly matter into the air. As these particles can drift down some distance from the trap, it is best to place these traps away from food-handling areas, or well removed from food-handling surfaces in these areas. Blue-lighted sticky traps, baited jug traps and strips, or sticky ribbons are a safer alternative in these areas. Dead flies should be removed from traps at regular intervals. Catch basins of electrocution traps or jug traps, and strips should be cleaned daily. Sticky devices should be replaced at least once a week. Other commercial methods utilize insecticidal sprays or fogs to suppress flies, but exclusion should be the main line of defense.

Pests of Stored Products

These are primarily invertebrates that use the food as both nourishment and a habitat. They are usually small insects that infest and destroy foods during all stages of their life cycles. This group includes beetles, weevils, borers, and moths. Stored product pests are not generally associated with disease, as are cockroaches and flies, but they are considered a major food contaminant. As a group, they prefer dry products such as cereal grains and flours, but other foods such as nuts and dried fruits may be infested, as well.

Weevils infest stored grain and cause economic losses worldwide. The life cycle of most weevils is 4–5 months, and they can infest nearly every cereal grain. Flour moths lay their eggs in flour or meal, where the larva destroys the product, and they are important grain pests. A variety of beetles can infest foods and food ingredients. These include grain beetles, flour beetles, and others.

The purchase of quality, pest-free grain and food ingredients is the first step in the prevention of stored product pests. Regular cleaning of storage areas and processing equipment to remove ingredient spills and accumulated dust is also important. Fumigation of empty storage bins with phosphine, ethylene oxide, or carbonyl sulfide is an effective control option for stored product pests, subject to statutory approval in the country of operation. Similarly, fumigation may be used in facilities when processing operations are over for the day.

Traditional cheesemakers and affineurs (those who mature bought-in cheeses) can have significant problems with cheese mites, which feed on the rind of cheeses that are not encapsulated in barrier films or wax.

Integrated Pest Management

Integrated pest management (IPM) is a strategy to manage pest populations safely and economically through a well-balanced combination of control practices. The small processor should begin a pest control program by determining which activities will best control each pest most effectively.

1. *Inspection (monitoring)*: Thorough inspection of the entire plant by an expert to objectively identify pest problems is recommended. A written analysis should be provided, with details on problem areas within the plant. Inspections should be conducted at a predetermined frequency. For a small processor, it may be cost-effective to hire a pest management specialist
2. *Physical control*: A standard of cleanliness must be established, with direct accountability for cleaning. This includes all areas inside and around the outside of the facility. Exclusion practices combined with routine inspection and repair restrict the ability of pests to enter and move from place to place in the plant. Some examples of these practices would be proper landscaping, adequate door seals, no entrances from outside directly into the processing area, and proper placement of dumpsters.
3. *Mechanical control*: These are nonchemical means that stop pests or prevent infestations, such as the sticky traps, electronic fly traps, needle strips mentioned earlier. Storage insects can often be controlled by temporarily raising or lowering ingredient temperatures or by reducing the moisture content to levels at which they cannot grow.
4. *Chemical control*: IPM does not eliminate the need for pesticides, and they should be used when necessary. Only qualified personnel should apply pesticides. Application of restricted-use pesticides requires certification, and it may be practical to hire a professional exterminator.

Once the methods of control have been chosen, they must be written down in a concise program with specific instructions, frequency of monitoring, responsible persons, monitoring activities, and reassessment. The program should be available for viewing by government inspectors. Many small processors completely contract out the pest control program to private exterminators who provide all procedures, monitoring, and documentation.

Verification of the Pest Control Program

All food safety programs (HACCP, recall, sanitation, pest control) must have validation documentation that demonstrates that the instituted procedures are effective. For example, if the pest control program calls for air curtains on the loading dock door, is this measure effective at preventing incoming insects? Often, manufacturers of pest control products provide documentation of the effectiveness of their products. This is evidence that the procedures in the program are effective. Most importantly, the pest controls must also be verified by evaluating data collected on pest numbers and frequencies and by visual checks of the processing plant.

Action Steps for Dairy Processors

- Read and obtain a copy of regulations pertaining to pest control in dairy plants.
- Decide whether to create an internal program or hire a private company.
- Assess current pest control procedures and define areas that need correction or addition.
- Document the pest control program in concise form with required procedures, recordkeeping materials, verification materials, frequency, and so on.
- List the individuals responsible for each aspect of the program.
- If needed, contact pest control experts who can evaluate your plan for completeness and effectiveness.

STANDARDIZATION OF FAT AND PROTEIN CONTENT

P Jelen, University of Alberta, Edmonton, AB, Canada

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Milk of all mammals (including human milk as well as milk of cows, buffaloes, goats, and sheep) contains, in addition to water, four major types of components: fat, protein, carbohydrate, and minerals. As the cow (genus *Bos*) is by far the most important provider of the raw material used by the dairy industry worldwide, the following discussion focuses on cows' milk only, even though most of the information would be applicable to other milk types as well.

From an economic standpoint, milk fat has been considered the most valuable component of milk used for manufacturing dairy products for the regular consumers' market. Indeed, the economic value of milk was (and generally continues to be) directly related to the fat content. Thus, altering the fat content in market milk and other dairy products has been accepted as a widespread practice used by dairy processors for decades. In recent years, the value of milk protein has increased significantly, mainly due to the steadily increasing popularity of cheese (a milk protein-based product) as a major component of Western-style diets. The advances of modern dairy technology make it now possible to manipulate the protein content of fluid milk in a manner similar to that used for fat standardization. Although the technological approaches in the two cases are somewhat different, the reasons for the need to control the content of the two nutritionally as well as economically important milk components in various dairy products (destined for direct consumption or for further industrial use) are similar. The two aspects of the component standardization in milk and dairy products can be compared, focusing on the compositional, technological, nutritional, and economical determinants of the two processes.

Milk Composition and Properties Relevant to Component Standardization

It is well known that the fat content of raw milk fluctuates rather widely, depending on the breed, feeding practices, geographical location, and many other factors. The average fat content of cows' milk is approximately 4% with the range for this value being given in various textbooks as 2.5–5.5% or wider. Less well recognized is the fact that the average protein content of milk (3.3–3.4%) also shows relatively wide natural variations (2.8–4.2%) in international comparisons, with narrower limits (~± 0.5% or less) reported for individual countries. **Table 1** illustrates the fluctuation of the protein content of cows' milk in several main dairy producing countries.

Clearly, the wide fluctuations in the contents of the two most valuable components of milk can result in significant nutritional as well as economical and regulatory consequences when no standardization is practiced. The original aim of fat standardization was to divert some of the fat from the 'rich' raw milk to the production of cream and butter, considered premium dairy products. At present, however, fat standardization has assumed another important role, that of providing consumers with dairy products perceived by many to be 'healthier' because of their low fat content. Most modern dairy products are labeled (some are legally required to be) as to their fat content; thus, accurate fat standardization processes have become an integral part of the modern dairy technology.

In contrast to the well-established standardization of fat, protein standardization is still an issue being debated in international dairy circles. The technology enabling the online, continuous protein standardization has not been available until relatively recently, and this is why protein content standardization of milk is not practiced

Table 1 Protein content in cows' milk in different countries

Country	*Protein content (g per 100 g)*
Canada	2.75–4.09
Spain	2.80–3.25
Ireland	2.85–3.60
UK	2.96–3.54
Finland	3.11–3.40
Germany	3.26–3.48
New Zealand	3.16–4.22
World (min–max range)	2.75–4.22

Adapted with permission from Rattray W and Jelen P (1996) Protein standardization of milk and dairy products: A review. *Trends in Food Science and Technology* 7: 227–234.

widely, and, in general, only rarely approved by the various regulatory bodies in individual countries or states (e.g., some states in Australia).

Technological approaches to both fat and protein standardization are based on the forms in which these components are present in milk and on the physical properties of the system. The milk fat globules, present in the raw milk in diameters of approximately 0.2–10 μm, have a much lower density (~920 kg m^{-3}) than that of the aqueous fat-free fraction of milk (density ~1035 kg m^{-3}). Consequently, separation of the milk fat from the aqueous phase can be easily accomplished by centrifugation based on the density differential. In contrast, the milk proteins are distributed in the nonfat portion of the milk as individual molecules or as molecular clusters (containing up to 10^4 molecules in the case of casein micelles but only as little as 2–8 molecules in the case of whey proteins). Although the size of the largest micelles (~300 nm) is approaching that of the smallest milk fat globules, the molecular mass of even the smallest free whey protein molecules (~14 000 Da) is still much larger than that of the next molecular species on the milk component spectrum, lactose (molecular mass 342 Da). Differential molecular sizes are the basis for fractionating aqueous solutions using the 'molecular sieve' principle of membrane processes. Specifically, the molecular sizes of milk proteins are ideal for the use of ultrafiltration (UF) as the method of choice for separation of milk proteins from other components of the fat-free aqueous phase of milk. As a result, the protein content in skim milk can be standardized either upward by removing a portion of the protein-free UF milk permeate, or, more typically, downward by admixing excess protein-free UF permeate to regular skim milk. In theory, UF does not affect the ratios of the individual water-soluble molecules capable of permeating the UF membrane; thus, the upward or downward standardization of the protein content by adding or removing relatively small amounts of the UF permeate should not affect the lactose or the mineral compositions of the final product (*see* **Milk Protein Products**: Membrane-Based Fractionation). However, as discussed below, this theoretical assumption does not always hold perfectly.

Technological Principles of Fat Standardization

Centrifugal separation is a straightforward process. Raw milk entering the continuous dairy centrifuge is subjected to a centrifugal force that causes the heavier nonfat aqueous milk phase to migrate toward the perimeter of the centrifuge bowl and the lighter fat globules are concentrated in the volume toward the center of the bowl. To facilitate this movement, the bowl is filled with a multitude of conical disks. The separation occurring along these disks produces two fractions: the fat-free skim milk of greater density and the more concentrated emulsion of the fat globules in a smaller volume of the nonfat aqueous milk fraction, resulting in the production of cream. Depending on the running conditions of the separator, the fat content of the cream can be adjusted within wide variations of the required final fat content. Because the process does not affect the condition of the fat globules, the final cream structure is the same as in the original milk, that is, cream is still an oil-in-water emulsion (*see* **Plant and Equipment**: Centrifuges and Separators: Applications in the Dairy Industry; Centrifuges and Separators: Types and Design).

The production of the various low-fat liquid milk products demanded by the market is typically accomplished by reblending some of the cream into the skim milk produced as the high-volume stream emerging from the continuous centrifuge. The reblending may occur online with modern centrifugation equipment, or it can be accomplished in a storage tank by mixing known volumes of skim milk and cream of known composition.

Nutritional and sensory quality consequences of the fat standardization have been well documented in the literature and accepted by the market. As milk fat is the principal carrier of delicate dairy flavors, the taste of low-fat or fat-free liquid milk products is more bland and watery. The main nutritional effect of fat downstandardization is lower food energy value and lower content of saturated fat, features considered as positive by many consumers today. However, as some fatty acids are nutritionally indispensable especially for children and adolescents, the exclusive consumption of low-fat and especially skim milk products by these age groups without other adequate sources of the indispensable fatty acids may be a questionable nutritional practice. Downstandardization of fat in other dairy products may have either positive or negative effects. Dried dairy products containing fat are known to be prone to undesirable oxidation and other chemical changes, resulting in a potential for major quality impairment. On the contrary, reducing the fat content of standard cheeses can lead to major textural and flavor defects in comparison to full-fat products. In other classes of products (e.g., some fermented dairy foods such as yogurt or sour cream, as well as ice cream or dairy desserts), the removal of fat may be compensated for by using suitable fat mimetics, resulting in very minor quality alterations. Because the technology of fat manipulation does not affect other milk components (with the exception of minute quantities of components associated with the milk fat globule membrane), the nutritional consequences are primarily limited to the effects of the presence (or absence) of the fat itself.

Technological Principles of Protein Standardization

Similar to the fat standardization procedure, protein standardization may be accomplished online or in a batch mode using the UF membrane process. Typically, the milk is first skimmed, and the standardization of the protein content is then carried out on the skim milk. As shown in **Figure 1**, the UF plant, similar to the centrifuge in fat standardization, produces two streams: protein-free permeate (analogous to fat-free skim milk) and protein-enriched retentate (akin to the cream in the fat content manipulation process). Depending on the aim of the protein standardization process, one of the streams is then blended in varying ratios with regular fluid milk, which could then undergo additional fat standardization if desired. In a batch arrangement of this process, the permeate obtained by an UF process would be accumulated in a storage tank and then reblended with a batch of skim – or fat-adjusted – milk in a separate blending facility. In industrial practice, the permeate for protein downstandardization of fluid market milk could come from a separate department or factory, most often from a fresh cheese manufacturing plant, as the use of UF for pretreatment of the cheese milk before the cheese manufacturing process is practiced widely in some countries. Such practice could result in additional technological complications; as the transportation of the unconcentrated permeate is costly, a preconcentration could be used but this may result in precipitation of some mineral complexes.

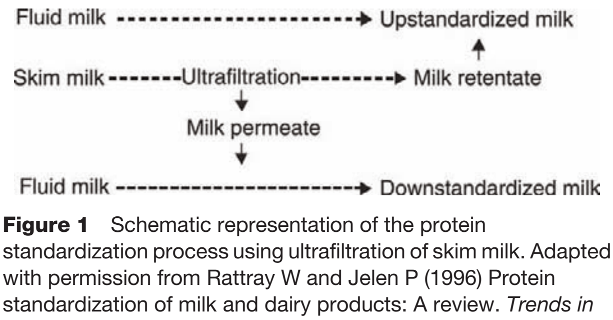

Figure 1 Schematic representation of the protein standardization process using ultrafiltration of skim milk. Adapted with permission from Rattray W and Jelen P (1996) Protein standardization of milk and dairy products: A review. *Trends in Food Science and Technology* 7: 227–234.

In some cases, upstandardization of the protein content may be desired, either to increase the nutritional value of a special product, or to bring the protein content of regular milk to a legal minimum, should such a minimum exist or be agreed upon. Present European Union (EU) legislation specifies that cows' milk shall contain not less that 2.8% w/v total protein (N × 6.38). It is thus conceivable that in some instances of low protein content, upstandardization could be required, especially if there were to be an international agreement on a minimum protein content in fluid milk (a value 3.0% has been proposed at various international discussions). Again, the UF offers the simplest alternative for such upstandardization; in this case, it is the retentate that is used directly as the upward standardized product (e.g., skim milk with increased protein content) or is blended with incoming unstandardized fluid milk (**Figure 1**).

In addition to the direct use of membrane processes, several technological alternatives to the UF-based protein standardization are now practiced by the industry. These include addition of skim milk powder to regular milk to increase the amount of protein and calcium in the market milk (thus also increasing the contents of lactose and other components), or addition of powdered lactose for protein downstandardization as approved by the Codex Alimentarius specifically for adjustments of protein content in milk powders. These two alternatives, together with the UF approach, do not violate the main principle governing the protein standardization considerations – that of maintaining the casein:whey protein ratio of the original milk unchanged. For this reason, using powdered whey or whey protein products for down- or upstandardization of market milk would not be permissible.

Sensory, Nutritional, and Technological Properties of Protein-Standardized Products

In contrast to the well-established sensory effects of milk fat, dairy proteins (both casein and whey proteins) have been shown to have a minimal impact on the flavor of fluid milk. Evidence in the literature confirms that protein standardization within rather wide limits (1.5–6.4% for whole milk, 2.4–6.5% for skim milk) by using UF milk permeate had no effects on the sensory properties of such standardized milk, which was indistinguishable from the nonstandardized controls. Investigations with other types of UF permeates (e.g., from acidified milk or cheese whey) showed that the acidity itself was not detrimental within relatively wide protein standardization limits (2.8–3.4%), but the use of permeates from fermentation-acidified products imparted major sensory changes in virtually all cases.

Using other membrane processes (e.g., reverse osmosis) for upstandardization of the protein content produced a noticeable salty-sweet sensation with as little as 0.3% total solids (TSs) (i.e., ~0.1% protein) adjustment. Similarly, addition of as little as 0.5% lactose to fluid milk was shown to result in a detectable increase in sweetness. Addition of some powdered lactose to the protein-standardized fluid milk to increase the low TSs content could be considered in the case that a minimum TSs in protein-standardized fluid milk products is required. The TS content of typical UF milk permeates is approximately 5.2–5.4% TS; thus downstandardization of protein in fluid milk with these permeates could be considered as adulteration, similar to the addition of water. Use of freezing-point measurement as a control technique for adulteration of raw milk with water is widely established; the same method could not be used to detect any 'dilution effects' of protein standardization of regular market milk.

Considering the relatively wide natural variations in the protein content in milk (**Table 1**), the nutritional consequences of the slightly lower protein content in the downstandardized milk should be considered of a very minor importance. However, in contrast to the fat standardization, the UF technique used for protein manipulation can have an effect on other nutritionally important milk components, especially calcium. Because of the association of most of the milk calcium with casein micelles under normal milk pH conditions (~6.6), the calcium content in the milk UF permeate (~270 mg kg^{-1}) is much lower than in milk (~1150 mg kg^{-1}); using this permeate for protein downstandardization will thus lower the calcium content of such milk. Published calculations show than within the rather narrow limits of the protein standardization being considered (where less than 10% of the final product milk solids would come from the permeate) the changes in some of the affected micronutrients (in addition to calcium, also zinc and vitamin B_{12}) will be minimal, certainly lower than resulting from natural variability. However, unlike lowering of the fat content, manipulation of the protein content could be viewed negatively by consumers, especially if accompanied by decreases in contents of other valuable nutrients, no matter how small.

Use of permeates from UF processing of milk to downstandardize protein in dried skim milk can have small but technologically important effects in such powders. As the profile of the mineral fraction of the standardized milk may be slightly different and the mineral content slightly increased, this may affect the buffering capacity and ionic strength of the reconstituted milk, resulting in needs for small adjustments in established processes where such milk may be used (e.g., in recombination or evaporation). Also, the total protein profile of the standardized product will be slightly altered by the additional nonprotein-nitrogen content of the UF permeate.

Regulatory Aspects and Current Status of Protein and Fat Standardization

Although fat standardization and production of low-fat – or even fat-free – dairy products have been the accepted practice for decades, protein standardization is still an issue hotly debated in the regulatory bodies such as Codex Alimentarius, EU, and national agencies. Protein downstandardization in concentrated and dried dairy products has been approved by the Codex Alimentarius; however, similar practice is generally unacceptable for regular market milk. Use of protein downstandardization for specific unregulated products such as UHT milk may have been practiced in the past without labeling the products as protein standardized; such practice is now expressly forbidden in the EU. Published research indicated no unusual sensory quality or technological problems in UHT products that were downstandardized with UF milk permeate to 3.2–2.6% protein.

Fluid milk products with a higher-than-normal protein content are now quite common in various countries; their market positioning is as being nutritionally and/or sensorically superior to the corresponding regular products. In California, skim milk or low-fat milk is routinely fortified with skim milk powder to improve the sensory properties; this practice also increases the protein content without the products being labeled as protein standardized. In Australia and other countries, fluid milk products with increased calcium content are being promoted. Such products can be obtained easily by subjecting the regular milk to limited UF, which increases not only the calcium but also the protein content.

Protein adjustment (i.e., *de facto* standardization) in other dairy products and in milk used as a raw material for manufacture of products such as cheese or yogurt is being practiced widely, mostly as upstandardization. The main reasons are technological, increasing the output of specific equipment (e.g., in cheesemaking) or improving the technological and/or sensory properties of final products (e.g., gelling properties of yogurt, overrun control of ice cream). Downstandardization of protein content in certain products (e.g., sour milk, buttermilk) could lower the sometimes undesirable high viscosity of such products, although no published reports of such practices seem to exist. Fat adjustment in these products is a well-established practice with no controversial consequences.

Conclusions and Future Prospects

The international dairy community is currently divided on the issue of general protein standardization of milk. Although there are no technological barriers and no real nutritional issues of major consequence (other than the general distrust of the consumers if such a practice were to become common), the major issues concerning widespread downstandardization of protein are economical. It has been calculated that if all fluid milk produced by the EU, the United States, Australia, and New Zealand were to be standardized to 3% protein, the additional amount of protein that would be available for processing into other dairy products (principally cheese) would be over 170 000 tonnes annually, corresponding to more than 500 000 tonnes of cheese. With this extra cheese production, the market could experience similar distortions as used to be common in the days of butter surpluses, resulting in fact from the downstandardization of fat in dairy products. The milk production aspects (with negative consequences for the farmers) could be also severely impacted by protein adjustments, as would be the general credibility of the dairy industry in the eyes of consumers.

Downstandardization of milk fat in many dairy products, combined with the nutritionally unfavorable image that butter has been saddled with in recent times on one side, and the continuing practice of rewarding producers for high fat content in their milk on the other, has resulted in difficulties for the dairy industry still searching for new uses for butterfat. Similarly, large surpluses of UF milk permeate, resulting from modern cheese manufacturing practices, are becoming a major industrial problem. Use of at least some of this permeate for slight adjustment of the protein content in milk and other dairy products is a tempting and technologically fully justifiable option. Some consumer research indicates that if several types of fluid milk products with varying protein content (and correspondingly adjusted prices) were to be available on the market, the downstandardization of protein content might be viewed favorably. It can be expected that protein standardization of milk and dairy products will remain one of the highly controversial issues for the dairy industry for the foreseeable future.

Introduction

Environmental stresses, which include temperature, humidity and wind speed, can alter both nutrient utilization and animal performance. The effects of heat stress have received the majority of attention in research studies. The impact of cold stress on nutrient metabolism and animal performance in ruminant animals has received minimal research attention, the majority of investigations being conducted with beef cattle. The quantity of data relating to the effects of cold stress on dairy cattle is very limited. A primary reason for this dearth of information is the housing systems utilized in dairy production systems. Typically, dairy cattle are housed in barns that minimize the impact of environmental temperature fluctuations on the animal. Pasture systems are used in dairy production systems in many parts of the world. However, these systems are usually limited to the warmer months of the year. It is rare to find dairy cattle housed outside during the winter months in most dairy areas. The result is that very few dairy cattle are actually exposed to cold stress conditions. Dairy replacement heifers may be housed outside during the winter months and could be exposed to cold stress in some situations.

There are a number of terms that need to be defined prior to examining the influence of cold stress. These terms include:

- thermoneutral zone (TMZ), i.e. the range of environmental temperatures where normal body temperature is maintained and heat production is at the basal level
- lower critical temperature (LCT), i.e. the environmental temperature at which an animal needs to increase metabolic heat production to maintain body temperature.

There are a number of factors that determine the LCT for a specific animal. These factors include body surface area (SA), heat production by the animal (HE), retained energy (RE), external insulation (EI), internal insulation (TI), evaporative losses and respiratory losses. The quantity of subcutaneous fat and thickness of the skin are the main factors that determine TI. The primary factors that influence EI are hair coat depth, wind, precipitation and mud on the hair. Thus, there will be a specific LCT for an animal as the above factors vary. The LCT for dairy heifers may range from 10 °C to −20 °C. The LCT for lactating dairy cows may range from −20 °C to −50 °C. The lower LCT range for lactating dairy cows is mainly due to the HE of the animal (**Table 1**).

Heat Loss

There are four primary ways in which animals can lose heat to the environment. These are:

Table 1 Estimated lower critical temperatures for dairy animals (°C)[a,b]

Animal type	*Body weight (kg)*	*Average daily gain (kg)*	*Milk (kg)*	*LCT–A*[c]	*LCT–B*[d]
Heifer	220	0.8	–	−6.7	4.8
Heifer	440	0.8	–	−19.4	−9.8
Dry cow	700	–	–	−9.3	−3.8
Milking cow	635	–	45	−35	−24
Milking cow	635	–	25	−21	−13

[a] Heifer LCTs estimated using the 2001 Dairy–NRC program.
[b] Dry and milking cow LCTs estimated using the Cornell Net Carbohydrate and Protein System (CNCPS) model, version 4.
[c] Situation A: hair depth, 1.28 cm; wind speed, 1 kph; hair coat, clean and dry; ambient temperature, 20 °C.
[d] Situation B: hair depth, 1.28 cm; wind speed, 10 kph; hair coat, wet and matted; ambient temperature, 20 °C.

1. Evaporation. The body heat is used to evaporate water mainly from the skin and hair.
2. Conduction. This is heat loss that occurs as result of direct contact by the animal with items such as bedding or stall surfaces.
3. Radiation. This is the transfer of heat through the air from a warm object.
4. Convection. This loss occurs when air passes over the body. Exposure to wind increases the heat lost by this mechanism.

Metabolic and Physiological Adaptations

A number of adjustments take place in animals exposed to cold stress. These can be grouped into the following categories:

1. Increase in response to cold stress:
   - rumination
   - gastrointestinal tract motility
   - rate of passage of feed in both the rumen and total tract
   - liquid passage rate in the rumen
   - protein flow to the small intestine
   - basal metabolic rate
   - whole body oxygen consumption
   - cardiac output
   - circulating epinephrine, cortisol and growth hormone levels
   - increased lipolysis, gluconeogenesis and glycogenolysis
   - increased hepatic glucose output
   - increased hepatic uptake of glucose precursors (propionate, glycerol).
2. Decrease in response to cold stress:
   - rumen volume
   - *in vivo* and *in situ* cell wall digestion
   - diet dry matter digestibility
   - insulin response to a glucose infusion
   - temperature of skin, ears, legs and other extremities.

Nutrient Requirements

Research literature has very little data on the effect of cold stress on nutrient requirements. The primary change is an increase in the maintenance energy requirement as environmental temperature decreases. **Table 2** contains metabolizable energy (ME) requirements for dairy animals at varying temperatures. These requirements are

Table 2 Maintenance ME multipliers for animals at varying environmental temperatures[a,b]

Temperature (°C)	*Heifer*[c] *(220 kg)*	*Heifer*[d] *(440 kg)*	*Dry cow*[e] *(700 kg)*	*Lactating cow*[f] *(635 kg)*
20	1.0	1.0	1.0	1.0
10	1.05	1.05	1.05	1.05
0	1.13	1.13	1.13	1.13
−10	1.24	1.23	1.23	1.23
−20	1.57	1.36	1.37	1.37
−30	2.00	1.61	1.64	1.52

[a] Simulations carried out with the Cornell Net Carbohydrate and Protein System (CNCPS) model, version 4.
[b] Hair depth, 1.28 cm; wind speed, 1 kph; hair coat, clean and dry.
[c] Base maintenance ME requirement, 7.9 Mcal day^{-1} (33 MJ day^{-1}).
[d] Base maintenance ME requirement, 13.8 Mcal day^{-1} (57.7 MJ day^{-1}).
[e] Base maintenance ME requirement, 20.2 Mcal day^{-1} (84.5 MJ day^{-1}).
[f] Base maintenance ME requirement, 17.1 Mcal day^{-1} (71.5 MJ day^{-1}).

listed as a multiple of the base maintenance ME requirement for an animal with no stress. The effect of cold stress on requirements for protein, minerals and vitamins has not been defined.

Ration Formulation Programs

The challenge for nutritionists is how to account for and incorporate the effects of environmental conditions on nutrient requirements, feed utilization and projected animal performance. The majority of the available ration formulation programs do not contain equations to assist in making these adjustments. There are at least three ration formulation programs that can account for some of these factors: the 2001 Dairy-NRC, CPM Dairy and the Cornell Net Carbohydrate and Protein System (CNCPS) models. All of these programs adjust maintenance requirements for changes in environmental temperature (*see* **Feeds, Ration Formulation**: Models in Nutritional Management; Lactation Rations for Dairy Cattle on Dry Lot Systems). None of these programs adjusts feed passage rate or feed digestibility in response to cold stress.

Milk-Fed Calves

The LCT for newborn calves is estimated to be 10 °C; this LCT is for a calf housed under dry conditions with no wind. This temperature decreases to about 0 °C by the time the calf is 1 month old. If the calf is subject to wind, precipitation or a wet hair coat, the LCT could be considerably higher.

The 2001 Dairy-NRC program was used to estimate the impact of environmental temperature on the ME maintenance requirement and predicted energy allowable gain. A milk replacer containing 20% fat and 20% crude protein was used. The feeding rate was 0.6 kg dry matter (DM) day^{-1}. The results of this simulation are given in **Table 3**.

Table 3 Impact of environmental temperature on the ME maintenance requirement and predicted energy allowable gain[a,b]

	ME for maintenance		
Temperature (°C)	*Mcal*	*MJ*	*Energy allowable gain (kg day^{-1})*
20	1.74	7.28	0.41
10	2.21	9.24	0.26
0	2.68	11.21	0.09
−10	3.23	13.51	Weight loss

[a] For a dairy calf with a body weight of 45 kg.

[b] Feeding 0.6 kg day^{-1} of dry milk replacer.

A number of options exist to increase energy intake to maintain average daily gain as the temperature decreases. One option would be to feed a higher quantity of the milk replacer powder each day. This would require about 17% more DM from the milk replacer as the environmental temperature decreases from 20 °C to 10 °C. A second option would be to formulate a milk replacer with a higher fat content. A third option would be to add a fat supplement to the currently used milk replacer. The addition of 0.1 kg of tallow would provide adequate supplemental energy to maintain average daily gain as the temperature dropped from 20 °C to 10 °C.

It is important to remember that the above calculations are relevant only for calves in a clean, dry and draught-free environment. These calves are assumed to have a clean, dry hair coat. If calves are exposed to more severe environmental conditions, the maintenance requirement would increase and the projected average daily gain would decrease. One option that has become available in the United States is the use of calf blankets. These coats keep the hair coat dry and decrease the heat loss to the environment from the calf. This would increase the proportion of the daily energy intake available to support weight gain. It is also important to have water available to the calves and to keep it from freezing in cold weather.

Replacement Heifers

Environmental conditions will alter both the dry matter intake (DMI) (**Table 4**) and growth rates (**Table 5**) of dairy heifers. **Table 5** contains model predicted energy allowable gains for dairy heifers exposed to three environmental temperatures, and the effects of wind speed, hair depth and coat condition. The same diet is fed in these examples. However, DMI was predicted to increase at colder temperatures. This would result in an increase in daily energy intake. Note that energy allowable gain decreases by more than 50% in the most severe environmental conditions used in this example. These differences in average daily gain reflect the combined effects of temperature, wind speed and hair coat condition.

Dry Cows

The maintenance requirement of dry cows increases as the environmental temperature decreases (**Table 2**). The data in this table assumes a dry cow with a clean, dry hair coat, a hair depth of 1.28 cm and a wind speed of 1 kph. Cows with mud on the hair coat, a different hair depth or subjected to higher wind speeds would have changes in both the ME maintenance requirement and the predicted LCT.

Table 4 Predicted daily dry matter intake (kg day^{-1})[a,b]

[d] ME maintenance requirement.

Milking Cows

A series of simulations were run using both the 2001 Dairy-NRC program and the CNCPS 4.0 programs (**Table 4**). A mature cow weighing 635 kg was used. The food ration contained 2.66 Mcal of ME kg^{-1} of DM (11.1 MJ of ME kg^{-1}). Clean, dry hair coats with a hair depth of either 1.28 or 2.54 cm were used. Environmental temperatures ranging from 20 °C to −30 °C were used with wind speeds of 1 or 10 kph. The maintenance ME requirement changed with decreasing environmental temperature as indicated in **Table 1**. There was also an increase in the predicted DMI as temperature decreased. The predicted DMI for a cow exposed to an environmental temperature of −30 °C was 17% higher than a cow in a 20 °C environment. There was no change in the predicted daily milk production of 30 kg day^{-1} as environmental temperature decreased. Previous reviews have indicated a potential for depressed milk production when environmental temperatures are less than −10 °C to 15 °C. However, as indicated earlier, no adjustments in either rate of passage or feed digestibility are included in these ration formulation programs.

One concern for dairy cattle exposed to cold temperatures is the potential for frostbite or frozen teats. One approach to minimize the risk of frozen teats is to make sure that teats are dry after milking before cows return to the cold environment. A second option is to use some specialized teat dips that contain emollients. Commercial ointments or salves could also be applied to the teats if evidence of chapping becomes visible.

Summary

There are a number of metabolic and physiological adaptations that occur in animals exposed to cold environmental temperatures. The basal metabolic rate and maintenance energy requirements increase. Dry matter intake also increases while diet digestibility decreases. There are a number of factors that alter the effects of cold temperatures on animals. These include wind, hair depth and hair coat condition. An animal with a clean, dry hair coat has a lower LCT at the same environmental temperature than an animal with a wet, matted hair coat. This emphasizes the value of a clean, dry environment for animals exposed to low environmental temperatures.

In most dairy production systems, dairy cattle are rarely exposed to environmental temperatures lower than 0 °C because of the housing systems used. This temperature is higher than the LCT for milking cows. However, the LCT is higher for calves and heifers versus cows (**Table 1**). Cows can withstand a colder outside environmental temperature than either heifers or calves. In some cases, replacement heifers may be housed outdoors for the winter months. In this situation, the LCT could be used as an index of the need for a windbreak or housing. This would be true as the environmental temperature approaches or is lower than the LCT. A simple windbreak, increased DMI and a clean, dry hair coat can minimize the decrease in ADG in dairy heifers housed outdoors in the winter months.

Management practices have the ability to counteract many of the effects of cold stress on dairy animals. A key component is to keep animals in a clean, dry environment with minimal wind. Maintaining a clean, dry hair coat will also help to decrease the impact of cold stress on dairy animals. One key adjustment to make on the nutrition side is to ensure that animals can consume additional DMI to compensate for the higher maintenance energy requirements of animals exposed to cold stress conditions.

Introduction

Providing environments for dairy calves, heifers and cows that permit them to grow, mature, reproduce and maintain health is a primary goal in housing design. While climate in a particular geographic area influences design choice, the barn environment finally provided for the animal must positively influence the animal's health, welfare and productivity. In winter, outdoor winter air is used to provide the ventilation necessary for barns or other enclosures. Since dairy animals adapt well to cold climates, maintaining indoor air temperature equal to or slightly above outdoor air temperature is quite tolerable to the housed animals. Coincidentally, providing the ventilation rate necessary to maintain this minimum temperature difference leads to good air quality. Protecting the animal from extreme drafts, providing dry lying places that contribute to a dry, fluffy, erect haircoat, meeting the nutritional needs of the animal and allowing the animal sufficient freedom of movement are essential.

Ventilation

Ventilation permeates all aspects of the animal environment. Most often associated with respiratory health of animals, ventilation – directly and indirectly – impacts many other aspects of health as well. Good ventilation in the stall area of the lactating cow helps to keep bedding dry, a factor favoring good udder health. Good ventilation along alleys helps to keep walking surfaces dry, contributing to healthy feet. Good ventilation may lead to greater productivity, dry matter intake during hot weather may be maintained as a result of good air movement and more comfortable cows in the area of the feed manger. A comfortable, well-ventilated stall area encourages animals to lie down, an important contribution to many aspects of animal health.

Ventilation is bringing outside air into a barn where it collects moisture, heat and other contaminants, all produced by the animals, then exhausting it to the outside. Ventilation is an air exchange process – contaminated air inside the barn is exchanged for fresh outside air. To determine ventilation rates, we focus on the moisture content of the air, measured by relative humidity. But moisture is only one aspect. Ventilation removes other undesirable contaminants as well.

Air Quality

Animal health and disease are influenced by air quality. Air quality, in turn, is related to ventilation and the positive result of removing contaminants from the air. Empirical observations and field trials suggest that the aerosol spread of pathogens between animals and the influence of air pollutants on pulmonary defense mechanisms are important, especially to respiratory health. Excess moisture, gases and other contaminants in the air are considered to be problematic as well. But the exact relationship among these factors is not fully understood.

The term air quality is not easily defined. With respect to animal spaces, good air quality generally implies that the characteristics of ambient air bear no harmful effects on the animals in the space. Actually, the ambient air itself is not at issue – the contaminants in the air are the source of concern. Ambient air, in itself, begins as a mixture of clean, dry air (a mixture of gases, chiefly nitrogen and oxygen) and varying amounts of water vapor. When moisture in the air in an animal space is considered to be a problem, it is actually the concentration of moisture in the air above some arbitrary level that is of concern. Moisture is considered to be an air contaminant above some concentration. Other contaminants may include pathogens, harmful gases, dust and undesirable odors. But it is the concentration of a contaminant above some predetermined level that is considered a threat to animal health.

Dilution Effect of Ventilation

Ventilation is truly a process of dilution. Air moved through a barn actually serves to dilute the inside air and, very importantly, to dilute all of its components. Dilution reduces concentrations of moisture and heat. Dilution reduces concentrations of airborne disease organisms, harmful gases and dust, and undesirable odors as well. One air change can theoretically reduce the concentrations of air pollutants by 63.2%.

Conversely, concentrations of air pollutants increase when ventilation is lacking. For example, a 7.8-fold increase in airborne bacteria was observed when the outlet ventilation openings in a 15-stall dairy barn were closed. Odors increase also and, in fact, can be an important indicator of the poor air quality that results from underventilation. Terms like 'barny', 'close' and 'stuffy' are sometimes used to describe the environment inside a barn that is suffering from underventilation and poor air quality.

Indeed, concentrations of gases are related to ventilation. In an Alberta study of air quality in six freestall barns, average ventilation rates could, in fact, be estimated by measuring building carbon dioxide concentrations.

When ventilation is reduced below the recommended level – usually in a misguided effort to warm the barn using animal heat – less moisture is removed. Sometimes the consequences of the resulting moisture build-up and lack of proper ventilation are masked by: (1) insulating the barn, (2) using a greenhouse effect, (3) providing supplemental heat, or (4) dehumidifying the inside air. For example, adding heat to the air reduces relative humidity, without the need for air exchange. So it is possible to have substantial quantities of moisture added to the air and, if accompanied by heating of the air, have the relative humidity remain in an acceptable range. Thus, air quality may be deemed to be satisfactory if relative humidity is the only measure of air quality. But even though excess moisture may not be apparent, the reduced dilution does indeed result in increased concentrations of airborne disease organisms, harmful gases and dust, and undesirable odors. If these increases are ignored, animal health problems are inevitable.

Essential to maintaining a healthy animal is providing an environment that does not needlessly stress or challenge the animal (*see* **Stress in Dairy Animals**: Management Induced Stress in Dairy Cattle: Effects on Reproduction). Maintaining good air quality is a fundamental aspect of that healthy environment with ventilation providing the key. But air quality is more than just measuring relative humidity. Through ventilation the air inside the barn is continually diluted, assuring that the air the animal breathes has low concentrations of all contaminants that threaten the animal's health. If sufficient ventilation is provided for moisture control during the winter, the undesirable effects of other airborne pathogens and noxious gases apparently are minimized.

The Air–Water Vapor Relationship

Because ventilation involves moisture in the air, relative humidity – a measure of the concentration of moisture in the air – is of primary interest. Understanding the relationship between relative humidity and ventilation is helpful to comprehending the ventilation process itself.

Relative humidity expresses, as a percentage, the relationship between the amount of moisture present in a quantity of air and the amount of moisture the air is capable of holding. For example, if the air in a room is at 40% relative humidity, 40% of the moisture-holding capacity of the air is occupied (**Figure 1**). From the standpoint of ventilation and the need to pick up moisture, 60% of the air's moisture-holding capacity remains. If no air exchange occurs, the air can take on moisture only until its relative humidity reaches 100%. Thus, ventilation requires continuous air exchange and the rate of exchange must be sufficient to maintain relative humidity below 100%. A range of 60% to 75% is preferred for animals.

The relative humidity of a quantity of air varies with the air temperature. This fact is useful in controlling the ventilation process (**Figure 2**). As moist air is warmed, its moisture-holding capacity increases markedly. Although

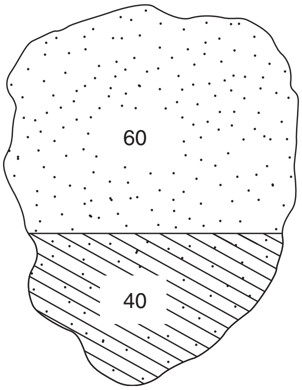

Figure 1 An illustrated quantity of air at 21 °C and 40% relative humidity. Forty percent of the air's moisture holding capacity is occupied; 60% remains.

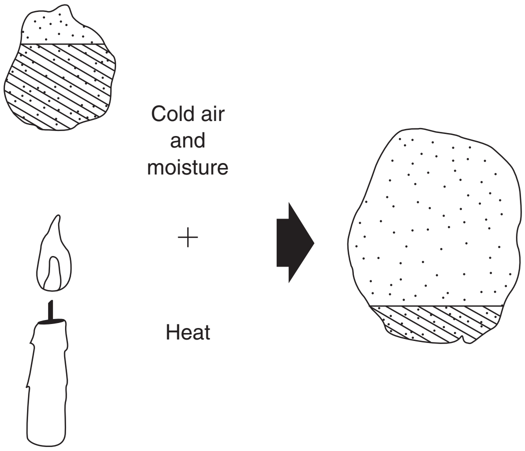

Figure 2 Heating a quantity of air and raising its temperature reduces its relative humidity and increases its moisture-holding capacity; the change in relative humidity is dependent on the temperature rise.

the air expands as it is warmed, its moisture content, expressed in absolute terms, does not change; relative humidity therefore drops. This warmed air of lower relative humidity becomes more able to pick up moisture.

For example, if typical outside winter air at −18 °C and 80% relative humidity is used for ventilation (**Figure 3**), this air will not be very useful for picking up additional moisture and certainly not for achieving a relative humidity of less than 80%. But if this air is used for ventilating a warm calf barn kept at 7 °C, the air will be heated to 7 °C as it mixes with inside air and passes through the barn, reducing its relative humidity to about 10%. From the standpoint of ventilation for moisture control, heating the air increases its moisture-holding capacity. What remains is to carefully balance the calves' moisture production rate, the rate at which heat must be added to the air, and the necessary ventilation rate so the resultant relative humidity in the calf barn is controlled at 60–75% and the desired temperature is maintained. This is the basis for determining the minimum continuous ventilation rate for moisture control.

If calves are to be kept in a warm barn, say 10 °C, supplemental heat must be provided. Calves simply do not produce enough heat to properly warm the amount of ventilation air that is required to remove the moisture they produce. On the other hand, mature cows do produce substantial amounts of heat in relation to their moisture production. This heat, when used to warm the ventilation air required for moisture removal, allows stanchion and tie stall dairy barns to be kept above freezing in the winter. But there is a limit to the temperature rise that cow heat can impart to the ventilating air. In a well-insulated tie stall barn, filled to capacity with cows, the maximum temperature rise of the ventilating air that can be obtained from cow heat alone is of the order of 20 K. This means that ventilation can proceed without interruption until outdoor temperature falls below about −20 °C. Beyond that, the indoor barn temperature would fall below freezing and water lines would freeze, a condition that is avoided by installing a safety thermostat on the fan providing the minimum continuous ventilation.

In a cold barn, the temperature rise of the ventilating air is limited to 3–6 K. Even so, the dependence of relative humidity on temperature is beneficial. For example, if the −18 °C, 80% relative humidity outdoor air is warmed by only 5.5 K, its relative humidity decreases to less than 50%. Thus even this cold air, warmed just slightly, is useful for picking up moisture. Moreover, the heat produced by the animals themselves can cause this slight temperature rise. Care must be taken, however, to assure sufficient air movement, preferably by natural means, to limit the temperature rise to 3–6 K. This is the basis for cold housing, a preferred alternative for all dairy animals.

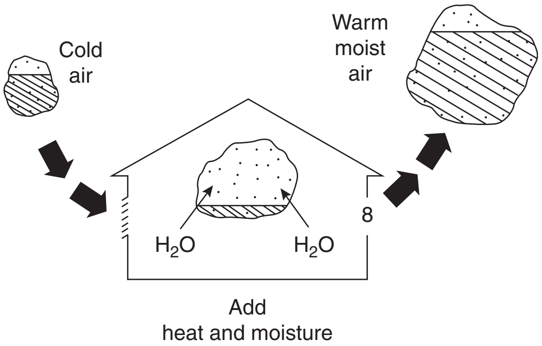

Figure 3 Cold outside air with a high relative humidity can pick up large quantities of moisture in a barn if the air is heated. Even a slight temperature rise of 5.5 °C to 8.3 °C, as can occur in cold dairy barns, is useful.

Minimum Continuous Winter Ventilation

A minimum rate of ventilation is required for removing animal moisture from barns in the winter regardless of outside temperature. This applies to barns designed to be warm barns and cold barns alike in winter. In addition, the minimum ventilation should be continuous. Continuous dilution of inside air acts to maintain concentrations of moisture and contaminants in the air at minimal levels. The minimum rate depends on outside weather design conditions, number and type of animals in the barn, age and size of animals, and whether the barn is intended to be cold or warm.

With mechanical ventilation, the capacity of the fan chosen to supply the minimum continuous rate should closely match the rate of ventilation that is calculated for a particular housing situation. Mechanical ventilation is most often associated with warm housing where ventilation must have a high degree of control.

With natural ventilation, minimum ventilation is less controlled. Depending upon thermal and wind forces, natural ventilation is most often associated with cold housing. As will be described in later sections, deciding between warm and cold housing is critical to the design and subsequent management of the ventilation system. Understanding the differences between the two types of environments is especially important as related to the need for maintaining the minimum continuous ventilation for winter in either situation that is in the best interest of animal comfort and health.

Barn Categories and Winter Temperatures

Barn environments are often categorized according to temperatures maintained in the barn in winter. The particular environment, based on desired indoor temperature, is the first determination in ventilation system design.

In a cold barn, indoor temperatures fluctuate with outdoor temperatures. Ventilation maintains indoor temperatures within 3–6 K of outdoor temperatures in winter. Usually, the barn is not insulated and ventilation is largely unregulated, except to adjust for seasonal changes. Adequate air exchange during cold weather to assure moisture control eliminates the need for insulation.

Warm barns are well insulated and, by necessity, have a well-controlled ventilation system. These barns are designed to provide a relatively uniform environment throughout the winter. Tie stall barns, where indoor temperatures are to be maintained at least above freezing, remain the principal example of this type of housing for dairy animals. The key to success is ventilation that is regulated in order to compensate for changing outside climatic conditions.

Some barns do not fit into either the warm or cold category. An in-between barn or modified environment barn usually has indoor temperatures in winter above freezing, even though it is substantially colder outdoors. Minimum insulation (perhaps only under the roof) reduces evidence of condensation. Recommended ventilation features include open ridge, eaves and side walls. Unfortunately, ventilation openings may be closed or blocked during extreme weather to keep manure from freezing and for other reasons. This practice can result in inside temperatures rising 10–20 K above the outside temperature, significantly higher than the 3–6 K temperature difference limit considered acceptable for cold barns. This alone can create problems because of excess moisture build-up and a high relative humidity. But, even more seriously, openings that may remain closed or blocked after severe weather conditions have passed restrict airflow during less severe conditions. The result of this mismanagement is underventilation and poor environmental conditions. A properly designed and managed in-between barn is more like a warm barn, in terms of both design and operation. Thus, to avoid problems, the design and management of in-between barns should follow the guidelines for a warm barn.

Consequences of Mismanaged Ventilation in Winter

Underventilation in winter is one of the most serious threats to air quality and to the environment of animals. Both improper design and improper management of the ventilation system may be reasons that wintertime ventilation is lacking, compromising animal health. Problems are most likely during colder seasons of the year, especially during rainy weather and times of warmer days coupled with cold nights.

Underventilation occurs after ventilation is adjusted for the worst case – severe winter weather – and is not readjusted to allow increased ventilation when milder winter weather appears. Cold barns with manually controlled natural ventilation can be a particular problem. Perhaps ventilation openings are closed in anticipation of a windy, cold, blustery night, but are not opened the next day when, although the temperature may still be cold, the wind subsides and the sun shines. Very simply, reduced wind reduces ventilation, reducing air exchange and reducing the positive effects of dilution.

In a cold barn, the inside temperature is maintained no more than 3–6 K above the outside temperature in winter. Usually this is accomplished through largely unregulated natural ventilation with appropriately sized ridge and eaves openings along with adjustments in door and wall openings.

The danger of mismanaging ventilation in a cold barn in winter increases when insulation is installed under the roof. Insulation suggests that the barn is something other than a cold barn, that an available option is to close or block ventilation openings during extreme weather conditions to restrict ventilation. The most serious deficiency associated with this approach is the lack of automatic control to restore ventilation rates when extreme weather has passed. The consequences of this mismanagement are even more serious if high-producing cows are in the barn because of their higher rates of heat and moisture output.

Condensation on the underside of the roof of a cold enclosed barn may, in fact, be considered a management tool, a signal to the farmer that underventilation is present. Condensation is a sign that additional ventilation is needed for a higher rate of air exchange to reduce moisture build-up. The presence of insulation can take away this important indicator resulting in a potentially unfavorable environment.

If a barn is to be insulated, it must be designed, constructed and operated more like a warm barn than a cold barn. Adequate insulation, a high level of management and well-regulated ventilation are necessary ingredients.

Barn Ventilation – Construction and Management

In general, a cold barn with natural ventilation has these minimum characteristics: (1) no insulation, (2) open ridge and eaves, and (3) side walls and end walls that open. Providing an open ridge along with open eaves has long been recognized as a means of utilizing a stack effect to cause air exchange, especially for controlling moisture in winter. Indoor temperatures are expected to be a few degrees warmer than outdoor air temperature due to the heat being given off by the animals being housed. Current recommendations call for providing a ridge opening of 5 cm per 3 m of barn width and equivalent open area divided between the two eaves. Raised ridge caps are to be avoided. Their performance has been unpredictable due to local wind patterns, often channeling winds into the structure, thereby increasing the entry of wind-blown snow and rain.

Very importantly, the combination of the open ridge and eaves should be viewed as the sole source of ventilation only during the most severe winter weather – during periods when temperatures reach the lowest levels or times when especially windy, stormy conditions are present. During all other times in winter, additional ventilation must be provided. Typically, doorways are left open for this purpose, or portions of the end wall sections of the gable roof may be left uncovered, or side walls away from prevailing winter winds may be left open. Then, as temperatures rise into spring and summer, side walls and end walls are opened fully. As a general rule, too much ventilation is preferred over too little. In winter, air movement through the barn should be sufficient to maintain inside temperature within 3–6 K of outside temperature.

Natural ventilation has been used successfully for warm housing. Such barns are temperature controlled in cold weather and guidelines for construction and for sizing chimney and side wall openings must be followed carefully. Moreover, if ventilation openings are not operated automatically, frequent attention to management of the ventilation system is essential to avoiding underventilation and associated consequences. Except for higher initial and operating costs, a well-controlled mechanical ventilation system is desirable for a warm barn in order to minimize risks associated with the reduced rate of air dilution that accompanies warm housing.

Other Factors Related to Cow Comfort

Besides ventilation, other aspects of housing influence cow comfort. A reasonably clean, dry, resilient bed upon which to lie down helps maintain a dry erect haircoat for the small calf in cold weather as well as providing the larger cow with a clean, comfortable place to lie down for rest and to relieve stress on feet and legs. An animal will lie down for longer periods of time and more total hours per day when provided a dry, comfortable lying place. The outcome is longer resting time, less time for the animal to be standing in wet manure and more drying time for wet feet, especially important to a mature cow.

Bedded areas, including bedded manure packs, are common in cold climates for housing groups of young animals and dry cows. Bedded pens that are frequently cleaned are recommended for calving as well. However, in most areas today, when barns are provided for lactating cows, these barns are equipped with freestalls.

Cleanliness and comfort are two basis prerequisites that must be satisfied in freestall design and construction. Cleanliness relates to clean, dry conditions, especially a clean, dry stall bed in the vicinity of the udder. Comfort means a comfortable bed to allow the cow to lie comfortably in the stall along with roomy dimensions that make it easy for the cow to enter the stall, lie down, rise and exit. In simplest terms, the main purpose of a freestall is to reduce exposure of the teat ends to mastitis-causing organisms. What follows is to make the stall so appealing that a cow chooses no other place but a freestall to lie down 10–14 h day^{-1}.

Adequate supplies of feed and water, besides being of suitable quality, must be easily accessed as a result of proper feed manger and waterer space and design. Providing a minimum manger space of 60 cm per cow is recommended. Waterers should provide a space for every 15–20 cows in a group. Two waterer locations per group are recommended.

Skid-resistant walking surfaces reduce injuries, improve movement to feed, water and resting areas and enhance estrus detection. As in all aspects of facilities design, a compromise must be reached. On the one hand, the surface should provide enough texture so as to keep the animal from skidding. On the other hand, the surface cannot be so aggressive as to injure the underside of the foot of the cow. Grooves in concrete surfaces, up to 1 cm deep and 1 to 1.5 cm in wide, spaced 8–9 cm in on centre, are an acceptable method.

Summary

Proper ventilation system design and management is essential to providing an environment that allows dairy animals to grow, mature, reproduce and maintain health during cold weather. Stalls and beds, access to feed and water and walking surfaces must be considered also. Dairy farm profitability relies on sound management and quality animal environment. Both factors depend on the buildings and equipment on the dairy farm. Understanding the sometimes complex interactions involved, such as between cow comfort and barn design or between grouping strategies and the management plan, is essential when building new facilities as well as remodelling existing ones.

Heat Stress: Effects on Milk Production and Composition

C R Staples and W W Thatcher, University of Florida, Gainesville, FL, USA

Heat Stress Defined by Environment and Cow Response Measurements

The most productive dairy breeds predominantly used around the world were developed in temperate climes, and are most productive between the temperatures of 5 and 15 °C. As temperatures increase from 15 to 25 °C, cows experience a small degree of loss in production. However, as temperatures exceed 25 °C, dramatic reductions in milk production can occur. As a result, 25 °C is usually considered the upper critical temperature for lactating dairy cows.

In addition to ambient temperature, relative humidity should be considered when assessing the heat stress effect of the environment on dairy cows. The temperature–humidity index (THI) is a single value combining the air temperature and humidity. It has been developed to better define the environmental conditions under which productivity and the well-being of animals are likely to be compromised. This THI is also called the 'discomfort index'. It can be calculated for outside cattle using the following equation:

$$\begin{aligned}\mathrm{THI} = {} & (1.8 \times \text{dry bulb temperature } (\mathrm{C}^{\circ}) \\ & +32)-((0.55-0.0055 \times \% \text{ relative humidity}) \\ & \times(1.8 \times \text{dry bulb temperature } -26))\end{aligned}$$

Traditionally, the THI system has been used to describe the expected negative effects of a hot environment on milk production. Milking dairy cows are considered to experience no stress when THI is <72, mild stress when THI is between 73 and 77, significant stress when THI is between 78 and 88, severe stress when THI is between 89 and 99, and possible death when THI is >99. However, recent research conducted at the University of Arizona indicates that milk production by today's higher producing dairy cows is negatively affected starting at a THI less than 72. In eight separate studies involving 100 Holstein cows housed in environmental chambers and producing at least 35 kg of milk, production of milk was reduced when the daily minimum THI was 65 or when the daily average THI was 68 for more than 17 h per day. For example, when the minimum temperature settles at 19.6 °C and 50% humidity (THI = 68), effects of heat stress will start taking a toll. These guidelines may shift somewhat depending on the degree of air movement and direct solar radiation. Current research suggests the need to adjust the THI equation to place more weight on humidity for hot, humid areas and more weight on ambient temperature for semiarid regions in order to make THI a more accurate tool for predicting heat stress. This is based upon examination of the effects of heat stress on first-parity milk yield by cows managed in the semiarid region of Phoenix, AZ ($n = 81\,889$ cows) and in the hot, humid region of Athens, GA ($n = 12\,473$ cows). Yet recent work from Florida indicates that temperature alone had the greatest influence on predicting comfort of dairy cows managed under subtropical conditions.

Although THI is a useful tool to assess the degree of heat stress potential on the cow, her own responses to the hot weather are a more true indicator of her degree of heat stress. Increased breathing and sweating are classified as evaporative cooling techniques and are the primary means of dissipating excess heat under heat stress conditions. A rise in body temperature indicates the cow's inability to completely dissipate her heat load. **Figure 1** plots body temperatures and respiration rates collected from lactating dairy cows (<13.6 kg day^{-1} of milk) housed in chambers at eight different ambient temperatures. Points in each curve at which the measured responses made a dramatic shift upward were at ~60 respirations per minute and at ~39.2 °C rectal temperatures. In 2009, Arizona scientists reported a linear relationship between respiration rates and rectal temperatures of higher producing dairy cows expressed as $y = 0.028x + 37.438$. Based on this equation, a rectal temperature of 39.2 °C would be accompanied by 63 respirations per minute, values that support **Figure 1**. These values may be used as reference points to identify cows on the verge of experiencing significant heat stress: points at which the cow will heat up exponentially if exposed to increasing temperature and humidity.

Heat Stress Effects on Cow Performance

Studies that have been conducted to evaluate the effects of heat stress on cow performance have utilized three main approaches. Animal performance comparisons have been made between (1) cows milking during cool and hot seasons, (2) cows managed with and without methods of heat stress abatement such as shade, fans, and sprinklers, and (3) cows managed in environmentally controlled chambers.

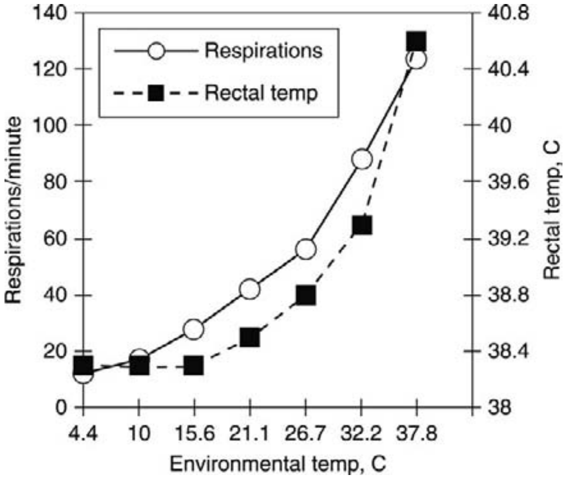

Figure 1 Effect of environmental temperature on respiration rates and rectal temperatures of lactating dairy cows. From Regan WM and Richardson GA (1938) Reaction of the dairy cow to changes in environmental temperature. *Journal of Dairy Science* 21: 73–79.

The Prepartum Period

Reducing the effects of heat stress during a cow's nonlactating, pregnant stage of life has shown benefits. Florida and Israeli workers provided either little or significant relief from heat stress conditions to cows during their last 60 days of pregnancy. Upon calving, both groups were managed the same. Cows provided relief from thermal stress gave birth to heavier calves (~3 kg) and produced more milk during the next lactation. Animals exposed to heat stress conditions likely consume less dry matter (DM) (evidenced by greater plasma nonsterified fatty acids (NEFA)), which may limit fetal growth in the last trimester, leading to smaller birth weights of calves and lower milk production. In addition, uptake of glucose and amino acids by the fetus is reduced under heat stress conditions, which contributes to reduced birth weights of calves according to research conducted at Colorado State University.

Cooling during the close-up dry period also has improved colostrum quality. Holstein heifers were exposed to (1) a THI of 65 or (2) a THI of 82 from 09.00 to 20.00 h and a THI of 76 from 21.00 to 08.00 h during the last 3 weeks before calving and 36 h postcalving. Concentrations of immunoglobulins G and A were lower in the first four milkings of heifers exposed to greater THI.

The Postpartum Period – Milk Production and Dry Matter Intake

The production of heat by a cow increases when she is in the metabolic state of lactation. This is due to (1) an increase in feed intake, which increases the heat of fermentation and nutrient metabolism, and (2) the output of a daily renewable product (milk) whose synthesis generates heat within the body. Both sources of metabolic heat must be dissipated from the body; this is more difficult when the environment has a high THI.

At the upper critical temperature of 25.5 °C, the cow often begins to eat less feed. Elevations in body temperature may signal the hypothalamus to reduce voluntary intake. As the temperature increases, the amount of energy expended by the cow to maintain homeothermy is increased. It is estimated to be 20% greater at 35 °C compared to that at 20 °C. In order to cover this additional energy cost, the intake of DM must increase. However, during hot weather, DM intake decreases. Therefore, the energy status of the cow is challenged due to greater energy costs required to maintain homeothermy and less energy consumption. Thus, it is not surprising that milk production goes down because availability of energy for lactation is less. However, the decrease in DM intake may only account for 35–50% of the decrease in milk production. Arizona research suggests that heat-stressed cows partition more nutrients toward other tissues and less toward the mammary gland, contributing to reduced milk production.

A review of 12 studies from the scientific literature indicates a simultaneous drop in feed intake and milk production as cows experience heat stress. As rectal body or milk temperatures increased from an average of 38.8 to 39.9 °C, average DM intake decreased from 18.4 to 15.6 kg day^{-1} and average milk production decreased from 22.4 to 19.2 kg day^{-1}. For the most part, these cows are considered 'lower producing cows'. To examine whether higher producing cows are more sensitive than lower producing cows to thermal stress, the studies were divided into two groups. Three studies in which cows produced an average of >30 kg milk day^{-1} under thermoneutral conditions were grouped together. A second group of nine studies was composed of cows that produced an average of <25 kg milk day^{-1} at thermoneutral conditions. As the average body temperature of 'lower' producing cows increased from 38.9 to 39.9 °C, average intake of DM decreased from 17.4 to 15.0 kg day^{-1} and average milk production decreased from 19.0 to 16.3 kg day^{-1}. Milk production decreased 2.7 kg day^{-1} per 1 °C increase in body temperature. As the average temperature of 'higher' producing cows increased from 38.5 to 39.8 °C, average intake of DM decreased from 21.3 to 17.5 kg day^{-1} and average milk production decreased from 32.6 to 27.9 kg day^{-1}. Milk production decreased 3.6 kg day^{-1} per 1 °C increase in body temperature. Based upon limited information, it appears that heat stress is more detrimental to cows of greater milk production. When Holstein cows (summary of 8 studies involving 100 cows) were housed in environmental chambers to control THI, milk production decreased linearly by 2.1 kg day^{-1} for every 1 °C increase in body temperature between 38 and 41 °C.

Other studies have implied this same principle. As temperature and humidity rose, milk production decreased to a greater extent for Holstein cows than for Jersey and Brown Swiss breeds. Cows in the early part of lactation experienced a greater depression in feed intake than cows in midlactation during the summer season. The use of bovine somatotropin (bST) as a lactational promotant can increase body temperature as a result of increased milk production. Cows injected with 20 mg day^{-1} of bST were reported to increase their milk production by ~4 kg day^{-1} and milk temperature was increased between 0.4 and 0.5 °C. As cows are managed to produce more milk, we should be equally dedicated to providing them the means to cope with the additional heat load that comes with this additional milk during hot weather.

In a 10-year study, involving 100 purebred Holstein cows in their first lactation in Maryland, cows calving in January and February produced 17% more milk than cows calving in July and August. Major differences in performance took place in the first 50 days of lactation. Environmental conditions, mainly temperature, had a negative effect on appetite. Cows that calved in July and August consumed 14% less feed and produced 21% less milk than cows that calved in winter. As a result, loss of body weight was greater for summer calvers compared to winter calvers.

Cows can inadvertently increase the heat load on themselves by consuming much of their ration prior to the hottest part of the day. Peak heat production by the cow occurs about 3–4 h after eating. Therefore, the rising body temperature due to feed intake may coincide with the rising ambient temperature, thus increasing the maximum heat load on the cow. Cows fed in the evening cooled down more quickly after exposure to elevated THI in environmental chambers than cows fed in the morning. The pattern of eating also differs during cool and hot conditions. Under hot conditions, cows often eat more frequent meals of smaller size resulting in a lower intake per day, yet they experience a greater increase in body temperature.

Cows may attempt to eat more feed at night than during the day. Under conditions when the THI still exceeded the upper critical THI of 72, Florida workers reported that the amount of feed consumed at night did not compensate for the greatly depressed intake during the day. The ability of a cow to cope with heat stress may be dependent upon the extent to which she can cool down at night. Very warm evenings (i.e., lack of night cooling) can prevent cows from making up the DM intake they lost during the day. Daily intake of DM began decreasing when the minimum environmental temperature was above 19 °C for lactating Holstein cows. Scientists in Arizona documented that milk production of Holstein cows suffered when THI failed to drop below a THI of 65. Loss of milk averaged 2.2 kg per cow per day for cows producing at least 35 kg day^{-1} at thermoneutral temperatures. Jersey cows in Arizona were able to maintain milk production until nighttime THI failed to drop below 75 and then production dropped 2.8 kg day^{-1}.

Sometimes, it is the intermittent heat waves that are more dangerous than the regular episodic thermal stress. In 1997, more than 100 feedlot cattle died due to extreme THI over a 4-day period. It was the third such heat wave in 3 weeks. What made the third heat wave so lethal may have been an increased DM intake of animals just prior to the third event. Relatively cool weather had come in right after the second heat wave so the animals had compensated for their reduced intake during the second heat wave by eating much more feed. Greater gut fill during the third heat wave increased their metabolic heat load on top of the environmental heat load, which may have prevented the animals from dissipating the heat needed to survive.

Without question, water is the nutrient of greatest importance in hot weather. Cows drink more water under heat stress conditions. This undoubtedly aids in cooling the body core of the cow. In addition, the cow loses additional water from the skin and lungs as she works to minimize her increased body temperature. Intake of drinking water by lactating cows increased 29% (16.8 kg day^{-1}), and loss of water via the skin and respiration increased 59 and 50%, respectively, when ambient temperature increased from 18 to 30 °C (**Table 1**). Any factor that may inhibit cows from

Table 1 Intake and excretion routes of water by lactating cows at two environmental temperatures

Measurement	*18 °C*	*30 °C*	*Percentage difference*
Water drank (kg day^{-1})	57.9	74.7	29.0
Feed water (kg day^{-1})	1.6	1.4	−14.3
Urine volume (kg day^{-1})	11.1	12.8	15.0
Fecal water (kg day^{-1})	17.9	12.0	−33.0
Evaporation			
Surface (g m^{-2} h^{-1})	94.6	150.6	59.3
Respiration (g m^{-2} h^{-1})	60.6	90.7	50.0

drinking must be eliminated. If water intake is restricted in hot weather, the drop in milk production will be precipitous. The cows will become hotter than normal, and DM intake will decrease to a greater extent as intake of DM and water are closely linked. Providing cool, clean water in *ad libitum* amounts is simply good management.

The Postpartum Period – Milk Composition

Milk fat concentration

In 6 of 14 scientific studies, milk fat percentage decreased significantly (4.05 vs. 3.58%) when heat stress conditions were intensified. All other studies reported no change in milk fat percentage as rectal temperatures increased. An additional study involving nearly 23 000 observations on Florida dairy farms examined the relationships between many variables, including milk composition and environmental temperature. As temperatures increased from 9.4 to 36.1 °C, the authors reported that milk fat concentration dropped from 3.85 to 3.31% and milk protein dropped from 3.42 to 2.98%. Milk constituents were not influenced by the degree of relative humidity. The effect of heat stress on milk fat content appears to be influenced by the forage-to-concentrate ratio of the diet. Fat concentration of milk from cows fed a 35% hay diet was lower during hot conditions compared to thermoneutral conditions (3.69 vs. 3.90%). However, milk fat concentration was unchanged by heat stress when cows were fed a diet containing 65% forage. In a separate study, cows were fed diets of 16, 17.9, 19.4, and 21.2% acid detergent fiber during warm (THI between 64 and 77) and hot weather conditions (THI between 72 and 84) (**Table 2**). Milk fat percentage was unchanged by the diet during the period of warm temperatures. However, under greater heat stress conditions, milk fat content decreased linearly as the fiber content of the diet decreased. The authors speculated that a slight acidosis was corrected with the higher fiber diet, resulting in improved ruminal efficiency and digestion.

It appears that cows subjected to heat stress may be at increased risk to ruminal acidosis. It appears that heat-stressed cows can have lower ruminal fluid pH, less ruminating activity, low milk fat percentage, and reduced buffering capability by the saliva. Fistulated Holstein cows were kept at either 18 °C and 50% relative humidity or 29 °C and 85% relative humidity for 5 weeks. Ruminal fluid was measured 12 times postfeeding for pH and lactic acid concentration. Cows kept in the hotter environment had lower ruminal pH (~5.8 vs. ~6.3) and greater lactic acid (~1.9 vs. ~0.45 meq l^{-1}). In another study, mean ruminal fluid pH (24 h average) was lower (6.53 vs. 6.66) for Holstein cows denied access to shade. Fecal pH was lower (5.92 vs. 6.08) for unshaded compared to shaded lactating cows.

A predisposition to acidosis during heat stress is indicated by the report that elevated environmental temperatures negatively affected ruminal contractions. The number of ruminal contractions decreased from 2.4 to 1.7 per minute when lactating cows were not provided shade (rectal temperatures of 38.7 vs. 39.6 °C). Missouri workers kept ruminally fistulated Holstein cows at an ambient temperature of 38 or 18 °C for 5 days (rectal temperatures of 40.9 vs. 38.4 °C). The hotter cows had less rigorous ruminal contractions as evidenced by a 50% reduction in the average amplitude. The frequency of contractions (2.2 vs. 1.7 per minute) closely followed the pattern reported earlier but was not significant. A lower DM intake by cows at the higher temperatures in the Missouri study was not responsible for the difference in rumen movement because DM intakes were equalized by placing uneaten feed into the rumen via fistula. A decreased number or intensity of ruminal contractions due to heat stress may have a negative effect on saliva production, thereby reducing the buffering activity in the rumen, resulting in a lower ruminal pH. This decreased activity of the rumen musculature of heat-stressed cows may be related to a reduced concentration of volatile fatty acids (VFAs) in

Table 2 Effect of heat stress on milk production (kg day^{-1}) and milk fat percentage of cows fed diets differing in ADF concentrations

	Milk production (kg day^{-1})		*Milk fat percentage*	
Percentage ADF of diet	*Warm temperatures*[a, b]	*Hot temperatures*[c, d]	*Warm temperatures*[a]	*Hot temperatures*[b, c]

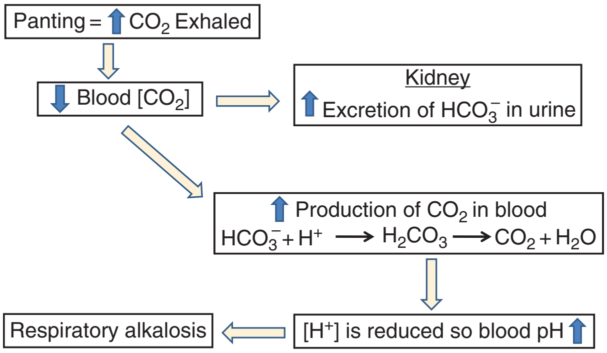
the rumen. That ruminal VFAs may play an essential role in stimulating rumen motility by influencing the neural receptors in the rumen wall may partially explain the reduced motility noted under heat stress conditions. When ruminally fistulated Holstein cows were kept at either 18.2 or 37.7 °C, the concentration of VFAs decreased by more than 50% in heat-stressed cows despite maintaining equal intake of DM through placement of uneaten feed into the rumen.

Respiratory alkalosis is an additional physiological mechanism operating during heat stress conditions that may contribute to ruminal acidosis and thereby lower the fat content of milk. As cows become heat stressed and respiration rates increase, CO_2 is eliminated from the lungs faster than it is produced. This results in decreased blood CO_2. In an attempt to keep the CO_2-to-bicarbonate (HCO_3^-). ratio constant in the blood, the kidney excretes more HCO_3^-. With more CO_2 leaving from the lungs and more bicarbonate leaving in the urine, bicarbonate concentration in the blood drops, H^+ concentration in the blood drops as H^+ is used to produce more CO_2, and blood pH becomes more alkaline (termed respiratory alkalosis) (**Figure 2**). This drop may, in turn, reduce the bicarbonate concentration in saliva, thus reducing the buffering activity in the rumen and increasing the risk of ruminal acidosis.

A last factor that may contribute to lower milk fat content is the habit of cows to selectively consume concentrates and minimize intake of forages to a greater degree in hot compared to cooler weather, thus predisposing them to acidosis and lower milk fat content.

Milk protein concentration

Lactating cows exposed to heat stress conditions can experience lowered protein concentration in milk. In 5 of 10 studies examining heat stress effects on animal performance, milk protein concentration was significantly reduced by an average of 0.18 units. The solids-not-fat content was reduced due to heat stress in three other studies by 0.2–0.4 units. These decreases in milk protein percentage due to heat stress may be due to lowered microbial protein synthesis in the rumen and lowered protein intake due to lowered intake of DM.



Panting = ↑ CO_2 Exhaled

[H^+] is reduced so blood pH ↑
Respiratory alkalosis

Figure 2 Metabolic responses to heat stress work to maintain equilibrium of CO_2 and HCO_3^- in bloodstream.

Milk somatic cell count

In five of six studies, somatic cell counts (SCCs) were higher in the milk of cows exposed to greater heat stress and two of these five studies reported significant increases. The number of white blood cells in plasma was reduced 16% in cows exposed to heat stress conditions using environmental chambers. The immune system of the cow is likely under greater strain during heat stress conditions and therefore the cow is less able to manage subclinical mammary infections.

Other milk constituents

The fatty acid profile of milk fat is changed as cows are exposed to greater heat stress conditions. The concentrations of the shorter chain fatty acids (C_6–C_{12}) were reduced in the milk of cows housed in chambers kept at 29.4 °C and 70% relative humidity compared to those housed in chambers kept at 18.3 °C and 50% relative humidity. This is possibly because of lower production of VFAs in the rumen due to lowered feed intake. The proportion of $C_{18:1}$ in milk fat was also decreased whereas the proportion of $C_{18:0}$ was increased in hotter conditions. This is thought to be due to lower feed intake that results in slower passage of feed from the rumen, thus allowing a greater degree of biohydrogenation of dietary polyunsaturated fats.

The potassium content of milk decreased from 2005 to 1853 ppm when cows were denied access to shade but sodium content was unchanged (521 vs. 543 ppm). Unlike man, the primary electrolyte lost in skin secretions of cattle is K (K_2CO_3 and $KHCO_3$) rather than Na. As heat stress conditions intensify, the production of secretions by the skin and the concentration of K in the secretions increase resulting in an exponential loss of K. The decreased potassium in milk may reflect a conserving mechanism by the cow for prioritized secretion of potassium from the skin.

When exposed to heat stress conditions, milk concentrations of growth hormone increased 38% and prolactin increased 85%. Prolactin may be involved in helping the heat-stressed cow meet increased requirements of water and electrolytes.

Conclusion

Lactating dairy cows begin to experience seriously the negative effects of heat stress when rectal temperatures exceed 39.2 °C. A respiration rate of >60 per minute is an indication that stress due to heat and humidity is becoming excessive. Pregnant cows provided relief from thermal stress during the nonlactating period will have heavier calves at parturition, show improved colostrum quality, and will produce more milk postpartum. Intake of feed is reduced as cows attempt to maintain homeothermy in thermal stress conditions. Intake was reduced 15% in a review of 12 scientific studies as rectal temperatures increased from 38.8 to 39.9 °C. As a result, production of milk was reduced 14% as well. Higher producing cows as well as all cows in their first 50 days of lactation are most sensitive to heat stress. Management of feed and water intake is important in helping cows cope with conditions of thermal stress. Cows exposed to significant heat stress are more susceptible to ruminal acidosis. Ruminal pH may be lowered because of reduced buffering of the rumen and a reduction in the number and intensity of ruminal contractions. Percentages of milk fat and protein are often lowered (∼0.5 and 0.2 percentage units, respectively) during the times of heat stress and during the summer season. The decrease in milk fat percentage may be aggravated by feeding diets that contain borderline concentrations of fiber. There is an increase in SCC, growth hormone, and prolactin and a decrease in potassium content in the milk of cows exposed to greater heat stress.

Introduction

Mammals are homeotherms and regulate heat production and heat loss to maintain a constant and high body temperature. It becomes difficult for mammals to successfully regulate body temperature when heat production increases (such as during vigorous exercise or associated with lactation) or when the environment limits the degree of metabolic heat loss from the animal. Heat stress represents the combination of high air temperature, intense solar radiation, and high humidity that together reduce the flow of heat from the animal so that body temperature increases. The condition of elevated body temperature is known as hyperthermia. Biological and productive functions are compromised by heat stress because the physiological adjustments animals undergo to regulate body temperature can have other deleterious effects on the animal and because hyperthermia itself can alter cellular function. One example of a physiological adjustment to heat stress that can compromise biological function is a reduction in feed intake. About half of the decrease in milk yield in dairy cows exposed to heat stress is caused by reduced appetite and feed intake. An example of alterations in cellular function caused by hyperthermia is the embryonic death that occurs when preimplantation embryos are exposed to temperatures above normal body temperature.

All mammals are susceptible to heat stress but lactating cows are particularly so. The large amounts of heat produced as a result of lactation make it difficult for the lactating female to regulate its body temperature. Indeed air temperatures as low as 25–29 °C can cause hyperthermia in lactating dairy cows. As a result, heat stress has greater effects on body temperature and reproduction in lactating animals than in nonlactating animals (**Figure 1**). In addition, cows producing more milk experience a greater decline in reproductive function during heat stress than do cows producing less milk.

There are two consequences of the relationship between milk yield and heat stress. First, lactating dairy cows intensely managed to produce large amounts of milk are susceptible to heat stress in most temperature regions of the world and not just in regions considered to have a hot climate. Indeed a reduction in fertility in summer has been reported in Alberta, Canada. Second, further increases in milk yield, due to genetic improvement or changes in management, are likely to make cows more susceptible to heat stress in the future. This, coupled with the possibility for global climate change, are likely to increase the economic losses and reduce animal comfort associated with heat stress.

Actions of Heat Stress on the Female

Expression of Estrus

Reduced intensity of estrus limits the use of artificial insemination (AI) and other reproductive management techniques dependent upon visualization of estrus (*see* **Reproduction, Events and Management**: Mating Management: Detection of Estrus). The reduction in estrus behavior involves reduced mounting activity and shorter periods of estrus. In a Virginia study, Holsteins in estrus during the summer had about half the number of mounts of cows in estrus during the winter. In another study, the duration of estrus was 20 h for cows maintained in cooled conditions compared to 11 and 14 h for heat-stressed cows in temperature control chambers or the natural summer environment, respectively. As a result of a reduction in behavioral estrus, the proportion of cows not detected in estrus can rise to 80% in summer, as has been reported in Florida. Lack of detected estrus in summer is a result of suboptimal estrus behavior rather than because cows become acyclic in the summer. Once established, cyclicity is generally unaffected by heat stress.

Fertility

Even if lactating cows are detected in estrus, the probability that pregnancy will be established and maintained after mating is low during heat stress. Depending upon the degree of heat stress, first-service conception rates in lactating dairy cows exposed to heat stress can be 10% or less as compared to rates of 25–40% in cows not exposed to heat stress. Fertility is also reduced by heat stress in other mammals used for milk production, including sheep.

The reduction in fertility caused by heat stress is due to a combination of reduced fertilization rate and increased embryonic mortality. Changes in oocyte function are responsible for some of the infertility. The early embryo is very susceptible to elevated maternal

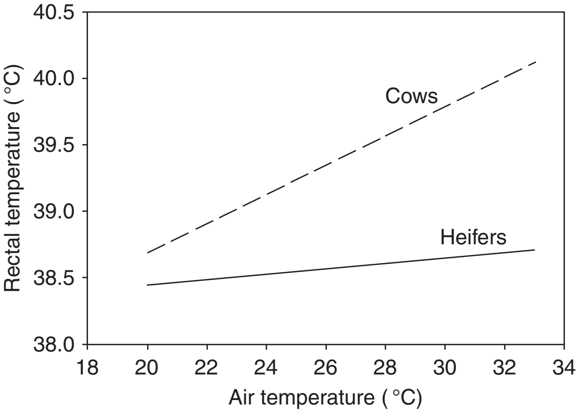

Figure 1 The relationship between air temperature and rectal temperature for nonlactating heifers and lactating cows. Data were collected in Wisconsin and are from Sartori R, Sartor-Bergfelt R, Mertens SA, Guenther JN, Parrish JJ, and Wiltbank MC (2002) Fertilization and early embryonic development in heifers and lactating cows in summer and lactating and dry cows in winter. The figure was prepared by PJ Hansen and is reproduced with permission of Intervet.

temperature, but resistance increases as development proceeds so that by the morula stage (day 5 after estrus) a single day of heat stress has no effect on embryonic survival.

As illustrated in **Figure 2**, there are three windows in the reproductive life cycle of cows where heat stress results in reduced pregnancy rate after mating. The first is the period before ovulation. The oocyte that ovulates coincident with estrus is located in a follicle that initiated growth 90–110 days previously, and it is possible that heat stress during some or all of this period of follicular growth can lead to ovulation of an oocyte with reduced competence for fertilization and development. It has been demonstrated experimentally that heat stress 20–26 days before estrus alters follicular function. Studies in Israel indicate that there is a lag in restoration of fertility in autumn and that the length of this lag can be shortened by removing follicles that experienced growth during summer. The second window is the periovulatory period. Experimental heat stress during this time did not decrease fertilization rate, but the ability of the embryos formed after fertilization to develop normally was reduced. The third window is the period of embryonic development. As mentioned above, embryos are initially sensitive to heat stress but become resistant by the morula stage. The reason why embryos acquire thermotolerance during development is not known for certain but probably involves decreased free radical formation and acquisition of biochemical mechanisms to stabilize cells exposed to elevated temperature (e.g., antioxidants such as glutathione and heat shock protein 70).

Although embryos become resistant to heat stress by the morula stage, heat stress can cause some embryonic

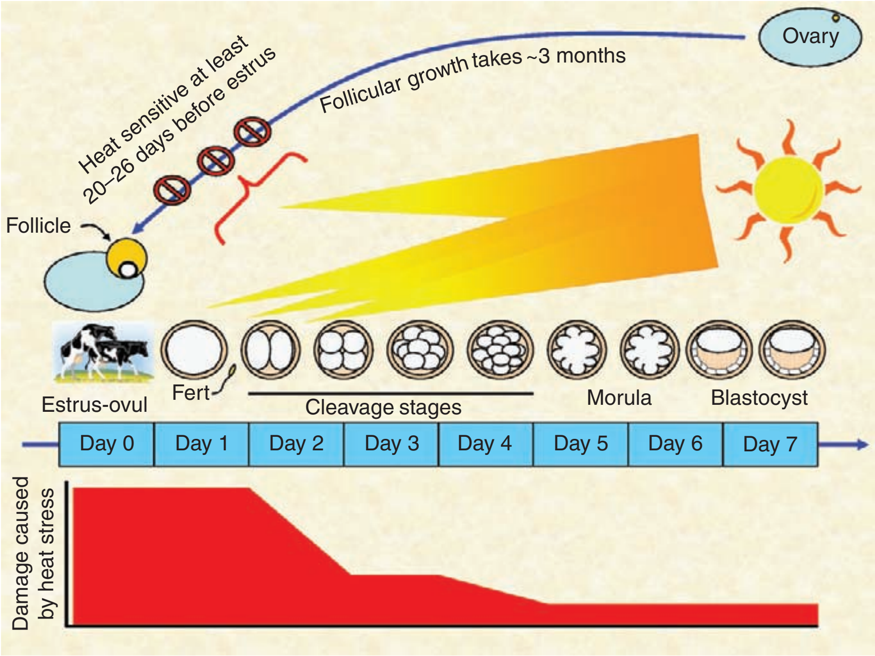

Figure 2 (see color plate 94) Changing sensitivity of the cow to heat stress. The follicle takes about 3 months to complete growth. Heat stress can disrupt follicular function at least as early as 20–26 days before estrus. Heat stress can also disrupt the oocyte on the day of estrus and inhibit development of the early embryo. By day 3 after breeding, however, heat stress has little effect on embryonic survival, and the morula and blastocyst present beginning at about day 5 after breeding are resistant to elevated temperature. The figure was prepared by PJ Hansen and is reproduced with permission of Intervet.

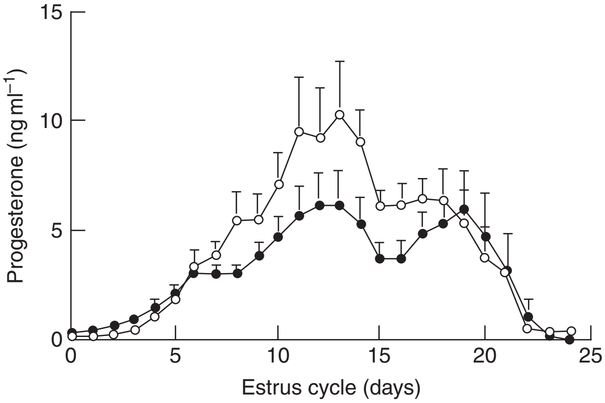

Figure 3 Average daily serum concentration of progesterone during spring (○) and summer (●). Reproduced with permission from Howell JL, Fuquay JW, and Smith AE (1994) Corpus luteum growth and function in lactating Holstein cows during spring and summer. *Journal of Dairy Science* 77: 735–739.

loss later in pregnancy. Effects of heat stress that can contribute to pregnancy loss at the morula stage or after are a reduction in circulating concentrations of progesterone (**Figure 3**), reduced uterine blood flow, and disruptions in the process by which the embryo antiluteolytic signal, interferon-τ, causes reduced synthesis and release of prostaglandin $F_{2\alpha}$ by the uterus (*see* **Reproduction, Events and Management**: Pregnancy: Characteristics; Pregnancy: Physiology).

Fetal Growth

Heat stress during the latter half of pregnancy has been implicated in intrauterine growth retardation, resulting in smaller birth weights (**Table 1**). Intra-uterine growth retardation has been seen in sheep, especially those carrying twins, and in cattle. One consequence of intra-uterine growth retardation caused by heat stress is increased neonatal mortality, especially in sheep.

Data are from Brown DE, Harrison PC, Hinds FC, Lewis JA, and Wallace MH (1977) Heat stress effects on fetal development during late gestation in the ewe. *Journal of Animal Science* 44: 442–446.

Some effects of heat stress on placental function represent redistribution of blood to the periphery and reduced perfusion of the placental vascular bed. However, placental blood flow per gram of fetus was similar both in the heat-stressed and in the control ewes in one study, and it may be that increased vascular resistance in the placenta caused by aberrant angiogenesis is more important. In addition, placental capacity to transport glucose using the glucose transporter GLUT8 can be reduced by heat stress.

Another consequence of heat stress during gestation is a decrease in milk yield after calving. This effect presumably reflects alterations in secretion of placental hormones by the thermally compromised placenta.

Actions of Heat Stress on the Male

Semen Quality

Summer conditions in most regions of the world are severe enough to lower semen quality. In one study, ambient temperatures above 27 °C for as little as 6 h day^{-1} were sufficient to lower semen quality in *Bos taurus* bulls. Effects of heat stress include a reduction in sperm concentration and progressive motility as well as an increase in sperm with abnormal morphology (**Table 2** and **Figure 4**). The reason why germ cells are damaged by heat stress is not completely understood but increased oxidative stress in the testis is one cause. Spermatocytes, spermatids, and, to a lesser extent, B spermatogonia are the germ cells most sensitive to heat

Table 2 Mean semen characteristics of breeds of bulls before, during, and after heat stress

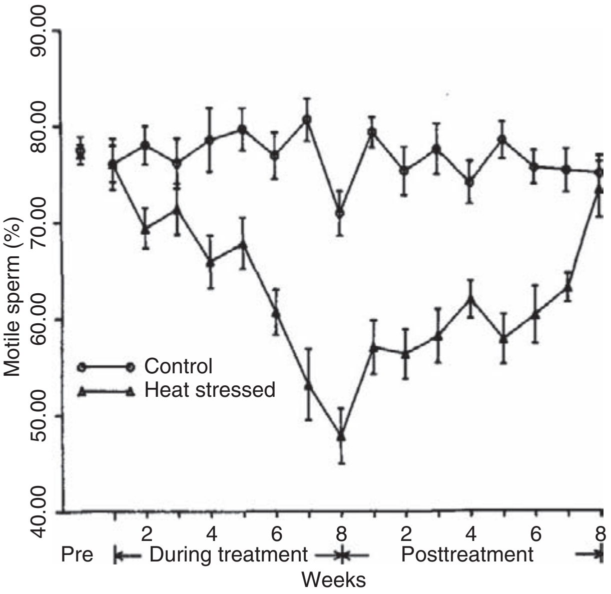

Figure 4 Time course of effects of heat stress on motility of ejaculated spermatozoa in bulls. Control bulls were maintained in a chamber at 23 + 1 °C for 16 weeks. Heat-stressed bulls were maintained for 8 weeks in a chamber that was at 31 + 1 °C for 8 h and 35 + 1 °C for 16 h each day. Thereafter, heat-stressed bulls were returned to an environment of 23 + 1 °C for 8 weeks. Reproduced with permission from Meyerhoeffer DC, Wettemann RP, Coleman SW, and Wells ME (1985) Reproductive criteria of beef bulls during and after exposure to increased ambient temperature. *Journal of Animal Science* 60: 352–357.

stress. One consequence is that semen characteristics are not immediately affected by heat stress because damaged spermatogenic cells do not enter ejaculates immediately. Similarly, elimination of heat stress does not lead to improved sperm quality until the damaged germ cells have completed spermatogenesis. In the bull, for example, where spermatogenesis takes about 61 days, semen characteristics change about 2 weeks after heat stress and do not return to normal until up to 8 weeks following the end of heat stress.

Libido

It is reasonable to expect that heat stress would decrease libido but the experimental evidence to support this idea does not exist. In addition, changes in testosterone secretion in response to heat stress are transient, with an initial decrease in testosterone secretion after heat stress reversed within 2 weeks.

Management to Reduce the Effects of Heat Stress

Environmental Modifications to Reduce the Magnitude of Heat Stress

As shown in **Figure 5**, a wide range of housing systems have been developed to reduce the magnitude of heat

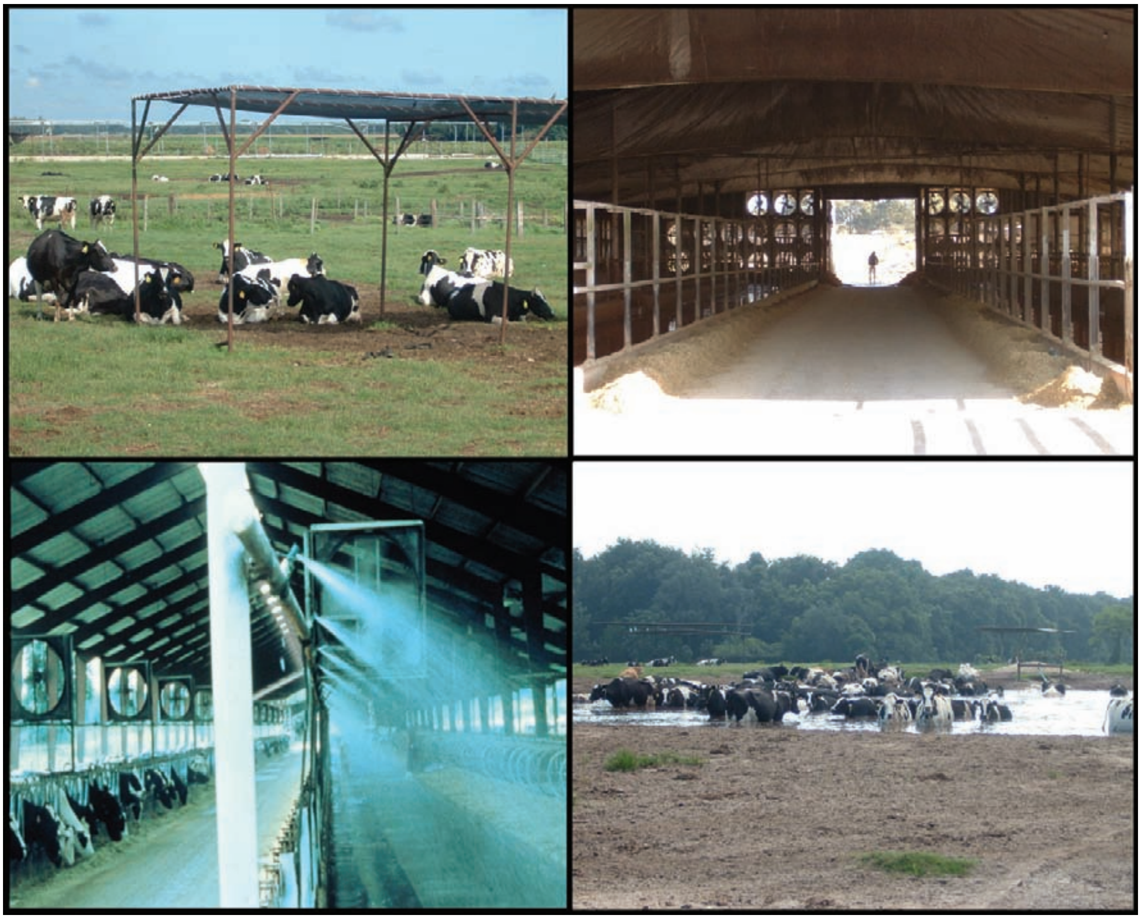

Figure 5 (see color plate 90) Some housing systems to cool dairy cattle during heat stress. The shade structure shown in the upper left panel is insufficient for adequate cooling in lactating cows. The photograph in the lower left shows a barn with sprinklers and fans installed over the feeding area. Such a system can provide significant cooling but often reproduction is still compromised during heat stress. A barn with tunnel ventilation is shown in the upper right photograph. Tunnel ventilation can be an effective system for cooling cows but is also expensive to construct. The photograph in the lower right panel shows cows cooling themselves in a man-made cooling pond. Reproduced from *Horizons* with permission of Genex Cooperative (2006) 12(3): 12–13.

stress faced by lactating animals (*see* **Dairy Farm Layout and Design**: Building and Yard Design, Warm Climates). Provision of fans, sprinklers or misters, shade, and cooling ponds can reduce the magnitude of heat stress affecting the cow, improve the animal's ability to regulate its body temperature, and enhance milk yield. There can be reproductive benefits also. For example, in a Mississippi study, fan cooling of shaded, lactating Holsteins that were synchronized with two injections of prostaglandin $F_{2\alpha}$ resulted in 71% exhibiting estrus, compared to 33% for shaded cows without fan cooling. Under on-farm conditions, however, seasonal variation in reproductive function persists in most herds even when environmental modifications are present. Recently, the so-called tunnel ventilation barns and cross-ventilation barns have received much attention in popular press as effective structures for cooling cows. In these low-ridged barns, fans are located at one end of the barn to create a wind tunnel-like effect. Evaporative cooling is by means of misters or evaporative pads through which air is drawn by the fans. A comprehensive study to evaluate reproductive function in tunnel ventilation or cross-ventilation barns has not yet been conducted.

Overcoming Poor Detection of Estrus

Detection of estrus during heat stress can be improved by various methods, including application of paint to the tailhead, commercial mount detectors, and radiotelemetric pressure transducers, such as the HeatWatch^{TM} system. The advent of hormonal programs to synchronize ovulation for fixed-time insemination can eliminate the need for estrus detection during heat stress (*see* **Reproduction, Events and Management**: Control of Estrous Cycles: Synchronization of Ovulation and Insemination). In a study in Florida, Holsteins subjected to synchronized ovulation with timed insemination for

Table 3 Seasonal variation in pregnancy rate in dairies in Florida and Georgia as affected by mating system

	Natural service (%)	*Natural + AI (%)*	*AI (%)*
Summer	9.8	9.3	8.1
Winter	18.0	17.8	17.9

From De Vries A, Steenholdt C, and Risco CA. (2005) Pregnancy rates and milk production in natural service and artificially inseminated dairy herds in Florida and Georgia. *Journal of Dairy Science* 88: 948–956. Pregnancy rate was the proportion of cows that became pregnant out of those eligible to be bred in a 21-day period. Herds were designated natural service if 90–100% of cows were bred with bulls, natural + AI if the proportion of matings with bulls was from 11 to 89%, and AI if 0–10% of breedings were with bulls. Season × mating system, $p < 0.001$.

the first insemination had more pregnancies (16.6%) at 90 days postpartum than did controls (9.8%). In another Florida study, pregnancy rates at 90 days were 34.3% for cows given the synchronized ovulation with timed insemination treatment compared to 14.3% in controls. The improvement in the proportion of cows pregnant through the use of a timed AI program is the result of inseminating more cows and not of fertility to service, which remains compromised by heat stress.

Some producers utilize natural service to reduce the requirement for estrus detection and AI. A study in Florida indicates that the pregnancy rate (defined as the percentage of cows that become pregnant out of those eligible to be bred in a 21-day period) in summer was slightly higher for herds using bulls or a mix of bulls and AI than for herds using AI alone (**Table 3**). In winter, pregnancy rates were similar for all three types of herds. Loss of genetic progress and increased feed costs associated with natural service may negate the economic advantage of the higher pregnancy rates achieved with use of bulls.

Improving Embryo Survival

One important cause of damage to gametes and the embryo due to heat stress is increased production of free radical species. There is some evidence that feeding the antioxidant β-carotene can improve fertility in dairy cows exposed to heat stress; further studies are required to verify this effect. A variety of hormonal treatments has also been used in attempts to improve fertility in lactating dairy cows exposed to heat stress (*see* **Reproduction, Events and Management**: Mating Management: Fertility). Among these treatments are bovine somatotropin, human chorionic gonadotropin, and gonadotropin-releasing hormone. Unfortunately, no hormonal treatment that can consistently improve embryo survival has been identified. It is probable that damage to the oocyte before ovulation caused by heat stress leads to a reduction in the oocyte's competence to be fertilized or to develop into an embryo and that this damage is not reversible by hormonal treatments given at or after breeding.

As mentioned previously, restoration of fertility after the end of the hot season is gradual because follicles that were damaged early in development need to complete folliculogenesis and be cleared from the ovary by atresia or ovulation. Research in Israel indicates that restoration of fertility in autumn can be hastened by ablation of follicles on the ovary by increasing follicular turnover through bovine somatotropin or follicle-stimulating hormone treatment, or by physical ablation of follicles.

Use of Embryo Transfer to Bypass Effects of Heat Stress on the Oocyte and Embryo

From an examination of **Figure 2**, it is apparent that embryos that reach the blastocyst stage at day 7–8 after estrus have already passed through the most thermosensitive periods of development. It follows, therefore, that pregnancy rate for embryo transfer during summer would be higher than pregnancy rate for AI. Indeed, this is often the case, as illustrated in a large-scale study in Brazil in which lactating cows were either inseminated or subjected to embryo transfer. In cool weather, fertility was the same for both groups. However, the decline in fertility in summer seen in cows bred by AI did not occur for cows subjected to embryo transfer (**Figure 6**).

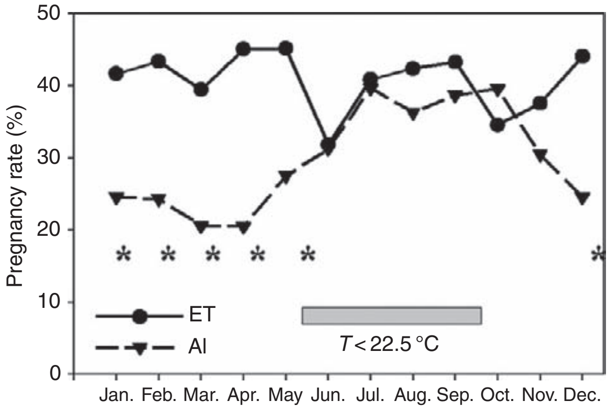

Figure 6 Differences in pregnancy rate between embryo transfer recipients and inseminated animals in lactating cows in Brazil. Lactating Holstein cows either were inseminated or received a fresh or frozen-thawed embryo produced by superovulation. Data are either the number pregnant/number inseminated or number pregnant/number receiving an embryo. Months in which the average ambient air temperature was less than 22.5 °C are shown with the gray bar. Note that embryo transfer increased pregnancy rate in hot weather but not in cool weather. Data are redrawn from Rodrigues CA, Ayres H, Reis EL, Nichi M, Bo GA, and Baruselli PS (2004) Artificial insemination and embryo transfer pregnancy rates in high production Holsetin breedings under tropical conditions. In: *Proceedings of the 15th International Congress on Animal Reproduction*, vol.2, p.396. Porto Seguro, Brazil (abstract) with permission.

In fact, embryo transfer represents the only consistent method for improving pregnancy success in heat-stressed cows. Estrus detection is not a limiting factor in the utilization of embryo transfer during heat stress because embryos can be transferred at a fixed time when ovulations are programmed using hormonal regimens developed for timed AI. One limitation is the high cost of embryo production, especially for embryos produced by superovulation or *in vitro* after harvesting oocytes via transvaginal ultrasound-guided follicular aspiration (*see* **Gamete and Embryo Technology**: *In Vitro* Fertilization; Multiple Ovulation and Embryo Transfer). The most inexpensive embryo is one produced by *in vitro* fertilization using oocytes recovered from abattoir material. The genetic merit of cows sent to slaughter is only slightly lower than average, and embryos can be produced inexpensively using semen from bulls of high genetic merit because one straw of semen can fertilize 100 or more oocytes.

Genetic Selection

As illustrated in **Table 2**, there are distinct breed differences in the ability to regulate body temperature during heat stress. In cattle, *Bos indicus* are better able to regulate body temperature during heat stress than *B. taurus*, which evolved in temperate climates. Under conditions where feed availability, housing, and veterinary care are low, *B. indicus* dairy breeds or their crosses with *B. taurus* may produce a greater economic return than the breeds of *B. taurus* selected for milk yield. In most cases, however, European dairy breeds outperform *B. indicus* or *B. indicus* cross-breeds, even under situations where heat stress is severe.

Even among European dairy breeds, however, there are genes that control the regulation of body temperature and selection for body temperature regulation is possible (*see* **Genetics**: Selection: Concepts). One gene that has been demonstrated to control body temperature is the ‘slick-hair’ gene. Introduced into Holsteins from Senepol cattle, cows with the slick-hair gene have short hair coats, increased capacity for sweating, and lower body temperatures during heat stress.

There is some evidence for genes controlling cellular resistance to elevated temperature. Thus, preimplantation embryos from two thermally adapted breeds, the Brahman and Romosinuano, are more resistant to disruption in development when exposed to elevated culture temperature than embryos from the Angus, Holstein, or Angus × Holstein. Identification of the genes responsible for these breed differences could lead to their introduction into thermosensitive breeds.

Conclusions

Lactating animals are among the mammals most sensitive to heat stress because of the metabolic demands of lactation. The result is reduced intensity of behavioral estrus, low fertility, and compromised fetal growth. In males, too, heat stress can affect reproduction with the most noticeable effects being compromised sperm output and increased sperm abnormalities. Prevention of heat stress effects on reproduction is difficult but the magnitude of effects can be reduced by provision of housing that contains shade, sprinklers or misters, and fans, and by using reproductive management tools such as timed AI and embryo transfer.

Management Induced Stress in Dairy Cattle: Effects on Reproduction

M C Lucy, H A Garverick, and D E Spiers, University of Missouri, Columbia, MO, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The correct definition of stress is important in any discussion of dairy reproduction. A *stress* or *stressor* is a force external to a system which acts to displace the system. A stress condition can be quantified and applied equally across animals. A *strain* is the animal's response to stress (the magnitude of the displacement). The strain often represents a cost to the individual animal and the level of strain can vary from animal to animal. Stressors assume a variety of forms including environmental, physical, physiological, and psychological stressors. Environmental stress caused by heat and humidity in the summer is common in dairy cattle and its effects are discussed elsewhere in this encyclopedia. Physical stress involves an acute injury that causes a dramatic physiological response, for example, when a cow sustains a life-threatening injury involving hemorrhage. Physical stress is uncommon in dairy cattle. Physiological stress is common in dairy cattle and includes high milk yield and disease. Psychological stress is also common in dairy cattle. The common forms of psychological stress include social interactions with other farm animals and people.

There are many examples of stress and the associated strain on dairy reproduction. For example, when dairy cows have high milk production (a stress), their reproductive efficiency will decrease (a strain that is caused by the high milk production). In this example, the stress is applied equally across animals but the strain will vary because some high-producing cows remain reproductively healthy whereas others become infertile.

Endocrine Pathways Associated with Stress and Reproduction

It is impossible to understand the mechanisms linking stress and reproduction without a cursory knowledge of the pituitary gland and the endocrine mechanisms controlling pituitary function. The pituitary is an endocrine gland that synthesizes and secretes hormones that control many aspects of animal physiology. The major hormones synthesized and secreted by the pituitary are growth hormone, prolactin, luteinizing hormone (LH), follicle-stimulating hormone (FSH), adrenocorticotrophic hormone (ACTH), and thyroid-stimulating hormone (TSH). Hormones of the pituitary play major roles in coordinating growth, reproduction, lactation, and metabolism of animals. They are also involved in the stress response. The pituitary is positioned below a specialized region of the brain called the hypothalamus. Neurons within the hypothalamus synthesize releasing factors that control pituitary hormone synthesis and secretion. Releasing factors are secreted into the median eminence, a region of the hypothalamus that contains the terminals of hypothalamic neurons as well as a capillary bed. Releasing factors enter the capillaries and travel from the median eminence to the pituitary via portal vessels. The portal vessels lead to a second capillary bed within the pituitary. The system of two capillary beds and the connecting blood vessels is called the hypothalamic-pituitary portal system. Binding of releasing factors to endocrine cells within the pituitary causes the secretion of pituitary hormones. The hypothalamus also synthesizes and secretes hormones that inhibit the secretion of hormones by the pituitary. The balance between stimulatory and inhibitory factors determines the level of secretion for individual pituitary hormones.

The Hypothalamic-Pituitary-Gonadal (HPG) Axis

The hypothalamic releasing factor responsible for reproduction is gonadotropin-releasing hormone (GnRH). GnRH is released in pulses from the hypothalamus and the pulsatile release of GnRH causes the pulsatile release of LH from pituitary cells called gonadotrophs. The release of FSH from gonadotrophs is also under the control of GnRH but FSH release is less pulsatile because other hormones modify FSH release. Pulses of LH in blood stimulate ovarian follicular growth. A massive release of LH into blood (the LH surge) causes ovulation. FSH will also stimulate follicular growth but in most instances LH and not FSH is the limiting factor that controls reproductive processes in dairy cattle. Collectively, the endocrine system controlling reproduction is called the HPG axis (**Figure 1**).

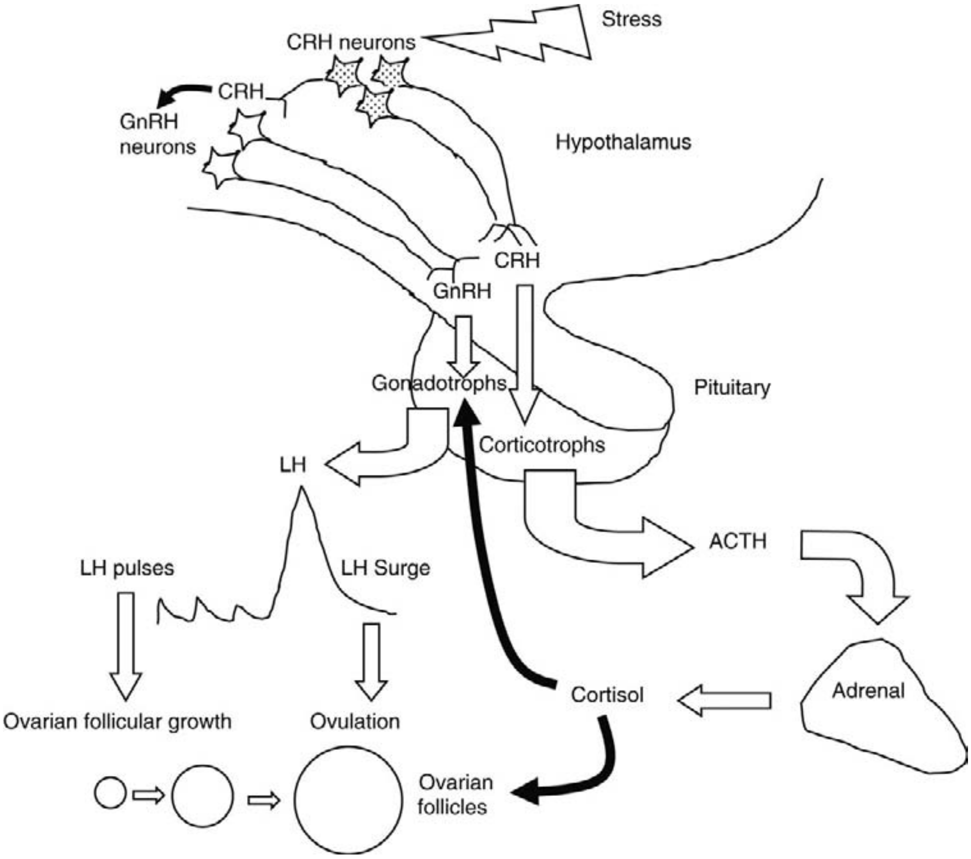

Figure 1 The interaction between the hypothalamic-pituitary-gonadal (HPG) axis and the hypothalamic-pituitary-adrenal (HPA) axis in animals. Neurons within the hypothalamus synthesize and secrete pulses of GnRH. The GnRH travels through the portal vessels into the pituitary where it causes the secretion of LH from pituitary gonadotrophs. Pulses of LH cause follicular growth. A high blood concentration of estradiol from the preovulatory follicle triggers an LH surge that causes ovulation. When the HPA axis is activated, CRH inhibits the activity of GnRH neurons and blocks GnRH release. Thus, follicular growth and ovulation are inhibited. Cortisol is also inhibitory to the reproduction because cortisol decreases the responsiveness of the gonadotrophs to GnRH and decreases the responsiveness of ovarian follicles to LH. Heavy black arrows show pathways for HPG inhibition by an activated HPA axis. The diagramed mechanisms are still under investigation and do not apply to all stresses that affect reproduction.

The Hypothalamic-Pituitary-Adrenal (HPA) Axis

A second endocrine axis called the HPA axis is activated in response to stress. The magnitude of HPA axis activation is not an accurate reflection of the degree of stress. Furthermore, not all stressors activate the HPA axis. Nevertheless, there is evidence that the reproductive system can be affected through the HPA axis. Therefore, the HPA axis will be presented here.

Neurons within the hypothalamus secrete corticotropin-releasing hormone (CRH) into the median eminence. The CRH travels through the hypothalamic-pituitary portal system and causes the release of ACTH from pituitary corticotroph cells. A second hypothalamic hormone, arginine vasopressin (AVP), can increase the activity of CRH on corticotrophs. ACTH travels through the blood and causes the adrenal gland to synthesize and secrete glucocorticoids. The primary glucocorticoid in dairy cattle is cortisol. Glucocorticoids are initially permissive to the stress response and improve an animal's ability to cope with stress. After their initial permissive effects, glucocorticoids are suppressive to the stress response and may play an important role in limiting the potentially damaging effects of stress-activated defense mechanisms.

Control of Reproductive Processes by the HPG axis

LH is a critical hormone for the attainment of puberty in heifers and the resumption of normal estrous cycles in postpartum cows. In heifers, ovarian follicles grow and develop throughout the prepubertal period. Follicles grow in cycles (known as follicular waves) and achieve progressively larger sizes until they reach physiological maturity and trigger estrus and ovulation (puberty). Following ovulation, cells within the follicle differentiate and form the corpus luteum (CL) that secretes the hormone progesterone that is required for pregnancy. The process is similar (but not identical) in postpartum cows. The maternal ovary is relatively inactive during pregnancy. Ovarian follicles grow and develop but follicles do not ovulate (i.e., release an oocyte for fertilization). This makes physiological sense because ovulation and the potential to establish pregnancy are futile in animals that are already pregnant. Shortly after calving, however, the ovary resumes the cyclical process of ovarian follicular growth. Ovarian follicular development within the first 2 weeks after calving can lead to ovulation (i.e., a follicle grows to ovulatory size and ovulates with subsequent CL formation). However, alternative ovarian follicular development may also occur. These alternative processes represent the strain caused by the stress of pregnancy, calving, disease, and lactation. The first possibility is anestrus. Anestrus occurs when ovarian follicles resume the cyclical process of development but fail to grow to an ovulatory size and fail to ovulate. A short period of postpartum anestrus (3–4 weeks) is normal for dairy cattle. Longer periods of postpartum anestrus lead to infertility because estrus is not expressed and cows do not ovulate. The second possibility is a follicular cyst. Follicles grow to an abnormally large size (a cyst) and fail to ovulate. Estrus may occur with cysts but cysts fail to ovulate resulting in infertility.

In heifers, the frequency of LH pulses increases before puberty and stimulates maturation of preovulatory follicles. The same is true for postpartum cows; greater frequency of LH pulses leads to maturation of preovulatory follicles. Preovulatory follicles secrete large quantities of estradiol that cause the hypothalamus to release a surge of GnRH. The estradiol-dependent release of GnRH causes the LH surge. The LH surge is necessary for ovulation and formation of the CL. Stress can cause a strain on reproduction by slowing the pulsatile release of LH or blocking the LH surge.

Mechanisms Linking the HPG and HPA Axes

Tentative links have been made between the HPG and the HPA axes. These links remain under scientific investigation and will require additional research. As mentioned above, not all stressors affect the HPA axis. Thus, stress-induced changes in the HPG axis that affect reproduction are not always caused by activation of the HPA axis.

The stressors that cause activation of the HPA axis may cause infertility by affecting LH (**Figure 1**). Some CRH neurons within the hypothalamus terminate on the cell bodies of GnRH neurons. When CRH neurons are stimulated and release CRH, GnRH release from GnRH neurons may be blocked. The inhibition of GnRH neurons decreases the pulsatile LH release and prevents the LH surge. Decreased LH pulsatility leads to a decrease in follicular growth that delays the onset of puberty in heifers and delays the onset of estrous cycles in postpartum cows. Blocking the LH surge prevents ovulation. The increase in cortisol that occurs in response to the increase in ACTH may also affect the endocrine physiology of GnRH and LH. Cortisol inhibits the pituitary release of LH in response to GnRH. Furthermore, cortisol may decrease responsiveness of ovarian follicles to LH. Therefore, GnRH release (through a CRH-mediated mechanism), the release of LH in response to GnRH (through a cortisol-mediated mechanism), and the response of ovarian cells to LH (through a cortisol-mediated mechanism) may all be inhibited when the HPA axis is activated by stress.

Stressors that affect ovarian function in dairy cattle commonly do so by interfering with the normal process of LH release. Not all stressors, however, affect reproduction through the HPA axis. For example, undernutrition in dairy cattle (a stress) will cause a decrease in the frequency of LH pulses (a strain). The decrease in frequency of LH pulses delays puberty in prepubertal animals because LH secretion is inadequate and follicles fail to mature to a preovulatory size. Likewise, in postpartum cows, undernutrition or severe weight loss shortly after calving will decrease the frequency of LH pulses and cause anestrus. The exact mechanisms through which undernutrition slows the frequency of LH pulses are poorly understood but a variety of mechanisms that are acting independently from the HPA axis are probably involved (see later).

Common Stressors and Their Effects on Reproduction in Dairy Cattle

Physiological Stressors

Nutrition

Underfeeding energy or protein or failing to supply adequate amounts of essential vitamins and minerals are stressors that affect reproduction in dairy cattle. Inadequate vitamin and mineral nutrition in dairy cattle is an uncommon stressor that will not be reviewed here. The stress of mineral and vitamin deficiency will have dramatic effects on health and reproductive function of the animal but effects will vary depending on the specific deficiency.

Underfeeding energy is an important nutritional stressor because the pulsatility of LH depends on caloric intake. Postpartum cows are fed *ad libitum* but nonetheless may be ‘undernourished’ because they are producing large quantities of milk and cannot consume enough feed to meet their energy requirements. They reside, therefore, in a state of negative energy balance for several weeks postpartum (see later). Cattle that are in negative energy balance fail to achieve normal LH pulsatility. In prepubertal heifers, the onset of puberty is caused by an increase in frequency of LH pulses. Undernutrition in heifers delays onset of puberty by delaying the age when the frequency of LH pulses increases. In postpartum cows, negative energy balance delays the onset of ovarian activity after calving through a similar mechanism. Cows that are in negative energy balance fail to resume normal LH secretory pulsatility and do not ovulate. These cows are termed 'anovulatory' (failing to ovulate) or 'anestrus' (failing to express estrus). Although the psychological stress of a short-term fast may activate the HPA axis, effects of chronic undernutrition on the HPG axis are probably independent of the HPA axis. Mechanisms linking undernutrition or negative energy balance to LH pulsatility are still obscure but may involve metabolic hormones like insulin, leptin, and insulin-like growth factors that are closely tied to nutrition and adipose tissue mass of the animal. Brain hormones like opiod peptides and neuropeptide Y also play a central role in regulating activity of GnRH neurons in response to changes in nutritional status.

Once heifers are pubertal or once dairy cows initiate regular postpartum estrous cycles, the effects of undernutrition or negative energy balance are slightly different. Several weeks of severe undernutrition are required to force cattle back into the prepubertal state or back into anestrus (cows). Therefore, even when they are undernourished, cattle will temporarily (several estrous cycles) continue to express estrus and ovulate. Conception rate, however, is decreased in undernourished cattle. The decrease in conception rate may be caused by a decrease in progesterone synthesis by the CL of undernourished animals.

Protein intake also affects reproductive efficiency. Underfeeding protein results in slow growth in heifers and low milk production in lactating cows. Underfeeding protein can therefore delay onset of puberty and may affect interval to estrous cyclicity in postpartum cows. Overfeeding protein is the more common stress in lactating dairy cows. Diets high in crude protein are fed during early lactation so that milk production is increased. Lush springtime grasses can also have high protein content. The stress of high protein feeding causes a strain on reproductive efficiency. Blood concentrations of ammonia and urea are increased. The increase in ammonia and urea does not delay the time of postpartum cyclicity. However, increased ammonia and urea cause a change in uterine pH that alters uterine secretions. These secretory and pH changes create a toxic uterine environment and cause early embryonic death and infertility.

High milk yield

Dairy cattle have been genetically selected for greater milk production. Currently, the best dairy cows are capable of producing over 30 000 kg of milk in a single lactation. The ability of dairy cattle to produce large quantities of milk depends on their ability to partition nutrients and body reserves toward milk production and away from other biological processes. In early lactation, the energy requirements for milk production increase rapidly and are greatest during peak lactation (4–6 weeks after calving). The ability of cows to consume feed, however, lags behind their ability to produce milk (**Figure 2**). Therefore, early postpartum cows must mobilize nutrients stored in the body (primarily adipose tissue) to support milk production during early lactation. Cows that cannot consume adequate feed are in 'negative energy balance' because their intake energy is less than the energy required for milk production and maintenance. By selecting for

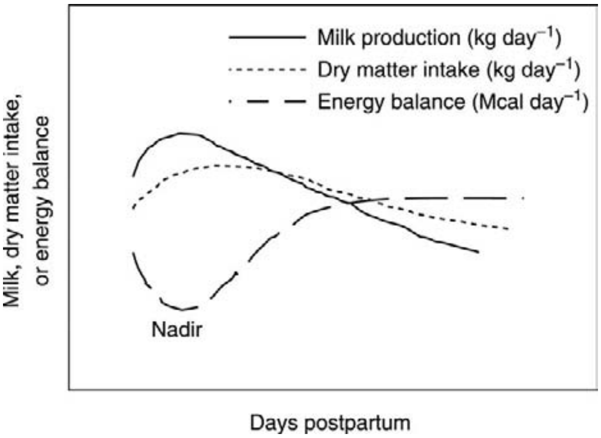

Figure 2 Conceptual diagram of changes in milk production, dry matter intake, and energy balance in postpartum dairy cattle. Energy balance is negative in early postpartum dairy cattle because milk production increases faster than dry matter intake. Cows reach their energy balance nadir within 1–2 weeks postpartum.

greater milk production we have created cows that will enter negative energy balance and mobilize adipose tissue to support high milk production during early lactation. We have also created cows that are larger and have the body capacity to consume large quantities of feed.

Negative energy balance is a stress that creates a strain on reproduction in dairy cows. Cows in more negative energy balance initiate estrous cycles later postpartum and are more likely to develop cystic ovarian follicles. Anestrus in negative energy balance cows is caused by reduced LH pulsatility. Cows in negative energy balance have fewer LH pulses than cows in positive energy balance. The mechanisms linking energy balance to LH pulsatility may be similar to those that link undernutrition to LH pulsatility.

Once the cow becomes cyclic, the strain that high milk production places on fertility is much less. Several large epidemiological studies suggest that high-producing dairy cows are only slightly less fertile than low-producing dairy cows. Postpartum cows with a low body condition score (indicative of inadequate fat mass), however, are susceptible to infertility. The low body condition score during lactation is usually caused by extreme negative energy balance shortly after calving. High-producing as well as low-producing cows are susceptible to infertility caused by low body condition.

Disease

The effects of increased milk production or rbST on reproductive performance are relatively minor compared to the effects of disease on reproduction (**Figure 3**). Diseases that place a strain on reproduction include metabolic diseases (ketosis and fatty liver), uterine and mammary infections (mastitis, metritis, and pyometra), and periparturient disorders (dystocia and retained placenta). The strain is manifested as either anestrus (secondary to a reduction in feed intake and excessive body condition loss), cystic ovarian follicles, or a decrease in conception rate following insemination.

The mechanisms through which diseases affect reproductive processes vary. Dystocia predisposes cattle to retained placenta and uterine infection (metritis and pyometra). Uterine infections lead to a uterine environment that is not conducive to early embryonic development. Some forms of mastitis generate endotoxins that can activate the HPA axis. Activation of the HPA axis inhibits the reproductive axis by inhibiting the activity of GnRH neurons (see earlier). It is also possible for cytokines (hormones released from activated immune cells) to block GnRH release. The decrease in activity of GnRH neurons reduces LH secretion and can block follicular growth and ovulation. Acute mammary infections can also increase release of prostaglandin $F_{2\alpha}$ from the uterus, which in pregnant cows is especially problematic because prostaglandin $F_{2\alpha}$ can regress the CL and cause abortion. This may explain why dairy cows that contract mastitis within the first 21 days after insemination have a decrease in conception rate.

Metabolic diseases (ketosis and fatty liver) are risk factors for infertility in dairy cattle but mechanisms through which their effects are exerted are less clear. Ketosis and fatty liver are sometimes secondary to a displaced abomasum, an inversion of the intestinal tract that blocks normal digestion and decreases feed intake. The drop in feed intake creates excessive mobilization of fatty acids, an excessive loss in body condition, accumulation of fatty acids in liver, and excess metabolism of fatty acids to ketones (ketosis). Displaced abomasum, fatty liver, and ketosis typically occur in early postpartum cows so that the strain on reproduction is initially manifested as anestrus. However, there can be carryover effects of these diseases on conception rates during the breeding period, especially in cows that lose considerable body condition.

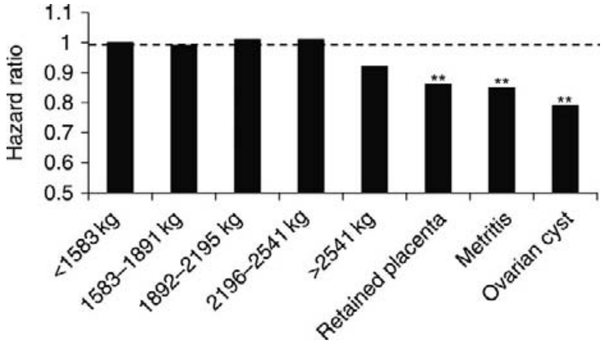

Figure 3 Effect of milk yield (first 60-day cumulative yield in kilogram) and disease on hazard ratio for conception in 13 307 New York State Holstein cows. The hazard ratio is the relative risk of conception. A hazard ratio of 1.0 equates to a neutral effect (dashed line). Hazard ratios less than 1 indicate reduced likelihood of conception (i.e., cows experiencing a disease with a hazard ratio of 0.86 are 14% less likely to conceive compared to a healthy cow). $^{**}p < 0.01$. From Gröhn YT and Rajala-Schultz PJ (2000) Epidemiology of reproductive performance in dairy cows. *Animal Reproduction Science* 60–61: 605–614.

Housing and facilities

The consolidation of the dairy industry into larger farms with more cows per farm has necessitated movement of dairy cattle into confinement housing. Confinement housing is different from traditional grass pastures because cows are kept in large barns with concrete floors and open stalls (free stall barns) or in large corrals with concrete or dirt floors. Convenience and productivity of cows in confinement housing has forced the move from grass pastures. Moving cows into confinement housing and managing cows in larger herds are stressors that increase risk of mammary and uterine infections. Increases in mammary and uterine infections create a strain on reproductive efficiency (described earlier). Managing cows in large groups can also cause psychological stress (see later).

In addition to disease stress, the stress of concrete floors also creates a strain on reproduction by decreasing estrous activity. Dairymen use mounting behavior to determine when a cow is in estrus and when cows should be inseminated. Duration of estrus, mounting activity, and standing activity are greater on dirt than on concrete. Therefore it is difficult to appropriately time insemination in cows that are housed on concrete floors because it is more difficult to determine when cows are in estrus. Concrete floors also predispose cows to lameness. Thus, poor expression of estrus may be secondary to lameness (a strain) caused by the stress of concrete floors on the feet and legs of cattle.

Psychological Stressors

Transportation

Transportation of cattle in a vehicle (trucking) causes immediate activation of the HPA axis. Activation of the HPA axis can potentially inhibit the HPG axis through mechanisms described earlier but the effect is only temporary. Transportation stress is uncommon in lactating dairy cows because dairy cows are generally not trucked during lactation. Heifers may be purchased and trucked from other locations prior to breeding but there is no evidence that trucking has any long-term effect on reproduction in cattle.

Social interactions with cattle

Cattle are social animals that live in groups with a dominance hierarchy. Mixing groups of cattle inevitability leads to decreased productivity because cows must spend time and energy to reestablish the dominance structure within the group. A recent study of dairy cows showed that dairy cows losing social status during the breeding period had a longer interval from calving to conception and required more inseminations per conception (**Figure 4**). The mechanisms linking changes in social status to reproductive efficiency are not clear but may involve activation of the HPA axis and subsequent inhibition of the HPG axis in animals that are subjected to aggression from other cows.

Establishment of a dominance hierarchy depends on the ability of cattle to recognize one another. Cows may have difficulty recognizing one another when they are penned in large groups. The optimum group size for maintaining a stable social order may be as small as 50–60 cows. Therefore, cows in large dairy herds may be especially susceptible to psychological stress caused by an unstable social structure.

Isolation

Social interactions create stress in cattle (see earlier) but isolation from the herd also creates a stress. Isolation is a stress that activates the HPA axis. Although the effects of isolation on reproduction are unknown, activation of the HPA axis during isolation can potentially affect the HPG axis. Therefore, isolation could potentially create a strain on reproduction in dairy cows.

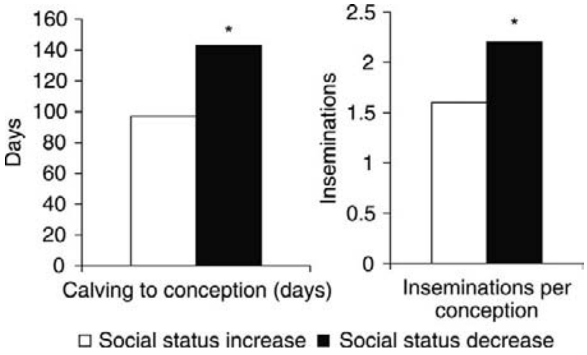

Figure 4 Calving-to-conception interval and inseminations per conception in dairy cows with increasing or decreasing social status. *$p < 0.05$. From Dobson H and Smith RF (2000) What is stress, and how does it affect reproduction. *Animal Reproduction Science* 60–61: 742–752.

Human–cow interaction

Dairy cattle can recognize individual people and have better performance when handled by gentle people compared with aggressive people. For example, cows milked in the presence of an aggressive handler had 70% more residual milk left in the udder following milking. The effects on milk yield may be directly related to a stress response. Cows have an increase in heart rate during milking when an aggressive handler is present. The increase in heart rate is suggestive of epinephrine release and psychological stress caused by the aggressive person. To our knowledge, no studies have evaluated the effects of aggressive versus gentle handling on conception rate. However, there are clearly differences in conception rates across individuals that perform artificial insemination. Part or all of the conception rate differences could be related to handling of the animals before and during insemination.

Conclusions

Stress is an everyday part of the lives of dairy cattle. Physiological and psychological stressors generally inhibit the HPG axis and cause a decrease in LH release. The decrease in LH release slows follicular growth and prevents ovulation. Some stressors activate the HPA axis and affect LH through a HPA-dependent mechanism. Other stressors (i.e., negative energy balance or undernutrition) have similar effects on LH but act through pathways that do not involve the HPA axis. A certain amount of management-induced stress is unavoidable in dairy farms. The best reproductive performance, however, will be achieved when management-induced stress is minimized so that the HPG axis can function at its maximal level.

This article is a revision of the previous edition article by B. Creedon, Volume 4, pp 2470–2476, © 2002, Elsevier Ltd.

Introduction

Water is an important utility in the dairy Industry; its uses are numerous and diverse, ranging from product ingredient to cleaning agent.

The utilization of water in the dairy industry can be divided into processes in which water has direct contact with the product, and those in which water has indirect contact with the product.

To comply with EU legislation, water that comes into direct contact with the product (e.g., steam injection of milk in the production of UHT milk, or when used as a cleaning or rinsing agent) must be of 'drinking water' quality as defined by EU legislation (Council Directive 98/83/EC on the quality of water intended for human consumption).

For water that has only indirect contact with the product, for example, when used as a coolant, the EU legislation has not stipulated any water quality requirements. However, in many dairy plants drinking water is used as the coolant to ensure that accidental leaks of cooling water into the product will not cause contamination.

Some special applications such as readymade infant formula require water of higher specification than that of 'drinking water'. Such applications are beyond the scope of this article.

This article examines drinking water generation and distribution in the dairy industry, and also outlines treatment processes required for boiler and cooling waters.

Generating Drinking Water for the Dairy Industry

Water of EU-defined 'drinking water' quality required in the dairy industry may be delivered to the facility from a municipal water distribution system, or it may be generated onsite using natural water sources such as groundwater or river water.

Drinking Water Sourced from Municipal Water Systems

Should the water be supplied to the site via a municipal drinking water system, filters are typically installed at the factory boundary to ensure that the intake of water is free from particulate contamination, which might have been picked up en route. Finer-rated filters may be installed closer to delivery points of supplies that feed particularly sensitive processes. EN13445 or similar standards may provide guidance on the selection of filters for drinking water systems (DWSs).

Water from Natural Sources

Untreated water from natural sources used for DW generation onsite may contain

- dissolved natural minerals, gases, and possibly some other chemicals
- insoluble debris – vegetable and mineral
- microorganisms – living or dead.

Some of these constituents may make the water unsuitable for use in specific applications in the dairy industry (see **Table 1**). The aim of water treatment is simply to modify these constituents to render the water suitable for a desired application. The following are some water treatment processes routinely employed in the production of drinking water:

Table 1 Specific problems caused by common constituents of water

Suspended solids	Settlement to form deposits on equipment and piping Facilitation of the growth of microorganisms
Iron and manganese	Fouling and staining of equipment and piping
Microorganisms	Microbiological contamination of equipment surfaces Secondary contamination of products or potable supply
Organic compounds	Promotion of growth of microorganisms Imparting of taste or odor to product Staining of equipment and piping
Calcium and magnesium	Scale formation when water is heated or evaporated Increase in detergency requirement (and reduced performance)
Dissolved gases (O_2 and CO_2)	Increased corrosion of pipework, etc.
Other dissolved materials	Contamination of product
Total dissolved solids (TDS)	Increased blowdown requirement in boiler and cooling systems

Removal of suspended solids and turbidity

Suspended solids and turbidity are typically removed by coagulation, flocculation, and settlement, followed by filtration. Chemical coagulants exploit the electrostatic charges on suspended particles, encouraging coalescence to form larger particles. Flocculants provide a chemical bridging between these particles to form yet larger and heavier flocs that may be removed by sedimentation. After flocculation the suspended solids are allowed to settle out. The clear supernatant liquid is removed and filtered.

The process of filtration can be achieved by a number of methods, although the traditional method of sand filtration is still the most common. The water is allowed to percolate through appropriately graded sand and suspended materials become trapped within the bed. A backwash process is used to clean and regenerate the sand filters periodically.

For filtering smaller amounts of water, disposable or washable cartridge-type filters may be suitable. There are two standard types of cartridge: the depth type (where the solids are trapped within the cartridge itself) and the pleated filter type (which depends on the surface layer to perform the filter duty, similar to filter papers used in the laboratory). Most filter elements are disposable, though washable types are available. Cartridge filters are rated either absolute or nominal, depending on the percentage of suspended solids of a particular size held back by the filter. Water can be filtered up to 5 nm using present technology but, in general, the finer the filtered particle specification, the more expensive the element.

Bag filters offer a variation on the cartridge filter and can normally hold a larger quantity of filtered materials between filter changes. The water is fed into the centre of the bag and forced to flow outward through the bag to service. Filtered material trapped within the bag is removed periodically by manual or automatic procedures. Many systems depend on periodic disposal of the bag.

The limiting factors for the sizing of filters are the maximum flow rate required, the concentration of suspended solids present, and the desired treated water quality.

Removal of Organic Compounds

Organic materials appear occasionally in groundwaters and commonly in surface- and postprocessing waters. The high costs of both water extraction and effluent treatment have led to a renewed interest in techniques for the recovery and reuse of postprocessing waters, for example, the second condensate from milk evaporators, for reuse as process water.

One method for removing organics in this scenario is dosage of the condensate to a high level with an oxidizing agent. Chlorination at 6–10 mg l^{-1} or ozonation at 0.1–1.0 mg l^{-1} per 1 mg l^{-1} of organic material present would suffice. The contact time required depends on the oxidant used. The treated water is then passed through a carbon filter that destroys residual oxidizing agent and removes excess and oxidized organics by absorption into the carbon matrix. Carbon filters require periodic backwashing and the activated medium requires replacement from time to time. This process combines microbiological disinfection with organic removal.

Ultrafiltration is also used to remove organic contaminants from water. These filters comprise molecular pore sizes of 5–10 nm and are used in a cross-flow configuration. Water is split into two streams by the ultrafiltration element. The reject stream, containing the bulk of the solid materials, is diverted to the drain while the product water or permeate becomes the treated water stream. The cross-flow configuration allows the process stream waste constantly and tangentially to wash the upstream surface of the membranes, thereby reducing the risk of fouling.

Removal of hardness

Scale formation and degradation of detergents due to the presence of calcium and magnesium salts are widely experienced problems in the dairy industry. The most common method of removing hardness salts is by base-exchange softening. Typically, the water is passed through an ion-exchange resin, held in a pressure vessel fitted with some type of control valve system, usually automatic. Base exchange removes the hardness salts by adsorbing calcium and magnesium ions on to the resin in exchange for the ionic equivalent in sodium ions. Sodium salts rarely form scale. In time the resin will become saturated with the adsorbed hardness metal ions, and regeneration is effected by passing a concentrated sodium solution (NaCl brine) through the resin bed. This solution displaces calcium and magnesium ions and leaves a sodium-rich resin recharged for the next service period. Concentrated hardness salts are washed to the drain during regeneration. The process involves exchange of metals and does not lead to a reduction in the overall dissolved solids.

Water softeners should be sized to maximum flow rate, total hardness of the influent, and the required hardness of the effluent, thus determining the quantity of resin and the control-valve design.

Reduction in dissolved solids concentration

It is sometimes desirable to reduce the total dissolved solids (TDS) in the water supply. Two processes in the dairy industry requiring low TDS are waters used for boiler makeup or in the manufacture of cream liqueurs. Two systems are commonly in use.

Ion exchange

Ion-exchange systems typically use two resin beds, housed in separate pressure vessels in series. The first stage contains a cation exchange resin that will exchange positively charged metal ions for hydrogen ions. The cation exchanger is normally regenerated (while offline) using hydrochloric acid. The water from the cation exchanger is fed to the anion exchanger unit, which exchanges the negatively charged anionic salts (e.g., chloride, bicarbonate) for hydroxide ions. The anion exchanger is regenerated using a caustic (sodium hydroxide) solution. The resultant hydrogen and hydroxyl ions react to form water. The major factors affecting the size of deionization equipment are flow rate and the quantity of dissolved solids in the raw water.

Reverse osmosis

The second method of TDS reduction in common use is reverse osmosis, which uses a membrane system similar to that described for ultrafiltration. However, this membrane has a pore size of 0.1–1.0 nm. By applying upstream pressure higher than the natural osmotic pressure of the feed water, water can be forced to flow through the membrane. This effectively allows the dissolved materials to be concentrated in the reject stream and produces a purer permeate stream with a low dissolved-solid content. Reverse osmosis is particularly cost-effective for waters with very high TDS. Typically, chemical pretreatment is required.

Removal of microbial contamination

Disinfection of water is the process of destroying or inactivating the microorganisms present in the water and thereby providing drinking water fit for human consumption.

Disinfection of water entering a water distribution system can be relatively easily achieved; however, the subsequent maintenance of the water distribution system itself to maintain water quality within the distribution system offers more challenges. Both will be considered together in the following section.

Disinfection and Sanitization of DWSs

Depending on the source of the water, conditions of use, and magnitude and extent of microbiological contamination of the water, in addition to microbiological contamination of the distribution surfaces in the form of a biofilm, disinfection may be needed on a continuous basis or occasionally as shock short-term sanitization (see **Table 2**) should the microbial contamination in the DWSs exceed some threshold.

Table 2 Typical concentrations and application times for shock sanitization of some chemicals

Chemical	*Normal conc. (mg l^{-1})*	*Min. conc. (mg l^{-1})*	*Application time (hours)*
Hypochlorite	50 as Chlorine	10 as Chlorine	8–12
Chlordioxide	5–10 as Chlorine	50 as Chlorine	8–12
Hydrogen peroxide	150	150	24

If the presence of a potentially contaminating biofilm is factored in and understood, then the management of the quality of the DWS becomes easier to control (*see* **Biofilm Formation**).

In low-nutrient DWSs, bacteria can only grow and multiply in the so-called biofilms attached to surfaces; planktonic, or free-floating, bacterial cells released from the biofilm are important for dissemination only.

These planktonic bacterial cells are easier to enumerate and destroy than the bacterial cells attached to a surface existing in a community as a biofilm. Because of the structure of the biofilm, with its protective polysaccharide coating and altered phenotype cells, bacteria in biofilms are greatly protected from chemical attack from biocides, drying, and mechanical removal. Bacteria in biofilms may be up to 500 times more resistant to chlorine than in their planktonic state, well exceeding shock concentration limits.

In practice biofilm activity can only be suppressed below a certain level, but not completely reduced. Therefore, only disinfection, not sterilization, of DWS can be achieved in practice.

There are three commonly used techniques for the destruction of microorganisms in water. The advantages and disadvantages of these are summarized in **Table 3**

Oxidizing Agents

Oxidizing agents in common use are chlorine and its compounds (e.g., calcium hypochloride, sodium hypochloride), ozone, and chlorine dioxide (bromine normally in cooling systems). All oxidizing agents require an adequate contact time to disinfect properly. Stronger oxidizing agents require lower concentrations and shorter contact times. The water may be treated before the

Table 3 Advantages and disadvantages of most commonly used disinfection methods for water supply

Chlorination	
Advantages	*Disadvantages*
Very effective; proven in practice	May give the water a chlorine taste
Provides residual disinfectant	Turbidity may reduce the effectiveness of chlorine
Residual easy to measure	May require high concentrations of chlorine to kill certain bacteria and viruses
Chlorine readily available at reasonable cost	Special storage and handling requirements for gaseous chlorine are required
Can be used for multiple water problems (bacteria, iron, etc.)	May cause corrosion of system components
Appropriate as both primary and secondary disinfectant	
Ozone	
Advantages	*Disadvantages*
Very effective being a strong oxidant, proven in practice	Must be generated onsite, as ozone is unstable. Ozone generator is more complex than chlorination generator
Effective against virtually all bacteria and viruses	Relatively high cost
	May cause corrosion of system components
	May require a secondary disinfectant (chlorine), as ozone does not maintain adequate disinfection residual
Ultraviolet light	
Advantages	*Disadvantages*
No chemical added to the water. Does not change taste or odor of water nor causes corrosion of system components	Relatively high capital cost
Kills bacteria and viruses almost immediately	High electrical demand
Simple operation and maintenance for high-quality water	Local operation only, may require a secondary disinfectant, as there is no disinfection residual
Handling and storage of chemicals is not required	Requires pretreatment of surface water as water must be clear
	Requires frequent cleaning and installation of new UV lamps

storage tanks or by installing an inline contact pressure vessel after the dosing point.

Ozone is a replacement for chlorine in some applications. As a strong oxidizing agent that does not form trihalogenated methanes (THMs), it is particularly suited for disinfecting waters with a high content of organics or colorants. Ozone naturally decomposes rapidly to oxygen, and for this reason does not provide the extended postprotection offered by other oxidizing compounds. Water treated with ozone may be chlorinated to a low concentration to provide postprotection.

All of the above chemicals should be dosed according to the volume of water to be treated, and in continuous processes the chemical flow rate needs to be set in proportion to the water flow rate so that the required concentration is reached. Chemical concentration is often monitored by an online analyzer to allow for automatic control of the chemical flow rate.

Ultraviolet Irradiation

Ultraviolet (UV) radiation used to control microorganisms has some advantages over chemical methods, which entail inconvenient and potentially dangerous handling. Chemicals may also leave undesirable residual products in the water. The major disadvantage of UV systems lies in the failure to provide postprotection. There is, then, the possibility of water becoming re-infected after treatment. Ideally, UV systems should be used as close to the point of use as possible. Sizing to the particular flow rate is critically important, as is matching to the UV transmittance of the pretreated water.

Nonoxidizing Biocides

Nonoxidizing biocides are usually microbiologically toxic organics and find maximum application in the treatment of cooling- and chilled-water systems. Typically, two chemicals are used alternatively to prevent the development of resistant strains.

Typically, DWS designed to the latest design standards, for example, EN 806, should not require disinfection. However, should it become necessary, the system should first be surveyed for problem areas, which should be rectified before disinfection to avoid rapid reoccurrence of microbial contamination. Typically, chemical disinfection is used. Disinfection of DWS itself is best applied by specialist companies.

As a guideline as to when it may be necessary to sanitize a DWS, the Austrian standard ÖN B5019 may be helpful. **Table 4** gives some details.

Guidelines for DWS Design and Operation

Drinking water is a valuable resource needing protection from contamination during its distribution from the source to the tap. Therefore, the water must be distributed in a suitable manner preventing contamination. The DWSs designed to the latest standards, for example, EN806, for distributions systems within facilities are not likely to exhibit premature aging (corrosion) or excessive microbial growth.

The design and maintenance of drinking water generation and distribution systems requires specialized knowledge. However, some general guidelines can be given as follows:

1. *Do not Oversize* To avoid the formation of local corrosion nests and excessive microbial contamination in stagnation and areas of low flow, drinking water distribution systems should not be oversized. Correct sizing of hot-water storage is essential to avoid temperature gradients in storage tanks, which may encourage bacteria to grow in some areas of the tank.
2. *Avoid Dead Legs* Dead legs or rarely used pipe sections where water may remain stagnant for long periods should be avoided. This is particularly important for hot-water systems, as in the stagnant sections the normal hot-water temperature may not be able to be maintained, which in turn may lead to excessive microbial proliferation. In addition, dead legs may reduce the service life of the pipes due to corrosion.
3. *Positive Pressure* Maintain a positive pressure in the DWS to prevent inward entry of contamination.
4. *Insulate Pipes* To impede microbial growth the temperature of the water in the cold-water pipes should not exceed 20 °C. Insulation of the cold water pipes which

Table 4 When is sanitization necessary according to Austrian standard ÖN B5019

Legionella cbu/100 ml	*Normal conc. (mg l^{-1})cfu/l*	*Assessment*	*Action*
>10 000	>100 000	Very high concentration	Stop using system for certain applications, i.e. showers
1001–10 000	10 001–100 000	High concentration	Sanitization is required
101–1000	1001–10 000	Medium concentration	Sanitization may be required
10–100	100–1000	Low concentration	Sanitization may be required
<10	<100	Low concentration	No sanitization necessary
Nondetectable	Nondetectable	Legionella not detectable	None

run close to hot services (steam, condensate, hot water, etc.) may be necessary.

5. *Material of Construction* Many different materials from plastics (PVC, PP, PE, etc.) to steels (ductile iron, galvanized steel, stainless steel) are used to convey drinking water. While no material of construction can be considered ideal, all materials used for a DWS should be approved for use by an authorized body.

A major problem with construction materials is corrosion. Corrosion is a term used to describe deterioration of materials over time. Corrosion may contaminate the DWS with corrosion products, reduce the throughput of the pipes, and lead to a foul taste and to other problems (see **Plant and Equipment**: Corrosion). Before these symptoms are detected, corrosion may have remained undetected for a long time. The root cause of corrosion in DWS may have many sources: galvanic, microbial influenced, pitting, and crevicing, to name but a few.

6. *Backflow Prevention* Backflow from non-DWS into the drinking water distribution system may contaminate the drinking water. Therefore all drinking water standards stipulate backflow preventers.

The incoming water from the municipal water distribution system must be protected from contamination by a suitable backflow preventer (see EN 1717). Water taps are generally protected from backflow by an air gap of a suitable length (>50 mm). Firewater, boiler water, wastewater, and other services not directly related to a DWS must also be segregated by backflow preventers from the DWS (see EN 1717).

7. *Construction, Pressure Testing, and Documentation* Install pipes in a hygienic manner to avoid contamination of the pipes, valves, and other DWS components during the construction.

Pressure tests should be carried out using either drinking water or oil-free air.

Construction debris should be removed using a drinking water rinse.

The documentation should as a minimum include all relevant P&IDs, layouts, maintenance records, and certificates on the materials of construction.

8. *Regular Inspection and Maintenance* Regular inspection and maintenance will help to maintain the availability of the DWS for the lifetime of the plant.

Boiler Water and Cooling Water Treatment

Treatment of makeup water for boilers frequently requires special consideration and is therefore often separated from that of the main water supply.

Boiler water influent is known as feed water and needs to have minimal dissolved solids and hardness, and low corrosive qualities. As a general rule the higher the operating pressure of the boiler, the purer the boiler feed water must be; for details, see standards such as EN 12953.

Evaporative cooling systems should also be fitted with automatic blowdown systems for TDS control. Cooling towers are normally dosed with biocides and either a scale or a corrosion inhibitor.

Chilled-water systems are typically treated with a corrosion inhibitor only, though microbiological protection may be required in some instances.

Introduction

Heat generation is a very broad subject and has many applications. These may be classified according to the amount of power involved, e.g. high power values are transferred in power plants where the expansion of water vapor in turbines generates electricity. Low powers are frequent in industrial applications.

In the dairy industry, heat generation is a vital service, because many of the processes require heat and vapor. Some examples include pasteurizing milk by heating it to a temperature of about 72 °C or above, heating milk with hot water in a heat exchanger, cooking coagulated milk and producing hot water for washing, all of which are processes in the production of cheese and in the manufacture of concentrated, dried or sterilized milk products.

Water is abundant in nature and is the preferred working fluid for heat transfer because of its thermodynamic properties.

Properties of Water and Steam

The thermodynamic properties of water have been determined experimentally for equilibrium states. A thermodynamic equilibrium state is reached when mechanical, thermal, chemical and phase equilibrium exists. It is characterized by two independent properties.

Consider a constant mass of liquid water at pressure $P_1 = 1\,\text{kPa}$ and temperature $T_1 = 20\,°\text{C}$ (state 1) contained in a piston-cylinder arrangement (**Figure 1**).

Heating the system with an external heat source will maintain a constant pressure and cause temperature and volume to increase. As can be seen in **Figure 2**, the system undergoes a change of state, from state 1 to state 2. As long as the temperature (T) is below the saturation temperature ($T_{\text{sat}} \approx 100\,°\text{C}$), vaporization will not occur. This region is the liquid water region ($T < T_{\text{sat}}$).

Additional heating will take the system to T_{sat}, bringing the liquid to the saturated state, state 3. Any more heating causes part of the liquid to vaporize. It is observed that, during this process, the temperature and pressure are constant and dependent variables, and the volume increases.

The heat transferred during the liquid–vapor change is known as the latent heat of vaporization, and the mixture of saturated liquid in equilibrium with saturated vapor is called humid vapor. In this region, state 4 for example, the state of the system may be defined by using the fraction relating the saturated vapor mass, m_{v}, to the total mass of the mixture, $m_{\text{v}} + m_{\text{l}}$:

$$x = \frac{m_v}{m_v + m_1} \tag{1}$$

where m_{l} is the saturated liquid mass.

This parameter changes from 0% (saturated liquid) to 100% (saturated vapor). It is used to determine the specific volume of humid vapor, $v = V/m$ (where V/m is the volume of the system divided by its mass):

$$v = v_1 + x(v_v - v_1) \tag{2}$$

where v_{v} is the specific volume of saturated vapor (some authors prefer v_{g}) and v_{l} is the specific volume of saturated liquid (some authors use v_{f}) (see **Figure 2**). This relationship is valid for other specific properties, such as internal energy, u, enthalpy, $H = u + Pv$, and entropy, S.

The vaporization process ends at state 5, at the instant when all the liquid is completely vaporized and only saturated vapor is present.

Further heating will cause increases in temperature and volume and take the system to a state called the overheated vapor state ($T > T_{\text{sat}}$), state 6 in **Figure 2**.

If the entire heating process described above is repeated for another pressure, achieved by putting weights on the piston, the lines obtained correspond to P_2, P_3 etc. in **Figure 3**.

It can be observed from **Figure 3** that the horizontal part of the isobar (phase change) tends to be smaller as pressure increases, until it disappears at pressure $P_{\text{c}} = 22.1\,\text{MPa}$, the critical point pressure corresponding to $T_{\text{c}} = 374.2\,°\text{C}$, $v_{\text{c}} = 0.00318\,\text{m}^3\,\text{kg}^{-1}$, where instantaneous vaporization of liquid occurs.

Joining the points corresponding to the saturated liquid states in **Figure 3** (i.e. a, b and c) results in the saturated liquid line. Linking the saturated vapor points (d, e and f) gives rise to the saturated vapor line. These two lines meet at the critical point (see **Figure 4**).

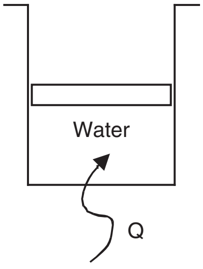

Figure 1 Piston–cylinder arrangement containing water.

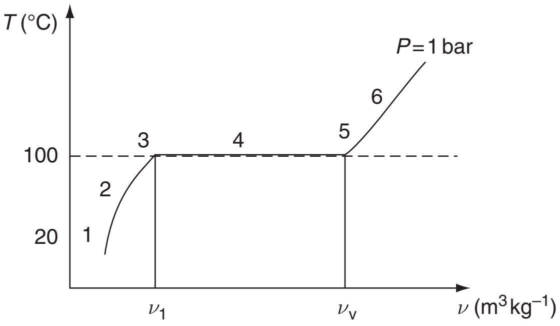

Figure 2 Temperature (*T*) changes for a specific volume of water during isobaric heating.

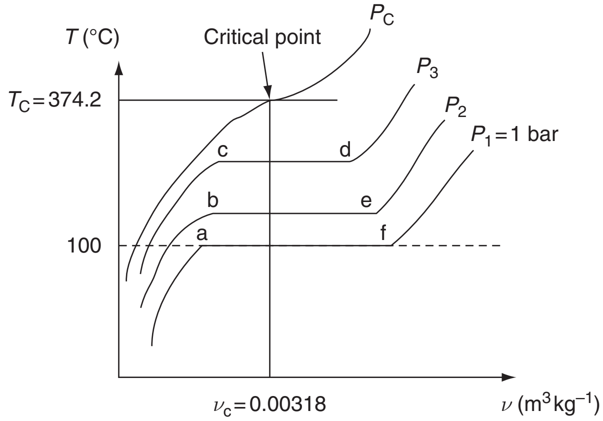

Figure 3 Temperature versus specific volume of water for various pressures.

In problem-solving, the thermodynamic properties of water are frequently obtained from tables: saturated vapor tables represent the saturated line, and overheated vapor tables represent both the overheated vapor and the liquid regions. There are also expressions that establish property relations but these are very awkward to use. In more advanced cases, computer programs generate the property values.

In most of the applications, the water temperature lies between freezing point and the critical point. Using water in this range of temperatures takes advantage of the latent heat. Boilers are the equipment used to convert cold water into hot water, or into steam, by burning fuel that releases heat to the working fluid.

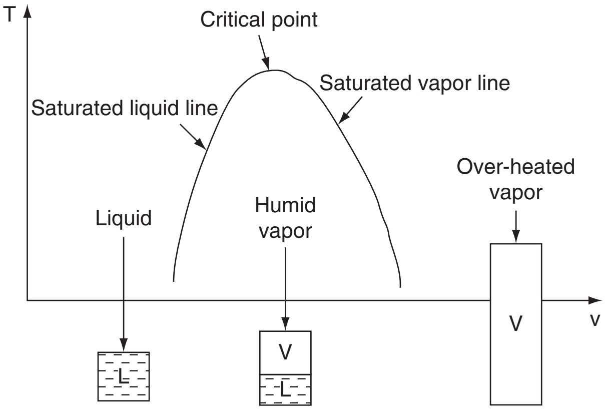

Figure 4 Representation of the saturated line of water in a diagram of temperature versus specific volume.

General Classification of Steam Boilers

Boilers are classified according to different characteristics as follows:

1. Location. The boiler may be moveable or installed in a fixed place.

2. Fuel. The fuel may be fossil, such as coal, fuel oil and natural gas, residual, or there may be none at all. In the latter case, flue gases from industrial processes or internal combustion engines heat the working fluid.

3. Working fluid. Water is the usual working fluid but other fluids may be used, such as thermal fluids. Water is treated to remove impurities. The pH must be controlled to prevent corrosion and should be maintained between 9.5 and 10.5, depending on boiler pressure.

4. Pressure level of the working fluid. The fluid undergoes a phase change and the energy required to vaporize the liquid varies with pressure. Therefore, boilers may be classified according to the working fluid pressure as: low-pressure boilers ($P < 0.15$ MPa), medium-pressure boilers ($0.15\ \text{MPa} < P < 9.0\ \text{MPa}$), high-pressure boilers ($9.0\ \text{MPa} < P < P_{\text{crit}}$ (critical point pressure)) and very high-pressure boilers ($P > P_{\text{crit}}$ – in this case, vaporization is instantaneous).

5. Form of flow promotion. The working fluid may travel through the boiler by natural convection or by forced convection.

6. Flow location. In water-tube boilers, the water flows inside the tubes while the hot gas products of combustion heat the tubes from the exterior. If, instead, the combustion gases flow inside the tubes, heating them internally, and the water surrounds the tubes exteriorly, then the boiler is of the fire tube type.

7. Tubular bank configuration. Tubes may be positioned horizontally, vertically or inclined. The tubes connect to boiler headers that are used to collect steam and water for distribution to other parts of the boiler or users.
8. Furnace position. The boiler is internally fired if the boiler shell contains an internal furnace, or externally fired if the combustion takes place outside the boiler shell and the products of combustion are directed to flow within the tubes inside the shell.
9. Firing arrangements. The firing arrangements may be horizontal (flame travels horizontally into the furnace; used in small- to medium-capacity boilers), vertical (the burner is located at the top of the furnace and the flame travels downward to the bottom of the furnace; used in small-capacity, fire-type tube boilers and also in large-capacity water-tube boilers that burn pulverized coal) or tangential (the furnace has a square or rectangular geometry and, at each of the four corners, the flame travels tangentially to a 'fire ball' where all the flames meet, located at the center of the furnace). The great turbulence favors the mixing of the fuel and air.
10. Number of combustion gas passes. The design may include one, two, three or four passes through the boiler. The latter configuration is the most efficient; however, the greater the number of gas passes, the more fan power is required.

In the dairy industry, small- to medium-capacity unit boilers are used. They may be water-tube or fire-tube boilers, and are equipped with all the boiler auxiliaries, such as water pumps, fans, burners, fittings, controls, etc. The only exterior connections that need to be made are electrical, water, fuel and stack. Stacks, made of steel or concrete, are used to deliver the flue gases to the atmosphere. In this way, dispersion of particles is simplified and has a low impact on the environment.

Prefabricated unit boilers are more advantageous than boilers constructed on site due to ease of installation, compactness of size and lower cost. They are limited to the existing design and produce small steam flow rates, below $250 \times 10^3\,\mathrm{kg\,h^{-1}}$.

The heart of the boiler is the furnace where combustion takes place.

Combustion

Combustion is a process of rapid chemical combination of fuel with air that releases the chemical energy of the fuel. Air and fuel are the reactants in the combustion reaction and the by-product is the flue gases (products of combustion) and heat. It may be represented by the following relation:

$$\text{fuel} + \text{air} \rightarrow \text{products of combustion} + \text{heat} \qquad (3)$$

For this process to occur efficiently, good mixing between the fuel and the air (essentially a mixture of oxygen (O_2) and nitrogen (N_2)) must be accomplished by intensified turbulence, and the ignition temperature of the fuel must be reached. In addition enough time must be allowed for the fuel to burn in the furnace.

Normally, fossil fuels are burnt and these always have in common carbon (C) and hydrogen (H). However, the composition varies greatly with the fuel type:

1. Coal is a solid fuel consisting of carbon, hydrogen, moisture (water), nitrogen, sulfur and ash. It is classified according to the carbon content: anthracite coal has 86–98% carbon (it has a caloric value of approximately $35\,\mathrm{MJ\,kg^{-1}}$, determined experimentally), bituminous coal has 70–86% carbon (and a caloric value of $25–36\,\mathrm{MJ\,kg^{-1}}$), lignite coal has a carbon content up to 70%. Coal needs to be prepared before combustion and its supply to the boiler has to be controlled. It is difficult to burn and produces a high level of ash and sulfur.
2. Fuel oil is a liquid fuel classified according to its ash and moisture content. Its caloric value is the highest of all fossil fuels and may be as high as $46\,\mathrm{MJ\,kg^{-1}}$. Fuel oil has advantages over coal in requiring less storage space, yielding less ash, being easier to control and requiring less equipment. However, it is more expensive because its distribution is not so even around the world.
3. Natural gas is a gaseous fuel with a caloric value of approximately $37\,\mathrm{MJ\,m^{-3}}$. It has advantages over other fossil fuels in requiring the least amount of equipment, being easy to control, mixing well with air and requiring the least amount of excess air, and producing little or no ash (it is the cleanest fuel to burn).

Combustion air is supplied to the reaction in a quantity greater than the theoretically least amount of air needed to burn all of the fuel, so that the combustion reaction is not limited by insufficient air. The amount of excess air depends on the fuel type. Relative to the theoretical amounts, the following are medium values for excess air: large coal particles, 30–40%; pulverized coal particles, 15–20%; fuel oil, 10–15%; and natural gas, 5–10%.

In theory, the fuel is completely burned if the products of combustion are composed mainly of CO_2 and H_2O, and no traces of fuel exist in these products. In practice, this ideal situation does not occur and, due to furnace design, insufficient turbulence, or insufficient residence time of the fuel in the furnace, some traces of fuel, such as CO, always remain in the flue gases, causing incomplete combustion. These gases are undesirable since they are poisonous and explosive and the caloric value is half of the value on complete combustion.

The combustion process may be measured by the combustion efficiency. Among the several notions that exist for this parameter, a simple one is to consider the conversion of carbon to carbon dioxide, given by η_c:

$$\eta_c = \frac{(X_{co_2})\ \text{real}}{(X_{co_2})\ \text{theoretical}} \tag{4}$$

where $(X_{co_2})_{\text{real}}$ is the measured CO_2 molar fraction and $(X_{co_2})_{\text{theoretical}}$ is the CO_2 molar fraction in the off-gas in the case of complete combustion.

The theoretical amount of air needed for combustion is determined by the stoichiometry of the reaction.

Stoichiometry

As mentioned above, normally the fuels burned in boilers are hydrocarbons of the type C_xH_y. The theoretical amount of air needed to burn this fuel completely is given by the following stoichiometric relation:

$$C_xH_y + a(O_2 + 3.76N_2) \rightarrow xCO_2 + \frac{y}{2}H_2O + 3.76aN_2 \tag{5}$$

where $a = x + y/4$.

It must be noted that, since air is a mixture of roughly 21% of O_2 with 79% N_2 by volume (having insignificant traces of other gases), each mole of O_2 is mixed with $79/21 = 3.76$ moles of N_2.

From eqn [5] it can be observed that $(4.76 \times a)$ moles of air are necessary to burn 1 mol of fuel completely. Normally, the stoichiometric air–fuel ratio, $(A/F)_{\text{stoich}}$, represents this relation on a mass basis as:

$$\left(\frac{\text{A}}{F}\right)_{\text{stoich}} = \left(\frac{m_{\text{air}}}{m_{\text{fuel}}}\right)_{\text{stoich}} = \frac{a(1 + 3.76)}{1}\frac{M_{\text{air}}}{M_{\text{fuel}}} \tag{6}$$

where M_{air} and M_{fuel} are the molar masses of air and fuel, respectively, $M_{\text{air}} = 0.21\ M_{O2} + 0.79\ M_{N2} = 28.85\ \text{g mol}^{-1}$, and $M_{\text{fuel}} = xM_C + y\ M_H$ where x and y are the number of carbon and hydrogen atoms in the fuel molecule, and M_C and M_H are the atomic mass of carbon and hydrogen, respectively $12.011\ \text{g mol}^{-1}$ and $1.00794\ \text{g mol}^{-1}$.

If a smaller amount of air is supplied, then the reactant mixture is said to be rich in fuel; if excess air is supplied, it is lean in fuel. The equivalence ratio, φ, is the ratio between the stoichiometric air–fuel ratio and the real air–fuel ratio, $(A/F)_{\text{real}}$:

$$\varphi = \left(\frac{A}{F}\right)_{\text{stoich}} \Big/ \left(\frac{A}{F}\right)_{\text{real}} \tag{7}$$

This parameter allows one to determine whether the combustion is stoichiometric, $\varphi = 1$, the reaction mixture is lean, $\varphi < 1$, or the reaction mixture is rich, $\varphi > 1$, and it is related to the following parameters: the percentage stoichiometric air is given by $100\%/\varphi$, the percentage excess air is equal to $(1 - \varphi)/\varphi \times 100\%$, and the percentage lack in air is given by $(\varphi - 1)/\varphi \times 100\%$.

Combustion and stoichiometry affect the global heat transfer from the fuel to the water in the boiler or, in other words, the boiler efficiency.

Calculation of Boiler Efficiency

Boiler efficiency, η_b, is the ratio between the heat power received by the water, $\dot{Q}_{\text{w}}$, and the heat content of the fuel, $\dot{Q}_{\text{f}}$, since the electrical energy that is necessary to drive the boiler's auxiliary equipment is comparatively much smaller than these values and is normally neglected:

$$\eta_b = \frac{\dot{Q}_w}{\dot{Q}_f} = \frac{\dot{m}_w \Delta h_w}{\dot{m}_f \text{LCV}_f} \tag{8}$$

where $\dot{m}_w$ and $\dot{m}_f$ are, respectively, the water and fuel mass flow rates; Δh_w is the enthalpy difference the water undergoes while it travels through the boiler, and LCV_f is the lower caloric value of the fuel (this is the caloric value usually considered since the water leaves the boiler as a vapor).

Normally, not all the parameters in eqn [8] are easy to determine, so the boiler efficiency must be calculated, by an indirect approach, from the following equation:

$$\eta_b = 100 - \sum L_i \tag{9}$$

This definition considers that the difference between the input and the output energy of the boiler is due to several energy losses. So, from the flue energy content, one subtracts the various energy losses, $\sum L_i$, expressed as a percentage of the LCV_f value, namely:

$$\sum L_i = L_{uf}(\text{unburned fuel}) + L_{ig}(\text{flue gas}) + L_p(\text{purges}) + L_b(\text{heat losses to surroundings})$$

These values may be calculated approximately by the expressions shown in **Table 1**.

The unburned fuel may be present together with the ash, and the energy loss is L_{ufa} (unburned fuel in the ash) because carbon may be carried away by the ash – either the fly-ash, which escapes in the flue gases, and/or the bottom ash, which settles in the boiler.

The flue gases may also contain unburned fuel and the energy loss is L_{uff} (unburned fuel in the flue gases) because CO may exist in the products of combustion due to incomplete combustion.

The energy loss due to the energy content of the fuel gases, besides unburned fuel, is represented by L_{fg} (flue gas). It must be noted that the latent heat of the water in the flue gases is not accounted for because it normally leaves the boiler in the vapor phase.

Periodic removal of debris from the bottom drums is necessary, as well as the removal of water for pH control purposes. The energy content of the water removed represents a loss designated L_p (purges).

Table 1 Boiler energy losses in eqn 9

Energy losses (L_i)	*Expression or value (%LCV_f)*	*Parameters in expressions*
$L_{uf}L_{ufa}$	$= ACLCV_c 100(1-C)LCV_f$	$A =$ mass of ash kg^{-1} of fuel
L_{utt}	$= \frac{F(1-L)_{ufa}COLCV_{co}}{LCV_f}$	$C =$ mass of carbon kg^{-1} of ash
L_{fg}	$= \frac{(1-L_{ufa})FCp_{fg}(T_{fg}-T_{at})}{LCV_1}$	$CO =$ CO mass percentage dry basis
L_p	$= \frac{W\Delta h_1}{LCV_1}$	$Cp_{1g} =$ specific heat of the flue gases
L_h	$= 2.0\%$ for $Q_w \leq 2$ MW	$F =$ fuel gas mass kg^{-1} fuel mass
	$= 1.6$ % for $2MW < Q_w < 5$ MW	$LCV_c =$ lower caloric value of carbon
	$= 1.4\%$ for $Q_w \geq 5$ MW	$LCV_{co} =$ lower caloric value of carbon monoxide
		$LCV_1 =$ lower caloric value of fuel
		$Q_w =$ heat power transferred to water
		$T_{fg} =$ flue gas temperature
		$T_{at} =$ atmospheric temperature
		$W =$ mass of water purged kg^{-1} of fuel
		$\Delta h_1 =$ enthalpy different between leaving and entering boiler liquid

Heat loss to the surroundings, L_h, is very difficult to determine accurately. It is usually obtained by the difference due to all the other losses, so that the energy balance of the boiler is satisfied. Medium values for fire-tube or water-tube boilers at full rate depend on the boiler power, as can be seen from **Table 1**.

By far the most important of the above energy losses is that in the flue gases. For this reason it is usual to recover heat from the flue gases after they leave the boiler, by passing them through economizers (to heat boiler feed water) and air heaters (to preheat combustion air).

To attain good boiler efficiency it is necessary to implement a control strategy that acts on several parameters during boiler operation.

Basic Control Techniques

Basically, the control strategy is implemented as follows: measuring instrumentation detects physical values, such as temperatures, pressures and flow rates; transducers convert these values into electrical signals and send them to data processing systems; these take a controlling action, by comparing the measured values to their preset ones, and send an electrical signal to control systems, e.g. electro-valves, that actuate on the components and regulate the physical values.

By this means it is possible to control the properties of the water vapor produced, the water supply flow and the water level that exists at the boiler's upper drum, the combustion process (regulating the operation of burners or fans), and also ash-removal systems, when applicable.

Obviously, the pressure level of the water vapor produced must be controlled, not only to attain the goal of the boiler, but also to protect it from excessive pressure build-up that may cause boiler explosion. By controlling the pressure, the corresponding saturated temperature is fixed automatically (during vaporization, pressure and temperature are dependent variables). Therefore, temperature control acts on the temperature of overheated vapor that is produced in the boiler. One technique, known as attemperation, may be implemented by regeneration of water vapor or by a spray process. Another technique uses an independent energy source at the boiler exit.

It is also essential to control the water supply flow and the water level that exists at the upper drum in order to guarantee that water in the liquid state is always present inside the boiler (ready to be vaporized) and to avoid a tube explosion due to an excessively high temperature.

The steam produced in the boiler is delivered by a steam piping system (normally made of steel) to the sites where it is used. A return piping system reintroduces the condensed water into the boiler. The design of these piping systems requires great attention because steam leakage losses and hot water losses occurring as a result of deficient design may assume such importance that they may reduce the measures adopted to increase efficiency of the steam generator and of the steam user.

Design of Steam Piping Systems

The design of the steam piping system is normally determined on an economy basis. The total cost of the system is equal to the sum of the capital, installation (an important part of the total cost) and operating costs. These costs depend upon the tube's internal diameter, *D*, as can be seen in **Figure 5** which shows the relationship between cost and *D*.

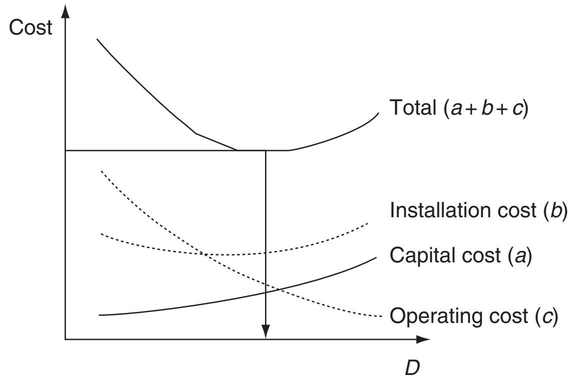

Figure 5 Cost of piping systems as a function of tube diameter (D).

The dependency of the operating cost on diameter results from the pressure drop due to friction between the steam and the tube's internal surface.

Assuming a given flow rate, $\dot{V}$, and considering suggested values for the fluid velocity, ν, saturated steam velocity between 30 and 50 $\mathrm{m\,s^{-1}}$ and overheated steam velocity in the range 50 to 100 $\mathrm{m\,s^{-1}}$, the diameter, D, results from:

$$D\left(\frac{4}{\pi}\frac{\dot{V}}{v}\right)^{1/2} \tag{10}$$

The next step is to select a normalized diameter close to this value, as well as at least two diameter sizes immediately above and immediately below it.

The pressure drop, Δp, is then calculated for each of these diameters from:

$$\Delta p = p\left(f\frac{L}{D} + \sum K\right)\frac{v^2}{2} \tag{11}$$

where ρ is the specific mass given by steam tables ($=1/\nu$); f is the friction factor; L is the tube length (a known quantity); and $\sum K$ is the localized pressure drop due to accessories (some authors convert $\sum K$ to L_{eq}, i.e. an equivalent straight pipe length of the same diameter having the same pressure drop as the accessories).

The friction factor in eqn [11] is given by the Colebrook equation:

$$\frac{1}{\sqrt{f}} = \left[-2.0\log\left(\frac{\varepsilon/D}{3.7} + \frac{2.51}{\mathrm{Re}\sqrt{f}}\right)\right] \tag{12}$$

where Re is the Reynolds number; $\mathrm{Re} = \rho\nu D/\mu$; μ is the steam dynamic viscosity; ε is the tube rugosity; and $\varepsilon = 0.000\ 05\,\mathrm{m}/D$ (m) (for commercial steel tubes).

The pressure drop normally adopted is approximately 5% of the value of the pressure in the main steam pipe. Should the calculated value be greater, it is recommended to redesign the piping system by choosing another value for D.

The outlined procedure allows calculation of the pressure drop, and hence the operating cost shown in **Figure 5**, for a range of possible sizes of tube (such that the steam velocity is within admissible values). Based on the economic criterion, the trend is to favor smaller pipe diameters, i.e. high steam velocities.

An important aspect not to be neglected is that steam at a high temperature flowing in a pipe loses heat to the surroundings (depending on tube insulation), which may cause superheated steam or saturated steam to condense. To prevent damage by erosion or water hammer, the condensed water should be drained by allowing the tube to have a continuous fall in the direction of flow of at least 4–5 mm in every 1 m, and by providing an adequate number of drain points (e.g. in a straight main pipe one every 20–40 m). During operation, condensed water is removed using steam traps; these automatic valves are able to remove liquid but prevent the escape of steam.

The piping system can be optimized using the following parameters:

1. The operating pressure may differ from the design pressure; review the capital cost of the steam generator or steam user due to variation of friction losses.
2. Additional operating costs of returned feed water may be incurred due to an increase in operating pressure; the condensed water is collected and reintroduced into the boiler.
3. Heat loss may differ from the design value; steam enthalpy change affects the steam user and the operating costs.

Vapor Compression Cycle

Principles

Refrigeration is the most common technology used for the conservation of perishable products. It involves the production and maintenance of a level of temperature in a space or object that is lower than ambient temperature.

A consequence of lowering the temperature of perishable products is that the reactions that cause their deterioration, mainly microbial and enzymatic reactions, slow down, enabling the conservation of products for longer periods of time. The lower temperatures needed for conservation of perishable products can be subdivided into two groups: positive temperatures, which are referred to as refrigeration, and negative temperatures, below the freezing point of the product, which are referred to as freezing. Whereas in the former, all water in the product is in the liquid phase, in the latter most can be in solid phase. However, we must bear in mind that the microbial and enzymatic reactions do not cease, they just slow down. As soon as the product is exposed again to ambient temperature, the reactions resume their normal rate. An advantage of freezing is that the products can be stored for much longer periods compared with that for refrigeration. As deteriorative reactions occur in aqueous media, the loss of liquid water to ice substantially reduces water availability, and hence reactions can be severely restricted well beyond the lowering temperature effect. In principle, at temperatures even lower, below the glass transition temperature, all water is in either ice or part of the amorphous vitreous structure, molecular mobility is restricted to mutarotation and vibration, and all reactions cease. Unfortunately, such temperatures depend on water content, and for most foods they are typically well below practical storage applications (-20 to $-50\,^{\circ}\mathrm{C}$ for typical foods).

In the old days, refrigeration was understood as natural refrigeration, that is, the lower temperatures were obtained with ice found in nature. Nowadays, it is understood as artificial refrigeration (i.e., the lower temperatures are obtained by mechanical systems, the most common one being the vapor compression system, shown schematically in **Figure 1**).

The basic system shown is composed of four components, namely the evaporator, which is generally located inside the refrigerated space, the compressor, the condenser, and the expansion valve, connected in series by piping. Inside the system there is a flowing fluid, called refrigerant, which exchanges energy in those components.

In state 1, the refrigerant is in the liquid phase, either saturated or sub-cooled. From state 1 to state 2 the liquid flows through the expansion valve, a device that controls the refrigerant flow rate to the evaporator, where its pressure and temperature are lowered. As in the expansion valve, the refrigerant does not exchange heat or work with the outside, it maintains its total energy – enthalpy (h). In state 2, due to the pressure drop in the expansion valve, the refrigerant has two phases in equilibrium: saturated liquid and vapor. Then it flows through the evaporator where it absorbs heat from the refrigerated space in which the products are stored, lowering or maintaining its temperature. This refrigerant heat gain in the evaporator (increase in enthalpy) causes the boiling of the liquid so that state 3 corresponds with saturated vapor or even super-heated vapor. This process occurs at constant pressure and at constant temperature if there is no super-heating at the outlet of the evaporator. The vapor then enters the compressor where it is compressed to a higher pressure – the same as in state 1 – and with an increase in temperature, and consequently with an increase in enthalpy, state 4. At this point the vapor flows through the condenser, again in a constant pressure process (ideally). In this component, the refrigerant loses heat to the outside (either ambient air or water, or both) with a decrease in enthalpy, changing phase again – condensation – so that at the outlet it is in the same state referred above as state 1.

As can be seen, this cycle operates between two constant pressure levels: a higher one in the condenser and a lower one in the evaporator, the pressure drop and increase being carried out respectively by the expansion valve and by the compressor.

To visualize the refrigerant's evolutions in the vapor compression cycle, different types of thermodynamic diagrams may be used, the most common one in refrigeration being the pressure–enthalpy (p–h) one. **Figure 2** shows a typical p–h diagram of the cycle shown in **Figure 1**. It was considered that no super-heating or sub-cooling exists in the refrigerant at the outlet of the evaporator and condenser.

By applying the first law of thermodynamics to the whole cycle and to each of its components and neglecting changes in kinetic and potential energy, it is possible to calculate the different energy fluxes in the cycle:

$$\dot{Q}_{\mathrm{evap}} + \dot{Q}_{\mathrm{cond}} + \dot{W} = 0$$

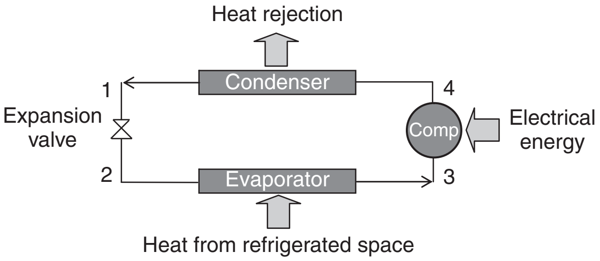

Figure 1 Vapor compression system.

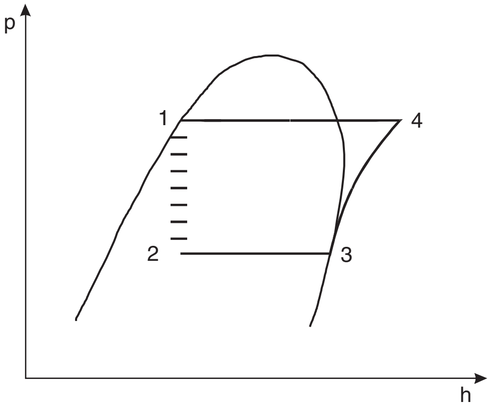

Figure 2 Pressure–enthalpy diagram of the cycle shown in **Figure 1**.

$$\text{evaporator} - \text{refrigeration effect: } Q_{\text{evap.}} = \dot{m}(h_3 - h_2)$$

$$\text{compressor} - \text{compression power: } \dot{W} = \dot{m}(h_4 - h_3)$$

$$\text{condenser} - \text{condensation heat: } \dot{Q}_{\text{cond}} = \dot{m}(h_1 - h_4)$$

$$\text{expansion valve: } h_2 = h_1$$

where $\dot{m}$ is the refrigerant flow rate, Q is the heat exchanged, W is the energy (work) supplied by the compressor, and h_i is the specific enthalpy of the refrigerant at the different points of the cycle.

As can be seen, all the energy fluxes can be easily evaluated if the refrigeration cycle is conveniently plotted in a p–h diagram of the refrigerant used. It is only necessary to read the different enthalpy values and make the above calculations. However, nowadays all the calculations can be performed analytically because the equations of state (equation that enables the evaluation of the different properties of the fluid used) of the different refrigerants are well known. Existing software allows these calculations to be performed easily.

Equipment

There is a wide range of equipment for each component in the vapor compression cycle. The choice of one or another depends mainly on the purpose of the system. In this text, only a general classification of the equipment will be given.

Evaporators are heat exchangers where the refrigerant boils while receiving heat from the surroundings. One possible classification of evaporators is based on their application. In that way, they can be classified as direct expansion or indirect expansion evaporators. In the first type, the coils of the evaporator are in direct contact with the space or body to be refrigerated (i.e., the refrigerant absorbs the heat directly from there). In the second type, the refrigerant takes the latent heat of vaporization from a secondary fluid, usually brine or water. This fluid flows in a closed loop making the connection between the evaporator itself and the objects to be cooled, where it withdraws heat.

The evaporators can be classified into two groups: direct expansion and liquid recirculation type. In the first type, the refrigerant coming from the expansion valve boils completely in the tubes of the evaporator, leaving it as a saturated vapor. The second type is designed so that only part of the liquid boils in the coils. At the outlet of the evaporator there are then two phases in equilibrium, liquid and vapor. The vapor flows to the compressor, while the remaining liquid is recirculated back to the evaporator.

The compressors can be classified as centrifugal compressors, vane compressors, rotary screw compressors, or reciprocating compressors, with the last types used in most refrigeration applications. When the pressure ratio of the compressor is typically above 10 (ratio between condensation pressure and evaporation pressure), the performance of the compressor falls and it is not possible to use only one compressor if it is of the reciprocating type. In this case, it is necessary to either use more than one compressor or choose another type. Usually, the compressors are coupled with electrical motors that provide the necessary running power. However, it is not unusual to find internal combustion engines instead of electrical motors driving the compressors.

Condensers, like evaporators, are heat exchangers, and they are classified as air-cooled, water-cooled, or evaporative. In the first type, the condensing refrigerant loses heat to the ambient air, whereas in the second type the removal of heat is to water that flows in a closed loop, where usually a cooling tower cools the warm water. In the third type, air and water in a packed tower are used in counterflow over the coils of the condenser, inside which the refrigerant condenses. This kind of condenser must be located outside the building and as the refrigerant flows inside it, the length of the pipe carrying it is much longer than the first two types of condensers. Therefore, the pressure drop in the high-pressure part of the system is also higher. Also, as the length of the piping increases, the probability of leakage is increased.

As already mentioned, the expansion valve controls the flow of refrigerant into the evaporator. There are different types of expansion valves, namely, the manually operated, automatic low side float valve, automatic high side float valve, automatic valve, thermostatic valve, and the capillary tube, the last two being very common in most applications. The capillary tube is used in small-capacity refrigeration systems, namely refrigerators and small-size air-conditioning equipment, whereas the application of the thermostatic valve is wider. This valve also controls the degree of refrigerant superheating at the outlet of the evaporator, comparing it with some pre-set value.

Coefficient of Performance

The cycle analyzed so far is an inverse thermal machine. It is therefore possible to evaluate its performance, like in any other thermal machine, as the desirable effect of the system divided by what must be paid for this effect. The performance of refrigeration cycles is expressed through the coefficient of performance (COP), which is the ratio of refrigeration effect (desirable effect) divided by the compression power (what must be paid):

$$\text{COP} = \frac{\dot{Q}_{\text{evap.}}}{\dot{W}} = \frac{h_3 - h_2}{h_4 - h_3}$$

COP values are always positive and usually greater than one, due to the fact that the refrigeration effect is greater than the compression power. Typical values of COP for the vapor compression systems are in the range 2–3. Even if the evaporation temperature is held constant throughout the year, the COP is not constant due to changes in air or water temperature feeding the condenser, which causes changes in the condensing temperature and also in the enthalpies appearing in the COP equation.

Refrigeration Systems

Vapor Compression Systems

The system analyzed so far is the basic vapor compression system that is used in several applications of refrigeration.

However, and keeping in mind this basic system, better performances can be achieved if some modifications are introduced. There are several possible modifications that can be implemented, for specific applications.

A very common modification is the use of multi-stage compression (i.e., the use of more than one compressor), with inter-cooling of the refrigerant between each pair of compressors. Inter-cooling is carried out with the refrigerant at a lower temperature withdrawn from other parts of the system. This technique reduces the system total work. **Figure 3** shows schematically such a system. As can be seen, in this system there are three levels of pressure, a lower one in the evaporator, an intermediate one between the two compressors, and a higher one at the condenser. Multistage systems usually have higher COP values than basic vapor compression systems. This is due to the fact that there is a decrease in compression work and an increase in the refrigerant effect. There are different ways to implement this technique, one of them being to couple the system with several evaporators, each one with a typical operating temperature.

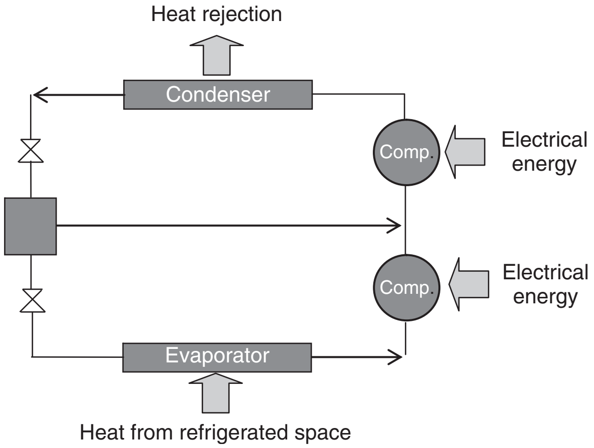

Figure 3 Multistage vapor compression system.

To achieve very low temperatures – much lower than the freezing point of the products – with a good performance, the so-called cascade systems are frequently used. In its simplest form it is composed of two basic vapor compression systems in a way that the evaporator of one cycle is simultaneously the condenser of the second system (see **Figure 4**).

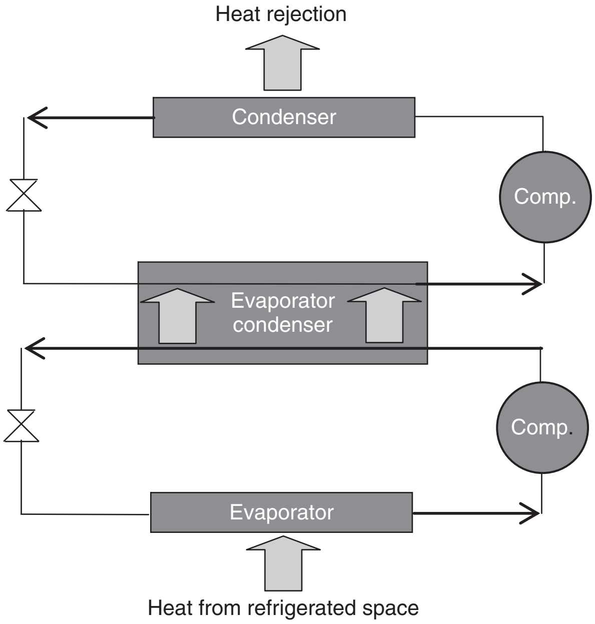

Figure 4 Cascade system.

In that way, the evaporator of the upper system absorbs the heat lost in the condenser of the lower system. Usually two different refrigerants are used, one in each cycle. The refrigerant in the lower cycle should have good characteristics at lower temperatures while the other refrigerant should have good characteristics at higher temperatures. It is also possible for each of the subsystems considered to operate as a multistage system.

Other Systems

One variant of the vapor compression system is the absorption system, also used for refrigeration. This system is as old as the vapor compression system but only recently has its utilization increased, due to the ozone depletion potential of most of the synthetic refrigerants used in the vapor compression system, as will be described later. The absorption system differs from the vapor compression system in that low compression of the refrigerant is carried out, having in common the other three components: the evaporator, the condenser, and the expansion valve. **Figure 5** shows only the part of the cycle that is different. In the absorption system, the compression is done using a secondary fluid that has the capacity of absorbing the main refrigerant flowing in the other three components. At the absorber outlet, where heat is lost to the outside in order to carry out the absorption process, there is a homogeneous liquid solution that is pumped to another component, the generator. Here, it is necessary to supply heat to separate the two fluids, a process opposed to the one in the absorber. The work of compression in the absorption system is much lower than in the vapor compression system due to the fact that a liquid solution is pumped instead of a vapor. But in an opposite way, a large quantity of heat at a higher temperature (typically over 100 °C) must be supplied to the generator. These two combined effects lower the COP value of the absorption system, compared with that of vapor compression systems, to values below 1.0, typically around 0.7. It is however possible to obtain higher COP values if the heat supply in the generator is waste heat (found in many industrial processes) or is complemented with solar energy. Because of the need to supply heat to carry out the compression process, this part of the system (see **Figure 5**) is also called a thermal compressor in opposition to the vapor compression system where a mechanical compressor is used. The absorption system is nowadays very common in household and camping refrigerators as well as in air-conditioning equipment. The most common fluids for the absorption system are H_2O–LiBr (water as refrigerant and lithium bromide as secondary fluid) and NH_3–H_2O (ammonia as refrigerant and water as secondary fluid). The first pair of fluids is used for positive temperatures in the evaporator (water freezes below 0 °C at ambient pressure) while the second one can also be used for negative temperatures. In spite of a fast increase in use, absorption systems are still more expensive than the classic vapor compression systems and are also larger.

Figure 5 Compression in the absorption system.

Other types of refrigeration systems are available, some already commercially, and some at the development stage. They can either be operated electrically (like the vapor compression system) or thermally (like the absorption system). An example of electrically operated systems is the one using thermoelectric coolers, where direct current is used to produce a cooling effect. There are more examples of thermally operated systems, namely, adsorption, desiccant, or ejector systems.

The combination of solar energy with refrigeration/cooling equipment is a way of reducing energy consumption and harmful emissions to the environment. Solar thermal collectors can be used with thermally operated cooling equipment, and solar photovoltaic (PV) collectors can be used with electrically operated cooling equipment. Solar cooling systems are interesting, due to the fact that cooling demands in summer are associated with high solar energy availability, which allows operation with maximum collector efficiencies.

Refrigerants

The first refrigerants used in vapor compression systems were inorganic or natural, and some are still widely used, namely NH_3 and H_2O.

However, new refrigerants were produced synthetically from methane (CH_4) and ethane (C_2H_6) being divided into two groups, depending on whether or not chlorine is in the molecular structure. In the first group there are two different kinds of refrigerants: the chlorofluorocarbons (CFCs), namely R-11, R-12, R-113, R-114, R-115, R-500, and R-502, and the hydrochlorofluorocarbons (HCFCs), namely R-22, R-123, R-141b, and R-142b. The second group is hydrofluorocarbons (HFCs), and some refrigerants belonging to this group are R-32, R-134a, R-143a, and R-152a.

Due to the ozone depletion potential (ODP) of CFCs and HCFCs, it was established in 1987 at the Montreal Protocol that the production and use of these refrigerants

[d] Threshold limit value (TLV) for exposure of 8 h day^{-1}, 40 h $week^{-1}$, without any adverse effect.

[e] At 100 °C.

should cease gradually. This leaves room for HFCs, the most common one nowadays being R-134a, and to inorganic fluids – air and CO_2 besides those already mentioned. Another problem regarding refrigerants is its global warming potential (GWP), related to the greenhouse effect. In spite of the null ODP of HFCs, they may have a significant GWP, which makes the choice of the refrigerant to be used not easy when taking into account the two parameters simultaneously.

Besides adequate thermodynamic and physical properties, each refrigerant must also have good chemical characteristics. From the safety point of view, these are its flammability and toxicity. Regarding flammability, ammonia is flammable as well as propane and butane, whereas the others are considered as nonflammable. All refrigerants are considered toxic in a small degree, except ammonia, which can be lethal above low concentrations in air.

Table 1 provides a comparison between some characteristics of the most common synthetic and natural refrigerants.

Introduction

Compressed air is a utility that consumes an important share of the energy consumption in industry. Great attention must be paid to the production of this form of energy for it is one of the most expensive. The following are some compressed air applications: driving power for some types of equipment, conveying materials such as chemicals, ventilation of buildings, supplying combustion air for boilers, as a power source for air-operated valves and shutters, and as a medium to transmit signals as in instrumentation.

Air compressors operate on a source of energy (normally electrical energy but other kinds are possible, e.g., internal combustion engines and vapor or gas turbines). Compressors take in air at atmospheric pressure (101 325 N m^{-2} (~100 kPa)) and produce compressed air at a desired pressure. This air is then sent to an air receiver and distributed *via* a piping system to the final points of use.

There are a great variety of compressors and selection depends on the pressure and volumetric flow rate of the compressed air, among other factors.

General Classification of Air Compressors

The general classification of compressors, showing their most important characteristics and applications is summarized in **Table 1**.

Air compressors are normally grouped into two classes: positive displacement and dynamic.

Positive-Displacement Compressors

These compressors operate intermittently, subjecting the air to non-flow processes. An important limitation is that they can handle a small flow rate compared to the dynamic compressors that operate continuously.

The flow proceeds in the same direction as the pressure gradient since these machines have parts that ensure positive admission and delivery of air, preventing undesired reflux.

In this group, a distinction is made between reciprocating and rotating compressors, depending on the motion of the solid boundary.

Reciprocating compressors

A crankshaft is used to transfer the power, e.g., from an electric motor to the compressor (**Figure 1**). A connecting rod joins the crankshaft to the piston, which moves back and forth in the cylinder, with a velocity of between 2 and 4 m s^{-1} at normal crankshaft-rotating velocities. The power received by the air is due to hydrostatic pressure forces acting on a piston during the compression stroke (valves 5a and 5b closed, and the piston moves toward the cylinder head). Consequently, the volume of air decreases and its pressure increases.

Regarding the pressure ratio (Pr, delivery air pressure/admission air pressure), for low values, single-stage compression is sufficient: compression takes place in one or more cylinders of identical size. Multistage (two or more stages) are used when a higher pressure ratio is needed: the air is first compressed in a large low-pressure cylinder, then flows to an intercooler (normally a finned tube), where the air temperature drops, before proceeding next to a small high-pressure cylinder where the final pressure is reached. This arrangement consumes over 15% less power than the single-stage type when producing air at the same volume and pressure.

Rotary Compressors

It is worth noting that rotary compressors are also positive-displacement machines because the fluid is prevented from flowing back in the direction of the pressure gradient by solid boundaries. They have lobes (Roots blowers), vanes or screws to reduce the air volume and increase its pressure (**Figure 2**). Other geometrical configurations exist on the market but, because of their less frequent use in compressed air applications, they are not discussed. The following is a brief reference to these compressors.

Table 1 General classification of compressors

Type		*Pressure ratio, Pr*[a]	*Free air delivery, $\dot{V}_1$ ($m^3\,min^{-1}$)*	*Some applications*

[a] =(delivery air pressure)/(admission air pressure).

[b] It is the only technical solution for high pressure ratios.

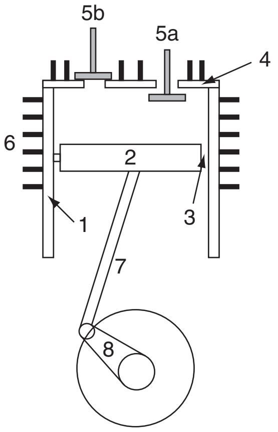

Figure 1 Schematic representation of a reciprocating air compressor: 1, cylinder; 2, piston; 3, piston ring; 4, cylinder head; 5a, admission value; 5b, discharge valve; 6, fins; 7, connecting rod; 8, crankshaft.

Lobe-type compressor (Roots blower)

The Roots blower is one of the simplest and best-known of the rotary compressors. It does not have valves. A gearing system synchronizes the movement of two symmetric rotors, which rotate in opposite directions in the form of a figure 8. Lubrication is not needed because they do not contact each other. This action forces the air to contact the compressed air that exists in the piping system, where oil-free compressed air is produced. Air is the cooling medium.

Compared to the reciprocating compressor, the power required is greater and it has a lower efficiency. For this reason, it is used when low pressure ratios are required, e.g., up to 3 in pneumatic transport, vacuum pumps and volumetric flow rate meters.

Vane-type compressors

The vane compressor action differs slightly from that of the Roots blower. These compressors are said to have internal compression because of the reduction in volume in the initial phase of the compression process (a feature which is absent from the Roots blower).

They have only one rotor, the axis of which is parallel to the stator's axis and is eccentric to it. The eccentric feature is the essence of the principle of operation. Pressure ratios of up to 10 are common. They do not have valves. The cooling medium can be air or water.

Screw-type compressors

These consist of two rotors that move in opposite directions. The rotors have an asymmetric design (made by computer-aided design and manufacture) that makes possible a lower energy consumption, a better gap reduction between rotors and less friction. Practically constant compressed air flow rates are produced.

They can be lubricated or oil-free. When lubricated, the oil and air mix together, so this mixture is compressed and three functions are simultaneously fulfilled: sealing, lubricating and cooling. In the case of oil-free compressors, there is no metallic contact between rotors so a gearing system is used to synchronize the rotor movements.

Dynamic Compressors

Dynamic compressors, or nonpositive displacement compressors, operate continuously, subjecting the air to steady flow processes. An important advantage is that they can handle large flow rates efficiently, as long as

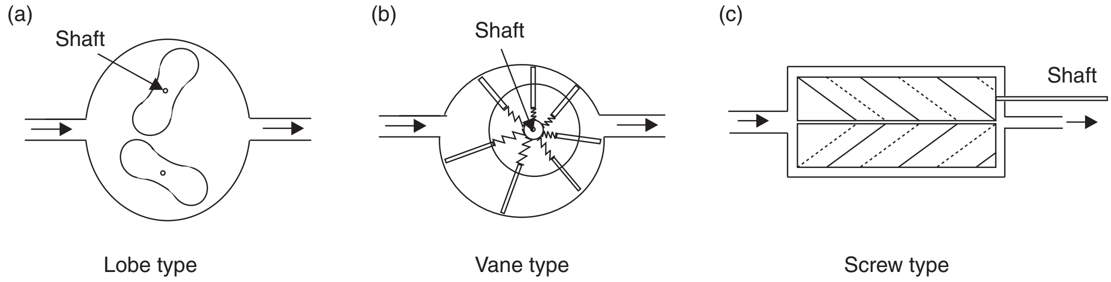

Figure 2 Schematic representation of some rotary compressors: (A) lobe type, (B) vane type and (C) screw type.

the pressure ratio is kept small in comparison to that of alternating and rotary compressors.

These machines have no means of preventing backflow. At a given compressor speed, only a limited range in air flow rate is possible: if it is reduced beyond a certain value, it is impossible to maintain the desired air velocity profile.

In this group, distinction is made between axial and radial compressors, depending on the direction of the air flow.

Radial compressors (centrifugal)

An external source applies an input torque that drives the rotors, which are constructed with recent technology in order to withstand high velocities between 20 000 and 30 000 rpm, accelerating the air in the radial direction (**Figure 3**): the work transfer is due to a change in momentum of the air stream. It then flows into the diffuser and volute casing, suffering a decrease in velocity and an increase in pressure. The combination of the inlet nozzle, impeller, diffuser and volute is called a ‘stage’. Pressure ratios of 4–6 are common. For greater pressure ratios, additional stages are needed.

They are adequate for the production of oil-free compressed air and have been used extensively, both in small sizes as superchargers and in large sizes as compressors for gas turbine plants.

Axial Compressors

In these compressors, the acceleration of the air takes place in the axial direction (parallel to the shaft) (**Figure 3**). Each stage consists of a pair of stationary and moving blade rows (like a turbine): the rotating blades, with velocities in the range 10 000–30 000 rpm, increase the pressure and the stator blades act as a diffuser by converting the air velocity into air pressure. Pressure ratios of 10 or more can be obtained.

Normally, high flow rates are produced (the minimum flow rate is approximately 900 $m^3\ min^{-1}$), making them a good choice for power-plant and aircraft gas turbines, as well as for the conveying of natural gas in pipelines.

Ideal versus Real Reciprocating Cycles

The reciprocating compressor is the most common type used in air compression, followed by the screw compressor. Since both are of the positive-displacement type, the basic theory of reciprocating compressors is also applicable to screw compressors.

The ideal reciprocating compressor cycle is an open cycle that consists of the following evolutions, shown on the *P–V* diagram in **Figure 4** (*P* being pressure and *V* being volume):

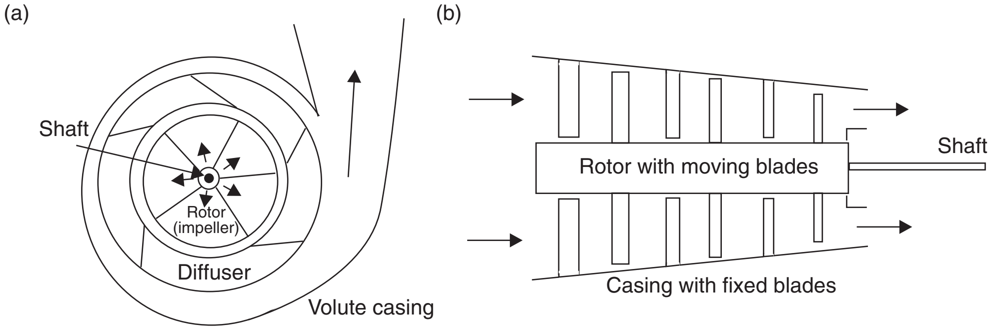

Figure 3 Schematic representation of dynamic compressors: (A) radial type and (B) axial type.

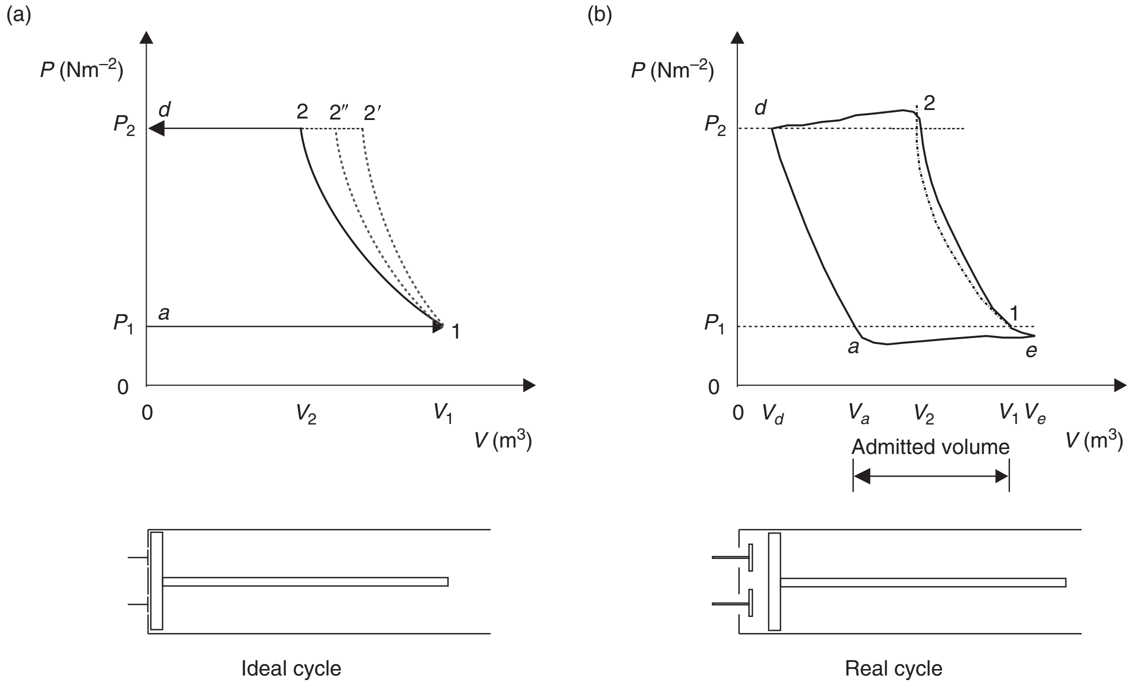

Figure 4 Ideal and real reciprocating compressor cycles: (A) ideal cycle and (B) real cycle.

1. The admission valve opens at a pressure level P_1 and admission of atmospheric air at P_1 and temperature T_1 takes place (state 1). The volume inside the piston cylinder arrangement varies from 0 to V_1.
2. The admission valve closes and the entrapped air suffers a frictionless isothermal compression between state 1 and state 2 (at P_2, T_1). The air volume is reduced from V_1 to V_2.
3. The discharge valve opens when the pressure level is P_2, and the air is discharged to the piping system at state 2. The volume inside the piston cylinder arrangement varies from V_2 to 0.

The work transfer (W) during each step of the cycle is given by $W = -\int PdV$. In terms of the P–V diagram, this is equivalent to the area underneath each evolution, namely:

Admission work performed by the incoming air on the piston: $W_{a\text{–}1} = -P_1V_1$ (area a, 1, V_1, 0, a).
Compression work performed by the piston on the air: $W_{1\text{–}2}$.
Writing the ideal gas equation in terms of P ($P = mRT/V$) gives:

$$W_{1-2} = -\int_{V_1}^{V_2} \frac{mRT_1}{V} dV = -mRT_1 \int_{V_1}^{V_2} \frac{dV}{V} P_1V_1\ln(\mathrm{Pr}) \quad (1)$$

(area 1, 2, V_2, V_1, 1); discharge work performed by the piston on the air: $W_{2\text{–d}} = P_2V_2$ (area 2, d, 0, V_2, 2).

The total ideal cycle work (W_i) is given by:

$$W_1 = -P_1V_1 + P_1V_1\ln(Pr) + P_2V_2 = P_1V_1\ln(Pr) \quad (2)$$

since $P_1V_1 = P_2V_2$.

It can be seen that W_i is equal to the compression evolution work, W_{1-2}. Ideally, this is the minimum work required to increase the pressure from P_1 to P_2.

The ideal power is obtained by dividing W_i by time:

$$W_1 = P_1V_1\ln(Pr) \quad (3)$$

The real compressor cycle is also shown in **Figure 4**. It deviates from the ideal cycle due to a number of differences that cause the flow rate to be smaller and the work/power absorbed by the compressor to be greater, i.e., the compression evolution is not isothermal, there is a clearance volume, there is a pressure drop in the admission and discharge valves, the air temperature increases during the admission stroke, and there are flow rate losses. These causes are analyzed briefly below.

Compression Evolution

If an adiabatic compression is considered (no heat transfer to the surroundings), the compression evolution is characterized by $PV^k = \text{const}$, with $k = 1.4$. Following the same procedure as in the ideal case to calculate the work, the compression work is:

$$W_{1-2} = \frac{P_2V'_2 - P_1V_1}{K-1} \quad (4)$$

and the cycle work, W_a, is given by:

$$W_a = kW_{1-2'} = k\frac{P_2V'_2 - P_1V_1}{K-1} \tag{5}$$

This work is equal to the area *a*, 1, 2′, *d*, *a* (see **Figure 4**). Since this area is greater than that corresponding to the ideal cycle work, $W_a > W_\mathrm{i}$.

In practice, the compression evolution can be considered polytropic, $PV^k = \mathrm{const}$, where normally $k = 1.3$ for low-speed compressors with good refrigeration, and $k = 1.35$ for high-speed compressors.

Clearance Volume

Not all the air is evacuated from the compressor at the end of the delivery stroke: some remains in the clearance volume, $V_d \neq 0$ in **Figure 4**. The air at pressure P_2 enclosed in this space therefore expands from *d* to *a* (**Figure 4**) until it reaches the pressure P_1 when admission commences. At this pressure, it occupies the volume V_a so there is a decrease in aspirated volume represented by $V_a - V_d$.

The clearance volume results in a lower flow rate, and also the work is decreased almost proportionally to the flow rate. This influence is more pronounced for higher pressure ratios; V_a tends to be greater.

This parameter is given as a percentage of the piston displacement (the volume displaced by the piston between the head end and the crank end).

Pressure Drop in the Admission and Discharge Valves

Before the discharge stroke begins, the air pressure must be greater than P_2, allowing the opening of the discharge valve and overcoming the pressure losses due to the flow from the cylinder through the discharge orifice into the piping system. As a consequence, the work increases and the air temperate rises because of its increased pressure.

During the admission stroke, the work increases and the air temperature rises: the air passes isothermally through the admission valve and the pressure depletion that occurs is always greater than that at the end of this stroke. Consequently, the flow rate decreases, causing a decrease in efficiency.

Air Temperature Rises during the Admission Stroke

During compressor operation, the temperature of the cylinder wall will be greater than that of the incoming air. This results in heat transfer to the air and, consequently, a temperature rise, in addition to that caused by pressure changes.

As the flow rate is measured at the inlet, this temperature increase has an important effect on the compressor efficiency and may justify the differences encountered according to their refrigeration modes.

Flow Rate Losses

The effect of these losses on the cycle work is negligible. However, its influence on efficiency must not be ignored because the effective flow rate decreases and the work is fairly constant.

Compressor Efficiency Calculations

The above differences between the real and the theoretical cycles result in a decrease in flow rate and in efficiency.

The volumetric efficiency (η_v) accounts for the decrease in flow rate. It is given by the ratio between the free air delivery ($\dot{V}_1$, the real volumetric air flow rate produced by the compressor measured at the inlet pressure and temperature) and the piston displacement per unit of time (**Figure 4**):

$$\eta_v = \frac{\dot{V}_1}{\dot{V}_e \dot{V}_d} = \Omega\left\{1 - \frac{V_d}{V_e - V_d}\left[\mathrm{Pr}^{1/k} - 1\right]\right\} \tag{6}$$

where Ω depends on Pr, the pressure losses at the valves and on the cooling medium (η_v water-cooled>η_v air-cooled).

An example of the dependency of the volumetric efficiency on clearance volume and pressure ratio is shown in **Figure 5**. It can be understood based on **Figure 4** that, for

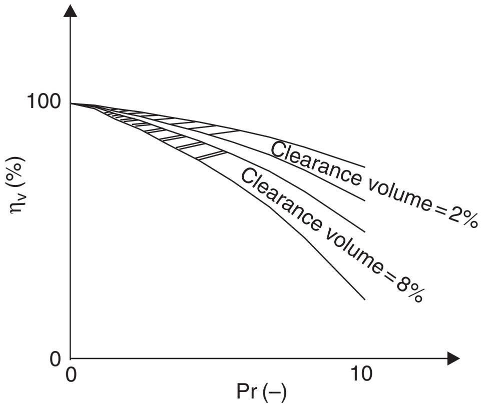

Figure 5 Volumetric efficiency versus pressure ratio with clearance volume as parameter.

a given clearance volume (V_d), as Pr rises ($P>P_2$), it causes the entrapped air to expand to a greater volume ($V>V_a$), reducing the admitted volume and therefore η_v; on the other hand, for a given Pr (e.g. P_2/P_1), if the clearance volume is greater than V_d, the air expands to another volume ($V>V_a$), causing a decrease in η_v.

Normally, η_v ranges between 60% and 90%. The clearance volume causes the greatest decrease of flow rate loss, up to 20% of the piston displacement per time unit.

As mentioned above, another consequence of the differences between the real and theoretical cycles is greater power consumption of the compressor when compared to the ideal power consumption.

The compressor efficiency, also referred to as the isothermal efficiency (η_i), accounts for this effect. It is given by the ratio between the power of a frictionless compressor (with an isothermal evolution) and the shaft power of a real compressor:

$$\eta_{\mathrm{I}} = \frac{\dot{W}_{\mathrm{i}}}{\dot{W}_{\mathrm{r}}} \tag{7}$$

where $\dot{w}_r$ is the shaft power.

This efficiency defines the global compressor efficiency. In order to analyse the compressor operation, one may divide this efficiency into two factors, namely the indicated isothermal efficiency (η_{ii}), and the mechanical efficiency (η_{m}):

$$\eta_{\mathrm{i}} = \eta_{\mathrm{ii}} \ \eta_{\mathrm{m}} = \left(\frac{\text{isothermal power}}{\text{indicated power}}\right) \times \left(\frac{\text{indicated power}}{\text{shaft power}}\right) \tag{8}$$

where η_{ii} is the losses due to cycle imperfections and η_{m} is the friction losses.

Therefore, the ratio $\eta_{\mathrm{i}}/\eta_{\mathrm{m}}$ = (isothermal power/shaft power)×(shaft power/indicated power) shows the power loss due to the fact that the compression evolution deviates from the isothermal evolution.

Another notion of efficiency related to the compressor operation is the polytropic efficiency (η_{p}):

$$\eta_{\mathrm{P}} = \frac{\dot{W}_{\mathrm{P}}}{\dot{W}_{\mathrm{I}}} \tag{9}$$

where $\dot{w}_p$ is the theoretical power of a frictionless compressor undergoing a polytropic evolution such that at the end of the compression the real air temperature is reached.

Relative to the isothermal efficiency, the polytropic efficiency includes the additional work converted to heat the air during compression: $\eta_{\mathrm{p}}-\eta_{\mathrm{i}}$ = losses in percentage of the shaft power.

The referred efficiencies are not the only criteria by which compressors are compared. It must be stated that their characteristics also come into play, namely the relationship between the delivery air pressure, free air delivery and power.

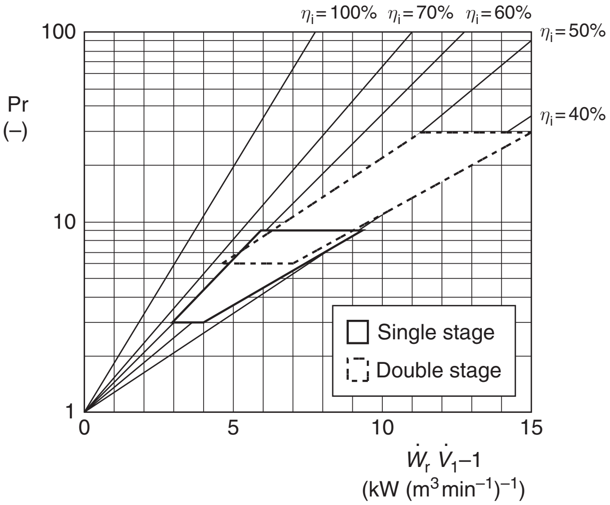

Figure 6 Characteristics of single- and double-stage reciprocating compressors.

It is the operating conditions that establish the delivery air pressure (which must equal the required pressure plus the line pressure losses), the free air delivery (which must equal the required flow rate plus the line flow rate losses), and the power consumption.

The characteristics of reciprocating compressors, Pr versus $W_r/V_I$with η_i as parameter are shown in **Figure 6**. The isoefficiency lines results by combining eqns [3] and [7]:

$$\ln\,(Pr) = \frac{\eta_{\mathrm{I}}}{P_{\mathrm{I}}}\frac{\dot{W}_r}{\dot{V}_{\mathrm{I}}} \tag{10}$$

Two superimposed regions on **Figure 6** show the characteristics of single- and double-stage compressors.

Basic Control Techniques

In general, a flow rate control is necessary because the need for compressed air varies greatly, depending on the number of users connected to the piping system. There are two basic control techniques: motor on/off operation (applied to compressors with shaft power ≤12 kW), and continuous motor operation (shaft power >12 kW).

During the on/off control, the compressor motor operates until the delivery pressure level is reached, turning off at this instant. When the line pressure drops, due to air consumption, below a pre-established value (normally 0.05 MPa below delivery pressure), the compressor turns on again. The maximum number of starts per hour is around 10.

In the continuous motor operation control mode, the motor does not have an intermittent operation, which may cause malfunction considering the powers involved. When the required pressure is reached, the admission valve opens and the discharge valve closes. In this way, the air enters and leaves the compressor without being compressed. The power absorbed is 7–20% of the power needed to produce the normal flow rate.

Treatment of Compressed Air

From the point of view of compressed air production systems, atmospheric air contains undesired constituents or ‘impurities’, mainly water vapour and dust particles. It is essential to treat the resulting compressed air, which may also contain lubricating vapours resulting from compressor operation. The degree of cleaning depends on applications, especially in the dairy and beverage industries.

Several air-intake filters are used before the air enters the compressor:

- viscous filters – as the air passes it impinges on an obstruction that traps the dust
- oil-bath filters – the incoming air agitates the oil in a reservoir, causing the impurities to settle in the bath
- travelling screen filters – air flows through a screen that rotates continuously; the screen is coated with oil to trap the debris, which is then washed out as the screen moves through an oil bath
- dry-type filters – utilizing a medium often made of felt or fibreglass.

It is common to install a silencer integrated with the air inlet filter to reduce the noise level where this is problematic.

Water and lubricant vapours are removed by condensation in cooling systems located at the compressor exit. Purges control the removal of water and oil condensed from the compressed air.

For the majority of applications, compressed air has a dewpoint temperature of 2 °C (below this temperature, water vapour condensation occurs) and the lubricant vapour concentration is $1\,\mathrm{mg\,m^{-3}}$. The concentration of dust particles in air is roughly $5\,\mathrm{mg\,m^{-3}}$, consisting of particles with an average diameter of 5 μm.

Design of Compressed Air Piping Systems

A piping system conveys the compressed air to the consumption points. An advantage of compressed air distribution systems is that no piping system is necessary for the return of the used air because it simply escapes to the atmosphere.

The main distribution system is made of rigid tubes (steel, galvanized iron and plastic are common materials), while flexible tubes join the system to the final users. Dilatation tubes are also used to compensate for temperature differences. Purges must be placed at low-level points (to remove further condensed water and oil), so the slope of the tubes towards these points must be at least 1%.

Large tube diameters favour small pressure drops caused by the air flow. The design of the piping system involves choosing all tube diameters on the basis of the admissible pressure drop through the tubes. However, it is suggested that the air flowing through the longest tube length, from the compressor to the furthest consumption point, should undergo a maximum pressure drop of 0.01 MPa.

Normally, the flow is turbulent and the pressure drop (Δp) is proportional to the square of the air velocity (v), i.e., inversely proportional to the fourth power of the internal tube diameter (D):

$$\Delta p = p\left(f\frac{L}{D}+\sum K\right)\frac{1^2}{2} \tag{11}$$

where ρ is the specific mass given by the ideal gas equation ($=P/(RT)$, $R=287\,\mathrm{J/(kg\,K^{-1})}$), f is the friction factor, L is the tube length, ΣK is the localized pressure drop due to accessories (some authors convert ΣK to L_{eq}, i.e., an equivalent straight pipe length of internal diameter D having the same pressure drop as the accessories) and v is the air velocity (suggested values for v range from $10\,\mathrm{m\,s^{-1}}$ for the main piping system to $20\,\mathrm{m\,s^{-1}}$ for the flexible pipes).

For pressure drop prediction, normally only an order of magnitude is sufficient. A more accurate value requires great calculation effort and it also requires the knowledge of the rugosity (roughness) of the tube’s internal surface and an accurate definition of all the piping system components.

In practice, an abacus is used to determine the pressure drop. The example shown in **Figure 7** was constructed considering smooth pipes, admission air at $P_1=0.1\,\mathrm{MPa}$ and $T_1=293\,\mathrm{K}$ (20 °C). Following the calculus sequence (follow the line with an arrow in **Figure 7**):

- Assume an internal tube diameter D and a delivery pressure P_2.
- For a given free air delivery $\dot{V}_1$, determine the air velocity $v=\dot{V}_1/\pi D^2/4$ and f, from the Colebrook equation:

$$\frac{1}{\sqrt{f}}\rho\left[-2.0\log\left(\frac{\varepsilon/D}{3.7}+\frac{2.51}{\mathrm{Re}\sqrt{f}}\right)\right] \tag{12}$$

where Re is the Reynolds number, $\mathrm{Re}=\rho vD/\mu$, $\mu=1.81\times10^{-5}\,\mathrm{Ns\,m^{-2}}$ (is the dynamic air viscosity at T_1), ε is the tube rugosity ($\varepsilon=0$ (smooth tube)).

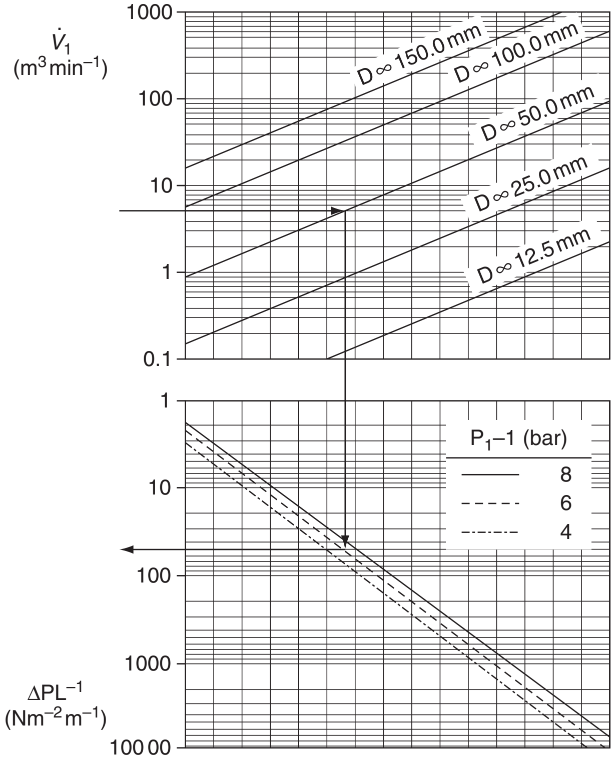

Figure 7 Abacus for determination of the pressure drop in smooth pipes.

- Determine the pressure drop per unit tube length, assuming $\Sigma K = 0$ (no localized pressure drop):

$$\frac{\Delta p}{L} = \rho \frac{f}{D} \frac{1^2}{2} \tag{13}$$

Roughly, one may increase the value of $\Delta P/L$ by 30% to account for the rugosity effect.

The design is confined to determining D since the other variables are known: P_2, the delivery pressure, and $\dot{V}_1$ are imposed by the users of compressed air and the maximum value suggested for $\Delta P/L$ is 0.01 MPa L^{-1}. It must be borne in mind that the equipment consuming compressed air deteriorates with use, so higher pressures and flow rates must be considered, respectively between 0.05 and 0.1 MPa (depending on L) and flow rates between 30% and 40% relative to the operating characteristics when new.

The piping system design is important for it is responsible for energy losses due to pressure drops (caused by the flow) and due to flow rate losses which occur mainly at the tube joints. The latter are the most important (for pipe lengths below 1000 m it may represent 5–10% of the flow rate) so frequent inspection of the piping system is suggested.

To meet the requirements of the piping systems, the choice of the compressor characteristics must be such that it has a small variation in pressure ratio values for a great variation in the flowrate values.

Introduction

A well-designed electricity supply system is fundamental to the operation of all processing plants. It is the electricity supply that provides much of the heat, as well as the power to drive pumps, compressors, refrigeration plant, instrumentation, lighting (both standard and emergency), control systems of all types, and computers and communication systems.

It is important, therefore, that dairy scientists and plant operators have at least some understanding of the component parts of the electricity supply system.

Electricity for Power

Electricity is generated primarily in large power stations which are powered by coal, gas, oil or nuclear plants. These are often sited on a river or close to a sea coast because cooling water is a primary requirement for operation. Renewable sources of energy, such as wind, wave, solar and others, will become increasingly relevant as countries attempt to cap their greenhouse gas emissions and increase sustainability. The electricity, which is generated using synchronous generators, is transformed to a higher voltage using transformers and fed into an interconnected grid system, usually at a high voltage of 400–800 kV. This allows for the bulk transfer of power, which can be tapped into, using a transformer, to supply electricity to a city, perhaps at 200 kV or so, or downward to what is known as distribution level, for supply to factories or processing plant, often at a voltage around 11 kV or perhaps 6 kV, depending upon the concentration and size of the plant. Unless very large motors or heaters are involved, this voltage is further reduced to perhaps 415 V three-phase or 240 V single-phase. The exact voltage is determined by the standards of the country in which the plant is operating. Another factor which can vary between countries is the frequency of the supply, which can be either 50 Hz or 60 Hz. Users should be cautious when ordering equipment or instrumentation that is designed for use in plant in another country.

For larger processing plants, a substation containing primarily transformers, switches and circuit-breakers is a feature of the site, often at the roadside. If there are processes or systems within a plant that could be either commercially sensitive or unsafe if the electricity supply should fail, there might also be a diesel generator or some other standby supply of electricity which can be switched on if there is an emergency loss of power from the supply company.

Another feature of processing plant is the existence of a battery room, often associated with an uninterruptible power supply (UPS), which may be used for emergency lighting systems, protection systems, gas alarms, fire alarms, computer networks, or anything that has to be supplied with continuous power in the event of a supply failure.

The interaction of these primary and standby power supplies is determined by commercial and safety considerations. A factor which is becoming increasingly important, as electricity suppliers are becoming more competitive and sophisticated post-deregulation, is making use of, for example, standby generators at times when tariffs are very high due to high peak demand, in order to avoid exceeding agreed maximum demand levels.

Energy Management and Usage

All energy management is a compromise. Energy costs can be saved by use of insulation to prevent heat loss or by the reprocessing of low-grade heat to higher-grade heat. The level of insulation or recovery depends very much on the size of the plant and also on the operating temperatures of hot liquids and the refrigeration plant. It is also a function of the system involved and the life expectancy of the plant. The larger the plant, the higher the temperature differences, and the greater the life expectancy the more scope there is for energy management.

An important factor in the usage of electricity is to minimize costs by planning the optimum use of tariffs. This is a subject which gains in complexity with the size of plant because electricity suppliers, in order to reduce their installation and running costs, financially discourage the consumption of power during times of peak demand. It is therefore advisable to carry out periodic energy audits to see whether cost savings can be made by replanning production or by segmentation of plant so that only essential loads are attached during times of peak demand. For smaller systems, the tariffs tend to fall into four categories, depending on location. These are: (1) a flat rate service fee, (2) a fee for electrical usage measured in kW h, (3) a charge (or credit) for running with a power factor outside an agreed limit and (4) peak demand charges.

Apart from the power factor charge, these are largely self-explanatory.

Loads that are connected in a plant and draw a current which is not in phase with the applied voltage are said to have a poor power factor. This will happen where there is a large induction machine load on the system or when power converters are used to convert three-phase AC into DC for whatever purpose. This poor power factor obliges the supply company to install extra generating capacity and burn extra fuel.

The inductive loads can be balanced at plant level by installing power factor-correction capacitors that will pull the wave shape of the current into phase with the voltage. Depending upon the expected lifetime of the plant and the extent of the inductive load, power factor correction often turns out to be a good investment.

Another factor which sometimes has to be taken into consideration is the effect that installed plant can have on the power quality. If large numbers of AC-to-DC power converters are used, they may distort the incoming supply. If the supply is distorted beyond a certain level (known as the harmonic content) at the point of common coupling with other users, it may be necessary to fit tuned harmonic filters. These will remove the offending distortion close to the source.

Distribution and Safety Issues

The power distributed within a plant is fed from the incoming substation or switching room, primarily using cables. These are normally installed in ducts, using wall- or floor-mounted cable trays, or in the wall, floor or ceiling in spaces created during construction.

In designing the electrical supply to a plant, safety is paramount. Safety considerations fall into three categories: (1) the prevention of personal accidents due to electric shock or contact with rotating machinery, (2) the prevention of damage to plant and the process and (3) the prevention of fire.

The safety of personnel is catered for at several levels. All electrical connections should be covered or positioned inside enclosures to which entry is forbidden except with a permit. All rotating machinery should be fitted with a guard so that it cannot be touched inadvertently and it is impossible to fall onto rotating shafts. Shock prevention at low voltage is enhanced by the use of ‘residual current’ or ‘earth-leakage circuit-breakers’. These trip at very low levels of fault current imbalance and were a major advance when first introduced. Older plant should be retrofitted with such devices during plant maintenance.

Damage to plant and the prevention of electrically induced fires are prevented by using circuit-breakers and fuses. These either trip or blow if excess current is generated by a fault in a piece of equipment or if, for example, a cable is inadvertently cut by maintenance personnel or a vehicle within the plant. These will isolate the electrical supply until the fault is corrected.

Electric Motors

The problem of selecting the most suitable type of motor was at one time a significant factor in the design of new plant. Recent events have, however, simplified the choice.

In the past, processing plant tended to have a mixture of different types of motors, e.g. the DC motor was used widely where a variable shaft speed was required and induction (or asynchronous motors) were used where a fixed speed of operation was deemed necessary.

With the development of larger-powered, pulse width modulated (PWM) converters, the induction motor can now be used to power most variable frequency applications as well. The PWM drive, as the combination is known, is widely used for all applications from a small part of a kilowatt (low horsepower) up to the megawatt region.

Previously, the choice of motor type, which was based on the detail of the starting torque and speed range required, was a matter of much debate. The various grades of motors are based on the National Electrical Manufacturers Association (NEMA) classification A to F, from which different ratios of maximum torque compared to rated torque can be selected. Increasingly, the Class B general-purpose motor is used for all directly connected and variable-speed applications, making selection easier. In the author’s opinion, variable-speed drives should not be bought as a separate converter and motor because this can lead to coordination problems.

There is an exception to this new simplification of the selection process: such motors should not be used in conditions where there is a potential danger of explosions, e.g. in an environment where there are dust particles in the air or where distillation products are escaping into the air. Under these conditions, it may be desirable to purchase totally enclosed motors of the type developed for mining and offshore oil-platform applications. These can also be found in the NEMA standards.

Dairy Plant Effluents

G Wildbrett, Technical University of Munich, Weihenstephan, Germany

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Dairies are considered as a 'wet industry' since they consume much water. Water is used for very different purposes (**Table 1**). Therefore, dairies discharge large volumes of wastewater. Recent mean values vary between 0.5 and 2.0 m^3 wastewater per 1 Mg (tonne) treated milk. However, there are large differences according to different production lines:

milk and desserts: 1.0–12.9 $m^3\,Mg^{-1}$ final product;
cheese: 0.5–6.0 $m^3\,Mg^{-1}$ final product; and
milk powder: 0.9–10.0 $m^3\,Mg^{-1}$ final product.

Among other things, variations depend on the equipment and its maintenance, the working method, and the environmental engagement of the management in the dairy, but there is no influence of the amount of milk processed. The figures given include the volumes of cooling water.

As it is common for the food industry, pollution of the wastewater is the most important contribution to the pollution of the environment from dairies in both quality and quantity; contamination by solid waste and waste gas is less serious.

The pollution of wastewater must be considered under the following aspects:

- kind and quantity;
- ecological evaluation; and
- means for reduction.

Analytical Indices for Wastewater Pollution

Dairy effluent mainly contains milk components: organic substances are dissolved or suspended in the wastewater; their quantity is determined analytically using summary parameters. Adsorbable organic halogen (AOX) represents an unspecific value for a group of substances similar in chemical composition (**Table 2**).

Important values for quantification of the organic load of dairy effluent are the biochemical oxygen demand (BOD_5) and the chemical oxygen demand (COD). The quotient COD/BOD_5 indicates the biodegradability of the organic material under aerobic conditions. When the ratio is close to 1, the biodegradability is said to be good. The natural organic constituents of milk are very biodegradable but the aerobic degradation of milk fat requires much oxygen – for instance, the COD of skim milk is about 90 000 $mg\,l^{-1}$ but for cream (30% fat) it is 400 000 $mg\,l^{-1}$. Besides milk fat, the wastewater may contain other lipophilic substances, for example, mineral oils or grease, that are less biodegradable. Due to a relatively high protein content in dairy wastewaters, the nitrogen content is often used as a pollution index.

When comparing effluent loads from different dairies, the indices referred to are expressed in volumetric percent, as shown in **Table 2**. Thus, if a dairy discharges cooling water together with polluted wastewater, the indices will decrease. Therefore, low pollution indices do not conclusively indicate diligent working practice. For this purpose, the complete size of contamination must be considered, that is, the concentration of pollutants and the total volume of wastewater.

Other pollutants come from the regular hygienic operations; detergents represent the biggest portion of chemicals used in dairies. In some cases, NaOH or an acid alone is used, but mixtures of several chemical substances are advantageous to obtain really clean surfaces; **Table 3** lists the most important components of dairy detergents.

Besides, many cleaning solutions also contain residues of dairy products or other kinds of soil (**Table 1**) that have been displaced in the cleaning process. Often, the product residues are altered by the cleaning solution: proteins may be partially hydrolyzed by alkalies or enzymes or may be coagulated in acid solutions. Fats may be emulsified and in strong hot alkalies even soaps may be formed. Soaking alkalies from bottle-washing machines contain dissolved starch or protein glues from removed paper labels.

In contrast to most cleaning solutions, disinfecting solutions can be used only once, and then they must be discharged. Commonly, they contain only very small amounts of soil but always a surplus of the active disinfectant and of potential reaction products also, for instance halogenics and AOX.

Conditioning of boiler feed water demands some chemicals, that is, complexing agents to sequester the residual hardness of the pretreated water and to give an alkaline pH. Other additives, for instance starch, tannins, or synthetic polymers like polyacrylate or polystyrene derivatives, serve to improve the blowdown of the sludge from the boiler into the wastewater. Furthermore, sodium sulfate may appear in the effluent formed from sodium

Table 1 Consumption of water in dairies in view of effluent generation

Area of use	*Application*	*Examples*	*Main effluent pollutants*
Production	Manufacture	Washing of butter or cheese curd	Product streams like buttermilk or whey
		Electrodialysis of whey	Mineral salts
Hygienic operations	Prerinsing	Removal of product residues from equipment after use	Portions of raw materials or products
	Solvent	Solutions of detergents or disinfectants	Portions of raw materials or products, constituents of detergents and disinfectants
	Rinsing	Rinsing off residues of cleaning and disinfecting solutions	Constituents of detergents and disinfectants
Others	Solvent	Regeneration of plants for water conditioning	Ions of chloride, alkali earth metals, or hydrogen
	Cleaning	Washing the outside of transporters	Soil, mineral oil, any detergent used
	Rinsing	Rinsing of sludge from boilers	Alkali earth metals, organic dispersing agents

Table 2 Most important pollution indices for wastewater

Index	*Brief definition*	*Unit*	*Standard methods*
BOD_5	Biochemical oxygen demand; quantity of oxygen used for aerobic biodegradation of organic matter in the sewage during 5 days	mg O_2 l^{-1}	ISO 6060 (1989)
COD	Chemical oxygen demand; quantity of oxygen needed for the chemical oxidation of organic matter in the sewage by potassium dichromate	mg O_2 l^{-1}	ISO 6060 (1989)
TKN	Total Kjeldahl nitrogen; mass of bound nitrogen in the sewage, determined by the Kjeldahl method	mg N l^{-1}	ISO 5663 (1984)
AOX	Mass of adsorbable organic halogen compounds in the sewage	mg Cl l^{-1}	ISO 95625 (2005)
SS	Volume of sedimentable matter in the sewage	ml l^{-1}	ISO 11926 (1997)

Table 3 Common components of detergents and disinfectants for dairies

Range of application	*Kind of components*	*Substances*
Cleaning	Alkalies	Sodium hydroxide
		Sodium carbonate
		Sodium silicates
		Trisodium phosphate
	Acids	Nitric acid
		Phosphoric acid
		Sulfamic acid
		Gluconic acid
	Complexing agents	Phosphonates
		Nitrilotriacetate
		Ethylenediaminetetraacetate
	Surfactants	Linear alkylsulfonates (anionic)
		Alcohol sulfates (anionic)
		Alcohol ethoxylates (nonionic)
	Enzymes	Proteases[a]
Disinfection	Halogens	Iodophores
		Sodium hypochlorite
		Sodium trichloroisocyanurate
		Chloramine T
	Surfactants	Quaternary ammonium compounds (cationic)
	Peroxy compounds	Hydrogen peroxide
		Peracetic acid

[a] Technical grade, especially for cleaning of membranes.

sulfite, which is added to the boiler feed water in order to bind the residual oxygen in the pretreated water.

Quantities of Pollutants

Product Losses

First of all, product losses into the wastewater and discharged whey cause the organic load of dairy effluent and thus the BOD_5 as well as the COD.

Compared with other food industries, for example, starch or meat factories, a specific BOD_5 not higher than 4.0 kg O_2 per Mg processed milk indicates a relatively low organic loading of the wastewater. But the BOD_5 of dairy sewage markedly exceeds the average for domestic wastewater (300 mg $O_2\,l^{-1}$). In contrast, the dairy wastewater contains a very low quantity of sedimentable substances (**Table 4**); this is only a small fraction of the common content in domestic sewage.

Different equipment and production methods strongly influence the degree of pollution by organic matter and explain the varying indices in **Table 4**. Even for a single product, like spray-dried milk, BOD_5 values between 0.152 and 22.4 kg O_2 per Mg final product are reported.

Extremely high organic loads are probable from manufacturing specialities like cacao drinks or processed cheese. As a consequence of their viscosity, they leave more residues on each contact surface, which are discharged into the effluent together with soiled cleaning solutions.

Bottle washing has to remove not only product residues from the bottles but also the labels and glue from the outside. The quantity of glue depends on the gluing technology. The additional organic pollution of the soaking lye may be as high as 1–5 kg glue per 10 000 bottles.

Auxiliary Chemicals

Little is known about the consumption of chemicals for hygienic operations because exact documentation is lacking; only estimated quantities are available, and the data from 1990 are given in **Table 5**. Since dairies tend to reduce the chemical pollution of their wastewater, recycling of soiled alkaline solutions is commonly practiced nowadays. Thus, the consumption of alkaline detergents, NaOH included, should have decreased since 1990.

In the dairy industry, normally alkaline and less frequently acid solutions are used for cleaning. Therefore, wastewater usually contains a surplus of alkali, which must be neutralized to pH 6–9 before it is discharged into the public sewage system. Only in special cases is there a surplus of acid in the sewage. Therefore, more acid than alkali is needed to neutralize the effluent from cleaning operations (**Table 5**).

Figures for the consumption of auxiliary chemicals for purposes other than hygienic care are hardly available. Thus, it is nearly impossible to give any data on their quantity in dairy wastewater. The demineralization of whey by ion exchange demands NaOH and inorganic acids. Increasing degree of demineralization increases

Table 4 Indices for untreated dairy wastewater

	Average value		
		(over the day)	
Index[a]	*Unit*	*Doedens*[1]	*Bertsch/Doedens*[2]
Quantity of polluted effluent	$m^3\,Mg^{-1}$	0.8–2.0	1.0–2.0
BOD_5 load	$kg\,Mg^{-1}$	0.8–2.0	0.8–4.0
Specific BOD_5	$mg\,l^{-1}$	500–2000	500–2000
COD load	$kg\,Mg^{-1}$	-	0.8–4.0
Specific COD	$mg\,l^{-1}$	-	500–4500
COD/BOD_5	-	1.5–2.2	-
TKN	$mg\,l^{-1}$	30–50	30–250
NO_3-N	$mg\,l^{-1}$	20–130	10–100
BOD_5/ total N	-	-	3–14
Total P	$mg\,l^{-1}$	10–100	20–250
Lipophilic substances	$mg\,l^{-1}$	20–250	80–250
SS	$mgl\,l^{-1}$	1.0–2.0	1.0–2.0
pH	-	9–10.5	6–11

the required amounts of these chemicals disproportionately and also the chemical load of the sewage.

The quantity of chemicals needed for water conditioning depends primarily on the hardness of the available water and on the applied process; generally, demineralization needs more chemicals than softening would require.

Environmental Evaluation

General Remarks

Dairy effluent often blends with sewage from other industries or from households. This complicates the evaluation of the sewage pollution from dairies. Compared with the effects of product components in dairy wastewater, it is much more difficult to estimate the risks from auxiliary chemicals used. Ecological evaluation has to be based on the knowledge of the concentration of a chemical substance that is expected in the effluent or river. Moreover, fundamental knowledge of the resulting damaging potential is necessary for each applied substance. However, for cleaning and disinfection, dairies often apply mixtures of several chemical agents for increased effectiveness and not a single substance. This complicates environmental evaluation further, because the single components of such a mixture act very differently and may even develop antagonistic or synergistic effects in an aquatic system. The user cannot have the necessary knowledge. Therefore, only the manufacturer is responsible for the selection of suitable components for detergents and/or disinfectants. He has to combine sufficient effectiveness with environmental compatibility in his products as far as possible. But it is the responsibility of the user to apply detergents and disinfectants carefully and to follow the advice of the producer.

All these facts explain that the ecological importance of only single chemical substances and not ready-to-use products can be discussed here.

Product Residues

If untreated dairy effluent is discharged directly into rivers or lakes, the oxygen consumption by aerobic degradation of product residues would disturb the aquatic ecosystem considerably. Besides, such water is unsuitable for the production of potable water. The higher the organic load of the sewage, the more expensive the treatment in the sewage plant will be and the more sludge that will be produced. Milk proteins contribute to the phosphorus and nitrogen load of the effluent (**Table 4**) as well as solutions of detergents and some disinfectants (**Table 3**). Both elements support an unwanted growth of algae in lakes and slowly running waters. For the Federal Republic of Germany, an estimation of phosphorus and nitrogen content of dairy effluents has shown that the mass of nitrogen from product residues and losses and that from chemicals used for hygienic operations are nearly equivalent. But the main sources for phosphorus are detergents. It is possible to eliminate both elements and thus to prevent eutrophic effects (*see* **Utilities and Effluent Treatment**: Design and Operation of Dairy Effluent Treatment Plants). Nowadays, more and more effluent plants are equipped with these additional stages.

Auxiliary Chemicals

High hygienic standards make the application of chemicals for cleaning and disinfection inevitable. The chemical components in these products show very different effects in sewage, rivers, and lakes.

Alkalies and acids strongly change the pH of the wastewater and increase the salt load of running waters, because they pass through the sewage plant unchanged. About one-third of the phosphorus in untreated sewage is used by microorganisms in the biological stage of the effluent plant. The remaining phosphorus, similar to nitrogen, supports the growth of algae, especially in lakes. But nitrogen is not normally as critical as phosphorus because the latter is mostly the limiting factor for the development of algae.

Surface-active agents tend to form a foam on the surface of water and thus impede the uptake of oxygen into water or activated sludge systems. As a consequence of a low oxygen concentration in the water, fish may die. Besides, several surfactants or metabolites from these may impede the reproduction of fish by damaging sperm, eggs, or spawn. Other aquatic animals, like daphnia, are inhibited, too. Therefore, surfactants must be biodegradable. This does not mean total demineralization but at least loss of their surface activity by biodegradation in the effluent plant.

Special attention must be paid to disinfectants, because generally discharged solutions still contain a considerable portion of the active microbicidal agent. However, they are inactivated by the organic load in dairy wastewater. Only traces of reactive disinfectants may reach the treatment plant and do not inhibit the biodegradation of organic material. But exceptionally high concentrations of a disinfectant as a consequence of an accident or inattentive handling can markedly inhibit biodegradation processes. A more important problem results from the reaction of active chlorine with organic material in the sewage to form undesired AOX. They are persistent, accumulate in the food chain, and are more or less toxic. If there are organic substances with a free amino group, active chlorine in the wastewater may form chloramines, which still have a limited bactericidal effect.

Complexing agents can sequester metal ions and some of these compounds can also mobilize undissolved heavy metals from sludge or sediments in rivers or lakes. Especially in the case of ethylenediaminetetraacetate (EDTA), this effect seems dangerous, because it is scarcely biodegradable in contrast to nitrilotriacetate. EDTA passes through the effluent plant unchanged. Therefore, low concentrations of EDTA have been detected in rivers; possible metabolites are aquatoxic. Complexing phosphonates that have substituted for polyphosphates show a 'threshold effect': This means that very low quantities are sufficient to sequester alkaline earth ions in hard water; thus, the danger of eutrophication by phosphonates is considerably lower than by phosphates.

In addition to the quantities of alkalies and acids from cleaning operations, chemicals used for the regeneration of ion exchange plants increase the salt concentration in dairy sewages. Further pollution by salt results from brine bath overflow in cheese factories.

Steps Toward a Reduced Effluent Pollution

Each dairy should attempt to minimize effluent pollution; it saves costs for internal and public effluent treatment. Thus, losses of raw material, products, and auxiliary chemicals must be avoided as far as possible. Moreover, the auxiliary chemicals should be used as sparingly as possible. It is the task of management to detect critical points of sewage pollution, to create the technical conditions for reduced pollution, and to consistently motivate the employees to follow the special instructions.

The following general remarks may help to reduce effluent pollution or to reduce water consumption. These hints are examples; each dairy has to identify its own weak points and resolve them.

Equipment:

- Have short routes for flow and transportation of raw materials and products, because it minimizes the adhering residues after use.
- Ensure that all plants are easy to clean. Therefore, avoid blind pipes, which need additional volumes of cleaning and disinfecting solutions.
- Ensure by automatic control of the flow ways that products and fluids for cleaning and disinfection do not contaminate each other.

Production:

- Avoid losses of raw materials, products, additives, and auxiliary chemicals into the wastewater by splashing, leaking valves or pipe connections, or overflowing containers.
- Optimize operations aiming to have a minimum of residues on product-contacting surfaces. For instance, preheating for the production of ultra-high temperature milk reduces the deposits on heat exchange surfaces.
- Try to utilize whey fully.
- Never discharge solid sludge from centrifugal processing or residues from microfiltration by membranes into the wastewater.

Hygienic operations:

- Remove product residues from product-contacting surfaces. For instance, blowing out by filtered compressed air or rinsing with a small volume of water may be useful; rinsing with warmed skimmed milk is advisable for cream residues, because it makes it easier to recover and to utilize the cream rinsed off.
- Avoid needless dilution of chemical solutions by rinse water; it increases the consumption of detergents or disinfectants.
- Use mixed detergents instead of pure chemicals. Suitable additives can markedly improve the efficiency of alkalies and acids in many cases. Subsequently, the chemical pollution of the wastewater by used solutions decreases.
- Regenerate used cleaning solutions by sedimentation, centrifugation, or membrane techniques in order to extend their useful life whenever it promises success.

The sludge may be disposed or utilized for biogas production.

- Disinfect closed systems by heating instead of applying chemicals, if it is safe and the consumption of energy seems acceptable.
- Avoid chemicals that are dangerous for aquatic systems or may disturb wastewater treatment. If there are any doubts, ask the producer or the distributor of the detergent/disinfectant.

Conditioning of water and sewage:

- Reduce the water hardness only as far as necessary for the intended use. Water softening should be done by ion exchange or reverse osmosis. Other physical methods cannot be advised since at present too little is known about their effectiveness.
- Use as much condensate from evaporators as possible in order to reduce water hardness, but do not overlook possible microbiological risks.
- Use condensates also for cleaning purposes. The condensates from the production of evaporated milk or milk powder contain only small amounts of organic substances. Therefore, it is not necessary to discharge them into the general wastewater. Condensates may be used for cleaning of floors in uncritical areas, like offices, or for cleaning of cars and trucks. Following pollution with mineral oil or grease, they must be eliminated before this wastewater may be discharged into the general sewage. Condensate that is not used should be discharged with rainwater.
- Neutralize the surplus of alkalies from cleaning lyes by carbon dioxide or boiler flue gas but not by mineral acids. This reduces inorganic pollution of the wastewater. Further advantages of using boiler flue gas are less exhausted SO_2 and low running costs but it needs special installations.
- Separate the fat from the wastewater. This is normally not necessary for all the wastewater but essential for the part of the sections producing butter or cream. The separation may be done in gravity traps or by flotation. However, the separation will not work in case of emulsified fat.
- The separation of fat, oil, and grease from the wastewater by the dairy itself not only reduces the BOD_5 and COD, but it also prevents deposits in the drain. Moreover, these pollutants can cause severe problems in the biological wastewater treatment process on-site and in public sewage treatment facilities.
- Collect and discharge the normally unpolluted rainwater separately from the common wastewater. It saves money and avoids overflow of the wastewater plant in case of heavy rainfall.
- Further recommendations for minimizing product losses into the wastewater and also for reducing the cost of freshwater production as well as of wastewater treatment are given in the IDF document no. 382 (2003).

Glossary

Biochemical oxygen demand (BOD) It is an important measure of water quality. It is a measure of the amount of oxygen needed (in mg l^{-1}) by bacteria and other microorganisms to fully oxidize the organic matter present in a water sample. It is also called the biological oxygen demand.

Chemical oxygen demand (COD) It is defined as the oxygen equivalent of the organic portion of the sample that is susceptible to oxidation by a strong chemical oxidant. COD does not distinguish between refractory and inert organic matter. COD tests require approximately 3 h.

Five-day biochemical oxygen demand (BOD_5) It is defined as the amount of oxygen required by bacteria to decompose organic matter for a specified time (5 days) under aerobic conditions. The amount of oxygen reported with this method represents only the carbonaceous oxygen demand (CBOD) or the easily decomposed organic matter. BOD_5 is commonly used to measure natural organic pollution. The BOD_5 of drinking water should be less than 1, while that of raw sewage may run to several hundreds. The BOD_5 of dairy waste may run from several hundreds to hundreds of thousands.

Total dissolved solids The weight of solids in solution per unit volume of water, measured by evaporating a known volume of filtered water and weighing the residue.

Total solids The weight of all solids, dissolved or suspended, and organic or inorganic, per unit volume of water, measured by evaporating a known volume of water and weighing the residue.

Total suspended solids The measure of particulate matter suspended in a sample of water or wastewater. After filtering a sample of a known volume, the filter is dried and weighed to determine the residue retained.

Effluent Characteristics

Dairy effluents contain dissolved sugars and proteins, fats, and sometimes the residues of additives used in production. The effluent treatment plant designer is primarily interested in the following characteristics of the effluent: biochemical oxygen demand (BOD), chemical oxygen demand (COD), total suspended solids (TSS), total dissolved solids (TDS), phosphorus (P), nitrogen (N), and pH. **Table 1** shows typical losses from some of the principal activities in a dairy.

The typical characteristics of dairy effluent are given in **Table 2**.

The waste-load equivalents of specific milk constituents are

1 kg milk = 3 kg COD
1 kg lactose = 1.13 kg COD
1 kg protein = 1.36 kg COD

The wastewater may also contain pathogens from contaminated materials, grit or other particulates from truck washing, and paper and other packaging materials.

Discharge Standards

The design of the treatment plant depends on the discharge standards set by the licensing authority. A British Royal Commission in 1912 determined that where a receiving water body could provide a dilution of 8:1, a discharge standard of 20 mg l^{-1} BOD and 30 mg l^{-1} Suspended Solids (SS) was appropriate. However, much higher standards are now frequently required. **Table 3** summarizes the license requirements of a number of dairy facilities in Ireland.

Prevention and Control of Pollution

Given the very high capital and operating costs associated with wastewater treatment, not to mention the cost of water and chemicals and the value of lost product, it makes good sense for producers to initiate and maintain a program of pollution prevention. Prevention practices in the dairy industry include

Table 1 Typical losses in milk processing operations (in kg BOD m^{-3} milk)

	Operation	*Average*	*Range*
1	Milk reception, churn washing, cleaning up	0.26	0.11–0.66
2	Cooling raw milk, storage, washing tanks and pipelines	0.19	0.07–0.31
3	Washing road tankers	0.25	0.10–0.40
4	Separation, storage of skim milk and cream	0.14	0.09–0.24
5	Separation, storage of skim milk and cream plus cream pasteurization	0.66	0.46–1.25
6	Churning and washing butter	0.46	0.25–0.80
7	Evaporating skim milk to low total solids	0.23	0.16–0.30
8	Evaporating skim milk to high total solids and spray-drying	0.74	0.14–1.50
9	Roller drying	0.53	0.25–1.30
10	Pasteurizing milk and storage, bottling milk, bottle washing	0.85	0.49–1.70
11	Clotted cream	1.20	
12	Cheesemaking (hard pressed)	0.89	0.23–2.00
13	Cottage cheese (washed curd)	12.00	
14	Condensing fresh whey (to low total solids)	0.25	
15	Condensing sweetened separated condensed milk	1.40	1.20–1.70
16	Full-cream evaporated milk, with canning	0.75	0.50–1.00

Table 2 Typical characteristics of dairy effluent

BOD	*0.8–2.5 kg tonne^{-1} milk*
COD	1.5 times BOD
TSS	100–1000 mg l^{-1}
TDS	10–100 mg l^{-1}
Phosphorus	10–100 mg l^{-1}
Nitrogen	~6% of BOD level
pH	2–12
Flow	1–2 m^3 tonne^{-1} milk

- reduction of product losses by better production control;
- use of disposable packaging (or bulk dispensing of milk) in lieu of bottles where feasible;
- collection and reuse of waste product (where feasible) in lower-grade products such as animal feeds;
- optimization of water and chemical use; use of high-pressure nozzles; recirculation of cooling waters;
- use of condensates for cleaning;
- energy recovery; and
- avoidance of phosphorus-based cleaning agents.

Unit Processes for the Treatment of Dairy Effluent

The series of unit processes chosen for the treatment of any particular effluent will depend upon the characteristics of the wastewater, the location and space available, the outlets for residual products, and the final effluent quality required.

- Pretreatment and preliminary treatment processes
  - Coarse and fine screening
  - Removal of fats, oils, and grease
  - Grit removal
  - pH control
  - Nutrient balancing
  - Flow and load balancing
- Biological treatment processes
  - Activated sludge process
  - Biological filtration
  - Anaerobic treatment
- Clarification
- Sludge treatment
  - Solid–liquid separation
  - Stabilization

Pretreatment and Preliminary Treatment Processes

Coarse and Fine Screening

Screening is designed to remove suspended particles from the wastewater, in order to protect the remainder of the treatment plant from damage by gross solids and to protect subsequent treatment stages from solids overload. Usually, the screening process is divided into two stages:

- coarse screening – to remove solids of nominal size 20 mm and above; and
- fine screening – to remove solids of nominal size 0.25 mm and above.

Coarse screens can be either static, comprising inclined bars at a spacing of approximately 25 mm, or mechanically raked. In either case, it is important that the velocity of flow through the chamber is maintained at values between 0.3 and 0.8 m s^{-1} to ensure that grit or other

Table 3 Comparison of treated effluent discharge standards

Facility	*BOD mg l^{-1}*	*SS mg l^{-1}*	*P_{tot} mg l^{-1}*	*Ammonia as N mg l^{-1}*	*Nitrate mg l^{-1}*	*N_{tot} mg l^{-1}*	*Temperature °C*	*Flow m^3 day^{-1}*	*Discharge to*

detritus does not settle out and that the intercepted screenings are not dislodged and carried forward.

Fine screens can be installed directly after the coarse screens, except where the wastewater has a high content of fat or grease. Fine screens can be

- static – parabolic wedge-wire screens – sometimes called 'sidehill' screens;
- brushed – where the wastewater is screened through a curved perforated plate, which is brushed intermittently or continuously; a typical rotary brushed fine screen is shown in **Figure 1**; and
- rotating drum screens – where the wastewater is led to the center of the drum and flows via wedge wires to the next stage. This type of screen cannot be used where there are high levels of fat in the wastewater.

Provision should always be made for the high-pressure or steam cleaning of fine screens, particularly where the screens are subjected to fatty wastewaters.

Removal of Fat and Grease

Fat and grease will solidify and float to the surface of the liquid given time, temperate ambient conditions, and a quiescent flow pattern. On small plants it is still not unusual to find static grease traps designed on the basis of flow rate. Typically, a retention period of 30 min or more is provided and the accumulated fat/grease is removed manually. The principal drawback of such systems is the possibility of the accumulated fats being subjected to a higher temperature and becoming emulsified.

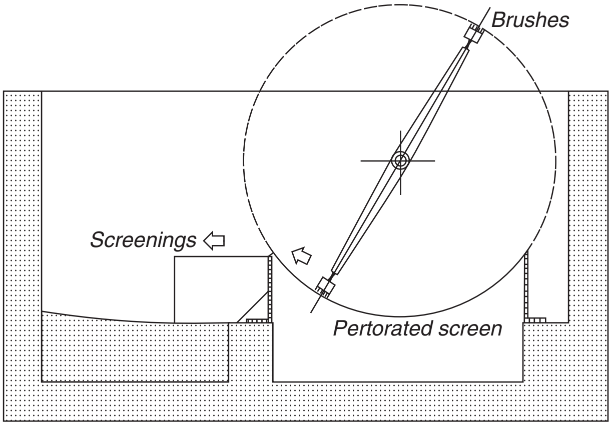

Figure 1 Rotary brushed fine screen.

Recently, however, flotation, particularly dissolved air flotation (DAF), has become the most frequently used process for the removal of fat/grease. In this process, air is dissolved in water under pressure and then the supersaturated air–water mixture is injected into a flotation tank. The process is shown schematically in **Figure 2**. The air comes out of solution in the form of microbubbles, which attach themselves to suspended matter, including fat/grease, which then float to the surface. The floating material forms a scum on the surface of the tank and is removed intermittently by a mechanical skimmer. Typical design parameters for a DAF unit are

- upward flow velocity: up to 7.2 m h^{-1};
- volumetric retention time at maximum inflow: 20–30 min;
- recycle rate: 20–35% of inflow; and
- air/solids ratio: 0.005–0.06 kg air kg^{-1} solids to be removed.

Where the efficiency of the process can be improved by the use of flocculating agents, it has also been found that 50% or more of the COD load can be removed by the DAF process.

Grit Removal

Grit particles, which can include sand, gravel, clay, and other detritus, generally enter the waste stream from the truck and tanker washing area or through the corrosion of concrete or paved surfaces. If allowed to pass through the process, grit could cause serious damage to pumps and other mechanical equipment in addition to combining with sludge to cause pipe obstructions.

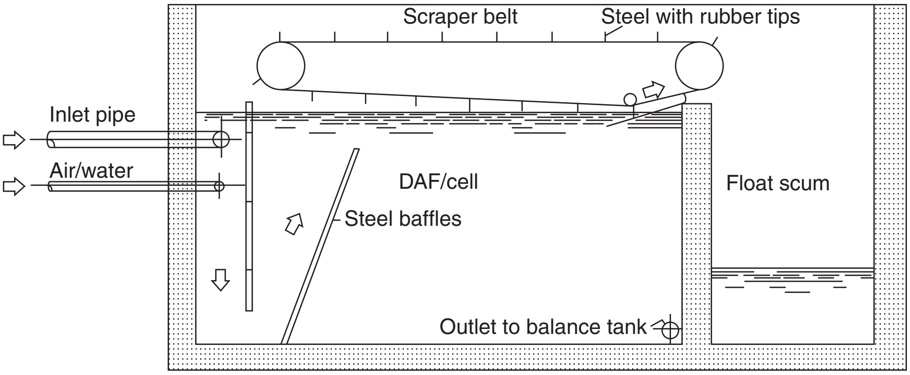

Figure 2 Dissolved air flotation.

Grit will settle readily, provided the velocity of flow is reduced to approximately 0.3 m s^{-1}. It is quite important that the velocity is not permitted to fall below 0.15 m s^{-1}, as this could result in the settlement of organics. Grit settles at about 30 mm s^{-1}, so where the length of the grit channel is 15–20 times the depth, the grit removal efficiency is high.

The maintenance of constant velocity in the grit channels is usually achieved either by the formation of parabolic channels or by using a Sutro Weir. This is a special type of weir that ensures that the velocity of flow is directly proportional to depth.

pH Control

The influence of pH within a treatment plant is both chemical and biological. Control of pH is necessary to ensure that the wastewater does not damage the structures, equipment, or pipework. Most biological processes operate best within the range 6.5–8.5; however, it has been found that process efficiency can be maintained even where the resulting pH is not optimal, provided the pH is reasonably constant and not subject to sudden change.

Nutrient Balancing

Biological treatment processes can be inhibited if the balance of available nutrients is insufficient to ensure that the microbes can break down the organic matter in an efficient manner. Frequently, dairy wastewater may have an excess of phosphorus and a deficiency of nitrogen or potassium. It is generally accepted that the ratio BOD:nitrogen:phosphorus should be 100:5:1 to facilitate microbial breakdown.

Nutrient deficiency can be overcome by the addition of urea (or any other source of N) and phosphoric acid. In addition, there are several proprietary products available that can provide nutrients in different proportions to meet the specified demand. It is important to ensure that the available N and P are measured at the entry to the biological treatment and not prior to other physical/chemical processes.

Hydraulic and Load Balancing

Biological treatment processes operate best under constant and consistent organic load, with only minimal, gradual variations in the substrate. Most physical and physiochemical processes are flow-dependent, as are pumps, pipework, and other items of mechanical equipment. It is therefore essential that adequate provision be made for balancing both pollution load and flows. Balancing can be effected by a combination of provision of adequate storage capacity and control of the forward flow. The theoretical capacity of a balancing tank can be determined as follows:

> buffer required to minimize substrate variations + provision for variations in inflow over day/week/month as appropriate + provision for equipment malfunction + freeboard

Provision must be made for mixing the balancing tank contents thoroughly, and consideration should be given to aerating the contents where the potential for biodegradation of the waste exists.

Biological Treatment Processes

Biological treatment processes have generally been classified as aerobic (where the degradation takes place in the presence of oxygen) and anaerobic (where oxygen is excluded). Processes classified as aerobic include activated sludge process and biological filtration, although in the case of the latter, both aerobic and anaerobic systems coexist on the surface of the media.

Activated Sludge Process

The activated sludge process, discovered in the early 1900s, is a biological wastewater treatment method in which microorganisms are bunched together to form sludge flocs. The flocs develop spontaneously when the wastewater is aerated.

The wastewater and the sludge flocs are mixed in the aeration tank. Most of the impurities in the wastewater are suitable nutrients for the bacteria in the flocs; these bacteria take up the nutrients in their cells. An activated sludge floc is a conglomerate of

- living and dead bacterial cells;
- protozoa and higher organisms;
- trapped inorganic particles and organic fibers; and
- precipitated salts.

The floc is held together by chemical forces and a slime matrix surrounding the cells. The composition of the floc is dynamic, not static, and can be changed through alterations in the process conditions.

The general processes that occur are

- stabilization – slow breakdown of adsorbed materials;
- mineralization – conversion of nutrients to substances like carbon dioxide;
- assimilation – conversion of nutrients to cell material; and
- endogenous respiration – microbial mass converted to new cell material for new cells.

The operating principle of the activated sludge process is that wastewater containing biodegradable organics is fed to a reactor containing a well-mixed, well-aerated population of microbes (biomass, in the form of a flocculent suspension). The resulting mixture of biomass and water is separated, with the solids (sludge) being returned to the reactor (**Figure 3**).

The key parameters used in the design of the activated sludge process are

- food (F), usually expressed in kg BOD;
- microbial population, usually expressed as kg mixed liquor suspended solids (MLSS); it is also referred to as mass (M); and
- the ratio of food to mass, which is usually called F/M ratio and is a measure of the loading rate.

Typical design data are shown in **Figures 4** and **5**.

Activated sludge is generally categorized based on the F/M ratio as follows:

high-rate activated sludge	F/M ratio in the range 0.6–1.8;
conventional activated sludge	F/M ratio in the range 0.2–0.5; and
extended aeration sludge	F/M ratio in the range 0.04–0.1.

Several configurations of the aeration tank have become popular in the treatment of dairy wastewaters, including

- plug flow – the wastewater and sludge are introduced into one end of an aeration basin where the ratio length:width is >12:1;
- the oxidation ditch (developed by Paasver in 1953) – the aeration tank is laid out as a racing track, and oxygen transfer and mixing are effected by horizontal rotors (**Figure 6**);
- the carousel – this is similar to the oxidation ditch; however, the oxygen transfer and mixing duties are frequently split. This configuration allows the establishment of an anoxic zone; and
- the sequencing batch reactor – aeration and clarification take place in the same tank (**Figure 7**).

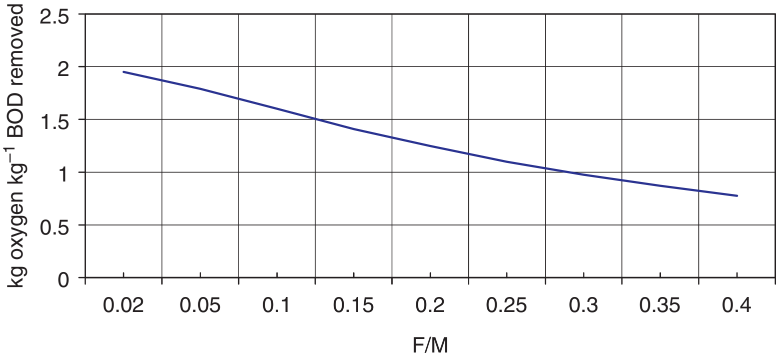

Figure 5 Oxygen demand (kg O_2 kg^{-1} BOD removed) versus food-to-mass (F/M) ratio for the activated sludge process.

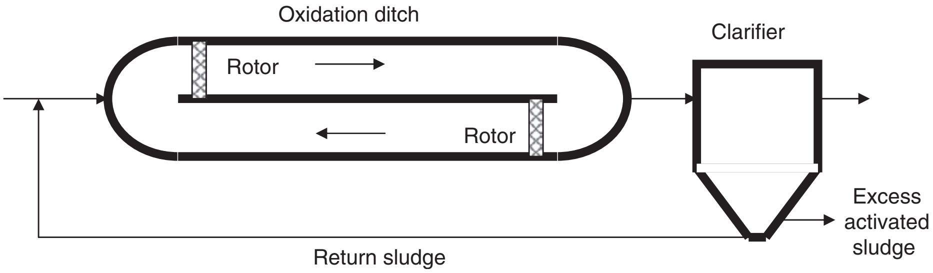

Figure 6 Typical oxidation ditch plant.

Biological Filtration

The principle of the biofiltration process is similar to that of the activated sludge process. In this process, the organic matter (food) is brought into contact with high numbers of microbes (film adhering to media) in the presence of oxygen (**Figure 8**).

Biological filters are not normally mechanically aerated, as the heat generated during the microbial degradation process is usually sufficient to maintain a temperature gradient between the wastewater and the surrounding air, ensuring an adequate draught.

The most common form of biofilter used in the treatment of dairy wastewater is the high-rate biofilter. The biofilter media, which are usually in the form of open-textured plastic, can be either random-packed or modular. High-rate biofilters are normally loaded above 0.6 kg BOD m^{-3} and generally remove 50–70% of the applied BOD (**Figure 9**).

The wastewater is distributed over the surface of the media at a minimum irrigation rate of 1.5 m^3 per m^2 plan area per h, and this ensures that no clogging of the media occurs and discourages insect life (**Figure 10**).

The most critical parameters in the operation of a biofilter are

- irrigation rate – it is essential that the irrigation rate is maintained at all times to ensure that the filter media do not become clogged;

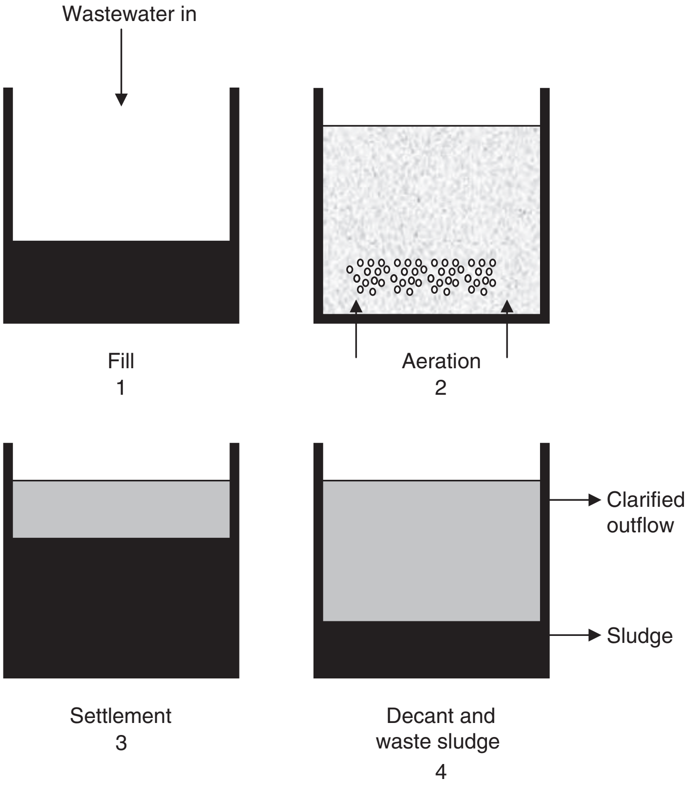

Figure 7 Sequencing batch reactor.

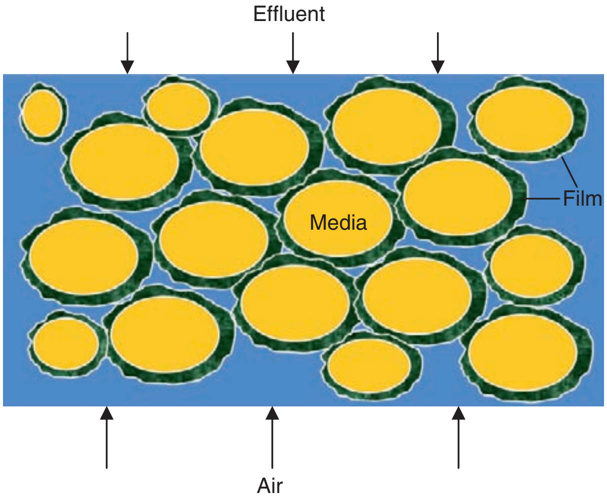

Figure 8 Activity on biofilter media.

- BOD applied – the application of excessive loading rates (shock loads) can also result in clogging of the media and ponding of the surface; prolonged BOD loading can give rise to odor problems;
- pH – inadequate control of the pH will reduce the efficiency of the biofilter and may even result in damage to the media and support structures;
- fats/grease – the presence of fats and grease in concentrations above 50 mg l^{-1} can result in the coating of the biological film; this can lead to uncontrolled anaerobic activity and significant odors in extreme cases; and
- temperature – a reduction in efficiency will occur when the temperature within the biofilter drops below 8 °C.

Usually, the outflow from high-rate biological filters, even after settlement, is not of sufficiently high quality to be discharged to watercourses and will require further treatment; activated sludge process is frequently used.

Nutrient Removal

Nitrogen

This is a two-stage process: nitrification, which is carried out under strongly aerobic conditions, and denitrification, which is carried out under anoxic conditions.

In the nitrification stage, ammonia is converted to nitrite and nitrate. For each kilogram of ammonia oxidized

- ~4.18 kg O_2 is consumed;
- 14.1 kg alkalinity as $CaCO_2$ is destroyed;
- 0.15 kg of cells is created (extra sludge); and
- 0.09 kg of inorganic carbon is consumed.

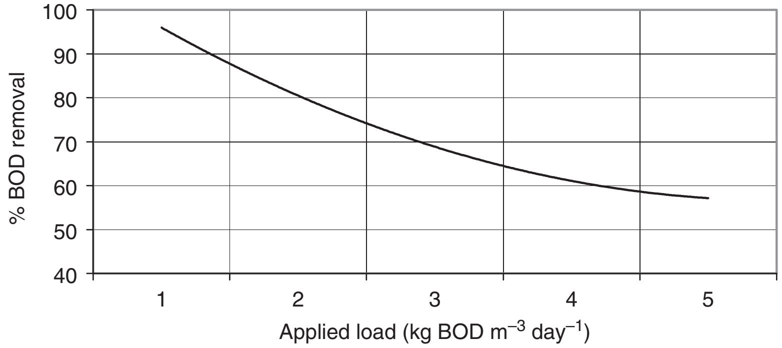

Figure 9 Distribution of wastewater over modular plastic media.

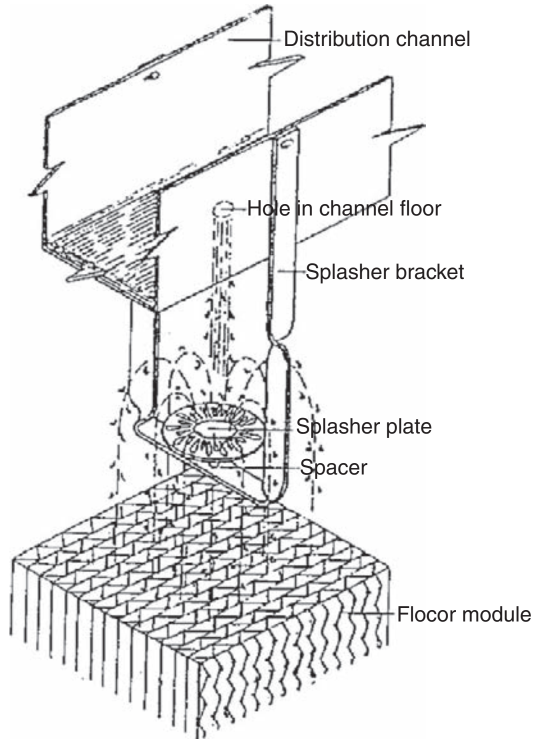

Figure 10 Biofiltration efficiency.

In the denitrification stage, the nitrate and nitrite are converted to nitrogen gas (N_2). For each kilogram of nitrate reduced

- 2.86 kg O_2 is recovered;
- 3.0 kg alkalinity as $CaCO_2$ is recovered; and
- ~0.4 kg of cells is created (extra sludge).

Biological phosphorus removal

Biological phosphorus removal is dependent mainly on the ability of the *Acinetobacter* spp. to release phosphorus under anaerobic conditions and to absorb it under aerobic conditions. The mechanism can be summarized as follows:

- under anaerobic conditions, readily degradable organic matter (BOD) is fermented to short-chain fatty acids (SCFA), which are stored in the cell as polyhydroxyl butyrates (PHB);
- under aerobic conditions, the stored PHB is oxidized and energy is released, allowing the assimilation of soluble orthophosphate; and
- the orthophosphate is metabolized by the cell and excess quantities are stored in the cell as polyphosphate. The storage of excess phosphorus is known as 'luxury uptake' of phosphorus, and it is this ability of the cell that is exploited in the biological phosphorus removal process.

A number of biological processes have been developed, many based on the activated sludge process, that are very effective in the biological removal of nitrogen and phosphorus from wastewater.

The A^{2}O® process

This continuous process (**Figure 11**), developed in the United States, is a refinement of the activated sludge process and takes advantage of the ability of denitrifying bacteria (abundant in the anoxic denitrification (DN) tanks) to convert the nitrate (which is recirculated from the nitrification (N) tanks) to nitrogen gas and phosphorus-accumulating bacteria in the anaerobic (AN) tanks to take up the available P. This process is capable of producing an effluent with $N_{TOT} < 10\,mg\,l^{-1}$ and $P_{TOT} < 1.0\,mg\,l^{-1}$.

The BIODENIPHO® process

This process (**Figure 12**), which was developed in Denmark, is based on the oxidation ditch configuration and utilizes the ability of a special culture of phosphorus-accumulating bacteria, which is cultivated in an anaerobic tank. This process is then incorporated into a nitrification–denitrification system. This process is capable of producing an effluent with $N_{TOT} < 10\,mg\,l^{-1}$ and $P_{TOT} < 1.0\,mg\,l^{-1}$.

The BIOSTYR® process

The BIOSTYR® process (**Figure 13**) was developed in France and is based on upflow filtration through

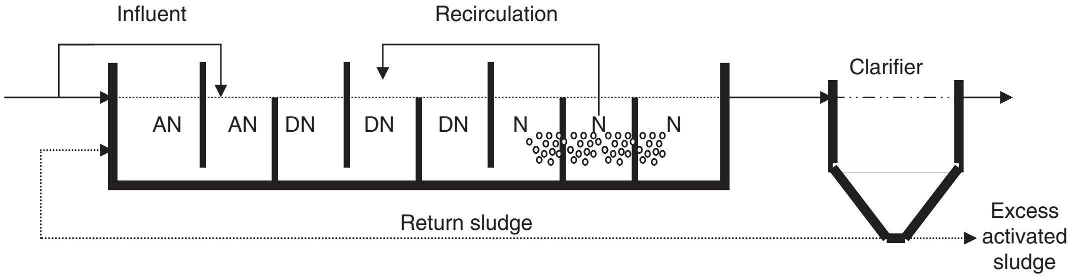

Figure 11 Biological N and P removal.

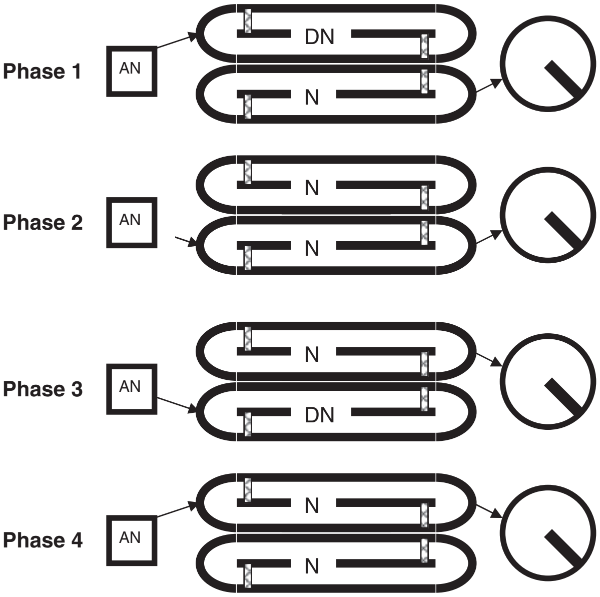

Figure 12 Phased oxidation ditch process for biological nitrogen and phosphorus removal.

submerged and floating fine granular media. Air can be injected at the base of the bed or into the media itself. In the latter case, the filter can simultaneously nitrify and denitrify. The BIOSTYR® process does not require separate clarification.

Special characteristics of the method are

- three processes in one tank, that is, no final settling tank;
- high treatment efficiency;
- compact, space-saving unit;
- can often be built into existing plants;
- low temperature dependency; and
- no odor nuisances, as the surface water is oxygen-saturated, treated water.

Anaerobic Processes

Anaerobic digestion is one of the many microbial processes that have existed since the earliest times for the recycling of organics within the natural environment. It occurs naturally in river and lake sediments, marshes, and so on, and although it has been used since the nineteenth century, it is only in recent times that the biochemistry and microbiology of the process have been understood.

The production of methane – for reuse – is the prime reason for using anaerobic processes in the treatment of dairy wastes. The anaerobic digestion of complex organic waste can be summarized as follows:

1. the breakdown of large molecules such as cellulose, proteins, and fats to simpler molecules such as sugars, alcohols, peptides, amino acids, and other products. This stage is accomplished largely by enzymes released by the microbes (bacteria, fungi, and protozoa);
2. the utilization of simpler molecules by the acid-forming bacteria to form volatile acids, carbon dioxide, and hydrogen; and
3. the production of methane from the products of the second stage by methane-generating bacteria.

The microbial population within an anaerobic digester comprises many different types of bacteria.

1. Non-methanogenic stage
   The non-methanogenic bacteria are obligate anaerobes and facultative bacteria. These bacteria feed on the primary substrate and produce a variety of organic acids and alcohols as end products, and are adaptable and could survive in the progressively decreasing pH.
2. Methanogenic stage
   The methanogenic bacteria are obligate anaerobes and include various methanobacterium, methanosacina, and methanobacilli. These use the acids and alcohols produced in the non-methanogenic stage as their growth substrate and produce a mixture of carbon dioxide and methane:

$$CH_3COOH = CH_4 + CO_2$$

If the process is balanced, the production of acids should be equal to the utilization of acids; however, the production of methane is the rate-limiting process. Methanogenic bacteria are very susceptible to pH

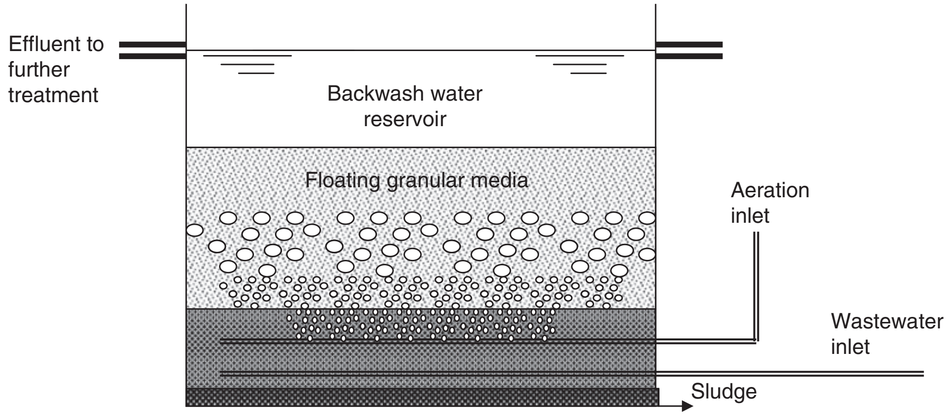

Figure 13 Upward flow submerged filter.

changes (6.8–7.8), so it is critical that the substrate load to the system be strictly controlled and that the system retains a significant buffering capacity.

Buffering

Buffering in an anaerobic process is provided largely by the presence of ammonium bicarbonate formed by anaerobiosis:

$$CO_2 + H_2O + NH_3 = NH_4HCO_3$$

If the waste being treated is mainly carbohydrate, with few proteins, it may be necessary to add some nitrogenous material.

Temperature

Anaerobic digestion generally takes place within two temperature ranges:

- mesophilic 30–37 °C and
- thermophilic 52–60 °C.

Although most anaerobic digestion plants operate in the mesophilic range, the thermophilic range offers the advantages of greater gas production, faster reaction rates, greater breakdown of organics, and, especially, pasteurization of product. The operation and control of thermophilic digesters is much more difficult. For this reason, thermophilic digestion is generally used only where the wastewater is already quite hot and the COD is very high (>5000 mg l^{-1}).

Clarification

An integral part of most biological treatment processes is the clarification of the wastewater to remove the sludge generated. In the activated sludge process, the sludge is generally returned to the aeration tank. Success in meeting the discharge standards is dependent on the efficiency of clarification, which, in turn, is dependent on the settleability of the sludge. In order to ensure that the sludge settles in the clarifier, conservative design parameters should be chosen:

surface overflow rate: 21–27 $m^3\ m^{-2}\ day^{-1}$
sidewall depth: >2.5 m
solids loading rate: 0.25–5 kg $m^{-2}\ h^{-1}$
sludge retention time: <1 h

Sludge Treatment

The on-site treatment of the biological sludge generally comprises a number of elements, some focused on solid–liquid separation and others on stabilization. The choice of the process is heavily influenced by the available disposal routes.

Solid–Liquid Separation

Solid–liquid separation usually comprises two distinct elements: thickening (see **Table 4**) and dewatering (which need not be sequential). Thickening is used to increase the solids content to 3–5% and generally removes the unbound water from the sludge. Dewatering is used to further increase the solids content. Filter belt pressing and centrifugation can increase the solids content to 18–25% (depending on sludge characteristics) and plate presses can increase it to ~40%, while drying can produce sludge granules with a moisture content of <10%.

Stabilization of Sludge

Stabilization of sludge is carried out to ensure that the sludge is suitable for long-term storage and ultimate

Table 4 Comparison of thickening processes

Method	*Advantages*	*Disadvantages*
Picket fence thickener	Simple to operate Low operating cost Low operator attention Minimal power consumption	Odor potential during stirring Thickened sludge concentration low (3–5%) High space requirements
Dissolved air flotation	Effective for excess activated sludge Will work without conditioning chemicals Relatively simple equipment components	Relatively high power consumption Thickened solids concentration limited Odor potential due to air-stripping effects Operator attention High space requirements
Centrifuge	Low space requirements Effective for excess activated sludge Minimum housekeeping and odor considerations High thickened sludge concentrations	Relatively high capital cost and power consumption Sophisticated maintenance requirements Best suited for continuous operation
Gravity belt thickener	Low space requirements Relatively low capital cost Relatively low power consumption requirements High thickened sludge concentrations and solids capture with minimum polymer consumption	Housekeeping Polymer dependent Moderate operator attention Odor potential Building corrosion potential, if enclosed
Rotating drum thickener	Low space requirements Low capital cost Relatively low power consumption High solids capture	Polymer dependent Sensitivity to polymer type Housekeeping Odor potential Moderate operator attention requirements

Table 5 Comparison of biological stabilization processes

Process	*Operating temperature °C*	*Retention period days*	*Comments*
Aerobic digestion	∼20	20–30	Can reduce organic content by up to 40%
ATAD (auto-thermal aerobic digestion)	45–60	<20	Kills most viruses and reduces organic matter by ∼50%
Mesophilic anaerobic digestion	∼36	10–18	Can reduce organic matter by up to 30% and produces about 1 Nm^3 of biogas for every kg of matter degraded
Thermophilic anaerobic digestion	∼55	<6	Can reduce organic matter by up to 30% and produces about 1 Nm^3 of biogas for every kg of matter degraded Process can be very unstable and difficult to operate
Composting	∼60	10–20 + maturation	Can be either in windrows with forced ventilation or regular mechanical turning, or in tanks with forced ventilation

Table 6 Comparison of chemical stabilization processes

Process	*Operating pH*	*Retention period*	*Comments*
Lime stabilization	∼12	Min 3–5 days Material normally stored for 20–30 days	Produces a product with a solids content in excess of 50% and highly desirable as an additive on lime-deficient soils
N-Viro	>11	3–5 days Material normally stored for 20+ days	Uses an alkaline admixture (cement kiln dust and quicklime). Produces a granular product with a solids content in excess of 50% and highly desirable as an additive on acidic soils
Chemfix	11.5–12.5	1–2 days	Produces a soil-like, odorless product with 50% dry solids

disposal without having adverse environmental or safety impacts. A well-stabilized sludge will be free of odors and pathogens, and will generally be free of biological activity. Stabilization can be achieved biologically (aerobic or anaerobic digestion, or composting), chemically (using alkaline admixtures), or thermally (drying) (see **Tables 5** and **6**). Pasteurization is normally required to eliminate pathogens.

Reducing the Negative Impact of the Dairy Industry on the Environment

V B Alvarez, M Eastridge, and T Ji, The Ohio State University, Columbus, OH, USA

Introduction

The dairy industry is important for providing a nutritious food source for millions of people and contributing to a major portion of the economical structure of many communities, states, and countries. Besides providing the livelihood of the family involved at the farm in the production of milk, there is about $2 generated elsewhere in the sector for each $1 earned on the farm and about 2.25 jobs generated elsewhere for every job on a dairy farm. Although the number of dairy farms has decreased (less than 2% of the population today produces food to feed the world), milk production in the United States and worldwide has been increasing. According to the UN Food and Agricultural Organization, the world milk production from cattle expanded by 1.2% from 2007 to 2008 (578 billion tonnes). India produces the most milk in the world, but in terms of total annual milk production from cattle, the United States ranks first, followed by India and China. From 1970 to 2009, the world population increased by about 1.7 times, and the population growth is expected to be about 1.8% per year. For a variety of reasons, the landscape of farms has changed significantly through the years. For example, the number of dairy cows in the United States has declined from about 12 million in 1970 to about 9 million in 2009. However, milk production has increased from 52.5 billion kg in 1970 to 85.8 billion kg in 2009. Thus, the production per cow has substantially increased during the same period from 4432 to 9353 kg $\text{cow}^{-1}\,\text{yr}^{-1}$, a 2.1-fold increase over a 40-year period. Although the total production and efficiency of milk production has increased, the increase in the world population, number of cows per farm, and farming methods and human population densities has necessitated the development of new best management practices (BMPs) and environmental policies for the production and processing sectors of the dairy industry.

Federal and local agencies in several countries, including the United States, closely regulate the environmental practices for dairy farms in order to protect the land, water resources, and air. Although the regulations may be different from country to country or from state to state, farmers employ a wide variety of BMPs to reduce the risk of environmental contamination by manure (animal manure, bedding, and wastewater) and to conserve the quantity of water used.

The manufacturing of fluid milk and other dairy products leads to the production of wastes. The various handling steps include product processing, storage, transportation, and distribution, with each generating waste that has a potential impact on the environment. More than 1000 dairy processing plants in the United States manufacture fluid milk, different types of cheese, butter, yogurt, ice cream, evaporated milk, condensed milk, nonfat dry milk, and other related products.

Approaches are being taken in each sector of the dairy industry to minimize the environmental impact of milk production, transport, and processing (**Figure 1**). This article focuses primarily on practices used to minimize this risk at the production and processing stages. However, it is also important to acknowledge that direct loading of tanker trucks on large farms and the use of ultrafiltration equipment to concentrate milk prior to shipment help to reduce the energy cost of transporting milk from the farm to the processor.

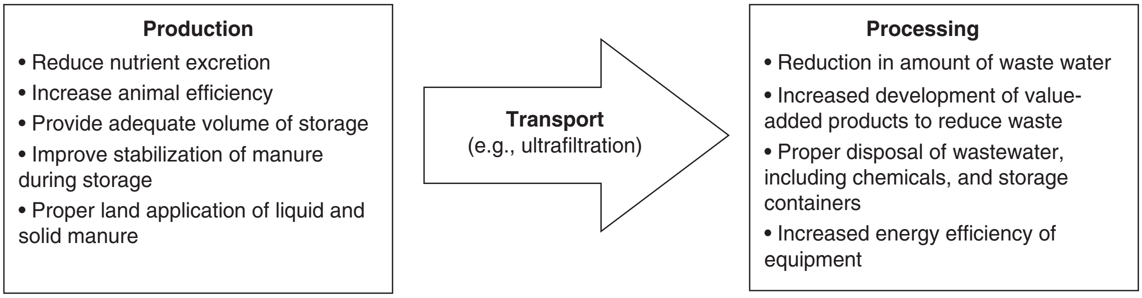
Farm Level

Manure

Manure consists of animal feces, urine, bedding, and any water coming in contact with these materials. The composition of manure varies depending on the type of bedding material used, types and amounts of feed used, and whether the manure is being mixed with parlor wastewater. Application of manure to land provides valuable nutrients for crop growth; however, it can be detrimental if it enters water resources.

One of the fundamental approaches to improving environmental compatibility at the farm level is by reducing the excretion of nitrogen (N) and phosphorus (P) in manure. This is done by improving the diet formulation of these nutrients to meet the animal's requirements for specific nutrients (i.e., amino acids and P). In addition, management practices and improved facilities for animal comfort have increased production per cow, resulting in greater efficiency of nutrient utilization. The increased milk yield of cows while reducing resource use aids in mitigating the dairy industry's environmental impact.

Adequate storage of manure is essential for facilitating land application at suitable times of the year, depending on weather conditions and cropping system used. At least



Production
• Reduce nutrient excretion
• Increase animal efficiency
• Provide adequate volume of storage
• Improve stabilization of manure during storage
• Proper land application of liquid and solid manure
Transport
(e.g., ultrafiltration)
Processing
• Reduction in amount of waste water
• Increased development of value-added products to reduce waste
• Proper disposal of wastewater, including chemicals, and storage containers
• Increased energy efficiency of equipment

Figure 1 Approaches to minimize the environmental impact of milk production, transport, and processing.

6 months of storage is needed, but at least 12 months is suggested. Farm manure is generally applied to croplands as a fertilizer, which reduces the dependence on commercial fertilizers. The manure provides nutrients for crops and improves soil quality if applied properly. Land application of manure, especially liquid manure, can cause problems if the land surface cannot absorb the manure or if a major rain event occurs soon after application. In addition, drainage tiles that are buried in fields should be plugged while liquid manure is applied in the event that manure leaches through the soil and enters the drainage tile. Adhering to established setbacks during application, using vegetative buffer zones near waterways, and not applying manure to frozen ground reduce the risk of runoff. In addition, injecting liquid manure and tillage after surface application reduce the risk of runoff, control odor emission, and prevent flies from populating the manure.

There are several techniques and treatments available to improve the utilization of manure and reduce the risk of manure contaminating the environment. Solid–liquid manure separation equipment allows for wastewater to be used in flushing feed alleys and for irrigating fields. The solids can be used as animal bedding (composted or air dried) and/or land applied. Other manure storage and treatment systems include lagoons, anaerobic digestion, activated sludge, and constructed wetlands. Lagoons must be constructed in such a manner that they have a very low permeability, or with certain highly permeable soil types an impermeable liner is needed. Lagoons may be constructed to be aerobic or anaerobic in function; a top-crusted, supplemental thatch (e.g., straw) or synthetic covering can help to reduce odors. In some countries, lagoon covers are required. Alternative farm waste treatment techniques, such as anaerobic digestion and activated sludge techniques, have been developed to recycle and reuse organic wastes more efficiently. The anaerobic fermentation of manure to produce methane allows farmers to produce enough electricity not only to run their farm operations but also to produce a surplus that can be sold to the local utility supplier. However, the cost of construction is quite high, and the price provided by utility companies is often low. The price for excess electricity is higher in some countries and areas within a country than other comparable areas. Constructed wetlands can improve water quality by intercepting the farm wastewater and retaining contaminants and nutrients through a series of vegetative ponds. New practices and innovative technologies to improve manure and odor management are being researched and incorporated in many dairy operations. Some dairy farms are using alternative natural energy sources (e.g., solar and wind). In addition, using plate coolers on dairy farms for heat exchange between the milk and water improves the quality of the milk because the milk is cooled more rapidly. Plate coolers reduce the energy required to operate the refrigerated bulk tank.

Milking Parlor Wastewater

Milking parlor wastewater contains cow feces, urine, chemicals, and wash water used in cleaning the milking units, pipelines, receiver, bulk tank, and the floor and wall surfaces. The volume of wastewater generated from cleaning the milking system can be up to 30% of the total farm wastewater. The wastewater from a toilet or employee comfort area in a milk house must, in most cases based on local and state health codes, be handled according to domestic sewage disposal regulations.

The parlor wastewater may be stored in a separate containment from manure or in the same vessel (e.g., lagoon). Land application is the most common method for discarding wastewater. Some pre-treatments being used prior to land application include facultative ponds, wetlands, anaerobic ponds, and fabricated reactors. Facultative ponds retain wastewater from 5 to 30 days. This retention time allows for some biological degradation, making the wastewater more suitable for land application. Anaerobic ponds utilize microbes to oxidize organic matter, especially to treat such wastes as oils and greases. Fabricated reactor systems, such as anaerobic reactors and sand filters, are also biological treatments for wastewater. A horizontal flow biofilm reactor can be effective for the removal of carbon and nitrogen from wastewater. The treatment process used for wastewater depends on the operating cost and the composition of the wastewater, for example, filtration for ammonium-nitrogen, potassium, and other dissolved solids, precipitation for phosphorus, and nitrification for nitrogen.

Environmental Impact of Dairy Processing

Processing Wastewater

Wastewater from food processing may contain acids or bases, organic chemicals that are toxic and cause depletion of dissolved oxygen, suspended solids, phosphorus, nitrogen, heavy metals (e.g., cadmium, chromium, copper, lead, mercury, nickel, and zinc), cyanide, oily materials, and volatile compounds. Effluents from dairy plants contain dissolved or suspended compounds, such as proteins, fats, sugars, residues of additives, and cleaning and sanitation chemicals. High concentrations of sodium, potassium, calcium, and chloride may also exist. Most of the water consumed in dairy processing plants is for the clean-in-place (CIP) operation, which is responsible for 50–90% of the overall volume of the waste stream. During milk processing, 0.2–11 l of wastewater may be generated per liter of processed milk. The water used for CIP contributes to the high pH (9–11) in wastewater purification stations. Wastewaters from the cleaning of equipment may contain milk or milk products, whey, brines, cleaning agents, and various acid and alkaline detergents, including caustic soda, nitric acid, phosphoric acid, and sodium hypochlorite. Due to the high concentration of dissolved solids ($\sim$1800 mg l^{-1}), dairy wastewater has a high biological oxygen demand (BOD) ($\sim$2000 mg l^{-1}).

Wastewater from dairy processing has been managed by direct land application, discharging wastewater to a nearby sewage treatment plant, removing semi-solids and special wastes through a waste disposal contractor, or operating an on-site wastewater treatment plant. However, most small dairy plants dispose of their wastewater by irrigation onto land, which causes a potential threat to the environment. Improper treatment and disposal may cause odors produced by biological decomposition of milk-derived organic matter.

Biological treatments (aerobic and anaerobic biological systems) are the most promising and cost-effective methods for the removal of organic compounds from dairy processing wastewater compared to other removal systems. Aerobic systems include conventional activated sludge processes, aerobic filter treatment, sequencing batch reactor treatment, rotating biological contactor treatment, lagoons, and the wetland system. Anaerobic biological systems include anaerobic digestion by conventional digester, anaerobic lagoon, completely stirred tank reactors, up-flow anaerobic filter, expanded bed, up-flow anaerobic sludge blanket reactor, fixed-bed digester, down-flow fixed-film digester, membrane anaerobic reactor system, and separated phase digesters. Specific separation methods that are widely used in the food processing industry have been incorporated into the purification, recycling, and treatment of wastewater. The most commonly used separation methods in the dairy industry are membrane technologies, such as ultrafiltration, nanofiltration, reverse osmosis, and microfiltration.

Whey

Whey is a liquid by-product generated from cheese manufacturing. It is composed of approximately 0.3% fat, 0.8% protein, 4.9% lactose, and 0.5% minerals. More than 145×10^6 tonnes of whey wastewater is produced per year worldwide; it is another potential source of environmental contamination. The major components mentioned above can be separated using advanced technologies to reduce the environmental risk of whey. However, approximately half of the world production of whey is not processed, and it is disposed of into waterways or loaded onto land. Whey has high BOD ($\sim$40–60 g l^{-1}) and chemical oxygen demand (COD) values ($\sim$50–80 g l^{-1}) due to the concentrations of lactose, proteins, and mineral salts.

Approximately 35% of the total production of liquid whey in the United States is converted to whey powder, whey protein for human food, and animal feed. An additional 10–15% of the total liquid whey is converted to other products, such as blends of whey with other protein sources (e.g., casein or soybean), lactose, and partially delactosed whey. The rest of the unprocessed whey is directly utilized for animal feed or mixed with wastewater. Serious waste volume is caused by the mixture of unprocessed whey and wastewater from cleaning and sanitizing in the cheese industry.

Whey can be converted through various technologies and processes to different products, such as condensed whey, dry whey, dry modified whey, whey protein concentrate, isolates, and dried lactose. However, separation technologies and storage of whey require high-energy processes that add to the cost and maintenance of cheese plants. Small cheese plants are usually not able to afford such equipment, so they may sell the whey to larger processors. Anaerobic systems are used to treat organic wastewater in the cheese industry, resulting in the production of methane (CH_4) gas. Ethanol can be produced by fermentation of lactose in whey. Ireland started producing fuel ethanol from whey in 1985, and New Zealand started using fuel ethanol produced from whey in August 2007.

Fats, Oil, and Grease

Milk, cheese, butter, whey separation, milk bottling, and plant machinery are the main sources of fats, oil, and grease. These materials in wastewater are a major concern in dairy industries when processing the wastewater. These materials may cause clogging of wastewater treatment systems, holding tanks, and septic tanks; cause sludge flotation; cause the formation of films on the surface of reactors; and result in malodorous wastewater.

Common pre-treatment systems for removing fats, oil, and grease are gravity traps, air flotation systems, or enzymatic hydrolysis. Gravity traps can remove fats, oil, and grease by trapping within a series of cells when wastewater flows through the cells. Despite their high efficiency, there are some disadvantages as the need for constant cleaning and monitoring to prevent variation in pH. Anaerobic digesters for oil and grease residues increase fat reduction rates in the range of 88–94%. Air flotation systems that apply air bubbles in wastewater at a pressure of 400–600 kPa allow for fat globules to attach to the air bubbles and become suspended. High-density solids are then settled at the bottom of the containment, whereas the bubbles are eliminated through the effluent, possibly improving the efficiency of fat removal by 35–60% in waste streams. Enzymatic hydrolysis, which hydrolyzes fat in dairy processing wastewaters by lipases, results in high COD removal efficiencies. A hydrolytic enzyme pretreatment system in grease traps can produce hydrolysis rates greater than 90% for lipid degradation in wastewater. Another alternative method that facilitates biodegradation of lipid concentrations is the use of surfactants. For example, the application of 500 mg l^{-1} of a surfactant derived from cactus to wastewater has been observed to improve the anaerobic biodegradability and reduce the COD level. Dairy industry wastewater pretreated with lipases in an up-flow anaerobic sludge blanket reactor may improve oil and grease removal efficiency by 90% of the initial value.

Energy

Operating dairy processing plants requires significant amounts of energy, which contributes to processing costs. The dairy industry uses about 80% of the energy for thermal processing to generate steam and hot water for process applications (e.g., pasteurization, evaporation, and milk drying) and cleaning purposes, and 20% for electricity to operate refrigeration, air compression, ventilation, and lighting. The combustion of wood, gas, fuel oil, diesel, or coal in turbines, boilers, compressors, and other engines to produce power and heat generates gas emission, such as carbon dioxide, nitrogen oxide, and carbon monoxide, which has a negative environmental impact.

The US Department of Energy estimates that 67.5% of the external energy is lost by electric power generation, transmission, and distribution, including piping for steam, hot water, chilled water, cooling water, and compressed air, steam condensate return piping, chilled water return piping, fuel piping, and wires for electric power transmission. Energy losses from boilers vary from 10 to 45%, and are mainly due to equipment aging, type of fuel, and lack of proper maintenance. The largest energy transmission losses are typically 20% in steam pipes. Equipment energy losses are typically 80% compressor, 35–45% pumps and fans, and 5–10% motors.

Improving energy efficiency in dairy processing plants reduces the risk to the environment and reduces reliance on natural resources. Therefore, improving energy efficiency also reduces energy use, operating costs, and greenhouse gas emission into the atmosphere. Many practices are currently being used to improve energy efficiency in the dairy processing sector, including solar or wind power; continuous pasteurizers instead of batch pasteurizers; multistage evaporators; insulating the refrigerated area; a centralizing CIP system; installation of more efficient heating, ventilation, and air-conditioning (HVAC) systems; or recovering and reusing waste heat. An example of heat recovery equipment in the dairy processing industry is a plate heat exchanger, commonly used for liquid–liquid heat exchange. Combined heat and power (CHP) system increases energy efficiency through on-site production of thermal energy (typically steam) and electricity from a single fuel source. Replacing or retrofitting existing equipment (e.g., lighting and HVAC) improves energy efficiency for on-site heat or power generation and distribution, and manufacturing processes. A CHP system, commonly operated by coal, natural gas, biomass, and fuel oil, increases energy efficiency 70–90% in providing electricity, hot water, and chilled water. Steam system improvement, such as replacing or relocating the steam systems, stabilizing steam pressure, or improving overall boiler efficiency, may save 10–20% in fuel cost per year.

Packaging

In 2005, dairy packaging demand in the United States was $3.5 billion, resulting from packaging of milk (30%), cheese (23%), frozen products (19%), cultured products (12%), and all other applications (16%). It is anticipated that packaging in the dairy industry will increase 4.1% annually from $2.7 billion in 2000 to $4.3 billion in 2010. The demand for pouches used in cheese, small containers of frozen dairy and cultured dairy products, and bottles with milk and drinkable yogurt is expected to grow.

The main packaging materials for dairy products are paper and paper-based products, glass, tin plate, aluminum foil, wood, plastic, and laminates. Most plastic milk bottles are made from high-density polyethylene, which is not biodegradable, taking about 500 years to decompose. Other plastic packaging materials are composed of polystyrene and polyvinyl. Milk containers made from laminated cardboard cartons coated with different layers of plastic or aluminum are extremely slow to biodegrade, and thus, this contributes to a negative impact on the environment. The degradation process of polymers depends on different environmental factors, such as sun rays, moisture and humidity, temperature, chemical compounds, bacteria, and mold. In 2008, the United States recycled about 1 billion kg of plastic bottles, a 27% increase since 1990. Current management of packaging wastes include recycling, combustion for energy recovery, and disposal through land filling.

New packaging materials and new processes are being developed in the dairy industry to reduce the environmental impact of dairy packaging materials. A modification of plastic's chemical structure by organic ketones can enhance its biodegradability. Biodegradable polylactic acid produced from renewable resources is a new packaging material developed to replace petroleum-based packaging films for cheese and yogurt. A new bottle system from molded recycled paper and low-density plastic liners has been developed to reduce waste and plastic usage. Manufacture of new bottles for fluid milk, juices, smoothies, and drinkable yogurt consumes about a third of the energy required to make a plastic bottle and has a 48% lower carbon footprint than plastic. Other new technologies include the use of an electron-beam emitter that sterilizes pouches without use of chemicals and water, and dry sterilization that is conducted with vaporized hydrogen peroxide, eliminating water consumption for sterilizing a lightweight polyethylene terephthalate bottle, additionally providing sustainability benefits by virtually eliminating the need for rinse water in this system.

Greenhouse Gas Emission

Global warming has been a focus for many years, with the focus especially on carbon dioxide (CO_2) and methane (CH_4) absorbing and trapping the heat in the atmosphere. Other gases of concern are nitrous oxide, chlorofluorocarbons, and hydrofluorocarbons, which are generated by the dairy processing industry. The contribution of reactive nitrogen to the atmosphere, primarily from ammonia but also from volatile organic compounds (VOCs; ozone concern), nitrous and nitrogen oxides are the focus of environmental regulators. In addition, the malodorous nature of farms, manure, and wastewater continues to generate many complaints from local residents.

The most notable odorous compounds detectable on dairy farms are ammonia, hydrogen sulfide and other sulfurous compounds, amines, organic acids, and heterocyclic nitrogenous compounds; however, with the exception of manure storage pits and covered silos, the maximum allowable concentrations are not normally found on or near the farm. Therefore, the most common concern with air quality in relation to animal agriculture is the nuisance of odors. Odor from manure on dairy farms can be minimized with proper installation of wind breaks and proper storage, handling, and application of manure to soils. Also, building positive relations with neighbors about the practices at the farm and informing them of major manure application events results in fewer complaints.

The US Department of Agriculture estimates that dairy waste output per billion kg of milk produced is 7.91 million kg nitrogen, 3.31 million kg phosphorus, 1.91 billion kg manure, 26.8 million kg methane, 230 000 kg nitrous oxygen, and 1.35 billion kg carbon dioxide, including CO_2 equivalents from CH_4 and N_2O. In dairy processing plants, gas emissions originate from the use of electricity (75%) and fuel (23%), and refrigerant leakage (2%). System improvements on steam and boiler systems reduce the equivalent of 616 tonnes of CO_2 per year. Optimization of compressed air reduces greenhouse gas emissions to the equivalent of 762 tonnes of CO_2 per year.

There are several ways to reduce greenhouse gas emissions. For example, optimizing processes with new technologies, better process control systems, and renewable energy sources can reduce CO_2 emissions. At the farm level, improvement in the efficiency of microbial fermentation in dairy cattle can lower CH_4 production, for example, feeding supplemental fat or an ionophore (e.g., Rumensin®, Elanco, Greenfield, Indiana, USA). Alternatives for stabilizing ammonia in manure continue to be investigated, including keeping pH low for a greater concentration of NH_4 versus NH_3. Manure can be converted into electricity through anaerobic digester technology, providing for a reduction in fossil fuel consumption and maximizing environmental benefits. This technology is currently being used by about 2% of the US dairy farms, but its use will likely increase in the future.

Historical Background

Vitamin deficiencies are as old as mankind; for example, as early as 3500 years ago people knew about treating night blindness by eating liver. In the centuries that followed, people learned to avoid numerous symptoms of diseases by choosing specific items of food without knowing anything about the vitamins they contained. However, by the end of the nineteenth century, feeding experiments with animals showed that specific deficiency symptoms could be caused by certain diets, which led to the hypothesis that organic micronutrients must be part of a healthy diet. Chemical identifications during investigations on beriberi (a disease caused by vitamin B_1 deficiency) disclosed that an amino group must be part of the unknown substance, and therefore, in 1912, Funk proposed the name 'vitamins' for these substances. This term is still in use today, although many of the known vitamins now do not contain an amino group.

By 1941, all the 13 known vitamins – vitamins A, D, E, K, C, and eight B-vitamins – had been described, and many scientists involved in the research were honored by a Nobel Prize for chemistry or medicine. It became more and more easy to understand vitamin deficiency-derived diseases and to treat these symptoms by optimal nutrition or supplementation. A number of recommendations were published in various countries, and recent investigations aim to understand the preventive effect of specific vitamins on a number of widespread 'modern' diseases like coronary heart disease, atherosclerosis, diabetes, and even cancer.

Today, vitamins are defined as organic compounds that cannot (or not in sufficient amounts) be synthesized by an organism but are indispensable for its life. Thus, vitamins have become essential parts of the diet, either as they are or as provitamins that can be converted to the respective vitamins (e.g., β-carotene = provitamin A). It must be mentioned that not all vitamins are vitamins for all species as per the above definition, owing to the fact that some vitamins can be synthesized by some species, whereas others cannot. For example, vitamin C cannot be synthesized by humans, monkeys, and guinea pigs; vitamins K and B_{12} cannot be synthesized by humans but they can be synthesized by microorganisms in the human intestine (though not in amounts sufficient for the respective person).

Although vitamins fulfill numerous functions, they are divided into only two groups, not based on their functions but based on their resorption, transport, storage, or excretion: fat-soluble vitamins (A, D, E, K) and water-soluble vitamins (C and B group) (for a brief overview, see **Tables 1** and **2**; details are given in the respective articles on each vitamin).

Sources of Vitamins

Most of the vitamins can be synthesized only by microorganisms or plants; hence, we have to consume them in fruits/vegetables or in animal nutrients (meat, fat, milk, eggs), the latter containing vitamins stored as such or as part of coenzymes. However, the animals in their turn have to obtain these vitamins either from vegetables or by resorption after synthesis by, for example, intestinal microorganisms in ruminants. The latter method is not a real possibility in humans, as in the colon – where most of the bacteria live – only vitamin K can be resorbed in detectable amounts and it is still under debate whether these amounts are adequate. Disturbing the colonic flora by long-lasting treatment with antibiotics leads to vitamin K deficiencies.

Table 1 A brief overview of fat-soluble vitamins, A, D, E, K

Vitamin	*RDA*	*Sources*	*Functions*
A (Retinol)	1 mg	Liver, milk, fish, egg yolk, fruits, vegetables	Vision, embryogenesis, cell proliferation and differentiation
D (Calciferol)	5 μg	Cod liver oil, milk, fish. About 90% are synthesized in the skin under UV light (sun!)	Ca^{2+} and P homeostasis, insulin release, inhibition of tumor cell growth, immune functions (?)
E (Tocopherol)	12 mg	Plant oil, germs, nuts	(Membrane-protective) antioxidants
K (Phyllochinon)	65 μg	Green vegetables, liver, wheat germ	Blood clotting

RDA, recommended dietary allowance.

Table 2 A brief overview of water-soluble vitamins

Vitamin	*RDA*	*Sources*	*Functions*
B_1 (Thiamin)	1–1.2 mg	Brewer's yeast, wheat germ, sunflower seed	Coenzyme for enzymes of the intermediary metabolism
B_2 (Riboflavin)	1.2–1.4 mg	Brewer's yeast, liver, almonds, dried whole milk, Camembert	Enzymes in the metabolism of, e.g., glucose, fatty acids, amino acids, drugs
B_3 (Niacin)	13–17 mg[a]	Wheat bran, liver, peanuts, salmon, halibut, Limburger, Brie, Camembert	NAD and NADP are coenzymes of dehydrogenases, and hydrogen and electron carriers
B_5 (Pantothenic) acid	6 mg	Liver, pea, soybean, lentils, dried whole milk, Blue cheese	Numerous functions as coenzyme A
B_6 (Pyridoxine)	1.2–1.6 mg	Soybean, salmon, liver, maize, Camembert	Coenzyme for transaminases
B_7 (Biotin)	30–60 μg	Brewer's yeast, liver, soybean, peanut, dried whole milk	Carboxylation and decarboxylation processes
B_9 (Folate)	400 μg	Brewer's yeast, liver, soybean, egg, Brie	Cofactor to carry one-carbon units
B_{12} Cobalamine	3 μg	Liver, kidney, mackerel, herring, Emmentaler, Camembert	Homocysteine metabolism
C (Ascorbic acid)	100 mg	Pepper, black currant, green cabbage, kiwi, oranges	Antioxidants, collagen synthesis

[a] 1 mg niacin-equivalent = 60 mg tryptophan.
RDA, recommended dietary allowance.

As we do not have any single food that contains all vitamins in optimal concentrations or in optimal relative proportions, we have to rely on a mixed healthy diet containing fruits, vegetables, cereals, dairy products, fish, and also meat to be on the safer side. For special risk groups (e.g., elderly, pregnant women, adolescents, competitive athletes; see below) supplementation of single vitamins might be inevitable. Good sources of the various vitamins and recommended daily allowances are given in **Tables 1** and **2** and in more detail in subsequent articles.

There are some reasons why vitamin deficiencies can occur even in developed countries; these include malnutrition, undernourishment, extreme diets, or destruction of vitamins while food preparation (e.g., cooking or heat-treatment of dairy products; storage under light). In addition, an insufficient intestinal absorption owing to chronic diarrhea, atrophic intestinal mucosa, or resections of the small intestine also leads to deficiencies, as does an enhanced need because of diseases accompanied by fever or cross-reactions with pharmaceuticals, alcohol, or nicotine, or an enhanced loss due to hemodialysis.

Risk Groups

Two of the major risk groups are pregnant women and breast-feeding women. Especially in the second half of pregnancy, large amounts of vitamins are transferred to the fetus via the placenta, in general independent of the vitamin status of the mother; that is, even under developing deficiencies in the mother, the fetus receives the vitamins. Unfortunately, the need for vitamins during pregnancy increases not in parallel with the enhanced energy needs (13%), but can reach levels of up to 50% (folate) or 58% (pyridoxine). In cases of pregnancies with twins or triplets, or short-interval births, the risk of deficiencies is even higher. During breast-feeding, for example, deficiency of vitamin A can occur, and the risk for the neonate is higher than that for the mother, especially in premature babies and babies lacking vitamins from the last weeks or months of pregnancy. In the case of sufficient maternal vitamin stores, no risk exists for the breast-fed suckling, except perhaps of vitamin K deficiency, which therefore is routinely supplemented during the first weeks of life. Strictly vegetarian mothers normally have very low vitamin B_{12} stores and produce almost vitamin B_{12}-free milk, which can lead to irreversible brain damage of the child.

Children and adolescents are other potential risk groups, due to an enhanced demand by the growing body or due to (additional) smoking or malnutrition (e.g., regular intake of fast foods). Also, alcohol and slimming diets can lead to vitamin deficiencies in adolescents as well as in adults.

Elderly people are also at risk of developing vitamin deficiencies due to a reduced food intake on account of reduced energy demand and changes in metabolism and lifestyle. Especially males who live alone have been shown to develop combined deficiencies, as they often use canned food and omit fresh vegetables or fruits.

Finally, ill people must be controlled regarding their vitamin status, but this depends on the kind and degree of their illness.

Prevention of Deficiencies

For healthy people in developed countries with an average workload and under European climatic conditions, a balanced and mixed diet is regarded as sufficient for supplying the necessary vitamins. However, nutrition organizations have tabulated (see **Tables 1 and 2**) the recommended daily allowances of vitamins, almost independent of their sources. Recently, it is being debated whether these recommendations are really sufficient or should be enhanced (and if so, by how much) for a better prevention of diseases like coronary heart disease, cancer, metabolic syndrome, and others. Hopefully we will find out from ongoing and future studies how we have to handle our vitamin stores and which recommendations, under which conditions, should be followed.

Fat-Soluble and Water-Soluble Vitamins

A brief overview of the most relevant data for the single fat-soluble vitamins and single water-soluble vitamins is given in **Tables 1** and **2**, respectively. Further details can be found in the respective articles dealing with each of the vitamins.

Introduction

Vitamin A is an essential fat-soluble vitamin involved in multiple critical biological functions such as embryonic development, growth, vision, and regulation of gene expression. Because most mammals cannot carry out its synthesis *de novo*, vitamin A must be provided by the diet. In human nutrition, plant products (like carrots or spinach) provide provitamin A (i.e., provitamin carotenoids, like α-carotene, β-carotene or β-cryptoxanthin), which may, after specific cleavage, yield retinal and then retinol. By contrast, animal products (such as cod liver oil or liver, but also ruminant milk and dairy products) provide retinol or its esters directly, and also serve as provitamin A. In this way, dietary provitamin A carotenoids participate actively in the supply of vitamin A to the organism. Because vitamin A is absolutely necessary for embryonic development, it should be provided to the fetus through the placenta. And because vitamin A is also greatly involved in growth after delivery, it must be provided to the newborn through milk consumption.

In the past, studies on the status of β-carotene and vitamin A in bovine plasma and milk have focused on the objective of achieving suitable plasma levels during the peripartum period to maintain the cow's health, to prevent reproductive disorders, and to ensure an adequate vitamin supply to calves via colostrum. More recently, the role of carotenoids and fat-soluble vitamins in the nutritional and sensorial properties (via antioxidant activity or the yellow color of fat) of dairy products and their potential use as biomarkers for the traceability of cows' feeding management have led to a renewed interest at the INRA research center at Clermont–Ferrand. In order to better characterize how the feed can influence the appearance and nutritional properties of milk and other dairy products, new studies that follow variations in vitamin A, carotenoids, and color in cow's plasma and milk during lactation have been carried out.

General Features of Vitamin A and Carotenoids

Vitamin A or retinoids are generic compounds other than carotenoids, which exhibit biological activities like those of retinol, the main component of this family. The International Union of Pure and Applied Chemistry–International Union of Biochemistry (IU-PAC–IUB) defines retinoids as compounds containing a β-ionone ring, substituted with an alkyl chain made of four isoprenoid units ended by a functional group R. The nature of this end-substitution forms the basis of the classification of retinoids (**Figure 1**). Nowadays, because many chemical compounds not based on this structure have been shown to have a retinol-like activity, a new definition based on the ability of retinoids to bind and activate their nuclear receptors (retinoic acid receptors (RARs) and retinoid X receptors (RXRs)) has been proposed. According to this definition, the retinoid family includes all the natural or synthetic derivatives of retinol in terms of structure or biological functions.

It is generally recognized that vitamin A is essential for vision. Retinal acts as the chromophore of vertebrate visual pigment, and vitamin A deficiency results in the loss of structural integrity of photoreceptors, alteration of night vision, and finally blindness. In addition, vitamin A exerts pleiotropic effects on vertebrate development, vitamin A homeostasis, epithelial integrity, gene regulation, and cell differentiation. Recently, it has been shown that these effects are mediated largely through interactions of retinoic acid bound to specific nuclear receptors with retinoic acid response elements (RAREs). Two main classes of receptors were identified: the RARs, which bind both all-*trans* retinoic acid and its 9-*cis* isomer, and RXRs, which respond exclusively to 9-*cis* retinoic acid. Excess of vitamin A supply, dietary or supplementary, can result in embryogenetic defects and fetus malformation.

Vitamin A, or more precisely retinyl esters, is present in animal products. Generally, mammals producing milk

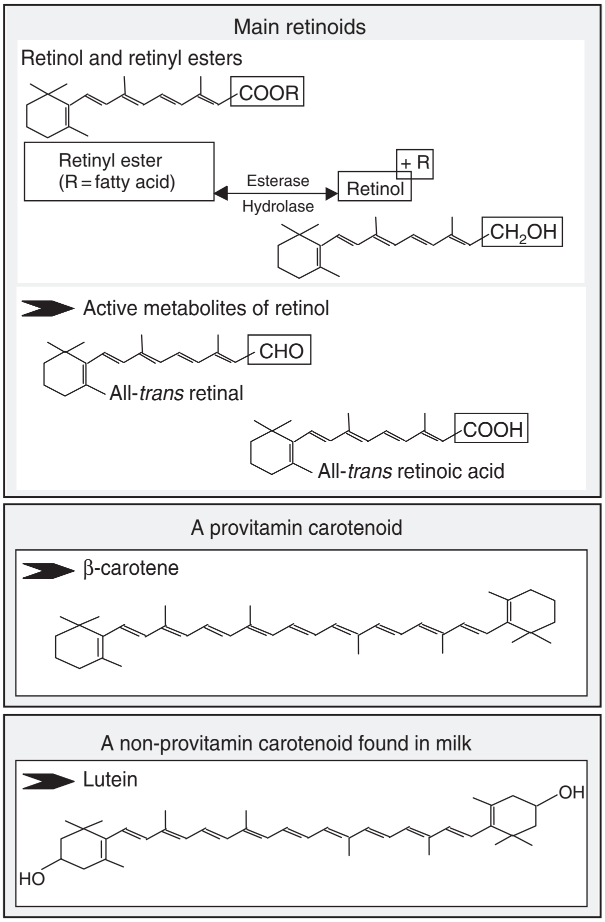

Figure 1 Retinoid family and examples of the main carotenoids found in milk (a provitamin A carotenoid: β-carotene; a non-provitamin A carotenoid: lutein).

consumed by humans (cow, goat, etc.) are usually herbivorous. They acquire vitamin A principally by the conversion of carotenoids from the diet into vitamin A. Preformed vitamin A is sometimes added, often together with other vitamins and minerals, as a supplement to the ration to meet the requirements of the animal and to improve the performance of lactating cows. Carotenoid is also a generic term used to describe plant pigments corresponding to the general formula $C_{40}H_{56}O_n$. In mammals, only 50–60 carotenoids, of the 700 discovered until now, exhibit a provitamin A activity. To be provitaminic A, these pigments should have at least one non-substituted β-ionone ring and an alkyl chain containing at least four conjugated double bonds. For example, among the carotenoids frequently found in cows' milk, lutein (because of its substitution on the two β-ionone rings) is not a provitamin A carotenoid, whereas β-carotene (the main carotenoid found in milk) exhibits the highest provitamin A activity (**Figures 1** and **3**). This conversion occurs mainly in the intestine and to a lesser extent in the liver, the *corpus luteum*, but may also occur in the mammary gland. The enzyme involved in this conversion, and identified as $\beta\beta$-carotene 15-15′ monooxygenase (E C 1.14.99.36), has been cloned in *Drosophila*, chicken, mice, and humans.

β-Carotene is an essential pigment of plants, associated primarily with chloroplasts and chromoplasts. Its primary function is to protect the plant against photooxidation and to contribute along with chlorophylls in collecting light energy. In vertebrates, β-carotene, and to a lesser extent, α-carotene and β-cryptoxanthin, can be converted to vitamin A mainly in the intestine and liver. Thus, β-carotene would contribute 40–60% of dietary vitamin A intake in humans and 100% in non-vitamin A-supplemented herbivores. Carotenoids have also been shown to have antioxidant activity through quenching of activated species of oxygen ($^1O_2$) and scavenging of free radicals. However, at a high concentration and under a high oxygen pressure, carotenoids can act as prooxidants. They might be active in the inhibition of neoplastic cellular transformation by inducing cell–cell communications. They have also been shown to stimulate the immune system.

In cattle, many studies have been focused on the role of β-carotene in reproduction, and the suggestion that it may be essential for normal reproduction in cattle is still a matter of debate. Moreover, studying the absorption and metabolism of β-carotene in cattle is particularly relevant because β-carotene is the main source of vitamin A in milk.

Metabolism of Vitamin A and Carotenoids in Dairy Cattle

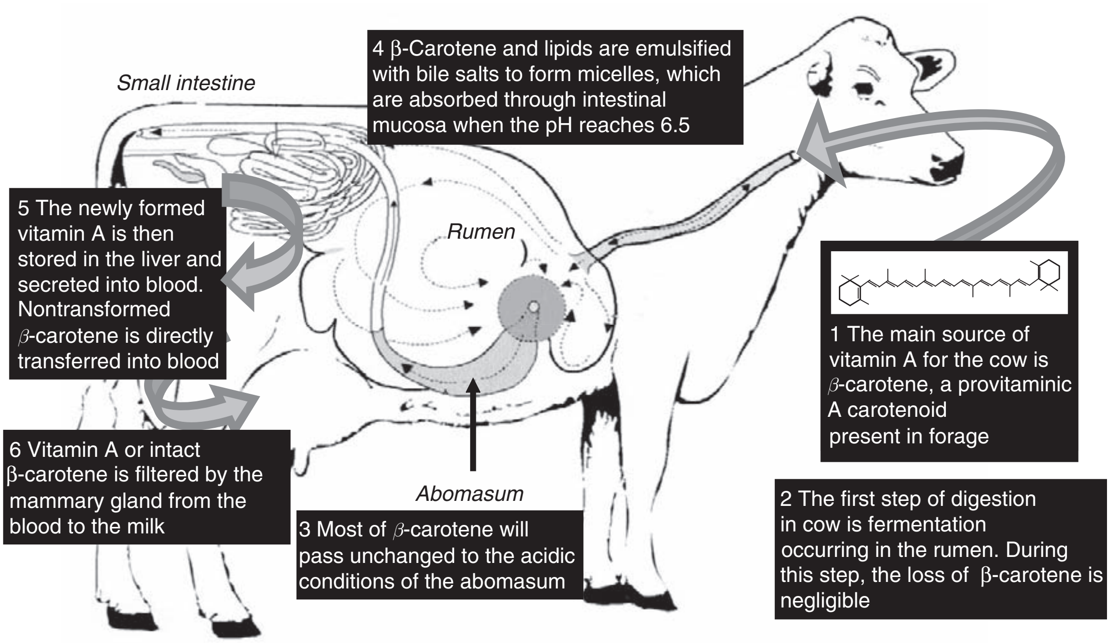
Cattle differ from most farmed animals in that they have a significant concentration of circulating β-carotene in their blood. The concentration of β-carotene in blood is dependent on the concentration in feeds, and is particularly high in animals grazing fresh forage. A high blood β-carotene concentration results in yellow coloration of both body fat and milk, and this can influence consumer acceptance of the product.

Both β-carotene and vitamin A are fat-soluble compounds, and consequently, they will be distributed in the lipid globules in milk. When fresh forage is ingested by cattle, about 60% of plant cells are ruptured by chewing (the first step of digestion), releasing cellular contents. Then, the intracellular contents are processed first in the rumen where negligible loss of β-carotene (in contrast to vitamin A) occurs during fermentation. Probably, most of the carotenoids consumed will pass unchanged to the acidic conditions of the abomasum. Lipids and β-carotene are then emulsified with bile salts in the small intestine to form micelles, and maximum lipid absorption occurs when the pH reaches 6.5. After this step of solubilization,

β-carotene is absorbed by enterocytes, and transported with other lipids as β-carotene or linked to specific protein carriers (the retinol-binding proteins) as vitamin A. The efficiency of β-carotene absorption in the cow has not yet been published. However, considering the respective levels of its ingestion with the diet (0.1 to 3 g day^{-1}) and secretion *per se* in milk (1 to 10 mg day^{-1}), the transfer rate of β-carotene from diet to milk could be estimated to be 0.1 to 1.2%. However, this value is underestimated since part of the absorbed β-carotene is converted to retinol to meet the cow's requirements for vitamin A, the latter being stored in the liver of the cow, used by the peripheral tissues, or secreted in the milk (3 to 4 mg day^{-1}) (**Figure 2**). Lactating cows producing 10, 20, or 30 l milk day^{-1} are estimated to require, respectively, 300, 500, and 700 mg β-carotene day^{-1}. These quantities are based on a daily requirement of 100 mg day^{-1} for biological functions and a supplement of 20 mg l^{-1} of produced milk.

The mechanism by which β-carotene is metabolized to retinaldehyde in the intestinal mucosa, or to a lesser extent in the liver, is well defined in humans and rats. This process involves the enzyme called 15-15′-β-carotene monooxygenase. Two theories have been proposed to explain the formation of vitamin A (retinol or retinoic acid) from carotenoids: (1) the central cleavage theory and (2) the eccentric cleavage theory. The first theory is based on the fact that the addition of one molecule of oxygen at the central double bond of carotenoids can lead to the formation of two molecules of retinaldehyde, which are then processed into molecules of retinol or retinoic acid. The second theory has been developed by Krinsky and Russel, who found apocarotenals after incubation of carotenoids with intestine or liver homogenates of rabbit or ferret. Indeed, the system of conjugated double bonds contained in the carotenoid could lead to a resonance phenomenon in which the central double bond of carotenoids is more stable than the others. Consequently, the eccentric cleavage of carotenoids occurs, leading to the formation of only one molecule of retinaldehyde, which is then processed into only one molecule of retinol or retinoic acid. However, today, most authors favor the central cleavage as the most prevalent physiological mechanism. The eccentric oxidation might be an artifact explained by a chemical and nonspecific degradation (nonenzymatic degradation) of carotenoids (**Figure 3**).

Because retinoic acid, the active metabolite of vitamin A, is a potent regulator of gene expression, its precursor (i.e., retinol) concentration has to be regulated precisely in circulating blood to avoid any deleterious effect due to a high concentration of vitamin A. The main plasma form of vitamin A is retinol, which circulates bound to retinol-binding protein (RBP) and transthyretin (TTR).



Small intestine
4 β-Carotene and lipids are emulsified with bile salts to form micelles, which are absorbed through intestinal mucosa when the pH reaches 6.5
5 The newly formed vitamin A is then stored in the liver and secreted into blood. Nontransformed β-carotene is directly transferred into blood
Rumen
1 The main source of vitamin A for the cow is β-carotene, a provitaminic A carotenoid present in forage
6 Vitamin A or intact β-carotene is filtered by the mammary gland from the blood to the milk
Abomasum
3 Most of β-carotene will pass unchanged to the acidic conditions of the abomasum
2 The first step of digestion in cow is fermentation occurring in the rumen. During this step, the loss of β-carotene is negligible

Figure 2 Metabolism of vitamin A and β-carotene in cow.

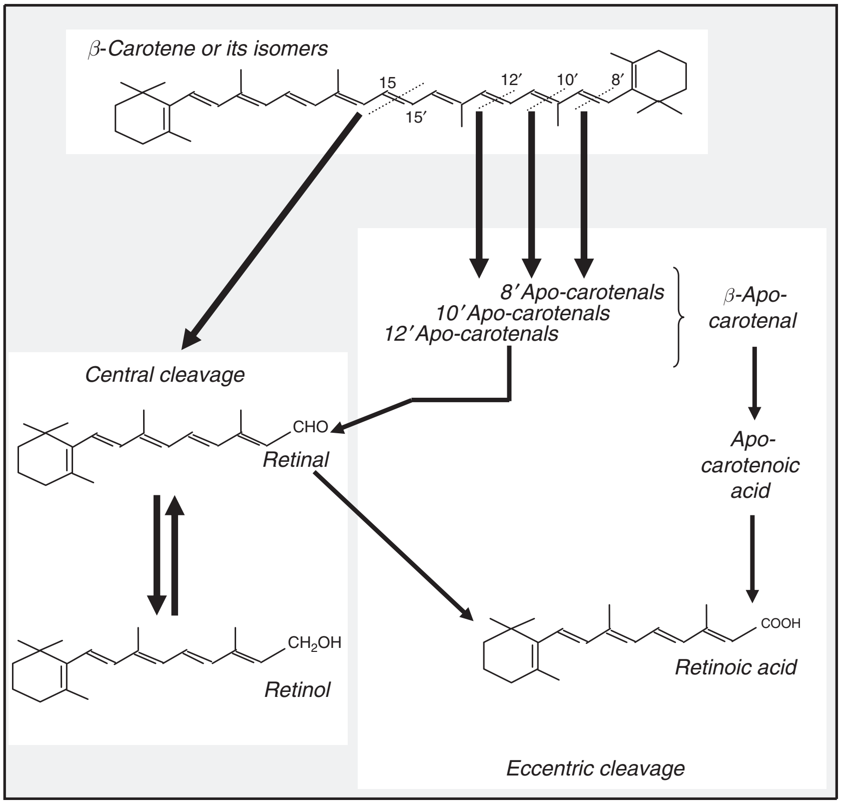


Figure 3 Different cleavage pathways for β-carotene.

Milk is produced by the mammary gland through filtration of blood. An increase in dietary α-tocopherol and β-carotene supply has been shown to lead to higher plasma concentrations of these nutrients in lactating cows but not of circulating retinol. However, in the milk of the same animals, α-tocopherol concentration increased accordingly, whereas β-carotene secretion seemed to saturate near $0.13\,\mathrm{mg\,ml^{-1}}$ and retinol content was stable ($0.19\,\mathrm{mg\,ml^{-1}}$). Elsewhere, the quantitative secretion of α-tocopherol and β-carotene from blood to milk has been shown to follow the Michaelis–Menten kinetics for active transport across membranes ($V_{\max}$ was, respectively, 32.4 and $2.5\,\mathrm{mg\,day^{-1}}$). These results suggest that the daily secretion of vitamin E and β-carotene is limited in quantity. Because retinol concentration is stable in plasma, retinol concentration in milk is also relatively stable.

Factors that Influence the Concentration of Vitamin A and β-Carotene in Milk

The composition of milk is a key factor in its economical value, as well as a relevant criterion in terms of nutrition. Factors that influence milk composition, especially β-carotene concentration, are the breed, the genetics and the age of the animal (mainly parity), the stage of lactation, and the composition of the diet. Channel Island cows, Jerseys and Guernseys, have a higher β-carotene and a lower vitamin A content in the milk fat than other breeds (Friesians). Genetic correlations between carotene yield and the production traits are positive. No significant differences have been observed between mastitic and non-mastitic cows for vitamin A and β-carotene levels in milk. The levels of fat-soluble vitamins (A, E, and β-carotene) in milk are also very much dependent on the amounts of these compounds consumed by the cow. The highest levels are normally found during spring and summer, when the cows are fed on fresh carotene-rich pasture. In forages, a gradient of β-carotene concentration is found from maize silage (1 to $4\,\mathrm{mg\,kg^{-1}}$ DM), hay (5 to $10\,\mathrm{mg\,kg^{-1}}$ DM), haylage (5 to $20\,\mathrm{mg\,kg^{-1}}$ DM), grass silage (25 to $100\,\mathrm{mg\,kg^{-1}}$ DM depending on direct cut or wilting intensity), and fresh grass (up to $400\,\mathrm{mg\,kg^{-1}}$ DM). In milk obtained under experimental conditions, the same trend was observed according to diet composition (from 1 to 2.5 and $2.8\,\mathrm{\mu g\,g^{-1}}$ fat for β-carotene and retinol, respectively, in milk from maize silage-fed cows, to more than $5\,\mathrm{\mu g\,g^{-1}}$ fat for both in milk from cows at pasture). However, under the real conditions at the farm, animal variability and the effect of the nature of forage are limited due to mixing of individual milks in the tank and to specific vitamin supplementations (A and E) through the feed concentrates. Such is not the case for β-carotene for which lower dietary intakes in winter result in a decrease of milk fat color.

Plasma carotene and fat color are generally correlated, with increases in plasma carotene being associated with increases in the concentration of carotene in the milk. In addition, plasma carotene level is well correlated with the amount of ingested carotene. So, β-carotene concentration in milk is usually quite low during the period when the cattle are kept in sheds, as compared with the grazing period. At the end of the grazing period (autumn), when the grass turns yellow, the concentration of carotenoids in forage decreases and, as a consequence, the level of β-carotene both in the blood serum and in milk decreases. Therefore, there is a clear seasonal effect on milk β-carotene content, essentially due to the β-carotene concentration in the pasture eaten by the cow. β-Carotene concentration in milk has been measured in very few studies (**Tables 1** and **2**).

Effects of Processing Conditions on Vitamin A and β-Carotene Content of Milk and Dairy Products

Milk or some of its components are raw materials for a great number of dairy products after various technological processes. These processes are, essentially, designed to improve the stability of milk.

To partially or totally eliminate the microorganisms found in raw milk, dairy industries use thermal treatment. Pasteurization (72 to 76 °C for 15 s) is a mild treatment, whereas ultra-high temperature (UHT) (130 to 140 °C for 3 to 20 s) treatment is more drastic. Under low oxygen tension, retinol is considered to be heat resistant. However, reports on retinol stability are sometimes inconsistent, which may be related to the analytical method used. Several studies in which total vitamin A and total carotenoid levels were measured after different thermal treatments showed that these levels are not affected by heat processing, especially because these treatments are carried out under a closed atmosphere (without removal of air). Nevertheless, using higher-resolution techniques, some authors have demonstrated that during heat treatment, isomerization of retinol may occur. Indeed, in raw milk, the main form of vitamin A is all-*trans* retinol, whereas the level of the 13-*cis* isomer is increased in heat-treated milk. This *cis–trans* isomerization can also be promoted directly by exposure to light, the relative amount of different *cis* isomers depending on the wavelength of the light and the light permeability of the container. A comparison among glass, plastic, and paperboard containers showed no significant loss of all-*trans* retinol in milk contained in paperboard boxes, while the loss was significantly lower in plastic containers than in glass. From a nutritional point of view, it is fundamental to evaluate the pattern of isomers produced in milk after heating or storage. Hence, isomerization of all-*trans* retinol reduces its vitamin activity: 13-*cis* retinol has the highest vitamin A biological activity (75%) relative to all-*trans* retinol (100%), while 9-*cis* retinol exhibits a biological activity as low as 19%. The other isomers have even lower vitamin A activity.

In order to stop the growth of microorganisms in milk, other thermal treatments, such as chilling and freezing,

Table 1 Influence of technical treatments and fat content on vitamin A and carotenoid concentrations in milk

		Retinol	*Carotenoids*	*Total vitamin A*	*Fat*
	Different types of cow's milk	*(μg per 100 g of milk)*	*(μg per 100 g of milk)*	*(μg RE per 100 g of milk)*	*(%)*

may be used. These treatments do not modify vitamin A or carotenoid content. Because vitamin A and carotenoids are fat-soluble compounds, their concentration in milk is increased after elimination of water, by concentration (375 IU 100 g^{-1} of milk) or by dehydration (1150 IU 100 g^{-1} of milk). These differences observed in the concentration of vitamin A during these treatments are due mainly to the degree of concentration occurring during each treatment (×2.5 and ×8, respectively, for concentrated and dehydrated milk).

Fresh, dehydrated, and condensed milk represent the principal sector (~46%) of the world's trade in dairy products and the most consumed dairy products. In these products, the amounts of vitamin A and carotenoids are not modified when compared to those in whole milk. The other main sectors are cheese (~36%), butter (~11%), and ice cream, which represent only 4% of the world sales of milk. Because vitamin A and carotenoids are located exclusively in milk fat, their concentrations decrease proportionally with the degree of skimming of milk (see **Tables 1** and **2**).

For cheeses, recent data have shown that the rates of transfer of retinol and β-carotene from milk fat to cheese fat average 66 and 95%, respectively, considering four different cheesemaking technologies (three from cow's milk: Abondance, Tomme de Savoie, and Cantal; one from goat's milk: Rocamadour) and with the original milk covering a large range of concentration of these micronutrients. Cow's milk cheeses were found to be richer in β-carotene (3.27 mg kg^{-1} fat) and poorer in retinol (5.17 mg kg^{-1} fat) than goat's milk cheeses (0 and 6.81 mg kg^{-1} fat, respectively). Moreover, these values did not vary according to the cheesemaking process (acidification level, heating temperature, ripening time) in agreement with previous reports. Elsewhere, large retinol losses have been reported during heating and ripening of Gruyère cheese, which would result mainly from retinol instability due to exposure to light during cheesemaking technology (photoisomerization into 13-*cis* isomer).

Nutritional Issues

In cows, as in all mammals, vitamin A homeostasis in blood is very well regulated by the liver, avoiding any deleterious effects related to an excess of vitamin A. Inversely, the level of carotenoids in blood is strongly influenced by the nature of the diet. Because milk is the result of a specific synthesis of proteins (caseins, etc.), glucides (lactose, etc.), and lipids (short-chain fatty acids, etc.) and of blood transfusion for vitamin A and carotenoids, the vitamin A content of milk is quite stable, whereas β-carotene concentration (the main provitamin A carotenoid in milk) follows the concentration of β-carotene in the forage consumed by the cow. Because the concentration in forage is highly dependent on season and altitude, milk composition also varies according to these conditions.

Vitamin A and β-carotene are relatively stable during food processing and storage. The main factors that may influence the stability of these compounds are exposure to light and the skimming process. Because milk is stored in opaque containers, their levels are not changed significantly during storage. Because vitamin A and β-carotene are fat-soluble, their concentrations are closely related to the fat percentage, and are dependent largely on the skimming process. This consideration is nutritionally important, in view of the recommendation to reduce the consumption of a fat-rich diet in an attempt to reduce the risk of cardiovascular disease. For example, in France, most of the milk consumed is half-skimmed milk, which results in a reduction in the intake of fat-soluble vitamins.

When the reduction of fat intake in the whole diet remains limited, the consequent reduction in the level of fat-soluble vitamins generally has little nutritional outcomes, especially for vitamin A, which can be obtained from β-carotene from fruits and vegetables. However, some special diets, including the slimming diets, can have a critically low nutritional density and may create infraclinical nutritional deficiencies. This problem is real in some population categories, and restoration (addition of the vitamins unavoidably lost because of the technological process) or enrichment (addition of vitamins above the level contained in the raw materials) is a good means to cope with it. With or without restoration or enrichment, milk and dairy products are excellent sources of vitamin A, a vitamin involved in several key physiological functions in animals and humans.

Vitamin D

W A van Staveren and L C P M G de Groot, Wageningen University, Wageningen, The Netherlands

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Vitamin D is the generic descriptor for all steroids having similar biological activity as cholecalciferol or vitamin D_3. Important forms of vitamin D in this context are the following:

- ergocalciferol (vitamin D_2): is sparsely present in natural sources, but it is the major synthetic form of vitamin D;
- cholecalciferol (vitamin D_3): is widely distributed in animals, in which its provitamin D form, 7-dehydrocholesterol, is a normal metabolite, but in contrast it has an extremely limited distribution in plants;
- calcidiol (25-hydroxyvitamin D (25(OH)D)): is produced in the liver from D_2 or D_3 and circulating calcidiol is a good indicator of the vitamin D status in humans;
- calcitriol (1,25-dihydroxyvitamin D ($1,25(OH)_2D$)): is the result of further hydroxylation of calcidiol in the kidney; it is the most active form of vitamin D.

In human beings, the main source of vitamin D is cutaneous formation when the skin is exposed to adequate sunlight. Therefore, vitamin D might be considered a hormone and not a vitamin. Deficiencies of vitamin D lead to structural lesions of bone. The role of vitamin D in the increasing prevalence of osteoporosis and related fractures in elderly people has led to new research in recent decades. The discovery that most tissues and cells have a vitamin D receptor (VDR) and that several possess the enzymes necessary to convert the primary circulating form of vitamin D, 25(OH)D, to the active $1,25(OH)_2D$ has provided new insights into the vitamin. Of great interest is the role it can play in reducing the risk of many chronic illnesses. The results of studies have led to ongoing discussions about daily requirements of vitamin D.

Historical Perspective and Discovery of Vitamin D

Vitamin D is a unique vitamin and hormone the origin of which dates back about 750 million years when it was first produced in ocean-dwelling phytoplankton and zooplankton while these were being exposed to sunlight. It is likely that most plants and animals exposed to sunlight have the capacity to produce vitamin D. In the nineteenth century, Bennett (1812–75) of Edinburg recognized the nutritional value of cod liver oil in the treatment of rickets. In the same century, Mellanby showed in experiments with puppies that rickets is a nutritional disease which responded to a fat-soluble vitamin present in cod liver oil. Rickets is a bone disease characterized by deformities of the skeleton, shortened stature, and muscle weakness. The disease was first identified in children living in industrialized cities of northern Europe. The relationship between lack of sunshine and rickets was demonstrated by Sniadecki in Poland in 1822, and McCollum and associates showed that the antirachitic activity of cod liver oil was due to vitamin D rather than vitamin A.

In the early twentieth century, Steenbock and Black exposed a variety of foods such as wheat, lettuce, vegetable oils, and animal feed to ultraviolet (UV) radiation. They found that this radiation gave antirachitic activity to these foods. It was in the early 1930s that Askew's and Windaus's groups isolated and identified 'ergocalciferol' or vitamin D_2 by irradiation of ergosterol. A few years later, after a suggestion of Wadell, Windaus's group also isolated 'cholecalciferol' or vitamin D_3 by irradiation of 7-dehydrocholesterol. Once the structure of vitamin D was established in the 1960s and a simple process was developed for its synthesis, vitamin D could be used as a supplement and was added directly to milk in the United States. In Europe, other supplementation programs were developed for the prevention of rickets.

In the 1970s, intensive research on vitamin D revealed that vitamin D is a hormone rather than a vitamin.

Chemistry

Vitamin D is the generic descriptor for all steroids exhibiting qualitatively the biological activity of cholecalciferol. These compounds contain the intact 'A', 'C', and 'D' steroid rings being ultimately derived *in vivo* by photolysis of the 'B' ring of 7-dehydrocholesterol (see **Figure 1**).

These compounds have either of two types of isoprenoid side chains attached to the steroid nucleus at C-17 of the 'D' ring. Ergocalciferol and derivatives have one side chain containing nine carbons and a double bond. Cholecalciferol and derivatives have a side chain with eight carbons and no double bond. Cholecalciferol (D_3) and ergocalciferol (D_2) are white to yellowish powders and are insoluble in water, moderately soluble in fats, oils,

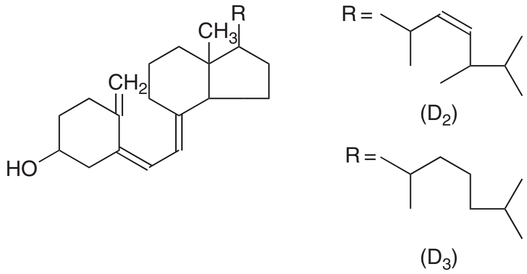

Figure 1 Structure of vitamin D (calciferol).

and ethanol, and freely soluble in acetone, ether, and petroleum ether. Each shows a strong UV absorption, with a maximum at 264 nm. Vitamin D is sensitive to oxygen, light, and iodine. Heating and mild acidity can convert it to an inactive form. Whereas the vitamin is stable in dry form, in organic solvents and most plant oils (due to the presence of α-tocopherol, which serves as a protective antioxidant), its thermal- and photolability can result in losses during such processes as saponification with refluxing. However, storage and processing of foods in general do not affect vitamin D activity.

Food Sources and Endogenous Synthesis

The main food sources of vitamin D are fish and fish products, many of which contain 5–15 μg per 100 g, and foods to which vitamins have been added. **Table 1** shows the main sources in Europe.

This list does not include dairy products, because the amount is only 0.7–1.0 $\mu g\, l^{-1}$ whole milk. Even a high-fat dairy product like butter does not contain more than 0.75 μg per 100 g. Also, human milk does not contain much vitamin D, at least 75% of which is available as calcidiol (vitamin D_2). The total activity in human milk is about 0.4–0.6 $\mu g\, l^{-1}$, which does not meet the daily requirement of infants; an extra supply is required either via exposure to sunlight or by vitamin D supplements.

Photosynthesis of pre-cholecalciferol occurs in the skin during exposure to sunlight. The high-energy UVB photons with wavelength between 290 and 320 nm penetrate into the skin, where they are absorbed by epidermal and dermal stores of 7-dehydrocholesterol (D_3). When the sky is clouded, exposure to this radiation is only 30% and via glass it is reduced to about zero. Only 2 h after pre-cholecalciferol is formed in the skin, it is converted to cholecalciferol. Once formed, cholecalciferol exits the skin into the dermal capillary bed where it is bound to a vitamin D-binding protein (DBP). In 1967, Loomis estimated that the pink cheeks of a European infant (area 20 cm^2) can synthesize daily about 10 μg of vitamin D if adequately exposed; this is sufficient to prevent rickets.

Absorption and Metabolism

Dietary vitamin D is predominantly in the D_3 form and is passively absorbed from the small intestine. The absorption is dependent upon micelle solublization and, hence, the presence of bile salts. Vitamin D enters the lymphatic circulation mainly with chylomicrons and is predominantly associated with the α-globulin fraction. The efficiency of this absorption process for vitamin D appears to be about 50%. After absorption, vitamin D is transported first to the liver and converted to 25-hydroxycalciferol (calcidiol), and then it is converted in the kidney to 1,25-dihydroxycalciferol (calcitriol), the metabolically active form of the vitamin.

Table 1 Important dietary sources of vitamin D

Source		*Vitamin D content*
Fish		The vitamin D content depends on where fish is caught
	Pike, perch	9–12 μg per portion (150 g)
	Salmon	20 μg per portion (150 g)
	Sardines, canned	2.2 μg per can (70 g fish)
	Tuna, canned	1.2–2.0 μg per can (70 g fish)
Wild mushrooms	Wild chanterelles	13 μg per 100 g
Meat products		The vitamin D content of meat products probably depends on the feed of the animals
	Liver	1.8–2.7 μg per 100 g
	Chicken	1.7 μg per 100 g
Eggs		1.4 μg per 110 g
Margarine		Vitamin D is added to margarine in most European countries
Milk	Whole	0.7–1.0 μg per 100 ml
	Low fat	0

1 μg vitamin D = 40 IU.

From European Commission (1999) Report on Osteoporosis in the European Community. Luxemburg: Directorate Employment: Social affairs and Health.

Vitamin D, like other steroids, is transported in the plasma in association with the protein called DBP. The appearance of vitamin D in the blood is short-lived, as it is either stored in the fat or metabolized in the liver. The half-life of 25(OH)D in the human circulation is approximately 10 days to 3 weeks. It has been suggested that the efficiency of endogenously produced vitamin D_3 is greater than that given orally because the former enters the circulation strictly via DBP, whereas the latter enters as complexes with DBP as well as in chylomicrons. This indicates that oral vitamin D remains longer in the liver and is therefore catabolized more quickly to excretory forms. Furthermore, cholecalciferol (D_3) is very photolabile and when it does not escape in the circulation after it is formed in sunlight, it will be converted efficiently into nontoxic substances.

DBP has a higher affinity for 25(OH)D than for $1,25(OH)_2D$, most likely because 25(OH)D is present in the circulation at concentrations about 1000 times higher than that of $1,25(OH)_2D$, and DBP binds 99% of it.

Metabolic Functions

The most clearly elucidated function of vitamin D is the maintenance of homeostasis of Ca^{2+} and phosphate in the extracellular fluid. Three organ systems are involved in the regulation: intestinal absorption; bone accretion; and mobilization and renal excretion. In these systems, control of the blood levels of Ca^{2+}, parathyroid hormone (PTH), and calcitonin (CT) is important (see **Figure 2**).

For example, when serum Ca^{2+} falls below the target level of $10\,mg\,dl^{-1}$, PTH is secreted by the parathyroid glands, which function to detect hypocalcemia. The kidney responds in two ways to increased PTH level: diuresis of phosphate and stimulation of 25(OH)D-1α-hydroxylase. The latter effect increases the production of

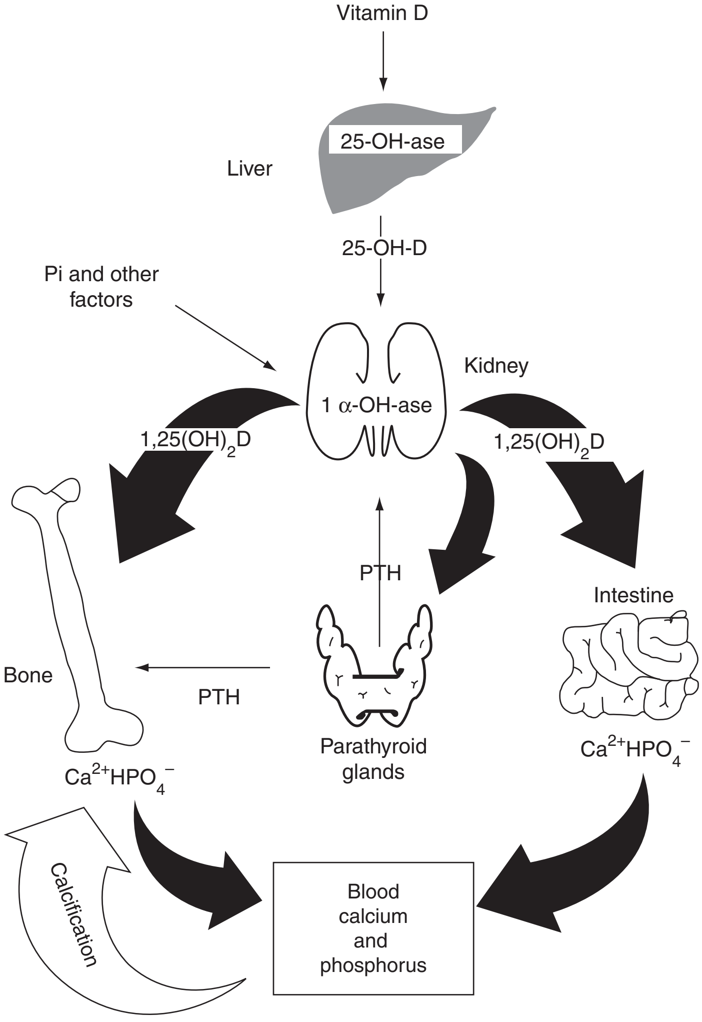

Figure 2 Metabolism of vitamin D and the biological actions of 1,25-dihydroxycholecalciferol ($1,25(OH)_2D$). PTH, parathyroid hormone.

$1,25(OH)_2D$, which will stimulate the enteric absorption of both Ca^{2+} and phosphate. Also, calcitriol acts jointly with PTH in bone to promote the mobilization of Ca^{2+} and phosphate. The combined result of these responses is an increase in the concentration of Ca^{2+} and phosphate in the plasma. Clearly, in the long run, this will lead to demineralization of bone and consequently to an increased risk of fractures.

In addition to maintaining homeostasis of Ca^{2+} and phosphate in the extracellular fluid, $1,25(OH)_2D$ exerts its effects by binding to a specific nuclear receptor (VDR), a ligand-dependent transcription factor that belongs to the superfamily of steroid–thyroid hormone–retinoid nuclear receptors. This VDR when activated switches on the gene that induces synthesis of a calcium transport protein (calbindin) in the epithelium of the small intestine. Until now, the main effects of VDR have been found in the small intestinal epithelium and the cells in the bone, osteoblasts (that form new bone), and osteoclasts (that break down bone). However, VDR appears to be present not only in these target cells, but also in a range of tissues. This observation will lead to promising research on the functional role of vitamin D in areas such as type I diabetes, some cancers, autoimmune disease (e.g., multiple sclerosis), and infectious diseases (e.g., tuberculosis).

Reference Intakes

The Institute of Medicine of the US National Academy of Sciences has estimated adequate intakes of vitamin D for those with no sun-mediated synthesis in the skin. For those aged 0–50 years (including pregnant and lactating women), the adequate intake is $5\,\mu g\,day^{-1}$; for those 51–70 years of age, $10\,\mu g\,day^{-1}$; and for those over 70 years of age, $15\,\mu g\,day^{-1}$. The European Community has an ongoing project (EURRECA) to harmonize dietary reference intakes. First results show that the median vitamin D intake recommendations for the European population vary from $5\,\mu g\,day^{-1}$ for people aged 5–50 years to 10–15 μg for younger and older age groups and for pregnant and lactating women. But note that the reference intake is already up to 20 μg according to EURRECA. With a few exceptions, in most countries the median recommendations are the same for males and females.

Factors Affecting Vitamin D Requirements

Availability of Calcium

Vitamin D requirement is inversely related to the intake of calcium. Calcium is absorbed by active transport, which is vitamin D-dependent, and passive diffusion, which does not depend on the availability of vitamin D. When the intake of calcium is high, the percentage absorbed is low, and is mostly by passive absorption. This makes the requirement for vitamin D also lower. The vitamin D requirements mentioned are based on an adequate intake of calcium and other nutrients.

Dietary Fiber

Studies have shown that increasing dietary fiber in a daily diet from 20 to 40 g shortens the biological half-life of calcidiol by about 30% and therefore may increase the requirements for vitamin D by 40%.

Skin Pigmentation

Melanin skin pigmentation determines the color of the skin. Increased melanin pigmentation reduces the efficiency of sun-mediated photosynthesis of pre-cholecalciferol. This is particularly important for dark-colored immigrants who live in Northern latitudes and who ingest little dietary vitamin D.

Effect of Latitude, Season, and Time of the Day

Latitude, season, and time of the day have a dramatic effect on the cutaneous production of vitamin D_3. Above and below latitudes of approximately 40° N and 40° S, respectively, vitamin D_3 synthesis in the skin is absent during most of the 3–4 winter months. This also holds for the middle of the day, when in summer production of vitamin D via sunlight is highest. Far-Northern and far-Southern latitudes extend this period to 6 months.

Sunscreen Use, Clothing, and Glass

Sunscreens protect against the damaging effect of high-energy UVB radiation; however, it is this radiation that produces pre-cholecalciferol in the skin. It is therefore not surprising that studies show that young adults covered with a sunscreen with a sun protection factor of 8 or higher are unable to increase circulating vitamin D above baseline after exposure to simulated sunlight. Similarly, clothing absorbs most UV radiation and exposure of the skin to sunlight that has passed through windowpane glass or Plexiglas will not increase circulating calcidiol levels.

Aging

In adults over 65 years, there is a fourfold decrease in the production of vitamin D compared with younger adults aged 20–30 years. This is well documented. It is not known whether the absorption of physiological amounts of vitamin D is altered. However, after the age of 20 years, skin thickness decreases linearly with age. This thickening reduces the synthesis of vitamin D. Nevertheless, it has been shown that 5 min exposure daily to UV light to

$0.1\ \mathrm{m}^2$ (about hands and face) has the same effect as a daily supplement with 10 μg vitamin D. Clearly, important additional risk factors in elderly people are immobility and protection against sunlight. Since dietary intake for most people will not exceed $5\ \mu\mathrm{g\,day}^{-1}$, unless sufficiently fortified foods are used, elderly people above the age of 70 (and in some countries even earlier) are advised to use a vitamin D supplement.

Obesity

Obesity is associated with vitamin D insufficiency and secondary hyperparathyroidism. It has been demonstrated that in obese individuals (body mass index (BMI) $>30\ \mathrm{kg\,m}^{-2}$), bioavailability of cutaneously synthesized vitamin D_3 is reduced by >50%. Obesity-associated vitamin D insufficiency is most likely due to the deposition of vitamin D_3 from cutaneous and dietary sources in body fat compartments.

Malabsorption Disorders

Patients suffering from various intestinal malabsorption syndromes, such as steatorrhea, sprue, Whipple's disease, Crohn's disease, and severe liver failure, often suffer from vitamin D deficiency, due to their inability to absorb vitamin D via the intestine; they should receive vitamin D either via exposure to UV light or intravenously.

Vitamin D Deficiency and the Relationship with Chronic Disease

Two forms of bone disease, caused by inadequate mineralization or demineralization of the skeleton, may accompany vitamin D deficiency. Severe deficiency results in rickets in children and osteomalacia in adults. Rickets in children is characterized by widening at the end of the long bones, rachitic rosary, and deformations in the skeleton including frontal bossing and outward or inward deformities of the lower limbs causing bowed legs or knocked knees, respectively. Signs of osteomalacia are more generalized than those of rickets, for example, muscle weakness and bone tenderness, especially in the spine, shoulders, ribs, or pelvis. Patients with osteomalacia are at increased risk to fractures of all types, but particularly to those of the wrist and pelvis.

In addition, the secondary hyperparathyroidism associated with vitamin D deficiency enhances mobilization of calcium from the skeleton, resulting in osteoporotic bones. It is one of the causes of osteoporosis, the etiology of which is not fully understood but appears to involve impairment of vitamin D metabolism and/or function associated with decreasing estrogen levels.

Vitamin D deficiency causes muscle weakness. This weakness and the susceptibility to infections in rickets or osteomalacia may reflect roles for VDR in the muscles and the immune system.

Causes of a vitamin D-deficient state can be any alteration in the cutaneous production of vitamin D_3, absorption in the intestine, or the metabolism of vitamin D to its active form, $1{,}25(OH)_2D$. Furthermore, an alteration in the recognition of $1{,}25(OH)_2D$ by its receptor can also cause vitamin D deficiency, metabolic bone disease, and accompanying biochemical abnormalities. Biochemical characteristics of vitamin D deficiency are

- reduced plasma calcium and phosphate concentrations,
- an elevated level of serum PTH ($>30\ \mathrm{ng\,ml}^{-1}$) in conjunction with a low level of serum 25(OH)D,
- a serum level of 25(OH)D below $20\ \mathrm{ng\,ml}^{-1}$ or $50\ \mathrm{nmol\,l}^{-1}$,
- an elevated level of serum alkaline phosphate, and
- urinary excretion of bone collagen by-products and an increase in their level, including hydroxyproline, pyridinoline, deoxypyridinoline, and *N*-telopeptide.

There is increasing evidence that in addition to osteoporosis, vitamin D deficiency may be associated with other chronic diseases. For instance, in epidemiological surveys, colon, breast, and prostate cancers seem to be less prevalent in people living at sunny (lower) latitudes and so is multiple sclerosis. A likely explanation is that colon, breast, prostate, and other tissues express 25(OH)D-1α-hydroxylase and produce $1{,}25(OH)_2D$ locally to control genes that help to prevent cancer by keeping cellular proliferation and differentiation in check. It has been suggested that if a cell becomes malignant, $1{,}25(OH)_2D$ can induce apoptosis and prevent angiogenesis, thereby reducing the potential for the malignant cell to survive.

It has been shown in culture experiments that $1{,}25(OH)_2D$ modulates T and B lymphocytes. In Finland, a 20-year trial including treatment of children with vitamin D reduced the risk of developing type I diabetes. Furthermore, psoriasis has long been known to improve in the summer and is now treated with $1{,}25(OH)_2$ derivates. Currently, a relationship between vitamin D and cardiovascular diseases, mental health, lung function, and other autoimmune diseases has also been found. How these findings will affect vitamin D requirements is not yet known.

Hypervitaminosis D

Hypervitaminosis D is characterized by raised circulating 25(OH)D plasma levels up to more than $160\ \mathrm{ng\,ml}^{-1}$, accompanied by thirst, nausea, and anorexia. Hypervitaminosis D involves increased enteric absorption and bone resorption of calcium, producing hypercalcemia, with attendant decreases in PTH and glomerular filtration rate and, ultimately, loss of calcium homeostasis. The result is calcinosis, expressed in various organ systems including kidney, bone, central nervous system, and cardiovascular system.

The upper level of intake per day for adults set by Institute of Medicine of the US National Academy of Sciences is 50 μg and for infants this is 25 μg.

For most people, vitamin D intake from food and supplements is unlikely to exceed the tolerable upper intake levels. However, persons who are at the upper end of the ranges for both sources of intake, particularly those who use many supplements and those with high intakes of fish or fortified milk, may be at risk for vitamin D toxicity.

Under some conditions, people are more sensitive to vitamin D (e.g., sarcoidosis and a rare condition in infants with elfin facial appearance, Williams syndrome).

Vitamin D and Dairy Fortification

As part of a nutrition policy to combat vitamin D deficiency in infants and children, many countries have a vitamin D supplementation program. In some countries, one of the items of this program is fortification of dairy products. Since there is a growing number of elderly people at risk for insufficient vitamin D supply, this might be one of the options to solve this problem. However, since the margin between an adequate vitamin D supply and the upper tolerable level of intake is rather small for elderly people (15–50 $\mu g\,day^{-1}$), caution should be taken to avoid an overdose. In the United States and Canada, where fortification is a long-standing practice, studies have demonstrated that the amount of vitamin D added to milk is variable and does not amount to that stated on the label.

Concluding Remarks

Vitamin D is considered a hormone rather than a vitamin. Nevertheless, as a dietary component it can prevent deficiency diseases, in concert with other sources such as exposure to sunlight and supplements. Undiagnosed vitamin D deficiency is not uncommon and 25(OH)D is the barometer for vitamin D status. Serum 25(OH)D is not only a predictor of bone health, but, according to recent research, is also an independent predictor of risk for cancer and other chronic diseases. In the Western world particularly, elderly people are at risk of an insufficient vitamin D supply. Also immigrants and particularly pregnant and lactating women, with a colored skin and who have moved to countries at a greater distance from the equator, are at increased risk for vitamin D deficiency. In these countries, a sensible and reliable supplementation program including fortification of dairy products may contribute to the prevention of vitamin D-related diseases.

This article is a revision of the previous edition article by P. A. Morrissey and M. Kiely, Volume 4, pp 2670–2677, © 2002, Elsevier Ltd.

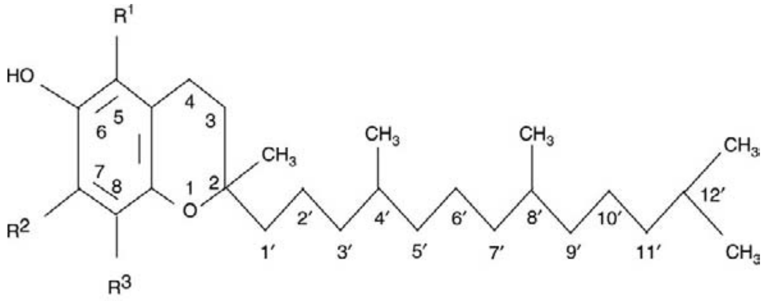
Introduction

In 1922, Evans and Bishop discovered a fat-soluble dietary constituent that was essential for the prevention of fetal death and sterility in rats fed a diet containing rancid lard. This was originally called 'factor X' or 'antisterility factor', but was later named vitamin E. Subsequently, the multiple nature of the vitamin began to appear when two compounds with vitamin E activity were isolated from wheat germ oil and characterized. These compounds were designated α- and β-tocopherol, derived from the Greek 'tokos' for childbirth, 'phorein' meaning to bring forth, and 'ol' for the alcohol portion of the molecule. Later, two additional tocopherols, γ- and δ-tocopherol, as well as four tocotrienols were isolated from edible plant oils. After the initial discovery, more than 40 years passed before it was proved that vitamin E deficiency could cause disease in humans. Vitamin E has been linked to several distinct clinical problems in humans, including hemolytic anemia in premature infants, reduced erythrocyte stability in patients with cystic fibrosis, and 'short bowel syndrome'. Other studies demonstrated that vitamin E plays an essential role in maintaining the integrity of neuromuscular systems and retina. Studies on children and adults with specific causes of fat malabsorption and patients with familial isolated vitamin E deficiency syndrome have conclusively shown that neurological dysfunction is associated with vitamin E deficiency and that vitamin E is an essential nutrient for the optimal development and maintenance of the integrity and function of the human nervous system. One of the more significant developments in the history of vitamin E was the identification that it is an effective lipid-soluble scavenger of lipid peroxyl radicals and, while present at very low concentrations, it is extremely efficient in protecting membranes against lipid peroxidation.

This article reviews the chemistry of the tocopherols and their dietary sources, absorption, transport, and storage mechanisms, and metabolic function. In addition, the potential role of dietary or supplemental tocopherol intake in the prevention of chronic diseases and possible mechanisms for the observed protective effects are discussed. Finally, a summary of the assessment of tocopherol status in humans, intake requirements, and an overview of the safety of high intakes is provided.

Chemistry

The chemistry of vitamin E is rather complex because there are eight structurally related forms – four tocopherols (α, β, γ, and δ) and four tocotrienols (α, β, γ, and δ) – that are produced at various levels and in different combinations by all plant tissues and in some cyanobacteria. All are amphipathic molecules with the general structures shown in **Figure 1**. The polar head group is derived from aromatic amino acid metabolism and the hydrophobic tail is derived from phytyl-diphosphate (phytyl-DP) or geranylgeranyl diphosphate (GGDP) in tocopherols and tocotrienols, respectively. α-Tocopherol is methylated at C-5, C-7, and C-8 on the chromonol ring, whereas the other homologues (β, γ, and δ) differ in the number and positions of the methyl groups on the ring (**Figure 1**). Tocopherols have a fully saturated 20-carbon phytyl side chain attached at C-2 and have three chiral centers that are in the R configuration at positions C-2, C-4^1, and C-8^1 in the naturally occurring form, which are given the prefix 2R, 4^1R, and 8^1R (designated RRR). They are more biologically active than their synthetic counterparts, which are mixtures of all eight possible stereoisomers and are given the prefix all-*rac*. Tocotrienols differ from the corresponding tocopherols in that the 20-carbon isoprenoid side chain at C-3^1, C-7^1, and C-11^1 is unsaturated and they possess one chiral center at C-2 in addition to two sites of geometric isomerism at C-3^1 and C-7^1. Natural tocotrienols have the 2R, 3^1-*trans*, 7^1-*trans* configuration. The phenolic hydroxyl group is critical for the antioxidant activity of vitamin E, as donation of hydrogen from this group stabilizes free radicals. The presence of at least one methyl group on the aromatic ring is also critical. The biological activity of vitamin E is defined in terms of α-tocopherol equivalents (α-TE) whenever possible. RRR-α-tocopherol has an activity of 1 mg α-tocopherol equivalents (α-TE mg^{-1} compound). The activities of RRR-β, RRR-γ, and RRR-δ-tocopherol are 0.5, 0.1, and 0.03, respectively. Synthetic all-*rac*-α-tocopheryl acetate has an activity of 0.74 mg α-TE mg^{-1}. Of the tocotrienols, only α-tocotrienol has significant biological activity (0.3 mg α-TE mg^{-1}). Lengthening or shortening of the side chain results in a progressive loss of vitamin E activity.



Compound	R^1	R^2	R^3
α-Tocopherol	CH_3	CH_3	CH_3
β-Tocopherol	CH_3	H	CH_3
γ-Tocopherol	H	CH_3	CH_3
δ-Tocopherol	H	H	CH_3

Figure 1 The four major forms of vitamin E (α-, β-, γ-, and δ-tocopherol) differ by the number and position of methyl groups on the chromanol ring. In α-tocopherol, the most biologically active form, the chromanol ring is fully methylated. In β- and γ-tocopherol, the ring contains two methyl groups, while in δ-tocopherol, it is methylated at one position. The corresponding tocotrienols have the same structural arrangement except for the presence of double bonds on the isoprenoid side chain at C-3^1, C-7^1, and C-11^1.

Dietary Sources

The composition and content of the different tocopherol components in plant tissue vary considerably, ranging from the extremely low levels found in potato tubers to the high levels found in oil seeds. α-Tocopherol is the predominant form in photosynthetic tissues and is localized mainly in plastids. The particular enrichment in the chloroplast membranes is probably related to the ability of tocopherols to quench or scavenge reactive oxygen species (ROS) and lipid peroxy radicals by physical or chemical means. In nonphotosynthetic tissues, γ-tocopherol frequently predominates and can be involved in the prevention of autoxidation of polyunsaturated fatty acids (PUFAs).

Most of the tocopherol content of wheat germ, sunflower, safflower, canola, and olive oils is in the form of α-tocopherol and these oils contain about 1700, 500, 350, 200, and 120 mg α-TE kg^{-1}, respectively. Vegetable oils such as of corn, cottonseed, palm, soybean, and sesame and nuts such as Brazil nuts, pecans, and peanuts are rich sources of γ-tocopherol. Corn and soybean oils contain 5–10 times as much γ-tocopherol as α-tocopherol-rich sources and each contains about 200 mg α-TE kg^{-1}. Because of the widespread use of these plant products, γ-tocopherol is considered to represent ~70% of the vitamin E consumed in the typical US diet. The level of vitamin E in nuts ranges from 7 mg α-TE kg^{-1} in coconuts to 450 mg α-TE kg^{-1} in almonds. Cereals are moderate sources of vitamin E, providing between 6 (barley) and 23 (rye) mg α-TE kg^{-1}. Fresh fruit and vegetables generally contain about 1–10 mg α-TE kg^{-1}. Different authors have reported concentrations of α-tocopherol between 0.2 and 0.7 mg l^{-1} in bovine milk; γ-tocopherol has also been found in addition to the presence of trace amounts of some other vitamers. Colostrum contains about 1.9 mg l^{-1} of α-tocopherol, and the level decreases in approximately 4 days to the level in fresh milk (0.3 mg l^{-1}). γ-Tocopherol is also present in small amounts. The concentration of vitamin E in milk appears to be dependent principally on the amount consumed by the cows. Even in the case of human milk, the concentration of vitamin E in colostrum is much higher than that in mature milk. Human colostrum contains 14.4 ± 2.3 mg α-TE l^{-1} compared to 3.1 ± 0.5 mg α-TE l^{-1} in mature milk. Ingestion of colostrum is therefore important to provide mammalian neonates with an adequate source of vitamin E to protect against oxidative stress and enhance the immune response. Following birth, colostrum intake induces a sharp increase in the circulating and tissue levels of vitamin E in the young.

Mean dietary intakes of 6.3–13.0 mg α-TE day^{-1} have been reported in various European and American population studies. Data from the Third National Health and Nutrition Examination Survey (NHANES III) (1988–94) in the United States indicate a median total intake (including supplements) of α-TE of 12.9 mg day^{-1} and a median intake from food only of 11.7 mg day^{-1} in men aged 31–50 years. In women in this age range, the median total intake (including supplements) of α-TE was 9.1 mg day^{-1} and the median intake from food only was 8.0 mg day^{-1}. In the United States, fats and oils used in spreads and other products contribute 20.2% of the total vitamin E intake; vegetables, 15.1%; meat, poultry, and fish, 12.6%; desserts, 9.9%; breakfast cereals, 9.3%; fruit 5.3%; bread and grain products, 5.3%; dairy products, 4.5%; and mixed main dishes, 4.0%.

The North/South Ireland Food Consumption Survey, published in 2001, reported that the median daily intake of vitamin E from all sources was 6.3 mg for men and 6.0 mg for women aged 18–64 years. The largest contributors of vitamin E to the diet were vegetables and vegetable dishes (18.9%) and potatoes and potato products (12.4%), most likely as a result of the oils used in composite dishes. Nutritional supplements contributed 5.5% of the vitamin E intake of men and 11.9% of women overall. In the subgroup that regularly consumed nutritional supplements (23% of total), vitamin E was the nutrient most frequently obtained in supplemental form by men (78%) and women (73%). In these people, supplements made a larger contribution to total vitamin E intake than did food.

Absorption, Metabolism, and Excretion

Following ingestion, fats are emulsified into smaller particles, first in the stomach and then in the small intestine, where they are mixed with pancreatic and biliary secretions. Pancreatic esterases convert triglycerides to monoglycerides and free fatty acids, which together with bile acids form micelles into which vitamin E and other hydrophobic molecules become solubilized. Vitamin E is absorbed in the proximal part of the small intestine, where transport across the brush border is thought to occur by passive diffusion. There are no selective differences in absorption between α- and γ-tocopherols, but β- and δ-tocopherols are absorbed poorly and are excreted in the feces. Together with triglycerides, phospholipids, and apolipoproteins, the tocopherols (α and γ) are reassembled to chylomicrons by the Golgi of the mucosal cells. The chylomicrons are stored as secretory granula and eventually excreted by exocytosis to the lymphatic compartment from which they reach the bloodstream via the ductus thoracicus.

The transfer of vitamin E from chylomicrons is regulated by complex mechanisms that control lipid and lipoprotein metabolism. Chylomicrons are degraded to remnants by lipoprotein lipase (LPL) and some α- and γ-tocopherols are transferred to peripheral tissues such as muscle, adipose tissue, skin, and brain by this enzyme-mediated mechanism. The resulting chylomicron remnants are then taken up by the liver, where most of the remaining α-tocopherol and only small amounts of γ-tocopherol are reincorporated into nascent very low-density lipoproteins (VLDLs) by a specific 32-kDa α-tocopherol transfer protein (α-TTP), which enables further distribution of α-tocopherol throughout the body.

Approximately 50% of the dietary intake of γ-tocopherol appears to be degraded in the liver by a cytochrome P450-dependent process and is then excreted primarily in the urine. Catabolism of α-tocopherol by this route occurs only when the daily intake of α-tocopherol exceeds 150 mg or plasma concentration of α-tocopherol is above a threshold of 30–40 μmol l^{-1}. Plasma or serum concentrations of α-tocopherol are typically around 20–35 μmol l^{-1}. γ-Tocopherol concentrations are approximately 5–15% of those of α-tocopherol and generally remain around 1 μmol l^{-1} even after supplementation. The highest concentrations of α-tocopherol in the body are in the adipose tissues and adrenal glands. Adipose tissues are also the major stores of the vitamin, followed by liver and skeletal muscle. The rate of uptake and turnover of α-tocopherol by different tissues varies greatly. Uptake is most rapid in the lungs, liver, spleen, kidney, and red blood cells (in rats $t_{1/2} < 15$ days) and slowest in the brain, adipose tissues, and spinal cord ($t_{1/2} < 30$ days). Likewise, depletion of α-tocopherol from plasma and liver during times of dietary deficiency is rapid, whereas adipose tissues, brain, spinal cord, and neural tissues are much more difficult to deplete.

A considerable, but variable proportion (typically 30–70%) of ingested vitamin E is unabsorbed and therefore excreted in the feces, making this the main route of elimination, and is influenced by experimental conditions and a variety of luminal and physiological factors. When large doses of vitamin E are administered, much of it is secreted in the bile, which may account for the relative safety of vitamin E compared to vitamins A and D. Both bile acids and pancreatic juices are important for the absorption of vitamin E. This has been established clearly in patients where secretion of either, or both, is severely diminished as in patients with cystic fibrosis or pancreatitis. The simultaneous intake of fat is necessary to stimulate bile flow and the secretion of pancreatic enzymes to allow micelle formation. However, the amount of fat necessary to ensure absorption may be small.

Vitamin E as an Antioxidant

Under normal physiological conditions, cellular systems are incessantly challenged by stressors arising from both internal and external sources. The most important potential stressors are reduced derivatives of oxygen, which are classified as ROS. ROS are toxic as they can oxidize biomolecules, leading to cell death and tissue injury, and are associated with the onset of a variety of chronic disease conditions in humans. ROS include the superoxide anion ($O_2^{\cdot -}$), hydroxyl radical ($^{\cdot}OH$, and oxygen-centered radicals of organic compounds (peroxyl ($ROO^{\cdot}$) and alkoxyl ($RO^{\cdot}$)) together with other nonradical reactive compounds, such as hydrogen peroxide (H_2O_2). In addition, reactive nitrogen species (RNS) such as nitric oxide ($NO^{\cdot}$), nitrogen dioxide ($NO_2^{\cdot}$), peroxynitrite ($ONOO^-$), and hypochlorous acid are involved.

Cell systems have evolved a powerful and complex antioxidant defense system to limit inappropriate exposure to these stressors. Much of the work on antioxidant defense has been confined to studies on the chain-breaking antioxidants vitamins C and E and the carotenoids. α-Tocopherol is quantitatively the most important antioxidant in plasma and biological membranes. α-Tocopherol is an indispensable component of biological membranes and has membrane-stabilizing properties. The molecule is anchored in the highly hydrophobic hydrocarbon part of the membrane layer by the isoprenoid chain (**Figure 2**). The chromanol nucleus lies at the surface of lipoprotein or at the membrane–water interface, and it is the phenolic group that quenches free radicals ($X^{\cdot}$) (**Figure 2**). In this position, the chromanol ring has considerable mobility; it is able to quench peroxyl radicals that partition to the water–membrane interface and can be regenerated by harvesting the antioxidant capacity of other lipid-soluble antioxidants (e.g., ubiquinols) and water-soluble reductants, such as ascorbate and glutathione. The overall mechanism of lipid peroxidation and antioxidant protection in biological systems is outlined in **Figure 3**. Steps a and b show the abstraction of a labile hydrogen from a methylene group adjacent to the double bond of an unsaturated fatty acid (RH) by an oxidizing radical ($X^{\cdot}$) and subsequent oxygenation to form a peroxyl radical. Step c shows how the peroxyl radical moiety diffuses out of the autooxidizable, nonpolar interior region of the bilayer and into the non-autooxidizable polar membrane–water interface. Step d shows how the proximity to the interface of the anchored phenol on the chromanol ring allows for rapid formation of the lipid hydroperoxide (ROOH) and tocopheroxyl radical ($TO^{\cdot}$). The $TO^{\cdot}$ can be regenerated, thereby recycling tocopherol. The remarkable antioxidant properties of vitamin E may be explained by its ability to be efficiently re-reduced from its radical form to its native state by ascorbate and other intracellular reductants. The ascorbate radical can be regenerated and the potentially toxic lipid hydroperoxide can be cleaved, detoxified, and repaired.

The antioxidant activities of chain-breaking antioxidants are determined primarily by how rapidly they scavenge peroxyl radicals, thereby preventing the propagation of free radical reactions. When the chromanol phenolic group of α-tocopherol (TOH) encounters a peroxyl radical ($ROO^{\cdot}$), it forms hydroperoxide (ROOH), and in the process a tocopheroxyl radical ($TO^{\cdot}$) is formed:

$$\mathrm{TOH} + \mathrm{ROO}^{\cdot} \xrightarrow{k_1} \mathrm{ROOH} + \mathrm{TO}^{\cdot}$$

The rate constant (k_1) for hydrogen abstraction from α-tocopherol is $2.35 \times 10^6\,\mathrm{mol\,l^{-1}\,s^{-1}}$, which is higher than that for the other tocopherols and related phenols. Because the rate constant (k_2) for the chain propagation reaction between $\mathrm{ROO}^{\cdot}$ and an unsaturated fatty acid (RH) ($\mathrm{ROO}^{\cdot} + \mathrm{RH} \rightarrow \mathrm{ROOH}$) is much lower than k_1, at approximately $10^2\,\mathrm{mol\,l^{-1}\,s^{-1}}$, α-tocopherol outcompetes the propagation reaction and scavenges the $\mathrm{ROO}^{\cdot}$ $\sim 10^4$ times faster than RH reacts with $\mathrm{ROO}^{\cdot}$. The concentration of α-tocopherol in biological membranes is approximately 1 mol per 1000–2000 mol phospholipids (i.e., $\sim$1:10^3). This effectively means that about 90% of $\mathrm{ROO}^{\cdot}$ are scavenged by tocopherol before they can attack another RH. Thus, the kinetic properties of antioxidants, and in particular α-tocopherol, require that only relatively low concentrations are required for them to be effective. Because γ-tocopherol lacks one of the electron-donating methyl groups on the chromonal ring, it is less hydrophobic and is somewhat less potent in donating electrons than α-tocopherol, and is, thus, a slightly less powerful antioxidant. However, the unsubstituted C-5 position on γ-tocopherol allows it to trap lipophilic electrophiles such as RNS. Excessive generation of RNS is associated with chronic inflammation in humans and animals.

Vitamin E Deficiency

Vitamin E deficiency is seen rarely in humans. However, there may be a risk of vitamin E deficiency in premature infants because the placenta does not transfer α-tocopherol to the fetus in adequate amounts. When it occurs in older children and adults, it is usually a result of lipoprotein deficiencies or a lipid malabsorption syndrome. Patients with abetalipoproteinemia or homozygous hypobetalipoproteinemia, those with cholestatic disease, and patients receiving total parenteral nutrition suffer from vitamin E deficiency. There is also an extremely rare disorder in which primary vitamin E deficiency occurs in the absence of lipid malabsorption. This disorder is a rare autosomal recessive neurodegenerative disease, and is caused by mutations in the gene for α-TTP. This disorder is known as ataxia with vitamin E deficiency (AVED). Patients with AVED have extraordinary low plasma vitamin E concentrations ($<5\,\mu\mathrm{g\,ml^{-1}}$) and have an onset between 4 and 18 years, with progressive development of peripheral neuropathy, spinocerebellar ataxia, dysarthria, absence of deep tendon reflexes, and vibratory and proprioceptive sensory loss. Therapeutic and prophylactic vitamin E supplementation (up to $2000\,\mathrm{mg\,day^{-1}}$) prevents the onset of the disease before irreversible neurological damage develops.

Vitamin E and Low-Density Lipoprotein Modification

It is generally accepted that low-density lipoprotein (LDL) undergoes oxidation *in vivo* when challenged by a variety of ROS and RNS and that oxidized LDL is the component central to the initiation and/or progression of atherogenesis at the molecular and cellular level. The typical LDL particle is not only rich in cholesterol, but also contains approximately 1300 molecules of RH, which are very sensitive to oxidation. Vitamin E, mainly as α-tocopherol, is quantitatively the most important lipophilic antioxidant present in LDL particles. On average, each LDL particle is protected by ~10 mol of α-tocopherol (range 3–15 mol), 1 mol of γ-tocopherol, and smaller amounts of carotenoids.

All major cells of the artery wall, such as monocytes–macrophages, endothelial cells, and smooth muscle cells, can modify LDL oxidatively *in vitro*. Monocytes have been shown to induce peroxidation of lipids such as those in LDL by the generation of reactive species, including superoxide anion, hydrogen peroxide, and hydroxyl radicals. Other oxidants have been implicated, including 15-lipoxygenase, myeloperoxidase-generated hypochlorous acid, and RNS such as peroxynitrite. *In vivo*, oxidized LDL particles are recognized by macrophage scavenger receptors and taken up by macrophages, forming lipid-laden foam cells in the fatty streak lesions. The free radical oxidation of LDL results in numerous structural changes that all depend on a common event, that is, the peroxidation of PUFAs in the LDL particle.

In vitro studies have indicated that increasing the vitamin E content of LDL particles increases LDL resistance to oxidation and decreases their uptake by macrophages. A number of research groups have concluded that vitamin E is the most important variable that determines oxidative resistance of LDL. This mechanism of protecting LDL may be significant when γ-tocopherol constitutes a major portion of vitamin E intake, as in the United States. It is worth noting that the ability of γ-tocopherol to attenuate oxidative damage produced by RNS may prevent or delay the progression of other diseases, in which inflammation plays a role, such as cancer, rheumatoid arthritis, inflammatory bowel disease, and neurodegenerative disorders, as well as cardiovascular disease (CVD).

Vitamin E and Other Metabolic Function

Vitamin E, in addition to having a protective role in the oxidative modification of LDL, may affect or limit the progression of atherosclerosis and a number of other conditions in ways that are unrelated to its antioxidant activity, as outlined below:

1. Vitamin E acts as a negative regulator of smooth muscle cell proliferation via modulation of protein kinase C activity and by activating protein phosphatase 2A. Protein kinase C is an important element in the signal transduction cascade mediated by growth factors such as platelet-derived growth factors, which are necessary for the progression and completion of the cell proliferation cycle.
2. Vitamin E may stabilize the atherosclerotic plaque and prevent its rupture and subsequent clot formation. This could be an important contributor to the prevention of ischemic heart disease, because plaque types that are most subject to rupture present the greatest threat.
3. Vitamin E reduces the expression of adhesion molecules that can cause neutrophils to stick to the endothelial cells lining the artery, leading to platelet aggregation.
4. Vitamin E may inhibit vitamin K-dependent clotting factors by the action of vitamin E quinone.
5. Vitamin E supplementation reduces the level of thromboxane A_2 *in vivo*, supporting the role of vitamin E as an antithrombic agent.
6. Vitamin E reduces the uptake of oxidized LDL by endothelial cells, preserves the barrier function, increases the activity of cytosolic phospholipase A_2 and cyclooxygenase, and augments the release of prostaglandin I_2 by endothelial cells. Thus, vitamin E may act both directly, by affecting the uptake of oxidized LDL by endothelial cells, and indirectly, by modulation of oxidized LDL formation and activity.
7. Vitamin E regulates mitochondrial production of ROS, changes the redox state and/or redox controlling factors, and in turn modulates redox-sensitive signaling pathways and transcriptional factors (e.g., activator protein 1, nuclear factor κB, mitogen-activated protein). High levels of ROS are likely to increase the expression of a number of 'atherogenic' genes and signal transduction pathways leading to inflammation and vascular dysfunction. At low levels of ROS, 'atheroprotective' genes are expressed, anti-inflammatory factors are produced, and the vascular system is protected. Thus, by regulating the production of ROS, vitamin E modulates the expression and activation of signal transduction pathways and other redox-sensitive biological modifiers, and thereby may prevent or delay the onset of degenerative diseases.

Vitamin E and Cardiovascular Disease

The effects of dietary vitamin E have been examined in several studies, and many have reported a clear association between reduction in the relative risk of CVD and high intakes of vitamin E from foods or supplements of vitamin E, although some have shown no such association. The Vitamin Substudy of the WHO/MONICA Project showed that in European populations whose classical risk factors for CVD were very similar, the sevenfold differences in CVD mortality could be explained at least to about 60% by differences in the plasma level of vitamin E and up to 90% by the combination of vitamins E, A, and C. The Edinburgh Case Control Study and Basel Prospective Study consistently revealed an increased risk of ischemic heart disease and stroke for low plasma level of vitamin E.

However, other European population studies have not found an association between blood levels of vitamin E and end points of CVD. In the European Community Multicentre Study on Antioxidants, Myocardial Infarction and cancer of the Breast (EURAMIC) study, the adipose levels of vitamin E did not correlate with the relative risk of myocardial infarction.

A number of prospective studies examined the association between vitamin E intake and risk of CVD. The Nurses' Health Study, conducted on 87 245 women, showed a 34% reduction in CVD in women who had consumed vitamin E supplements containing more than 67 mg α-TE daily for more than 2 years. However, there was no significant effect of vitamin E obtained from food sources. The Established Populations for Epidemiologic Studies of the Elderly (EPESE) trials showed that the use of vitamin E supplements significantly reduced the risk of all-cause mortality and mortality from heart disease. Another prospective study, performed in Canada, reported a consistent inverse association between CVD and vitamin E supplement usage. The Health Professionals Study, conducted on 39 910 men aged 40–75 years, also showed that dietary intakes of vitamin E were not significantly correlated with reduced risk of CVD or death. A protective effect was seen in those who took 67–160 mg supplemental α-TE daily for more than 2 years. In contrast, the Iowa Women's Health Study reported that dietary vitamin E (mainly γ-tocopherol) was inversely associated with the risk of death from CVD. This association was particularly striking in the subgroup of women who did not consume vitamin supplements. There was little evidence that the intake of vitamin E from supplements (mainly α-tocopherol) was associated with a reduced risk of death from CVD. The reasons for the differences between dietary and supplemental vitamin E are not clear. Other studies point to the potential importance of γ-tocopherol in preventing heart disease. High dietary intake of nuts, an excellent source of γ-tocopherol, lowered serum cholesterol, improved plasma lipid profiles, and was inversely associated with the risk of death from heart disease. γ-Tocopherol may also function in nitric oxide formation, which suppresses the expression of pro-inflammatory cytokines and maintains the integrity of the arterial wall. Several other human clinical trials have shown an improvement in markers of atherosclerosis by vitamin E supplementation. These findings have been contradicted by several vitamin E supplementation trials. It is important to note that, in general, women develop fewer cardiovascular events than do men. Thus, in studies in which many women are enrolled, the low incidence of CVD may weaken the statistical power of the overall trial. However, overall evidence from cell culture, as well as animal and human clinical and observational studies, strongly supports the contribution of dietary vitamin E in the maintenance of vascular function and health, in particular when used in combination with other foods containing antioxidants.

Vitamin E and Cancer

The capacity of vitamin E, particularly α-tocopherol, to quench free radicals damage, induce apoptosis, and impact expression of oncogenes makes it a strong candidate for chemotherapeutic strategies. Clinical and epidemiological data, together with evidence from experimental models, support a role for the involvement of free radicals throughout the cancer process. Several studies of oral, pharyngeal, and cervical cancer found a relationship between vitamin E status and cancer risk. The evidence for stomach and pancreatic cancers has not been consistent, and no association with breast cancer has been found.

Evidence for the role of vitamin E in cancer prevention was derived from a study conducted in Linxian, China, in a population with persistently low micronutrient intakes and having one of the world's highest incidences of esophageal/stomach cancer, where an overall reduction in cancer mortality, particularly mortality from stomach and esophageal cancer, was observed. The efficacy of supplementation with α-tocopherol on the prevention of certain cancers in male smokers was investigated in the Finnish ATBC study. There was no decrease in the incidence of lung cancer among men supplemented with synthetic α-tocopherol compared to those who were not fed supplements. In contrast, prostate cancer incidence and mortality rates were reduced by 32 and 41%, respectively, among the vitamin E-supplemented group. The overall results of epidemiological studies relating to vitamin E and colon cancer have been inconsistent and mixed.

Recent epidemiological experiments and mechanistic evidence suggest that γ-tocopherol may be a more potent cancer chemopreventive agent than α-tocopherol. A nested case–control study examined the association of α-tocopherol, γ-tocopherol, and selenium with the incidence of prostate cancer. The most striking finding was that men in the highest quintile of plasma γ-tocopherol concentrations had a five-fold reduction in the risk of prostate cancer compared with those in the lowest quintile. Other studies have shown that only the plasma levels of γ-tocopherol served as a biomarker of CVD and cancer.

In summary, inverse associations between dietary and supplemental vitamin E intakes and the incidence of several common chronic diseases have been noted in many observational studies, whereas results from studies using blood concentration of vitamin E have been limited and inconsistent. Randomized trials using supplemental vitamin E have not shown substantial effects on mortality end points. Recently, a prospective cohort study of 29 092 Finnish male smokers, aged 50–69 years, who participated in the ATBC study was carried out where the prospective association between circulating concentrations of α-tocopherol and total and cause-specific mortality in the group was evaluated. Higher circulating concentrations of α-tocopherol within the normal range were associated with significantly lower total and cause-specific mortality in older male smokers. The lower total and cause-specific mortality rates in older male smokers were observed as the serum α-tocopherol values increased from 9.1 mg l^{-1} (21 μmol l^{-1}) up to ~13–14 mg l^{-1} (~30– 33 μmol l^{-1}), after which no further benefit was noted.

Vitamin E and Other Diseases

Vitamin E appears to act as an immunosuppressant due to its ability to suppress both humoral and cellular immune responses. Tocopherol supplementation significantly enhances lymphocyte proliferation, interleukin-2 production, and delayed-type hypersensitivity skin response and decreases prostaglandin E_2 production by inhibiting cyclooxygenase activity. There appears to be compelling evidence that intervention with dietary antioxidants, such as vitamin E, may help maintain the well-preserved immune function of 'very healthy' elderly, restore the age-related decrease in immune function, and reduce the risk of several age-associated chronic diseases. Epidemiological evidence suggests an association between the incidence of cataract and vitamin E status. In a prospective study, the sum of serum α- and γ-tocopherol, but neither tocopherol alone, was inversely associated with the incidence of age-related nuclear cataracts.

Among the most common neurological diseases are neurodegenerative disorders, such as Alzheimer's and Parkinson's disease, which may be caused by oxidative stress and mitochondrial dysfunction leading to progressive neural death. An increasing number of studies show that antioxidants (vitamin E and polyphenols) can block neuronal death *in vitro*. In a 2-year, double-blind, placebo-controlled, randomized trial in patients with moderately severe impairment from Alzheimer's disease, treatment with 1340 mg α-TE day^{-1} significantly slowed the progression of the disease. Clinical treatment of Alzheimer's patients with large doses of vitamin E (670 mg α-TE twice daily) is one of the key therapeutic guidelines published by the American Academy of Neurology. In a multicenter, double-blind trial, vitamin E (1340 mg α-TE day^{-1}) was not beneficial in slowing functional decline or ameliorating the clinical features of Parkinson's disease. Administration of vitamin E significantly relieved symptoms in patients suffering from several types of acute or chronic inflammatory conditions such as acute arthritis, rheumatoid arthritis, and osteoarthritis.

Vitamin E Status and Requirements

Interest in the role of vitamin E in disease prevention has encouraged the search for reliable indices of vitamin E status. Most studies on human subjects make use of static biomarkers of status, usually α-tocopherol concentrations in plasma, serum, erythrocytes, lymphocytes, platelets, lipoproteins, adipose tissues, buccal mucosal cells, and LDL, and the α-tocopherol:γ-tocopherol ratio in serum or plasma. Other markers of vitamin E status include susceptibility of erythrocyte or plasma LDL to oxidation, breath hydrocarbon exhalation, and the concentration of α-tocopherol quinone in the cerebrospinal fluid. There is no consensus as to the threshold concentration of plasma or serum α-tocopherol at which a person can be defined as having inadequate tocopherol status, but values of <11.6, 11.6–16.2, and >16.2 μmol l^{-1} are normally regarded as indicating a deficient, low, and acceptable vitamin E status, respectively. It is now recommended that plasma or serum α-tocopherol concentrations be lipid-corrected (i.e., expressed relative to either the sum of cholesterol and triacylglycerol or cholesterol alone). The α-tocopherol (μmol):cholesterol (mmol) ratio is the simplest to obtain and probably the most useful, with values <2.25 indicating a risk or deficiency and values >5.2 optimal values. It has been estimated that an average daily dietary intake of 15–30 mg of α-tocopherol would be required to maintain this plasma level, an amount that could be obtained from dietary sources if a concerted effort was made to eat foods rich in vitamin E.

The US Institute of Medicine set an estimated average requirement (EAR) of 12 mg of α-tocopherol for adults >19 years on the criterion of vitamin E intakes that were sufficient to prevent hydrogen peroxide-induced hemolysis in men. The same value was set for men and women on the basis that although body weight is smaller on average for women than men, fat mass as a percentage of body weight is higher on average for women. As information is not available on the standard deviation of the requirement for vitamin E, the recommended dietary allowance (RDA) was established for men and women as the EAR (12 mg) plus twice the coefficient of variation (assumed to be 10%), rounded up, giving a value of 15 mg day^{-1}. The RDA values set by the US Institute of Medicine are estimates that meet the requirements of practically all healthy people and the values differ by life stage (**Table 1**). In the case of lactation, the average vitamin E secreted in human milk is calculated at 4 mg day^{-1} of α-tocopherol. For this reason, 4 mg α-tocopherol is added to the RDA for non-lactating women, giving an RDA for lactation of 19 mg day^{-1} of α-tocopherol (**Table 1**). In the case of infants aged 0–12 months, the recommended intakes of vitamin E are based on an adequate intake (AI) that reflects a calculated mean

Table 1 Recommended dietary allowance

Age (years)	*RDA*

vitamin E intake of infants fed principally with human milk. In Europe, the Scientific Committee for Food did not set a population reference intake (PRI) for vitamin E on the basis that there is no evidence for deficiency from low intakes, and the frequency of distribution of intakes is skewed to the right, making it difficult to set a PRI that is not inappropriately high, especially for those with a low consumption of PUFAs, whose requirements is lower than those with a high consumption of PUFAs.

It has been suggested that the optimum concentration of α-tocopherol in plasma for protection against CVD and cancer is $>30\,\mu\text{mol}\,\text{l}^{-1}$, given normal plasma lipid levels and in conjunction with a plasma vitamin C concentration $>50\,\mu\text{mol}\,\text{l}^{-1}$ and a β-carotene level $>0.4\,\mu\text{mol}\,\text{l}^{-1}$. This has not been proven in large-scale human intervention trials, but even in the absence of conclusive evidence for a prophylactic effect of vitamin E on the prevention of chronic diseases, some experts believe that a recommendation of a daily intake of 87–100 mg of α-tocopherol is justifiable based on the current evidence. Realistically, these levels can be achieved only by using nutritional supplements. The tolerable upper intake level (UL) for vitamin E is $1000\,\text{mg}\,\text{day}^{-1}$, based on studies showing hemorrhagic toxicity in rats, in the absence of human dose–response data. The Scientific Committee for Food proposed that the intake should not exceed $2000\,\text{mg}\ \alpha\text{-TE}\,\text{day}^{-1}$.

Introduction

Vitamin K (the coagulation vitamin) was discovered in the 1930s as a result of investigations into the cause of an excessive bleeding disorder in chickens fed on a fat-free diet. Its isolation and structural determination were accomplished in 1939 and its metabolic function was defined only after a new amino acid, γ-carboxylglutamic acid, was discovered in bovine prothrombin in 1974. Vitamin K is essential for the blood clotting process, where it serves as an essential cofactor for the specific carboxylation of a number of vitamin K-dependent coagulation proteins.

Chemistry

The term 'vitamin K' is a group name for a number of related compounds that have in common a 2-methyl-1,4-naphthoquinone ring system, but differ in the length and degree of saturation of their isoprenoid side chain at the 3-position. Three vitamin K compounds have biological activity (**Figure 1**).

Phylloquinone, vitamin K_1 (2-methyl-3-phytyl-1,4-naphthoquinone), is found in green leafy vegetables and represents the main dietary source of vitamin K in Western diets. Menaquinones (MKs), vitamin K_2 (2-methyl-3-1,4-naphthoquinone), are synthesized by the gut microflora, and have fully or partially unsaturated isoprenoid side chains of various length at the 3-position. The predominant forms of the MK compounds contain between 6 and 10 isoprenoid units, but Makes containing up to 13 units have been isolated. The parent structure of the vitamin K group of compounds is 2-methyl-1,4-naphthoquinone, commonly called menadione (vitamin K_3). This compound is not found in nature but is a synthetic form that can be metabolized to phylloquinone or MK and thus may be regarded as a provitamin. Menadione is also used as an animal feed supplement and in this way may indirectly enter the human food chain as preformed MK-4.

Previous analytical techniques to measure vitamin K compounds, such as the chick bioassay, were cumbersome and tended to overestimate the vitamin K content of foods. However, at present, the method of choice for vitamin K analysis in foodstuffs is high-performance liquid chromatography (HPLC) separation after lipid extraction. Electrochemical or fluorescence detection (after reduction to the hydroquinone form) offers the sensitivity and selectivity needed for quantification of the small amounts of vitamin K compounds. Food composition data for vitamin K derived from HPLC are generally lower than earlier data derived from the chick bioassay. The use of these HPLC-derived data on the vitamin K content of foods allows for a more accurate determination of the phylloquinone content of a typical Western diet.

Dietary Sources of Vitamin K

Green leafy vegetables are the best dietary source of vitamin K (as phylloquinone) (see **Table 1**). Some plant oils such as soybean oil and rapeseed oil are good dietary sources, containing 173 and 123 μg of phylloquinone per 100 g, respectively. Some vegetable oils, such as peanut, corn, sunflower, and safflower oils, have much lower phylloquinone content ($1–10\,\mu g\,100\,g^{-1}$). In general, meat, cereals, fish, and milk are poor sources of phylloquinone. MKs seem to have a more restricted distribution in the diet than does phylloquinone. In the Western diet, nutritionally significant amounts of long-chain MKs have been found in animal livers and fermented foods such as cheeses. The Japanese food 'natto' (fermented soybeans) has an MK content higher than the content of phylloquinone in green leafy vegetables.

Mean dietary phylloquinone intakes were reported for a nationally representative sample of US consumers ($n = 3967$), aged 13+ years, at levels of 81 and 73 $mg\,day^{-1}$ in men and women. There are limited data on dietary phylloquinone levels in European populations and, of those that are available, the use of different dietary tools precludes comparison in some cases. For example, mean intake estimates of phylloquinone in the United Kingdom, Ireland, and Norway of 60–85 $mg\,day^{-1}$ were obtained using food records, while estimates in the Netherlands (250 $mg\,day^{-1}$) were based on a food frequency questionnaire.

Phylloquinone intake decreases with age, especially for adults over the age of 65 years and, more notably, over the age of 85 years. However, consistently higher intakes for older adults (>40 years) than younger adults are reported, most probably due to lower green vegetable consumption by younger adults.

Absorption, Metabolism, and Excretion

Dietary vitamin K, mainly as phylloquinone, is absorbed into the lymphatic system from the proximal intestine after solubilization into mixed micelles composed of bile salts and the products of pancreatic lipolysis. In healthy adults, the efficiency of absorption of phylloquinone is about 80%. Intestinal bacteria can synthesize a variety of MKs, which are absorbed to a limited extent from the large intestine, transported into the lymphatic system, cleared by the liver, and released in very low-density lipoprotein (VLDL). However, it is not fully clear to what extent intestinal MK contributes to the vitamin K requirement. Approximately 50% of vitamin K is carried in the plasma in the form of VLDL, about 25% in low-density lipoprotein (LDL), and about 25% in high-density lipoprotein (HDL). Once in the circulation, phylloquinone is cleared rapidly at a rate consistent with its continuing association with chylomicrons. Vitamin K is extensively metabolized in the liver and excreted in the urine and bile. It has been demonstrated in tracer experiments that about 20% of an injected dose of phylloquinone is recovered in urine, whereas about 40–50% is excreted in the feces via the bile and the proportion excreted was the same regardless of whether the injected dose was 1000 or 45 μg. It seems likely, therefore, that about 60–70% of the amount of phylloquinone absorbed from each meal will ultimately be lost to the body by excretion. These results suggest that the body's stores of phylloquinone are constantly replenished. Vitamin K itself is too lipophilic to be excreted in the bile and is excreted as side chain-shortened carboxylic acid metabolites.

There is no evidence that phylloquinone and MK are toxic. However, high intakes of phylloquinone can negate the effects of the anticoagulant warfarin. The synthetic form of vitamin K, menadione, can interfere with the function of glutathione, one of the body's natural antioxidants, resulting in oxidative damage to cell membranes. Menadione given by injection has been shown to induce liver toxicity, jaundice, and hemolytic anemia (due to the rupture of red blood cells) in infants, and is no longer used for the treatment of vitamin K deficiency. No tolerable upper level (UL) of intake has been established for vitamin K.

Metabolic Function of Vitamin K

Vitamin K acts as a cofactor for a specific carboxylation reaction that transforms selective glutamate (Glu) residues to γ-carboxyglutamate (Gla) residues. The reaction is catalyzed by the microsomal enzyme vitamin K-dependent γ-glutamyl carboxylase, which, in turn, is linked to a cyclic pathway known as the vitamin K epoxide cycle. The resultant Gla residues are common to all vitamin K-dependent proteins and these have increased affinity for calcium. Prothrombin and other proteins of the blood clotting system, as well as certain bone matrix proteins, contain Gla.

The vitamin K epoxide cycle serves to recycle the nutrient via a cyclic interconversion. In this cycle, the vitamin K quinone form is reduced by the FAD-containing enzyme DT-diaphorase (NAD(P)H:quinone oxidoreductase) into the vitamin K hydroquinone (KH2), which then serves as a cofactor for vitamin K carboxylation of Gla proteins and, in so doing, is oxidized to vitamin K epoxide. Vitamin K epoxide is then recycled back to the quinone form by the enzyme vitamin K epoxide reductase (VKOR), completing the cycle. At a molecular level, vitamin K epoxide is reduced in two steps: first to the quinone form by VKOR and then to KH2 by DT-diaphorase.

Vitamin K-Dependent Proteins

Vitamin K-Dependent Coagulation Proteins

There are seven vitamin K-dependent proteins involved in blood coagulation, namely, prothrombin (factor II), factors VII, IX, and X, and proteins C, S, and Z, all of which are synthesized in the liver and contain between 10 and 12 Gla residues (**Table 2**). The Gla residues enable Ca^{2+}-mediated binding of the proteins to the negatively charged phospholipid surfaces provided by blood platelets and endothelial cells at the site of injury. Prothrombin and factors VII, IX, and X possess procoagulant activity and participate in the cascade that results in the formation of the fibrin clot. A key element in the formation of fibrin is the conversion of prothrombin to thrombin by activated factor X (which is, in turn, activated by activated factors VII and IX). In contrast, proteins C and S act as anticoagulants. Protein C inhibits coagulation by inactivating activated factors V and VIII and enhancing fibrinolysis, with protein S as a cofactor.

Bone Vitamin K-Dependent Proteins

There are two bone matrix proteins that contain Gla: osteocalcin (OC) and matrix Gla protein (MGP) (**Table 2**). OC is an osteoblast-derived, specific vitamin K-dependent protein that also contains hydroxyproline and is the most abundant of all the noncollagenous bone matrix-bound proteins. It has a molecular mass of 5700 Da and contains three Gla residues, which give this protein a high affinity for hydroxyapatite, in fact much higher than its affinity for calcium. The synthesis of OC is under the regulatory control of the active vitamin D metabolite, 1,25 dihydroxyvitamin D (1,25OHD), and its release into the circulation provides a sensitive index of vitamin D action. While a high proportion of newly synthesized OC is incorporated into bone, approximately 30% of it is released into the circulation and serum levels of the protein are used widely as an indicator of the rate of bone formation. The precise physiological function of OC remains unclear. The less well characterized MGP has a molecular mass of 9600 Da and contains five Gla residues and in contrast to OC, which is exclusively associated to mineralized tissues, MGP is present in cartilage and is expressed at a high rate in many soft tissues (heart, kidney, lungs), in addition to bone.

Vitamin K and Health

Deficiency

Newborn infants are at serious risk of hemorrhaging because of poor placental transfer of vitamin K, lack of

Table 2 The main vitamin K (Gla)-dependent proteins and their physiological function

Gla protein	*Tissue*	*Physiological function*
Blood coagulation		
Prothrombin (factor II), factors VII, IX, and X	Liver (then plasma)	Procoagulants
Protein C	Liver (then plasma)	Anticoagulant
Protein S	Liver (then plasma), endothelium	Cofactor for protein C
Protein Z	Liver (then Plasma)	Exact function unknown
Bone		
Osteocalcin (bone Gla protein)	Bone	Unknown, may be a matrix signal for osteoclasts
Matrix Gla protein	Bone, cartilage, and most soft tissues	Inhibitor of calcification
Protein S	Bone	Unknown
Others		
Nephrocalcin	Renal tissue	Undetermined, may inhibit the growth of calcium oxalate monohydrate crystals
Plaque Gla protein	May be present in artherosclerotic plaque	Undetermined
Growth arrest specific gene 6 (Gas 6)	Detected in cartilage and numerous soft tissues	Cellular growth regulation factor
Proline-rich Gla protein 1,2 (PRGP 1,2)	Broad tissue distribution	Undetermined

Data from Ferland G (1998) The vitamin K-dependent proteins:an update. *Nutrition Reviews* 56: 223–230; Shearer MJ and Bolton-Smith C (2000) *Food Chemistry* 68: 213–218.

intestinal bacteria, and the low vitamin K content in breast milk. For this reason, vitamin K is routinely administered prophylactically at birth in many countries. The risk of bleeding is greatest in prematurely born infants, in breast-fed infants, and in those with gastrointestinal conditions that impair vitamin K absorption. In normal infants, plasma prothrombin concentrations and those of the other vitamin K-dependent factors are approximately 20% of adult values at birth.

Normal or near-normal blood coagulation is usually maintained in older children and adults. Several factors protect adults from a lack of vitamin K and these include widespread distribution of vitamin K in plant and animal tissues, the vitamin K cycle, which conserves the vitamin, and the microbiological flora of the normal gut, which synthesizes MKs. The causes of the reduced levels of vitamin K-dependent coagulation factors in adults are largely secondary to diseases such as cystic fibrosis, celiac disease, ulcerative colitis, and short-bowel syndrome. Biliary obstruction and liver disease may also lead to vitamin K deficiency. There are numerous reports of bleeding episodes in patients treated with anticoagulant drugs and broad-spectrum antibiotics.

In children and adults, 'clinical' vitamin K deficiency in terms of blood coagulation is rare. However, 'subclinical' vitamin K deficiency in extrahepatic tissues, particularly in bone, is not uncommon in the adult population. From the multitude of proteins that require carboxylation of Glu to Gla residues for proper functioning, it is clear that poor vitamin K status may contribute to certain chronic vascular and skeletal diseases. Furthermore, it has been suggested that dietary phylloquinone levels that are sufficient to maintain normal blood clotting (which forms the basis of the recommended dietary allowance) may be suboptimal for adult bone health.

Vitamin K and Bone Health

The identification of γ-carboxyglutamyl-containing proteins in bone, notably OC and MGP, has generated considerable interest in the role of vitamin K in bone metabolism and bone health. In addition, another functional index of vitamin K status in bone metabolism is the level of undercarboxylated osteocalcin (ucOC). The extent to which OC is uncarboxylated has been assessed with respect to age, bone status, and risk of hip fracture. A high concentration of circulating ucOC has been associated with low bone mineral density and increased risk of hip fracture. The percentage of uncarboxylated OC is high (by 40%) in post-menopausal women compared with pre-menopausal women. The post-menopausal women responded to phylloquinone supplementation with an increase in total and carboxylated OC and a decrease in urinary calcium and hydroxyproline. The incidence of hip fractures in aged women correlates directly with the increase in ucOC and bone mineral density correlates negatively with the rise in ucOC. The relationship between ucOC and bone health in young growing teenagers has also received attention recently. For example, a significant inverse association has been reported between ucOC and bone mineral content of the total body and lumbar spine in peripubertal Danish girls.

Vitamin K intake has been associated with bone health in epidemiological studies. A cohort of elderly men and women from the Framingham Study in the United States showed an association of vitamin K intake with the incidence of hip fracture. In addition, there was evidence that phylloquinone intakes $<109\,\mu\text{g}\,\text{day}^{-1}$ are associated with an increased risk of hip fracture in 72 327 women participating in the Nurse's Health Study in the United States. In addition, among post-menopausal Scottish women, phylloquinone intake has been positively associated with bone mineral density of the femoral neck and lumbar spine as well as biochemical markers of bone turnover.

Based on the intervention studies to date that have investigated the effect of phylloquinone supplementation on bone loss in later life (generally >50 years), it appears that phylloquinone supplementation does not protect against loss of bone mineral in some skeletal sites (lumbar spine, total body, mid-distal radius). Furthermore, the evidence base for bone health benefits at the femoral neck from phylloquinone supplementation is mixed and may require further research. In particular, the inconsistent findings in relation to the effects of phylloquinone supplementation on bone mineral density of the hip do not explain the mechanism underpinning the protective effect of high phylloquinone intake/status against hip fracture observed in a number of prospective cohort studies. More research is needed on whether phylloquinone supplementation may be lowering the risk of fractures through other mechanisms such as effects on bone quality parameters. The finding that relatively low-dose phylloquinone supplementation improved bone mineral density of the forearm (ultradistal radius) of post-menopausal women is interesting even though it was investigated in only one study. It has been suggested that ultradistal forearm has a higher metabolic turnover rate than predominantly cortical bone and thus may be more responsive to dietary treatment.

Vitamin K and Cardiac Health

A role for vitamin K in atherosclerosis was hypothesized when proteins containing Gla residues were isolated from hardened atherosclerotic plaque, which were later identified as OC and MGPs. Increasing evidence is emerging suggesting a role for vitamin K in the calcification of arteries and atherogenesis. Moreover, the therapeutic potential of vitamin K_2 as an antihepatoma drug has been recently highlighted.

Results from human observational studies investigating relations between vitamin K intake and cardiovascular diseases are inconsistent. The Nurses' Health Study showed a modest risk reduction of coronary heart disease (CHD) for high phylloquinone intakes, while no significant associations were observed in the Health Professionals Follow-up Study and the Rotterdam Study. On the other hand, in the Rotterdam Study, a strong inverse association between MK intake and CHD mortality and severe aortic calcification was observed. These inconsistencies may relate to different effects of phylloquinone and MK on coronary calcification.

In a large study on 16 057 women, MK intake was inversely associated with coronary events, while phylloquinone intake was not related to CHD. Similarly, in animals, MK-4-but not phylloquinone-appears to inhibit warfarin-induced coronary calcification. The different effects of MK and phylloquinone probably reflect differences in metabolism as a result of different distributions over plasma lipoproteins.

Vitamin K Status and Requirements

Defining reliable indicators of vitamin K status has proven to be a difficult task. The serum concentration of ucOC is a more sensitive indicator of vitamin K status than the traditional blood coagulation tests, and a high serum level of ucOC is indicative of low vitamin K status and vice versa. UcOC has been reported to have a negative association with plasma phylloquinone concentrations. The difference between the vitamin K-dependent coagulation factors (all synthesized in the liver) and the bone Gla protein OC suggests that different tissues (at least bone and liver) may have different vitamin K requirements; hence, bone tissue may be more prone to vitamin K deficiency than liver. If this is the case, impaired synthesis of some vitamin K-dependent proteins may be far more prevalent in the human population than coagulation assays previously indicated, potentially resulting in an increase in dietary recommendations for vitamin K, especially for the elderly. A number of clinical trials have shown that high circulating ucOC levels are common in postmenopausal women as well as healthy young and elderly adults but levels are reduced significantly with vitamin K supplementation. Even in healthy newborns, whose vitamin K status is known to be precarious, very low levels of undercarboxylated prothrombin are detectable, whereas all babies tested exhibited high concentrations of serum ucOC. These data together with other evidence suggest that circulating OC is the most sensitive known marker for vitamin K status.

Until recently, the only widely accepted criterion for vitamin K sufficiency was the maintenance of plasma prothrombin concentration. It has been estimated that 0.5–1.0 $\mu g\,kg^{-1}\,day^{-1}$ was required to correct induced clotting changes. In adults, primary vitamin K-deficient states that resulted in bleeding were almost unheard of, except in a hospital setting. This is due to the widespread distribution of vitamin K in foods, the ability of the vitamin K cycle to conserve vitamin K, and endogenous bacterial syntheses of MKs. Therefore, a healthy population is not at risk of dietary vitamin K deficiency as the recommendation for optimal blood clotting is readily achievable. However, recent attention has focused on the importance of vitamin K for optimizing bone health and it has been proposed that vitamin K supplies believed sufficient to maintain normal blood coagulation may be suboptimal for bone health.

The Food and Nutrition Board (2001) has recently established an adequate intake (AI) value for vitamin K. The recently discovered indicators sensitive to vitamin K intake, although useful to describe relative diet-induced changes in vitamin K status, were not used for establishing an estimated average requirement (EAR) because of the uncertainty surrounding their true physiological significance and the lack of sufficient dose–response data. Therefore, the AI for adults was based on reported vitamin K dietary intake in apparently healthy populations. A large review, including 11 different studies, reported that phylloquinone intake ranged from 60 to 210 $\mu g\,day^{-1}$ with an average intake of approximately 80 $\mu g\,day^{-1}$ for younger adults (<45 years) and approximately 150 $\mu g\,day^{-1}$ for older adults (>55 years). Healthy individuals with a phylloquinone intake approaching 80 $\mu g\,day^{-1}$ have been investigated and showed no signs of deficiency, suggesting that this level is probably adequate for the majority of the adult population. Because dietary assessment methods tend to underestimate the actual daily intake of foods, the highest intake value reported for four adult age groups was used to set the AI for each gender rounding up to the nearest 5 μg. Therefore, the most recent guideline (AI) for vitamin K intake in the United States for adults (aged 19 years and older) is 120 and 90 $\mu g\,day^{-1}$, for men and women, respectively.

To date, no adverse effect has been reported for individuals consuming greater than the AI for vitamin K. However, the data on adverse effects from high vitamin K intake are not sufficient for a quantitative risk assessment and a tolerable UL of intake has not been established by the Institute of Medicine in the United States or by the Scientific Committee of Food in the European Union.

Introduction

Among specific nutritional deficiency diseases, scurvy was the dreaded disease of seamen and explorers forced to subsist for months on diets of dried beef and biscuits. The symptoms of scurvy are rather characteristic and consist of bleeding and rotting gums, swollen and inflamed joints, dark blotches on the skin, and muscle weakness. Scurvy afflicted nineteenth-century populations on land, including armies of the Crimean and United States Civil wars and the California gold rush communities. In 1907, scurvy was produced experimentally in the guinea pig and from 1928 to 1930, Albert Szent-Gyorgy and Glen King independently published their isolation of vitamin C or hexuronic acid. It was later named ascorbic acid for its antiscorbutic properties and its molecular structure was determined in 1933.

Ascorbate, also known as ascorbic acid (AA) or vitamin C, is synthesized *de novo* from glucose in the liver of most adult mammals. D-Glucose is converted into L-ascorbic acid via D-glucuronic acid, L-gulonic acid, L-gulonolactone, and L-gulono-γ-lactone as intermediates. However, humans and non-human primates, guinea pigs, the Indian fruit bat, several species of birds, and some fish have lost the ability to synthesize ascorbate *de novo*. As a result of a gene mutation, they lack a key ascorbate-oxidizing enzyme, L-gulono-γ-lactone oxidase, an essential oxidizing enzyme in the liver for the conversion of L-gulono-γ-lactone into 2-oxo-L-gulono-γ-lactone, a tautomer of L-ascorbic acid, which transforms spontaneously into the vitamin. In plants, the biosynthesis of ascorbate is more complicated than in animals. The vitamin is synthesized from guanosine diphosphate (GDP)-mannose, and the pathway shares GDP-sugar intermediates with the synthesis of cell wall polysaccharides and those glycoproteins that contain D-mannose, L-fucose, and L-galactose. Ascorbate is quantitatively the predominant antioxidant in plant cells and is found in all subcellular compartments, including the apoplast, and has an average cellular concentration of 2–25 mmol l^{-1} or more in the chloroplast stroma. This article discusses the chemistry of vitamin C. In addition, the role of vitamin C as a biological antioxidant, specific functions in humans, and role in health and disease are highlighted.

Chemistry

Ascorbic acid is the enolic form of an α-ketolactone (2,3-didehydro-L-threo-hexano-1,4-lactone). The molecular structure (**Figure 1**) contains two ionizable –OH groups at C_2 and C_3 that give the compound its acidic character, and since pK_{a1} at C_3 is 4.17 and pK_{a2} at C_2 is 11.79, a monoanion is the favored form at physiological pH where 99.95% of AA is present as ascorbate monoanion ($AscH^-$), 0.05% as AA ($AscH_2$), and 0.004% as ascorbate dianion (Asc^{2-}). Thus, the antioxidant chemistry of vitamin C is the chemistry of $AscH^-$. The asymmetric carbon 5 atom allows two enantiomeric forms, of which the L-form is naturally occurring. Oxidation of AA takes place as either two one-electron transfer processes or as a single two-electron reaction without detection of the intermediate ascorbyl radical. In the two one-electron oxidation processes, the first step involves loss of one electron from $AscH^-$ to form the neutral ascorbyl radical ($AscH^{\bullet}$), which is not protonated in biological systems and is present as the resonance-stabilized tricarbonyl ascorbate free radical ($Asc^{-\bullet}$), which is relevant in biology. $Asc^{-\bullet}$ is a weakly reactive radical, and *in vivo* it is likely that reducing enzymes are involved in its removal, resulting in the recycling of ascorbate. Loss of an additional electron yields L-dehydroascorbic acid (DHA). The oxidation of AA to DHA is reversible via the same intermediate radical process, and for this reason DHA also exhibits biological activity, since it can be easily converted to AA in the human body. However, DHA is highly unstable because of the susceptibility to hydrolysis of the lactone bridge. DHA has a half-life, in aqueous solutions at 37 °C, of approximately 6–20 min as a function of concentration, and catabolism beyond DHA is enhanced by alkaline pH and metals, especially copper and iron. Hydrolysis of DHA irreversibly forms 2,3-diketogulonic acid and leads to the loss of vitamin C activity (**Figure 1**). Further catabolism leads to the formation of a wide array of other nutritionally inactive products such as L-xylonic acid, L-lyxonic acid, L-xylose, oxalic acid, and L-threonic acid. The rate of oxidative degradation of the vitamin is a nonlinear function of pH because the various ionic forms of AA differ in their susceptibility to

oxidation: fully protonated $AscH_2 < AscH^- < Asc^{2-}$. Under conditions relevant to most biological systems, the pH dependence of oxidation is governed mainly by the relative concentrations of $AscH_2$ and $AscH^-$ species and this, in turn, is governed by pH (pK_{a1} 4.17). The rate of oxidation of ascorbate is generally observed to be first order with respect to the concentration of $AscH^-$, molecular oxygen, and the metal ion.

Dietary Sources

More than 80% of the vitamin C in western diets comes from fruits and vegetables, with citrus fruits, tomatoes and tomato juice, and potatoes being major contributors. A minor portion comes from enriched or fortified products, meats, fish, poultry, eggs, and dairy products, and essentially none from grains. The mean content of vitamin C is 2.11 mg per 100 g (range 1.65–2.75 mg per 100 g) in cow's milk, 5.48 mg per 100 g in goat's milk, 3.9 mg per 100 ml in summer human milk, and 3.02 mg per 100 ml in winter human milk. There is some evidence that the concentration of vitamin C in cow's and goat's milk changes with season. It has been observed that in raw milk sampled in March or August the concentration of vitamin C was higher (2.0–2.7 mg per 100 ml) than in samples collected in October (1.2 mg per 100 ml). The mean concentration of vitamin C in human milk also appears to be affected by the stage of lactation and declines from 6.18 mg per 100 ml in colostrum to 4.68 mg per 100 ml at 9 months. The influence of maternal vitamin C intake and its effect on the vitamin C content of human milk have not been clearly defined. It has been observed that the vitamin C level in human milk did not increase significantly in response to increasing maternal intake (up to 10-fold). It appears that a regulatory mechanism may be present in mammary cells to prevent an elevation in the concentration of vitamin C in milk beyond a certain saturation level. On the other hand, when the intake of vitamin C is low, breast milk levels are sensitive to supplementation.

In the United States, the median dietary intake of vitamin C by adult men from 1988 to 1994 was about 105 mg day^{-1} and the median total intake (including supplements) was about 120 mg day^{-1}. For women, the median intake was estimated to be 90 mg day^{-1} and median total intake (including supplements) was about 108 mg day^{-1}. The average consumption for children was 84 mg day^{-1}. The recent North/South Food

Consumption Survey in Ireland (2001) showed that mean daily intake of vitamin C was not significantly different in men (116 mg) and women (108 mg). The primary sources of vitamin C for the total population were potatoes and potato products (25.9%); fruit juices; nuts and seeds; herbs and spices (25.6%); and vegetable and vegetable products (22.1%). The contribution from supplements was 5.8% for men and 8.6% for women.

Ascorbic acid is also added to some processed foods for its antioxidant or functional properties and consequently the mean total vitamin C intake may be considerably higher than indicated above. Ascorbic acid is the nutrient taken most frequently as a supplement, particularly among the elderly population. The Boston Nutritional Status Survey of the Elderly (1992) estimated that 35 and 44% of males and females, respectively, took some form of vitamin supplements, with a median supplemental intake of 300 mg day^{-1}. Clinical signs of vitamin C deficiency are rarely seen in developed countries. The content of vitamin C in foods may be reduced significantly because of thermal destruction that occurs during cooking, losses in cooking water, and subsequent holding prior to consumption.

Absorption, Metabolism, and Excretion

In rats and hamsters (for which AA is not a vitamin), intestinal absorption is passive. In the case of guinea pigs and humans, both of which have an absolute requirement for exogenous AA in their diet, there is a sensitive sodium-dependent active transport system for AA in the brush border of the duodenum and upper ileum, and another sodium-independent transfer process in the basolateral membrane. There is also a passive transport mechanism, which in humans is predominant only at high intake levels. Ascorbate transport has been specifically shown to require metabolic energy, with a stoichiometry for Na^{+} from 1.1 to 2.1. Intestinal absorption of AA and its entry into cells are facilitated by conversion to DHA, which is transported across cell membranes more rapidly than ascorbate. Because DHA is structurally similar to glucose, its transport across membranes is facilitated by glucose transporters (GLUTS). Transport of DHA is primarily Na^{+}-independent in animal and human tissues, and does not require metabolic energy. Upon cell entry, DHA is reduced immediately to AA, which produces an effective gradient of DHA across the membrane. Intracellular reduction of DHA to AA is mediated by two major pathways: chemical reduction by glutathione and enzymatic reduction. The flux of ascorbate in and out of the cell via facilitated diffusion and active transport is mediated by distinct classes of proteins such as facilitative glucose transporters and sodium–vitamin C cotransporters, respectively.

Information on the bioavailability of vitamin C in foods is limited. It is generally agreed that at relatively low intakes (less than 30 mg day^{-1}), ascorbate is nearly completely absorbed, and 70–90% of the usual dietary intake of ascorbate (30–180 mg day^{-1}) is absorbed. Similar levels of absorption (~80%) have been reported for pure ascorbate, ascorbate in orange juice, and ascorbate in cooked broccoli, which suggests that the absorption of vitamin C is almost complete. However, absorption falls to approximately 50% or less with increasing doses above 1.5 g day^{-1}. Following absorption, ascorbic acid circulates freely in plasma, leukocytes, and red cells, and enters all tissues, with maximum concentrations of 68–86 μmol l^{-1} plasma being achieved with an oral intake of 90–150 mg day^{-1}. Excess is excreted by the kidney, which conserves the vitamin at plasma levels of up to 46–86 μmol l^{-1} by a saturable, sodium-dependent reabsorption process. The upper limit of plasma ascorbic acid concentration is controlled by the gastrointestinal absorption and renal reabsorption mechanisms, and fasting plasma concentration rarely exceeds 100 μmol l^{-1}, even with dietary supplementation. Specific proteins mediate the entry and exit of vitamin C in cells by facilitated diffusion or active transport. These cellular transport systems are responsible for high intertissue ascorbate levels found in the pituitary and adrenal glands (30–400 mg per 100 g tissue), followed by the brain, spleen, pancreas, kidney, liver, and tissues of the eye with 10–50 mg per 100 g of tissue. Vitamin C concentration also varies widely in different blood cell types. About 70% of blood-borne ascorbate is in plasma and erythrocytes. The remainder is in white cells, which have a marked ability to concentrate ascorbate; mononuclear leukocytes achieve 80-fold concentration, platelets 40-fold, and granulocytes 25-fold, compared with plasma concentration. Tissue-specific cellular mechanisms of transport and metabolism allow for wide variation of tissue ascorbate concentration in order to enhance its function as an enzyme cofactor and antioxidant. Intracellularly, and in plasma, vitamin C exists predominantly in the free form as AscH^{-}. DHA is either not detectable or found at only very low levels in the circulation of healthy people.

The total body pool of ascorbate is affected by limited intestinal and renal tubular absorption. It reaches a maximum value of about 20 mg kg^{-1} body weight or about 1500 mg for the average-size man when the ascorbate intake is increased from 30 to 180 mg day^{-1}; above this level of intake, excretion of ascorbate in the urine rises rapidly. Unabsorbed ascorbate is degraded in the intestine, a process that may account for the diarrhea and intestinal discomfort sometimes reported by persons ingesting large doses.

Antioxidant Activity of Ascorbic Acid

Ascorbate is often called the outstanding antioxidant. In chemical terms, this is simply a reflection of its redox properties as a reducing agent. In physiological terms, this means that ascorbate provides electrons for enzymes, for chemical compounds that are oxidants, or for other electron acceptors in biological systems. In addition to its redox potential, other properties of ascorbate make it an excellent electron donor in biological systems. Ascorbate undergoes two consecutive, reversible, one-electron oxidation processes forming the ascorbate radical ($Asc^{-\bullet}$) as an intermediate. The $Asc^{-\bullet}$ has an unpaired electron, making it a relatively unreactive free radical, especially with oxygen, and the ascorbate oxidation product, DHA, is reduced by cells to ascorbate, which then becomes available for reuse. These properties make ascorbate an excellent biological donor system. Thus, ascorbate is a reversible biological reductant and, as such, it provides reducing equivalents for a variety of biochemical reactions, is essential as a cofactor for reactions requiring a reduced metal ion (Fe^{2+}, Cu^{+}), and serves as a protective antioxidant that operates in the biological aqueous phase and can be regenerated *in vivo* when required.

Ascorbate is thermodynamically close to the bottom of the list of one-electron reducing potentials of oxidizing free radicals ($E^{\circ\prime} = +282\,\text{mV}$). For this reason, ascorbate is considered to be the most important antioxidant in extracellular fluids and is the first line of defense against reactive oxygen species (ROS) and reactive nitrogen species (RNS) (e.g., nitric oxide, $NO^{\bullet}$, and nitric dioxide, $NO_2^{\bullet}$) in plasma. It efficiently scavenges all oxidizing species with a greater one-electron potential (higher $E^{\circ\prime}$ values), which include the superoxide anion ($O_2^{-\bullet}$) and hydroxyl radical ($^{\bullet}OH$), and oxygen-centered radicals of organic compounds (peroxyl, $LOO^{\bullet}$, and alkoxyl, $LO^{\bullet}$) can be repaired by ascorbate as follows:

$$AscH^{-} + X^{\bullet} \rightarrow Asc^{-\bullet} + XH$$

where $X^{\bullet}$ is any of the oxidizing radicals. Although ascorbate itself forms a radical in the reaction, a potentially very damaging radical ($X^{\bullet}$) is replaced by the relatively unreactive $Asc^{\bullet}$. Overall, ascorbate is reactive enough to affectively interrupt oxidants in the aqueous phase before they can attack and cause detectable oxidative damage to DNA and lipids. In aqueous solutions, ascorbate also scavenges RNS efficiently, preventing nitrosation of target molecules. Consequently, both thermodynamically and kinetically, ascorbate can be considered to be an excellent aqueous antioxidant.

Ascorbate may also regenerate α-tocopherol (α-TOH) from the tocoperoxyl radical ($TO^{\bullet}$), which is formed upon inhibition of lipid oxidation by α-tocopherol. Ascorbate has a lower redox potential ($E^{\circ\prime} = +282\,\text{mV}$) than α-TOH ($E^{\circ\prime} = +500\,\text{mV}$) and, in addition, the α-$TO^{\bullet}$ is at the membrane–water interface, thereby allowing water-soluble ascorbate access to membrane-bound α-$TO^{\bullet}$ for the repair reaction and recycling of α-tocopherol:

$$AscH^{-} + \alpha\text{-}TO^{\bullet} \xrightarrow{\Delta E^{\circ\prime} = +200\,\text{mV}} Asc^{\bullet -} + \alpha\text{-}TOH$$

The rate constant for the reaction is $1.5 \times 10^{6}\,\text{l}\,\text{mol}^{-1}\,\text{s}^{-1}$.

Thus, in cellular membranes, ascorbate plays an indirect antioxidant role to reduce the α-tocoperoxyl radical (α-$TO^{\bullet}$) to α-tocopherol (α-TOH). Recycling of α-tocopherol by ascorbate has been demonstrated in liposomes and cellular organelles and may also spare and recycle α-tocopherol in erythrocyte membranes and intact erythrocytes (*see* **Vitamins**: Vitamin E).

The $Asc^{-\bullet}$ formed in the above reaction dismutates to DHA and is then regenerated to ascorbate at the expense of glutathione, dihydrolipoate, thioredoxin, and other enzyme systems. This process allows for the transportation of a radical load from a lipophilic compartment to an aqueous compartment where it is taken care of by efficient enzymatic defenses.

It should be noted that as a reducing agent, ascorbate has the ability to reduce Fe^{3+} to Fe^{2+} and Cu^{2+} to Cu^{+}, thereby increasing the prooxidant activity of the metals and generating $HO^{\bullet}$, $O_2^{\bar{\bullet}}$, and H_2O_2 that initiate lipid peroxidation in biological systems. It is considered unlikely that ascorbate shows prooxidant properties *in vivo* since the concentrations of 'free' transition metals in healthy biological systems are very small because they are effectively bound by metal ion storage and transport proteins.

Biological Functions

Many of the biological functions of ascorbic acid are based on its ability to provide reducing equivalents for a variety of biochemical reactions. The vitamin can reduce most physiologically relevant reactive species and, as such, functions primarily as a cofactor for reactions requiring a reduced iron or copper metalloenzyme and as a protective antioxidant that operates in the aqueous phase both intra- and extra-cellularly. Ascorbate is known to be a specific electron donor for eight human enzymes; three enzymes participate in collagen hydroxylation, two in carnitine biosynthesis, and three in hormone and amino acid biosynthesis. Evidence also suggests that ascorbate plays a role in or influences collagen gene expression, cellular procollagen secretion, and the biosynthesis of other connective tissue components, including elastin, proteoglycans, bone matrix, and elastin-associated fibrillin. Ascorbate is also involved in the synthesis and modulation of some hormonal components of the nervous system.

Collagen Formation

Scurvy, the classical disease of severe ascorbate deficiency, is characterized by symptoms related to connective tissue defects. Clinically, signs of scurvy are seen when the total body pool of ascorbate is below ~300 mg. Clinical features of scurvy include skin bruises, perifollicular hemorrhages, bleeding gums, joint pain and swelling, and fatigue. Oxidative degradation of some blood coagulation factors due to a low concentration of plasma ascorbate may contribute to hemorrhagic symptoms. Ascorbate-dependent aspartate β-hydroxylase is known to be required for the postsynthetic modification of protein C, the vitamin K-dependent protease that hydrolyses activated factor V in the blood-clotting cascade.

Ascorbic acid affects the biosynthesis of collagen at several levels from collagen transcription, to expression, including the regulation of the processing enzymes. It acts as a cofactor for several metal-dependent oxidative reactions, catalyzed by both monooxygenases and dioxygenases. Other cofactors required by the dioxygenases are Fe^{2+}, α-ketoglutarate, and O_2, whereas the monooxygenase requires Cu^{+} and O_2 for activity. Ascorbate functions as a reductive cofactor for posttranslational hydroxylation of peptide-bound proline and lysine residues during the formation of collagen. The hydroxyproline is required for normal triple-helical backbone structure and the hydroxylysine cross-linkages are needed for normal collagen fiber formation. The enzyme involved in proline hydroxylation, prolyl hydroxylase, requires molecular oxygen, ascorbic acid, iron, and α-ketoglutarate. The first step in the reaction is the attack on peptide-bound proline by oxygen, followed by condensation with α-ketoglutarate, the release of the hydroxylated substrate, and decarboxylation to release succinate. During the hydroxylation reaction, the enzyme-bound iron is oxidized to Fe^{3+}, which is catalytically inactive. The ascorbate is involved in reactivating the enzyme by reduction of Fe^{3+} back to the loosely bound ferrous form.

In an analogous reaction, ascorbate participates as a cofactor in the hydroxylation of lysine residues catalyzed by copper-dependent lysyl hydroxylase. Hydroxylysine cross-linkages are central for normal collagen fiber formation. Prolyl and lysyl hydroxylases are also called dioxygenases, referring to the ability of the enzymes to provide two oxygen atoms to the same or separate substrates. Ascorbate may also serve as a reductant for other metal-dependent polymerization and cross-linking reactions of connective tissue and as a carrier for sulfate groups needed for the production of glycosaminoglycans (e.g., chondroitin).

A deficiency of ascorbate results in a weakening of collagenous structures, causing tooth loss, joint pains, bone and connective tissue disorders, and poor wound-healing, all of which are characteristic of scurvy. This disease is now rare in developed countries, but is occasionally seen in individuals in classes with exceptionally poor or restricted diets, such as low socioeconomic groups and those who have a near total lack of fruit and vegetables, or those who abuse alcohol or drugs. Low ascorbate levels and scurvy are most often noted in men who live alone and eat a diet frequently low in fruit and vegetables. Because breast milk provides adequate ascorbic acid, infantile scurvy is seen more often after weaning, between 6 and 12 months. Modern infant formulae are fortified with sufficient ascorbic acid such that infantile scurvy is now almost nonexistent.

Neurotransmitter Synthesis

Ascorbic acid appears to be involved in catecholamine metabolism in two mixed-function oxidases, dopamine β-hydroxylase and *para*-hydroxyphenylpyruvate oxidase. Ascorbic acid is required as a cofactor for the copper-containing dopamine-β-monooxygenase enzyme, which catalyzes hydroxylation of the dopamine side chain to form norepinephrine. Ascorbate provided electrons for reduction of molecular oxygen, transferred by copper to dopamine, and hydrogen atoms to reduce the other oxygen to water. The active enzyme contains Cu^{+}, which is oxidized to Cu^{2+} during hydroxylation of the substrate: reduction back to Cu^{+} specifically requires ascorbate, which is oxidized to $AscH^{\bullet}$. Depression, hypochondria, and mood changes frequently occur during scurvy and could be related to deficient dopamine hydroxylation. Ascorbic acid also appears to be involved in the hydroxylation of tryptophan to form serotonin in the brain and in the degradation of tyrosine by *p*-hydroxyphenylpyruvate hydroxylase.

Carnitine Biosynthesis

Carnitine plays a central role in transporting long-chain fatty acids across the mitochondrial membrane wherein β-oxidation provides energy to cells, especially for cardiac and skeletal muscles. Esterification with carnitine appears to provide a mechanism for transport, storage, and excretion of long-chain fatty acid acyl groups. The biosynthesis of carnitine involves the methylation of lysine, with methionine as methyl donor, and requires ascorbate, ferrous iron, vitamin B_6, and niacin as cofactors for various enzymes of the pathway. The loss of fatty acid-based energy production because of limited carnitine biosynthesis may explain the fatigue and muscle weakness observed in humans with ascorbic acid deficiency.

Other Functions of Ascorbate

Ascorbate is also involved in the hepatic microsomal hydroxylation of cholesterol in the conversion and excretion of cholesterol as bile acids via 7α-hydroxycholesterol. These reactions require the microsomal enzymatic system containing cytochrome P-450 hydroxylase. Impaired cholesterol transformation to bile acids causes cholesterol accumulation in the liver and blood, and atherosclerotic changes in coronary arteries. Hydroxylation and demethylation of aromatic drugs and carcinogens by hepatic cytochrome P-450 appear to be enhanced by reducing agents such as ascorbate. Limited data suggest that ascorbate modulates prostaglandin synthesis and thus exerts bronchodilatory and vasodilatory function as well as anticlotting effects. Vitamin C has been shown to affect various components of the human immune response, including antimicrobial and natural killer cell activity and lymphocyte proliferation. The ability of phagocytes and lymphocytes to concentrate vitamin C at levels up to 100 times higher than in plasma may indicate that the vitamin has a physiological role in these immune cells. Cataracts which appear to be due to oxidation of lens proteins in the eye may also be protected by ascorbate. One report has shown that the use of vitamin C supplements (ranging from 400 to 700 mg day^{-1}) for 10 years or more reduced the number of lens opacities by about 80%. Women who consumed vitamin C supplements for less than 10 years were not protected. Data from other studies suggest that dietary measures to increase plasma ascorbate may be an important public health strategy for reducing the prevalence of diabetes. Ascorbic acid is a potent enhancer of nonheme iron absorption, both in its natural form in fruit and vegetables, and when added as the free compound. In addition, ascorbic acid increases the bioavailability of all iron fortification compounds. The mechanism of ascorbate action is believed to involve the reduction of intraluminal iron by ascorbate to the more absorbable ferrous state and/or the formation of soluble iron complexes in the duodenum. Generally, the enhancement of iron absorption is proportional to the amount of ascorbic acid in the meal, although observed differences in the effect of ascorbic acid may result from varying the amounts of substances in the food that promote or inhibit iron absorption. Ascorbate reacts with nitrite and other nitrosating agents, forming nitric oxide and nitrous oxide and thereby preventing the formation of carcinogenic nitrosamines by reaction between nitrites and amines present in foods in the acid conditions in the stomach.

Ascorbate and Cardiovascular Disease

It is generally accepted that the oxidation of low-density lipoprotein (LDL) particles and the accumulation of oxidized LDL in the vessel wall are key early events in the progression of atherosclerosis. Studies have shown that high plasma concentrations of ascorbate not only correlate with lower concentrations of oxidized LDL, but also function to protect endothelial cells against the detrimental effects of oxidized LDL once this is formed. Since ascorbate is water soluble and is not incorporated in LDL particles, it has been proposed that it may prevent oxidation of LDL particles by scavenging aqueous ROS and RNS in the aqueous milieu. Ascorbate is also capable of regenerating α-TOH from α-TO$^{\bullet}$, which is formed on inhibition of lipid peroxidation by vitamin E. Ascorbyl radicals formed in this process may be reduced to ascorbate by dismutation, chemical reduction, or enzymatic reduction.

Several epidemiological studies have examined the association between vitamin C concentration in blood and the risk of cardiovascular disease. A prospective study of 1605 Finnish men showed that those with increased plasma vitamin C (greater than 11.4 μmol^{-1}) had a 60% decreased risk of coronary heart disease. The Basel Prospective Study of 2974 Swiss men reported that plasma vitamin C concentrations greater than 23 μmol^{-1} were associated with nonsignificant reduction in the risk of coronary artery disease and stroke. In a 20-year follow-up study of elderly adults ($n = 730$) in Britain, plasma concentrations greater than 28 μmol^{-1} were associated with a 30% decreased risk of death from stroke compared with concentrations less than 12 μmol l^{-1}. The Second National Health and Nutrition Examination Survey (NHANES II) reported that the relative risk of coronary heart disease and stroke was reduced by about 26% with serum vitamin C concentrations of 63 – 153 μmol l^{-1} (1.1–2.7 mg dl^{-1}) compared with concentrations of 6–23 μmol l^{-1} (0.1–0.4 mg dl^{-1}). However, supplementation with vitamin C did not reduce the risk of major cardiovascular events. The EPIC–Norfolk Prospective Study in the United Kingdom showed that plasma ascorbate levels were inversely related to mortality from all causes and from cardiovascular disease and ischemic heart disease in men and women. A 20% fall in the risk of all-cause mortality, independent of other risk factors, was associated with a 20 μmol l^{-1} rise in plasma ascorbate, approximately equivalent to a 50 g day^{-1} increase in fruit and vegetable intake. It was also noted that a high plasma concentration of ascorbate was inversely related to various cardiovascular risk factors. Compared with people in the lowest quartile of the ascorbate distribution, those in the highest quartile had a 33% lower risk of coronary artery disease, independent of other known risk factors, including age, blood pressure, plasma lipids, cigarette smoking, body mass index, and diabetes.

Several prospective cohort studies have shown that vitamin C intakes between 45 and 113 mg day^{-1} are associated with reduced risk of cardiovascular disease. Results from the First US National Health and Nutrition Examination Survey (NHANES I) showed that cardiovascular mortality rates were 50% lower than average among participants with the highest vitamin C intake, defined as 50 mg or more per day from the diet plus regular supplements. A Finnish study on 5000 men and women found that women who consumed more than 91 mg day^{-1} vitamin C had a lower risk of coronary artery disease than those who consumed less than 61 mg day^{-1}. However, a similar association was not found for men. The NHANES I Epidemiologic Follow-up Study cohort of more than 11 000 adults showed a reduction in cardiovascular disease of 45% in men and 25% in women whose vitamin C intake from both food and supplements was approximately 300 mg day^{-1}. However, in contrast to the above, other studies reported no association between vitamin C intake and risk of cardiovascular disease. It is important to emphasize that much of these data were obtained from well-nourished populations.

Vitamin C and Cancer

Early epidemiological evidence indicated that high intakes of vitamin C-rich fruit and vegetables and a high vitamin C concentration in serum are inversely associated with the risk of certain cancers. Of 46 such studies in which a dietary vitamin C intake index was calculated, 33 found a statistically significant protective effect, with high intakes conferring approximately a two-fold protective effect compared with low intakes. The evidence for a risk-reducing role of vitamin C is not as strong as for fruit and vegetables. However, an extremely strong and consistent protective effect of vitamin C was found in 17 of 19 studies of stomach, esophageal, and pharyngeal cancers. The Iowa Women's Health Study found a 20% decrease in breast cancer risk with greater than 500 mg day^{-1} of vitamin intake from supplements; in contrast, the Nurses' Health Study, which used the same dietary assessment instrument, found no decreased risk of breast cancer at intake greater than 357 mg day^{-1}.

In a large case–control study in New York, the data showed that increased intake of vitamin C from food and supplements was associated with a reduced risk of rectal cancers. In contrast, the Iowa Women's Cohort Study found no association between vitamin C intake from fruit and supplements of approximately 300 mg day^{-1} and colon cancer risks. However, in women who consumed more than 60 mg day^{-1} vitamin C from supplements compared to no supplements, the risk was reduced by 30%. The association between vitamin C intake and the risk of lung cancer is generally weak, but still in a protective direction in several studies.

Epidemiological and experimental evidence has suggested that vitamin C may protect against the development of gastric cancer by several potential mechanisms, including the following: vitamin C reduces gastric mucosal oxidative stress, DNA damage, and gastric inflammation by scavenging ROS; it inhibits gastric nitrosation reaction for the formation of *N*-nitroso compounds by reducing nitrous acid to nitric oxide and producing dehydroascorbic acid in the stomach; it enhances host immunologic functions; it has a direct effect on *Helicobacter pylori* growth and virulence; and it inhibits gastric cell proliferation and induces apoptosis.

Recent reports on the NHANES II survey in the United States and the EPIC–Norfolk Prospective Survey in the United Kingdom showed that men with a low serum ascorbate concentration may have an increased risk of mortality, probably because of an increased risk of dying from cancer. In contrast, serum ascorbate concentrations were not related to mortality among women. The EPIC–Norfolk report concluded that increases in dietary foods rich in ascorbic acid might have benefits for all-cause mortality in men and women. A report from the World Cancer Research Fund and the American Institute of Cancer Research rated the anticancer effect of ascorbate as 'probable' only for stomach; 'possible' for prostate, mouth, pharynx, esophagus, lung, pancreas, and cervical cancer; and 'insufficient data' for cancers of the colon, rectum, larynx, breast, and bladder.

Vitamin C Status and Requirements

In setting values for average population requirements and individual nutrient intakes, the important question is how do we differentiate between preventing deficiency symptoms, ensuring an adequate intake, and promoting optimal intake for the prevention of disease? The recommended dietary allowance (RDA) of 60 mg day^{-1} in the United States, the reference nutrient intake (RNI) of 40 mg day^{-1} in the United Kingdom, and the population reference intake (PRI) of 45 mg day^{-1} in the European Union were aimed at prevention of the clinical deficiency state, scurvy. However, no obvious deficiency does not necessarily indicate adequacy, and subclinical or marginal deficiency of vitamin C owing to insufficient intake and/or to increased utilization may be common in many disease situations. Increased risk of chronic disease, including cancer, cataract, and coronary heart disease, is associated with low intake or plasma concentrations of vitamin C. However, the contribution of high intake or plasma levels of vitamin C to lowered risk of disease is difficult to assess, as other health-promoting habits generally accompany high vitamin C intake, and clinical trials have shown inconsistent and inconclusive results. The Institute of Medicine in the United States (2000) established an estimated average requirement (EAR) for vitamin C, which is the nutrient intake value that is estimated to meet the requirements of half of a specific gender and life-stage group and was based on evidence that 75 mg day^{-1} vitamin C can maintain near-maximal neutrophil concentration with minimal urinary loss. Thus, the EAR for men aged 19–50 years is 75 mg day^{-1}, with a value of 60 mg day^{-1} for women, based on women having less lean body mass and body water, and a smaller body size than men. There are no data on the distribution of vitamin C requirements in healthy adults; therefore the US RDA for vitamin C, which is the intake value considered to meet the requirements of 97.5% of the relevant life-stage and gender population group, is set at 90 mg day^{-1} for men and at 75 mg day^{-1} for women ($\text{RDA} = \text{EAR} + 2\text{CV}$), assuming a coefficient of variation (CV) of 10%. In Japan, Germany, Austria, and Switzerland, an uptake of 100 mg day^{-1} is recommended for both men and women. There is evidence to show that an average intake of 90 mg day^{-1} of vitamin C can maintain a plasma ascorbate concentration at 50 μmol l^{-1} and for this reason a 'potential protective plasma level' of 50 μmol l^{-1} has also been proposed. This concentration has been shown to inhibit plasma LDL oxidation *in vitro* and may have relevance for the prevention of heart disease *in vivo*. Smokers have been recommended by the United States to consume an additional 35 mg over and above the RDA value, but this recommendation has not been made explicit in other countries. Excessive consumption of vitamin C is unusual, and the upper intake level (UL) set by the United States is 2000 mg day^{-1}, which is achievable only by using chronic megadoses of concentrated vitamin C supplementation.

Cobalamin or Vitamin B_{12}

The terms vitamin B_{12} and cobalamin, represent a group of several cobalt-containing corroids. A corrin ring with four reduced pyrrole rings and cobalt as central atom, a nucleotide-like compound, and an additional variable compound are their common features (**Figure 1**). B_{12} is the only vitamin containing a metal ion. In biological systems, hydroxo-, aquo-, methyl-, and 5′-deoxyadenosylcobalamin occur, while cyanocobalamin is a decomposition product which, however, is used for therapeutic purposes as also is hydroxycobalamin.

Only microorganisms are able to synthesize vitamin B_{12}. Thus, some animal species have sufficient supply from their intestinal microorganisms. In humans, however, the synthesizing organisms are localized in the colonic part of the intestine which is too distal from the small intestine (ileum), where vitamin B_{12} must be taken up. Consequently, humans obtain B_{12} exclusively from their diet and only animal-derived foods contain sufficient amounts of vitamin B_{12} (**Tables 1** and **2**). Another prerequisite for the uptake of vitamin B_{12} is an intrinsic factor which is secreted from gastric parietal cells and facilitates ileal uptake of cobalamin.

While storage has only minor effects on the concentration of cobalamin in milk (~30–40% in sterilized milk after 90 days at room temperature) and radiation also has small effects, heat destruction plays a major role. Losses in cow milk caused by heat treatment are, sterilization: 20–100%; evaporation: ~50%; boiling: 20%; pasteurization: <10%; ultra-high temperature (UHT): 5–10%. In cheese, an overall loss of 10–50% can be assumed, although there are differences between cheese types, for example, in Gruyère cobalamin concentration even increases due to vitamin B_{12}-synthesizing microorganisms.

Functions of Cobalamin

Adenosylcobalamin (in the cytosol) and methylcobalamin (in the mitochondria) are the coenzyme forms of cobalamin. In humans, these coenzymes are involved in three metabolic reactions (for details see textbooks):

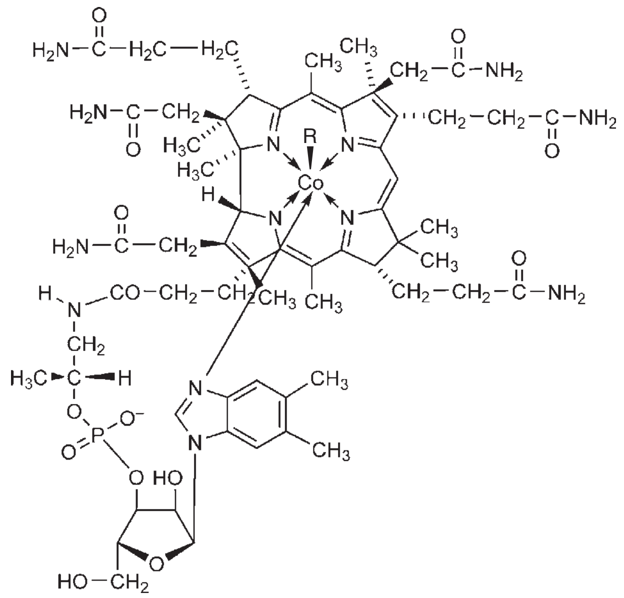
1. Leucine 2,3-amino-mutase reversibly changes α-leucine into β-leucine (3-aminocaproic acid), thus starting the degradation of this amino acid.
2. Methionine synthetase (*N*5-methyltetrahydrofolate homocysteine methyltransferase) reaction. Methionine synthetase needs methylcobalamin as a cofactor for the remethylation of homocysteine to methionine. During this process, the methyl group of 5-methyltetrahydrofolate is transferred to homocysteine, resulting in methionine and tetrahydrofolate. The latter is converted to *N*5,10-methylenetetrahydrofolate, a cofactor of thymidylate synthetase, finally ending up in DNA synthesis.
3. Adenosylcobalamin is needed by methylmalonyl-CoA-mutase for the isomerization of methylmalonyl-CoA to succinyl-CoA during the degradation of propionic acid, thus offering the entrance to the citric acid cycle.

Sources of Cobalamin

Cobalamin can be synthesized only by microorganisms and does not occur in plant-derived food. Therefore, animal-derived foods containing cobalamin are essential for humans; more or less good sources are listed in **Tables 1** and **2**. In cow's milk, the cobalamin content is very constant regarding feed, breed, season, or stage of lactation, except colostrum which has a very high level. In contrast, concentrations in human milk are markedly lower than in cow's milk and vary depending on the above-mentioned parameters. Concentrations in the milk of cow, human, and other species and in some dairy products are given in **Table 2**.

Cobalamin Deficiencies

Although normally in developed countries the vitamin B_{12} uptake meets the recommendations (**Table 3**), cobalamin deficiencies are the most numerous vitamin deficiencies requiring clinical treatment. This is due mainly to a reduced uptake in the intestine that can have various causes. One major prerequisite is a sufficient amount of intrinsic factor



R	Vitamer
–CN	Cyanocobalamin
–OH	Hydroxocobalamin
–5′-Deoxyadenosyl	5′-Deoxyadenosylcobalamin
–CH_3	Methylcobalamin
–H_2O	Aquacobalamin
–NO_2	Nitritocobalamin

or as cobalamin alone. After absorption, cobalamin is bound to transcobalamin and transported to the liver in the portal blood. Reasons for vitamin B_{12} deficiency can be

- chronic atrophic gastritis,
- defects of the gastric mucosa (loss of parietal cells),
- atrophic gastritis (chronic),
- gastrectomy (partial or total),
- malabsorption in the ileum,
- intestinal stasis,
- sucklings when the mother suffers from vitamin B_{12} deficiency,
- congenital disturbances of cobalamin metabolism,
- intestinal parasites, and
- age.

If normal stores in humans are sufficiently filled (2–5 mg) and enterohepatic recirculation occurs, it takes 10–15 years for deficiency symptoms to appear after stopping any B_{12} intake.

Characteristic vitamin B_{12} symptoms are macrocytic hyperchromic anemia (CAVE: this can also appear due to folic acid deficiency) and funicular myelitis, that is, neurological disorders like symmetrical paraesthesias in feet and fingers, disturbances of proprioception and vibratory senses, spastic ataxia, and degeneration of the spinal cord. Vitamin B_{12} delays the onset of signs of dementia (and blood abnormalities), provided it is administered before the onset of the first symptoms. Supplementation with cobalamin improves cerebral and cognitive functions in the elderly; it frequently improves the functioning of factors related to the frontal lobe, as well as the language function of those with cognitive disorders. Adolescents who have a borderline level of vitamin B_{12} develop signs of cognitive changes. Although the homocysteine-lowering effect of vitamin B_{12} and folate supplementation is well known, a protective effect on the development of vascular diseases by this supplementation can be seen as a tendency; however, the final results of some ongoing trials are required before making a final recommendation.

While, in former times, the ingestion of about 1 kg of raw liver per week was used to treat vitamin B_{12} deficiency, nowadays pernicious anemia is treated by a multistep therapy: 1 mg day^{-1} hydroxycobalamin intramuscularly for 7 days followed by the same dose applied weekly for up to 6 weeks, followed by the same dose every 2 months for life. Funicular myelitis is treated by a 2-week therapy with 250 µg day^{-1} to replenish stores followed by lifelong monthly injections of 100 µg if a disturbed absorption was the cause of cobalamin deficiency. Elderly people with reduced absorption due to gastric problems (reduced intrinsic factor) should be supplemented with 500 µg of crystalline vitamin B_{12} daily. Side effects have not been observed, even with pharmacological doses up to 5 mg. An overview of the varying strategies and the discussion of the different methods in different countries can be found in 'Further reading'.

This article is a revision of the previous edition article by C. M. Witthöft and M. Jägerstad, Volume 4, pp 2714–2721, © 2002, Elsevier Ltd.

Introduction

Folate is a B-vitamin present *inter alia* in milk and dairy products. The term folate is generic, referring to a class of compounds having similar chemical and nutritional properties as pteroyl-L-(mono)glutamic acid (folic acid) (**Figure 1**). Food-borne folates mostly have reduced pteridine moieties as dihydro- and tetrahydrofolates with different C1-substituents linked to the N_5 and/or N_{10} position (**Figure 1**). Up to seven glutamyl residues are attached, via γ-peptide linkages, to the *para*-aminobenzoic group. Especially reduced folates are labile to interconversion and oxidative degradation. The stability is pH-dependent, with the reduced folates being most stable between pH <2 and >8. Oxidative cleavage of the molecule at the C_9–N_{10} bond results in loss of biological activity. For fortification purposes, synthetic fully oxidized folic acid is used, which is not naturally present in foods, but shows higher stability during food processing and storage.

For mammals, folate is an essential micronutrient that has to be obtained from the diet. Folates are involved as a cofactor in one-carbon reactions in the cell, for example, during nucleotide synthesis, supplying carbon units for purine and pyrimidine bases (**Figure 2**).

They are also coenzymes in the methylation cycle, for example, for protein methylation and synthesis of neurotransmitters and phospholipids. Therefore, a good folate status is essential for normal cell division, and the requirement for folate is increased during, for example, growth, pregnancy, and lactation. A suboptimal folate status during pregnancy has been shown to increase the risk of birth defects, for example, neural tube defects (NTD). Deficiency leads to megaloblastic anemia, which is nowadays seldom observed in the United States and European countries.

Dietary folates occur mainly in their polyglutamate forms and are absorbed at physiological concentrations by an active carrier-mediated process in the small intestine after hydrolysis of the polyglutamate chain by the intestinal brush-border enzyme γ-glutamyl hydrolase. When present at higher concentrations, folate monoglutamates also pass through the cell membrane by passive diffusion. During transit through the intestinal mucosa cell, folates are reduced and converted to 5-methyl tetrahydrofolate monoglutamate, the transport form of the vitamin, which is released thereafter into the portal vein. It is estimated that, depending on hepatic folate status, during first pass through the liver, up to 20% of the portal folate is retained. The remaining folate is transported via peripheral blood circulation into the body tissues. In tissues or red blood cells, folates are retained as polyglutamates.

A good folate status is linked to several health benefits, for example, a reduced risk for NTD and other malformations during pregnancy. Furthermore, folate is assumed to play a key role regarding prevention of coronary heart disease by lowering serum homocysteine concentration, which is suggested as an independent risk factor. Less consistent is the evidence regarding the health-protective role and mechanisms with respect to the prevention of certain cancers. Unclear is, for example, the impact of folate status on initiation, progression, and growth of subclinical cancers, as well as on neuropsychiatric disorders, such as dementia and Alzheimer's disease. Consequently, this vitamin remains still today in research focus with the demand to further elucidate and evaluate the health-protective role of natural dietary folate as well as folic acid fortificant.

In the past, nutrient intake recommendations had the aim to prevent deficiency diseases, while today it is rather focused on health benefits in connection with a good nutritional status. Already a decade ago, the US Food and Nutrition Board included the concept of potential health-protective effects when publishing dietary reference intakes for folate by drastically doubling intake recommendations for adults to 400 μg per day. Similar recommendations were made in many European countries. However, food intake surveys in most Western countries show that the average intake of folate – from natural food sources – ranges between 200 and 300 μg day^{-1}, much below recommendations. Fortification policies were discussed as efficient ways to increase the average folate intake. The United States and Canada in 1989 introduced mandatory fortification of cereal-grain products with synthetic folic acid to reduce prevalence of NTD. This aim was achieved and epidemiologic data state that the US population improved their folate status by an increased average intake of folic acid fortificant.

Analysis

Folate food composition data derive traditionally from microbiological analyses with *Lactobacillus rhamnosus* (ATCC7469) (**Table 1**). The assay principle is based on estimation of growth of the organism, which is dependent on folate with up to three glutamate residues. This assay does not discriminate between the different folate forms and therefore 'total folate' is quantified. In order to differentiate between the individual folate forms, HPLC methods are used, for which an important prerequisite is commercially available standards of the numerous folate forms. After chromatographic separation, various detection modes can be used for quantification of folates. In the past, UV spectrophotometric or fluorescence detection was used widely, but in recent years, the use of LC–MS or MS–MS techniques resulted in improved sensitivity and specificity of the determination. For clinical routine purposes, (radio-) protein-binding assays (RPBAs) are used, which are based on the affinity of folate for bovine folate-binding proteins (FBP). RPBAs have also been used by some investigators for food applications.

Depending on the chosen method for folate quantification, the sample pretreatment (**Figure 3**) is more or less laborious, but it is always a crucial step. The extraction is usually carried out, in a stabilizing buffer with antioxidants, by means of heat, for example, in a boiling water bath or by autoclaving. The next step is an enzyme treatment, where samples are incubated with preparations of γ-glutamyl hydrolase in order to deconjugate the folate polyglutamate chain. Depending on the method of quantification, different sources for γ-glutamyl hydrolase can be chosen. Deconjugation with enzyme preparations from hog kidney or human plasma generates folate monoglutamates as usually required for HPLC quantification because most commercial folate standards are available only in their monoglutamate forms. For microbiological assays, incubation with chicken pancreas enzymes is usual, leading to folate di- and triglutamates. Depending on the food matrix, monoenzyme extraction may not be sufficient to release all folates from the matrix. Di- or trienzyme extraction methods have been developed, using, in variable order, additional enzyme preparations containing thermostable α-amylase or protease. The final step is the purification of the food extract, for example, by centrifugation and filtration. Especially in connection with HPLC quantification, solid-phase extraction methods or affinity chromatography using agarose gel immobilized bovine FBP is used. Different approaches for sample preparation were developed, omitting or replacing individual steps, for example, by sonication or microwave treatment. Thorough quality control and documentation during all steps of sample preparation, however, is required.

Folates in Dairy Products

Dairy products are considered to be moderate folate sources, but are reported to contribute between 10 and 15% to the dietary folate intake. The folate content of milk and fermented dairy products is in the range of a

Table 1 Common methods for folate analyses – an overview

Method	*Microbiological assay*	*Competitive binding assay*	*Biosensor*	*HPLC*
Principle	Estimation of growth of *Lactobacillus rhamnosus* (ATCC7469), responding almost equally to reduced and oxidized folate mono- to triglutamates	Competitive binding of the analyte to a protein or antibody, often using radio-labeled standard	Biosensor-based inhibition-immuno assay with monoclonal antibodies (surface plasmon resonance principle)	Chromatographic separation of folates, identification/ quantification by FLD, DAD, UV, EC, MS, MS-MS
Application	Food samples	Clinical samples	Folic acid-fortified food samples	Food samples
+ Advantages – Limitations	+ High sensitivity, high throughput when automated, accredited methods for food analysis – Quantification of total folate, no discrimination of individual folates	+ Kit commercially available, high throughput – Not suitable for food samples containing different folate forms due to varying affinity of folate binder	+ Kit commercially available, label-free, real-time quantification, suitable for analysis of binding kinetics – Quite expensive, no discrimination of individual folates	+ Determination of individual folates – Dependent on (commercial) availability of folate standards, usually only available as folate monoglutamates

FLD, fluorescence detector; DAD, diode array detector; EC, electrochemical detector; MS, mass spectrometer; MS-MS, tandem mass spectrometer.

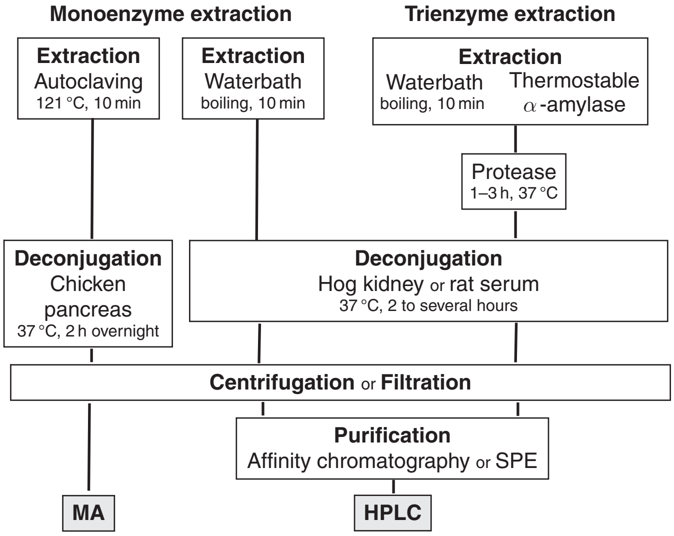

Figure 3 Principles of sample pretreatment prior to folate quantification. HPLC – high-performance liquid chromatography, MA – microbiological assay, SPE – solid-phase extraction.

few micrograms to around 40 µg per 100 g (**Table 2**). Typical folate sources, with rich or high folate content, are leafy green vegetables, pulses, liver, yeast, citrus fruits, and some berries, containing up to several 100 µg per 100 g folate. Fermentation of bovine milk with *L. rhamnosus* (ATCC7469), however, results in a three- to fourfold increase of the initial folate content from 4–8 µg per 100 g to around 20 µg per 100 g. The folate increase during fermentation seems to be dependent on the type of starter culture. Whey products and dairy products containing whey show a slightly higher folate content than milk, for example, up to 30 µg per 100 g folate was found in Cottage cheese. Hard cheeses, for example, Cheddar, Edam, and Gouda, are reported to contain 20–45 µg folate per 100 g and ripened soft cheeses like Brie and Camembert, around 100 µg folate per 100 g and more. The relatively high folate content in cheeses is assumed to be a result of both the reduction of water and biosynthesis of folate by microorganisms during ripening. The folate content of milk seems to undergo minor seasonal variation, which could be caused by feeding with folate-rich green pasture during summer.

The dominant folate derivative in milk is reported to be 5-methyl tetrahydrofolate amounting to about 90%, but some other folate forms like 5-formyl tetrahydrofolate and tetrahydrofolate were also found by some investigators using HPLC methods. Bovine milk contains folate in both monoglutamate and polyglutamate forms. Human breast milk contains similar amounts of folate to bovine milk, with around 5 µg per 100 g, while the folate content in goat's milk is only half as high and in buffalo's milk, for example, below 1 µg per 100 g.

Fortification

Food fortification is defined as the addition of a nutrient to a food above the level that is normally present. This practice is governed differently in countries, and both mandatory and voluntary fortification policies exist, with respect to folates. A prerequisite is the availability of a stable form of the nutrient, which survives food processing and storage and can be synthesized at low cost. For fortification purposes, commonly the synthetic and fully oxidized vitamer folic acid is used.

Risk and safety aspects are of importance with respect to fortification, but safety issues focus exclusively on synthetic folic acid, because natural folates ingested via food are considered safe over a wide intake range. The upper safe level for folic acid intake was set by the US Food and Nutritional Board in 1998 at 1 mg day^{-1}. In the United States, folic acid levels in fortified foods of 140 µg per 100 g are far below doses reported to show adverse epileptogenic and neurotoxic effects in animal models.

However, a potential risk of folic acid fortification is the masking of an undiagnosed vitamin B_{12} deficiency. Vitamin B_{12} deficiency is fairly common in the elderly population due to age-related atrophy of the gastric mucosa and can lead to irreversible neurological dysfunction and pernicious anemia. Due to the metabolic interrelationship of both vitamins, vitamin B_{12} deficiency can induce a secondary folate deficiency. According to the methylfolate-trap hypothesis, the activity of the vitamin B_{12}-dependent enzyme, methionine synthase, is reduced in B_{12} deficiency (**Figure 2**). This results in accumulation of methyl groups in the form of 5-methyl tetrahydrofolate

Table 2 Folate content of milk and dairy products

Dairy product		*Total folate content* (μg *per 100 g)*

Whipping cream	Average	4–7

Data given as ranges, as compiled from numerous publications and food composition tables, analyzed by microbiological assay or HPLC.

which is no further converted into tetrahydrofolate. Synthetic folic acid bypasses this reaction and is converted via dihydrofolate into tetrahydrofolate, thereby masking the B_{12} deficiency and reducing methionine synthase activity.

In 1998, the United States and Canada introduced nationwide mandatory fortification of cereal-grain products and ready-to-eat cereals, to reduce the incidence of pregnancies affected by NTD. The folic acid fortification level of 140 μg per 100 g, aiming to provide an additional 100 μg folic acid to the folate intake from the diet, was chosen to increase the average intake of women of childbearing age while preventing excessive intake by other population groups. Folate status of the US population improved in the post-fortification period, resulting in less than 1 and 5% being at risk from too low serum and erythrocyte folate levels, respectively. However, smaller concentrations of (unmetabolized) folic acid were found in peripheral blood of a certain group of the US population in addition to the normal plasma folate form 5-methyl tetrahydrofolate.

Also several other countries, for example, Chile and Costa Rica, introduced folic acid fortification of staple foods with the aim of reducing births complicated by NTD. Most European countries, however, have voluntary fortification policies, as to date no final agreement has been reached regarding potential risks from long-term exposure to folic acid from fortification. An alternative approach to the current fortification practice with folic acid, which was discussed with respect to potential risks of folic acid fortification, is the fortification with synthetic (6*S*)-5-methyl tetrahydrofolate, a natural food folate form. However, synthesis of the nonracemic (biological) diasteromer (6*S*)-5-methyl tetrahydrofolate is not cost-efficient and this form of folate is less stable than folic acid fortificant during food processing and storage.

While the protective role of folates with respect to the prevention of NTD is commonly accepted, no conclusive recommendations are made regarding the effect of folic acid fortification on initiation, progression, and growth of subclinical cancers.

Folic acid-fortified foods are, like in the United States and Canada, staple foods and foods of cereal-grain character. Other fortified products – offered in some countries by voluntary fortification – are beverages (juices, soft drinks, and mineral water), snacks, and table salt. Also, dairy products have been considered as vehicles for folic acid fortification.

Processing

Food composition data for milk and dairy products are usually presented as total folate content. Only few systematic data are available regarding the pattern of individual folate forms in milk and processed dairy products, but the folate forms, tetrahydrofolate, 5-methyl tetrahydrofolate, 5-formyl tetrahydrofolate, and 10-formyl folic acid, were reported to be present in fermented dairy products and cheese.

The chemical reactivity of reduced food folates makes the vitamin one of the most vulnerable with respect to losses during food processing. Following a number of different processes, considerable losses have been reported due to degradation enhanced by oxygen, light, and heat. Folates are also easily lost by leakage into water during processing.

Fermentation of milk increases folate content by 40–50%, as reported for yogurt and a Swedish fermented milk product, called filmjölk. The organism of the starter culture seems to have influence on the resulting folate content and pattern, with respect to species and strains. *Streptococcus thermophilus* species were reported to lead to a three- to fourfold folate increase, while fermentation with *Lactobacillus bulgaricus* resulted in only a minor increase or even a decrease in folate content in the final product. An increase of folate content was reported after fermentation with *S. thermophilus*, *Lactobacillus acidophilus, Bifidobacterium longum*, and *L. bulgaricus*, which thereafter during storage at 4 °C over a 3-week period decreased, suggesting folate utilization by the lactic acid bacteria.

The increase of folate content in hard cheeses can be explained mainly by reduction of the water content. The different starter cultures and length of ripening period influence folate concentrations in the final product.

Mild heat treatment seems to cause minor losses of milk folate amounting to less than 10%, while folate retention during ultra-high temperature (UHT) treatment is substantially lower. Folate retention is affected not only by the amount of soluble oxygen present in the milk before processing, but also by the amount of protective ascorbic acid.

Storage of pasteurized milk in the refrigerator during shelf-life does not affect folate content, while folate retention was lower during storage of UHT milk at ambient room temperature. Inconsistent data are available regarding refrigerated storage of fermented dairy products and cheeses, and most probably effects on folate content are also affected by the lactic acid bacteria strain.

Bioavailability of Dairy Folates

Bioavailability is defined as the absorption and metabolic utilization of a nutrient, thereby referring to the proportion of the ingested nutrient being absorbed and metabolized or stored. A nutrient’s bioavailability is dependent on host-related factors, for example, folate status of body stores, gastrointestinal function, health status, genetic factors, age, and possibly sex. Also extrinsic factors like properties of the ingested folate (oxidation status, substituent, and length of the polyglutamate chain), the food matrix (presence of pro- and antioxidants, fibers, binding proteins), and processing and storage were reported to influence bioavailability.

Different methods can be used to assess folate bioavailability (**Table 3**). *In vitro* methods, using everted sacs or Caco cell culture models, allow the study of mechanisms during absorption and affecting factors, but do not reflect the complexity of *in vivo* folate absorption. An advanced computer-controlled *in vitro* model simulating the gastrointestinal tract is the so-called TNO gastroIntestinal Model, TIM. The TIM model has been applied successfully to study effects of food processing on folate bioaccessibility in dairy products and other foods. Animal models were used to investigate the biological role of folate in growth and reproduction, but how relevant is the information from animal trials to predict folate metabolism in humans is questionable. Human *in vivo* trials are time- and cost-intensive and limited by ethical restrictions. However, as short-term protocols, they can supply information regarding folate absorption. Intervention trials can be used to study long-term effects on folate status. Several trials have been carried out with the aim of investigating effects of processing and fortification of dairy foods on folate bioavailability (*see* section ‘Bioavailability Studies with Dairy Products’).

Folate-Binding Proteins

Folate in milk is bound to an excess of FBP. At saturation, FBP binds approximately 1 mol of folate per mol protein. The function of FBP is to sequester folate from the blood in order to secure an adequate folate supply to the neonate although the concentration of folate in milk is relatively low. FBP occurs in two forms, whereby the major part exists in a soluble form and a very small amount as particulate FBP. The transport of folate in, for example, serum or milk has been suggested as the physiological function of soluble FBP. Particulate FPB is found in cell membranes and plays a role during membrane transport.

Table 3 Models used to study folate bioavailability

Model/assay	In vitro	*Animal*	*Human short-term*	*Human long-term*
Example	• Everted sacs/ dissected loop/cell culture model • TIM	Chicken, rat, pig, monkey	Investigator-controlled feeding trials	Random-controlled intervention trials (CRT)
Principle/studied effect	• Use of human cell culture model (Caco-2 cells) to study uptake and transport/ flux • Simulation of the human GIT to determine stability and bioaccessibility of nutrient	• Study biological role of folate on growth and reproduction • Study effects on tissue folate distribution and concentrations • Depletion/repletion models	Random application of supplements, foods, meals (with labeled compounds) as • single doses • multiple doses. Determination of folate concentrations and metabolites in body fluids, absorption kinetics by plasma AUC.	Effect of (ideally blind) intervention with supplements, foods, meals on folate status parameters/end points
+ Advantages − Limitations	+ No ethic restrictions − No reflection of complexity of *in vivo* absorption	+ Information on folate metabolism and deficiency − Limited (quantitative) information due to physiological differences between species	+ Information on absorbed folate − Problems with compliance and nonphysiological doses, expensive	+ Evidence of effect from intervention on status − Problems with compliance, choice of relevant intervention period, expensive

AUC, area under the curve; GIT, gastrointestinal tract; TIM TNO, gastroIntestinal Model.

Pasteurized milk contains between 160 and 250 nmol l^{-1} FBP. Data regarding survival of FBP in processed dairy products are conflicting; some investigators reported reduction of the FBP content while others observed reduction of the folate-binding capacity. While 80–90% of the initial FBP content of untreated milk survives pasteurization at 72 °C, it is almost completely destroyed by intense heat treatment, for example, UHT treatment or heat treatment before fermentation of milk. FBP concentrations of <15 nmol l^{-1} are found in yogurt, other fermented dairy products, and UHT milk. Skimmed milk powder and Cottage cheese, however, contain up to 2000 nmol kg^{-1} and 500 nmol l^{-1} FBP, respectively. During cheese-making, half of the FBP from the milk, around 100 nmol l^{-1}, is recovered in the whey fraction. Hard cheeses contain around 13 nmol kg^{-1} FBP. FBP was shown to enhance folate stability under certain processing conditions.

Initially, FBP was considered to stimulate folate absorption in general, as it could be shown that breast-fed babies had a better folate status than bottle-fed babies. This was attributed to the presence of intact FBP in human breast milk, while in infant formula FBP was destroyed by heat treatment. However, most of these studies investigating the effect of FBP on folate bioavailability were animal experiments. FBP was also suggested to prevent folate uptake by intestinal bacteria. Recent *in vitro* and *in vivo* studies, however, indicate reduced folate bioavailability by complex building with FBP.

Bioavailability Studies with Dairy Products

Only a few bioavailability trials have been carried out on dairy products fortified with synthetic folic acid or the alternative fortificant (6*S*)-5-methyl tetrahydrofolate.

Using the *in vitro* model TIM, folate bioaccessibility was estimated from pasteurized milk and yogurt samples which were fortified with folic acid or (6*S*)-5-methyl tetrahydrofolate with and without FBP in equimolar concentrations (ca. 900–1000 nmol l^{-1}). Unexpectedly, folic acid in both milk and yogurt was less bioaccessible in the presence of FBP (**Figure 4**). For added (6*S*)-5-methyl tetrahydrofolate, the folate form naturally present in dairy products, a decrease of folate bioaccessibility from FBP was observed only in yogurt, but not in milk. Both folate forms were more than 80% bioaccessible in yogurt without added FBP. Yogurt usually contains almost no FBP. A similar negative effect of FBP on short-term folate absorption was observed in human volunteers, who consumed, in random order, pasteurized milk or fermented milk (filmjölk) fortified with (6*S*)-5-methyl tetrahydrofolate with or without FBP. Absorbed folate was assessed by post-dose plasma concentrations (area under the plasma curve, AUC),

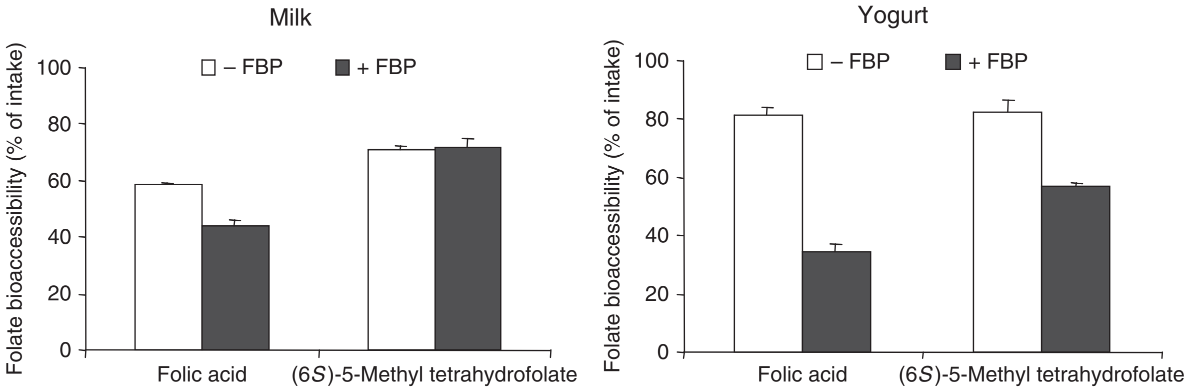

Figure 4 Effect of folate-binding proteins on the bioaccessibility of folate fortificants in dairy products as studied in dynamic *in vitro* TNO gastroIntestinal Model, TIM. TIM – TNO gastroIntestinal Model, FBP – folate-binding proteins, panels: left – milk, right – yogurt, -FBP (white bars) – no FBP added, +FBP (grey bars) – 1100–1200 nmol l^{-1} FBP added; added fortificants: 900–1200 nmol l^{-1} folic acid or 5-methyl tetrahydrofolate. Compiled from Arkbåge K, Verwei M, Havenaar R, and Witthöft C (2003) Bioaccessibility of folic acid and (6S)-5-methyltetrahydrofolate decreases after addition of folate-binding protein to yogurt as studied in a dynamic in vitro gastrointestinal model. *The Journal of Nutrition* 133: 3678–3683.

which were corrected for ingested doses (**Figure 5**). For seven of nine volunteers, FBP reduced short-term folate absorption, as shown by significantly greater AUCs after consumption of the fermented dairy product without FBP. Median apparent absorption was estimated to be 86% of the ingested dose of the FBP-free fermented milk and 62% and 55% for fermented milk and pasteurized milk containing added FBP, respectively. However, after a 12-week intervention with folic acid-fortified (400 μg day^{-1}) milk (resolubilized from powder), female volunteers improved their folate status. In a Dutch intervention trial with pasteurized and UHT milk, both fortified with folic acid (200 μg day^{-1}), the folate status of volunteers improved after 4 weeks. The Dutch investigators concluded that milk was a suitable matrix for folic acid fortification, and that the endogenous FBP content in pasteurized milk did not affect the bioavailability of folic acid fortificant significantly.

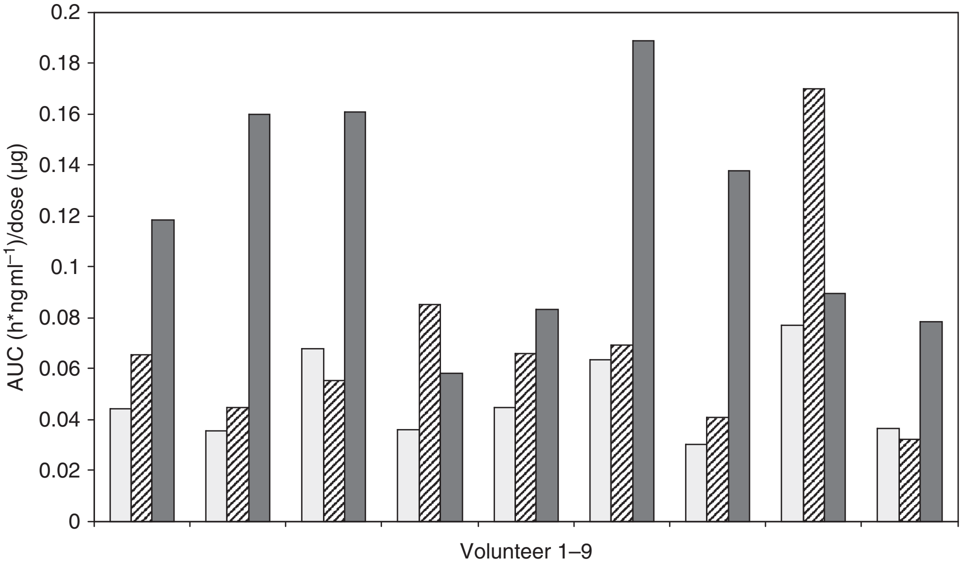

Figure 5 Relative absorption of (6*S*)-5-methyl tetrahydrofolate fortificant from dairy products with and without folate-binding protein in nine human volunteers. Relative absorption estimated by the area under the plasma folate concentration curve (dose-corrected AUC) for: light-grey bars – pasteurized milk with 250 μg (6*S*)-5-methyl tetrahydrofolate and 260 nmol FBP, striped bars – fermented milk with 180–205 μg (6*S*)-5-methyl tetrahydrofolate and 156–442 nmol FBP, dark grey bars – fermented milk with 187–234 μg (6*S*)-5-methyl tetrahydrofolate, no FBP. Test foods were ingested after overnight fasting on independent days in random order; blood was collected until 10 h postdose. Compiled from Witthöft CM, Arkbåge K, Johansson M, *et al*. (2006) Folate absorption from folate-fortified and processed foods using a human ileostomy model. *British Journal of Nutrition* 95: 181–187.

Summary and Future Trends

This article summarized data on the folate content of milk and processed dairy products. Systematic studies are, however, not many. Dairy products are 'moderate sources' of folate, but they provide between 10 and 15% of the average dietary folate intake in Western populations.

Folates have been recognized regarding their health beneficial effects, for example, with respect to their protective role against NTD. With regard to the gap between actual dietary folate intake and nutritional recommendations, mandatory folic acid fortification has been discussed or introduced in several European countries; here, cereal-grain staple foods are targeted. Milk and dairy products, however, were also discussed as suitable matrices for folic acid fortification. In order to develop folate-rich functional foods with benefit for the consumer, more research is required regarding effects of processing on fortified products and their physiological effects on humans.

Introduction

The chemical structure of biotin (hexahydro-2-oxo-1H-thieno (3,4-D) imidazol-4-valeric acid) is shown in **Figure 1**. Of the eight isomers that exist, only D-(+)-biotin is biologically active and occurs naturally. Although in milk (cow's as well as human) biotin occurs in the free form, most foods of animal origin or cereals contain it in an enzyme-bound form named biocytin (ε-N-biotinyl-L-lysine).

Biotin is essential for many microorganisms and numerous animals, including humans, and it can be synthesized by the colonic microflora. Although recent findings demonstrate an uptake of water-soluble vitamins (including biotin) by colonocytes, it remains unclear whether the amount produced is sufficient to fulfill all physiological functions or it is only a kind of fine-tuning of body homeostasis. The loss of biotin during processing or storage of food is generally small or negligible. There was no loss of biotin observed in milk kept in frozen state for some weeks or in dried milk stored at room temperature for 1 year or subjected to 2 h of sunlight or 10 Gray gamma radiation. Even UHT sterilization did not lead to biotin loss, whereas pasteurization and/or sterilization caused a <10% loss. In evaporated, condensed, or dried whole milk, the loss is <15%.

Functions of Biotin

Carboxylation and decarboxylation processes are the main reactions in which biotin is involved. It is linked to the enzymes by an amide bond between the amino group of a specific lysyl residue in the active center of the respective apo-carboxylase and its valeric acid side chain. During the (ATP-dependent) carboxylase reaction, a CO_2 molecule is attached to biotin at the ureido nitrogen, which is opposite to the side chain. The activated CO is then transferred from carboxybiotin to the substrate. The four representative biotin-dependent enzymes (as a prosthetic group) of the intermediary metabolism are

- Acetyl-CoA-carboxylase (catalyzes the first step in fatty acid synthesis)
- Propionyl-CoA-carboxylase (catalyzes the carboxylation of propionyl-CoA to form methyl-malonyl-CoA)
- Pyruvate carboxylase (catalyzes the carboxylation of pyruvate to form oxaloacetate)
- 3-Methylcrotonyl-CoA-carboxylase (plays an important role in the catabolism of leucine) which can be metabolized via alternative pathways as well. Such metabolites detected in urine suggest biotin depletion at the tissue level in individuals without congenital metabolic disorders.

Recently, some additional functions of biotin have been found: it induces dermal differentiation and has been used to treat lameness in animals and brittle nails in humans.

Sources of Biotin

Tables 1 and **2** give an overview of dietary sources of biotin and its appearance especially in the milks of various species and in dairy products; the recommended daily intake is given in **Table 3**. In cheese, changes in the concentration of biotin depend on processing procedures or maturation (microbiological synthesis, e.g., in Limburger or Brie); the highest concentrations are often found in the outer layers but can also extend throughout the cheese.

Biotin Deficiencies

One outstanding biotin deficiency is egg white injury, caused by extensive consumption of raw egg white, which contains the glycoprotein avidin, which binds biotin and is resistant to intestinal digestion. Symptoms of biotin deficiency are severe dermatitis, hair loss, and neuromuscular dysfunction. In several other species (mouse, rat, hamster), subclinical biotin deficiency has been shown to be teratogenic, and this may be the case also in humans.

From Deutsche Gesellschaft für Ernährung (DGE) (2007) Die Referenzwerte für die Nährstoffzufuhr. http://www.dge.de/modules.php?name=St&file=w_referenzwerte (accessed April 2009).

In humans, biotin deficiency is very rarely detected in industrial countries with an average biotin intake of 35–70 $\mu g\ day^{-1}$ which exceeds the recommended daily intake (see **Table 3**). However, it must be recognized that such recommendations are difficult to calculate, as the sources of biotin (diet, microorganisms, bioavailability) are quite variable. In general, biotin uptake seems to be adaptively regulated and the sodium-dependent multivitamin transporter hSMVT is involved in this regulation.

Besides those who consume raw egg white in excessive amounts, persons on long-term parenteral nutrition with insufficient biotin supplementation, people suffering from congenital biotinidase deficiency ('secondary biotin deficiency'; see below), or patients on a long-term anticonvulsant therapy are at risk of developing biotin deficiency symptoms, although only after biotin deprivation for months or even years. Symptoms like scaly/seborrheic and red/eczematous skin rash around the eyes, nose, and mouth, and anorexia, and also neurological symptoms like depression, lethargy, hallucinations, and paraesthesiasis of the extremities have been described. In children, generally comparable symptoms appear under parenteral nutrition, but earlier (3–6 months).

Biotinidase is an enzyme that catalyzes the hydrolysis of biocytine to biotin and lysine in the intestine, making biotin bioavailable; in addition, biotinidase plays a role in biotin recycling. Deficiency of this enzyme is therapeutically treated by a daily supplementation with 50–150 μg of free biotin. In this context, it is interesting to note that in such patients intestinal biotin production is insufficient.

This article is a revision of the previous edition article by H. K. Biesalski and E. I. Back, Volume 4, pp 2703–2707, © 2002, Elsevier Ltd.

Introduction

Niacin is the common name for a group of vitamers with a biological activity associated with nicotinamide. These include nicotinamide itself (pyridine-3-carboxamide), nicotinic acid (pyridine-3-carboxylic acid), and a number of pyridine nucleotide structures. Nicotinamide and nicotinic acid are white, crystalline structures. When dissolved in water, they have a maximum UV-absorbance at 263 nm. Each of these vitamers can be converted to the other; their structures are shown in **Figure 1**. Two coenzymes also exist, nicotinamide-adenine dinucleotide (NAD^+) and nicotinamide-adenine dinucleotide phosphate ($NADP^+$), and the structures of these are shown in **Figure 2**. These coenzymes are most prominent in animal food sources and possess a high bioavailability, in contrast to nicotinic acid which has a lower bioavailability and is present in lower concentrations, mainly in plants. Niacin in cereals is found mainly in the outer layer, bound to the protein niacytin and thus having a bioavailability of only 30%. In milk, almost all niacin appears in the free form.

Niacin is stable to sunlight, to various storage conditions, and also to heat used in dairy processes. High pressure-low temperature treatment leads to a significant loss from raw milk. Exposing liquid milk to gamma radiation (1 megarad) leads to a loss of about 30%, whereas milk powder resists even higher doses of radiation. During cheese production, most of the niacin passes to the whey, which can partly be compensated by an increase of the niacin content in the outer layers during maturation (~10–25-fold).

Functions of Niacin

Most important are the roles of NAD and NADP as coenzymes of dehydrogenases. The C4 position on the pyridine ring of the nicotinamide part of the molecule participates in oxidation as well as in reduction reactions by taking up the hydrogen ion. Thus, NADH and NADPH are intermediate hydrogen and electron carriers.

NADP-dependent coenzymes are involved in cytosolic syntheses (reductive biosynthetic processes), while NAD-dependent enzymes are located in the mitochondria, delivering H_2 to the respiratory chain for oxidation and energy metabolism. NADH is used in the respiratory chain and can be delivered by the tricarboxylic acid cycle, glycolysis, the β-oxidation of fatty acids, and the degradation of amino acids. NADPH is used for the synthesis of fatty acids, cholesterol, and steroids, and for hydroxylations; it can be delivered from the pentose phosphate pathway, photosynthesis, malic enzyme, and extramitochondrial isocitrate dehydrogenase.

In addition, NAD has non-redox functions: the energy provided by breaking the high-energy bond of the glycosidic linkage between nicotinamide and ribose allows the addition of ADP-ribose to quite a number of nucleophilic acceptors. NAD serves also as a substrate in poly(ADP-ribose) synthesis (important for DNA repair processes) and in mono(ADP-ribosyl)ation reactions (involved in endogenous regulation of various aspects of signal transduction and membrane trafficking in eukaryotic cells).

NADP serves as the substrate for the formation of nicotinic acid adenine dinucleotide phosphate (NAADP), which is involved in the regulation of intracellular calcium stores. Recent publications describe additional functions of nicotinic acid, which exhibits vasodilatory and antilipolytic effects, and of niacin, which lowers plasma levels of C-reactive protein (CRP), a general marker for inflammation, which is also involved in cardiovascular disease. The nicotinic acid receptor is also discussed as a target for the development of dyslipidemic drugs for the prevention and treatment of cardiovascular disease.

Sources for Niacin

Niacin Deficiencies

Owing to the coenzymes' major role in energy metabolism, the requirement is related to energy intake. The recommended dietary allowance in the United States has been set at 6.6 niacin equivalents (NE; see below) per 1000 kcal per day; the requirements have been established experimentally for adults and were set at a minimum of 8 mg NE day^{-1}. However, the overall calculation is difficult because the intestinal utilization rates are unknown and, in addition, NAD can be synthesized from tryptophan when the latter is available in sufficient amounts. Therefore, the niacin content of the diet is often given as niacin equivalents, that is, 1NE = 1 mg niacin = 60 mg tryptophan. The tryptophan content of some selected foods as a percentage of total protein is eggs 1.5%; milk 1.4%; animal products >1.1%; cereals, fruits, and vegetables ~1%; and maize ~0.6%. A 'normal, mixed diet' in industrial countries includes about 13 mg NE day^{-1}, thus providing more than the required amount. Milk, for example, is regarded as a good pellagra-preventing food (see below), not because of its niacin concentration, which is relatively low, but because of its high concentration of tryptophan. Other good sources of niacin are shown in **Table 1**. Niacin content of milk and other dairy products are listed in **Table 2**. The recommended daily uptake is shown in **Table 3**.

From Deutsche Gesellschaft für Ernährung (DGE) (2007) Die Referenzwerte für die Nährstoffzufuhr. http://www.dge.de/modules.php?name=St&file=w_referenzwerte (accessed April 2009).

The main disease caused by niacin deficiency is pellagra (pellagrosis; maidism; mal de la rosa, Saint Ignatius itch, erythema endemicum; Jolliffe syndrome). It is characterized by the three Ds dermatitis, diarrhea, and dementia. The name pellagra is derived form pelle agra = rough skin, that is, the prominent symptom is a rough skin in light-exposed areas with a symmetric appearance and with a distinct border to normal skin (glove-like appearance on the hands). Disorders of the gastrointestinal tract (GIT) can include nausea, abdominal pain, increased salivation, soreness of the mouth, inflammation of the mucosa, and diarrhea. Early neurologic disorders are depression, anxiety, and poor concentration; prolonged symptoms are disorientation, confusion, and delirium. The prevalence of pellagra is sporadic in USA and Europe but higher in poor and malnourished people, alcoholics, patients undergoing long-time parenteral nutrition with insufficient niacin supplementation, and also in some psychiatric patients. Pellagra is endemic in a few regions of Africa and Asia where maize (corn) represents a major part of the common food together with very low amounts of meat, fruits, and vegetables. Pellagra-like symptoms can also appear during tryptophan deficiency (cf. Hartnup syndrome).

The clinical diagnosis of pellagra is that of the (rough) skin, preferably in context with GIT symptoms. The laboratory diagnosis is still unsatisfactory in terms of a specific measurement to estimate niacin. Thus, fluorometric assays for urinary metabolites N′-methyl-nicotinamide (NMN) and N′-methyl-2-pyridone-5-carboxamide (2-pyridone) are used. Urinary NMN levels of <0.8 mg or a combined excretion of <1.5 mg per 24 h indicates niacin deficiency.

Acute therapy is by oral application of 100–300 mg day^{-1} niacinamide or niacin in three doses, niacinamide having less intense side effects (flushing). Mental changes disappear within 24–48 h, and skin lesions, within several weeks. Concomitant administration of riboflavin and pyridoxine, and a diet rich in calories and protein are reasonable.

Nicotinic acid is used as a supplement in the treatment of hyperlipidemia; high doses of up to 5 g day^{-1} resulted in the reduction of total serum cholesterol (−20%), serum triglycerides (−40%), and high-density lipoprotein (LDL; +15%). Such high doses ingested over longer periods can lead to some side effects: besides the immediate symptoms (mainly flushing and itching), hepatotoxicity, including elevated liver enzymes and jaundice, appears mostly after long-term treatment (3–9 g day^{-1}) for months or years, but has also been reported with 750 mg day^{-1} for 2 months. Nicotinamide potentiates the effects of chemotherapy and radiation treatment fighting tumor cells, perhaps attributable to increased blood flow and oxygenation. Interestingly, supplementation with 2 g day^{-1} led to a decreased insulin sensitivity in adults at high risk of insulin-dependent diabetes.

Pantothenic Acid

D Nohr and H K Biesalski, Universität Hohenheim, Stuttgart, Germany

E I Back, Novartis Pharma GmbH, Nürnberg, Germany

© 2011 Elsevier Ltd. All rights reserved.

Pantothenic Acid or Vitamin B$_5$

The natural form of pantothenic acid (**Figure 1**) and the only stereoisomer with biological activity is D(+)-pantothenic acid. However, the alcohol (D)-panthenol can be converted to pantothenic acid, thus having – although indirectly – also biological activity. The major portion of pantothenic acid in the diet occurs as coenzyme A (CoA) or pantetheine (**Figure 2**).

Pantothenic acid is a highly hygroscopic, light-yellowish viscous oil that is soluble in water as well as in ethanol. It is stable to heat and light, but otherwise is unstable; thus in pharmaceutical preparations, the Na$^+$ or Ca^{2+} salts of panthenol are usually used.

About 50–95% of pantothenic acid occurs as CoA or pantetheine (fatty acid synthetase complex) in the overall diet. In milk, about 25% of pantothenic acid is protein-bound, but this value rises to 40–60% in cheese, depending on the type of cheese.

Function of Pantothenic Acid

The main physiological activity of pantothenic acid is related to that of CoA, pantetheine being a part of both. The HS group of cysteamine in CoA and pantetheine represents the active site for the binding of acyl or acetyl residues. Furthermore, there is a pantothenate-dependent step in the synthesis of arginine, leucine, and methionine.

For the detailed synthesis of pantetheine and CoA and their numerous functions in the intermediate metabolism of animal cells (carbohydrates, fatty acids, nitrogenous compounds), the reader is referred to relevant textbooks on biochemistry or physiology or recent reviews (*see* Further Reading). In brief, CoA plays a role in

- acylation of proteins
- internal acetylation of proteins
- N-terminal acetylation of proteins
- transfer of C2-units released in β-oxidation of fatty acids and oxidative degradation of amino acids
- transfer of C2-units required for fatty acid synthesis
- introduction of C2-units in the tricarboxylic acid cycle
- transfer of fatty acids required for the synthesis of triglycerides and phospholipids
- synthesis of isoprenoid-derived compounds
- synthesis of hemoglobin, cytochromes, acetylcholine, taurine, and acetylated sugars

In summary, pantothenic acid, especially as part of CoA, plays numerous roles in animal and human cellular metabolism.

Pantothenic Acid Sources

Tables 1 and **2** give an overview of dietary sources of pantothenic acid, especially in the milk of various species and in dairy products; the recommended daily intake is given in **Table 3**. In cheese, amounts of pantothenic acid depend on the degree of proteolysis. While Cheddar and Cottage cheese lose large amounts (mainly of the free form) during manufacture, the concentration in some types of cheese (e.g., Limburger, Camembert, Brie) increases due to microbiological synthesis.

Pantothenic Acid Deficiencies

When suffering from a deficiency of pantothenic acid, chickens develop keratitis, dermatitis, degenerations of the spinal cord, and a fatty liver, while rats show retarded growth. For humans, only effects that occur under experimental conditions are known (e.g., application of an antagonist (ω-methyl pantothenic acid); severe undernutrition), as pantothenic acid occurs in almost all kinds of food and true requirements are hard to assess. The first symptoms of a deficiency are headache, fatigue, gastrointestinal tract (GIT) disturbances, palpitation of the heart, burning feet syndrome (first described in prisoners during World War II in Burma, Japan, and the Philippines). Prolonged deficiency leads to retarded wound healing, hypotonia, and uncoordinated movements. In general, all symptoms are reversible.

Due to large individual variations, both the level in blood and the amount in urine excretion are not good indicators of the vitamin status. However, a blood level between 1 and 4 mg l^{-1} is regarded as sufficient. A daily uptake of 4–6 mg is recommended by several nutritional societies because of epidemiological data: 1 mg day^{-1} does not lead to deficiency symptoms in humans. Interestingly, some intestinal bacteria can synthesize pantothenic acid, but this source seems to be ineffective in humans.

Pyridoxine or Vitamin B_6

The term vitamin B_6 represents a group of substances with vitamin B activity and these substances are derivatives of 3-hydroxy-2-methylpyridine: pyridoxine (PN, alcohol), pyridoxal (PL, aldehyde), and pyridoxamine (PM, amine; **Figure 1**), and their 5′-phosphorylated forms (**Figure 2**).

PN and PM and their phosphorylated forms are the predominant forms in plant-derived foods, while PL and pyridoxal-5′-phosphate (PLP) predominate in animal-derived foods. In cow's milk, 14% of vitamin B_6 is in the bound form and 86% is in the free form. It is sensitive to light and heat, partly depending on the pH of the medium. PM and PN are more stable than PL, particularly to light. In neutral and alkaline solutions, B_6 is destroyed by UV light. PL, PM, and PN are generally heat stable in acidic surroundings but heat sensitive in an alkaline medium. The amount of reported loss differs between different publications, maybe due to different procedures. However, some approximations can be made:

Heat treatment leads to a loss:

- Drying: insignificant effects
- Pasteurization: 0–8%
- Ultra-high temperature (UHT) treatment: <10%
- Boiling: 10%
- In-container sterilization: 20–50%
- Evaporation: 35–50%

UV light leads to a reduction of 10–45%, depending on the intensity and duration of exposure, and gamma radiation (10 Gy) causes a loss of ~90%.

Functions of Vitamin B_6

In general, PLP serves mainly as a coenzyme for about 100 enzymes in amino acid metabolism. It is covalently bound to its enzyme by a Schiff base linkage to the ε-amino group of lysine in the enzyme. During the enzymatic reaction, the amino group of the substrate and the aldehyde group of PLP form a Schiff base. All subsequent reactions can occur at the α-, β-, or γ-C of the respective substrate. In the following, a brief list of common reaction types is given; for further details, the reader is referred to specific literature (see Further Reading):

- Transamination (transfer of the amino group of one amino acid to the keto analogue of another amino acid)
- Decarboxylation (deletion of a CO_2-group from a molecule; e.g., resulting in biogenic amines)
- Elimination (deletion of 2 subsituents from neighbored (C-)atoms; e.g., by Serine dehydratase)

Pyridoxamine-5′-phosphate (PMP) acts exclusively as a coenzyme for transaminases:

1. Transferase
   a. Serine hydroxymethyl transferase (C1 metabolism)
   b. D-Aminolevulinate synthase (porphyrin biosynthesis)
   c. Glycogen phosphorylase (glycogen mobilization)
   d. Aspartate aminotransferase (transamination)
   e. Alanine aminotransferase (transamination)
2. Oxidoreductase
   a. Lysyl oxidase (collagen biosynthesis)
3. Hydrolase
   a. Kynureninase (niacin biosynthesis)
4. Lyase
   a. Glutamate decarboxylase (γ-aminobutyric acid (GABA) synthesis)
   b. Tyrosine decarboxylase (tyramine biosynthesis)
   c. Serine dehydratase (β-elimination)
   d. Cystathionine β-synthase (methionine metabolism)
   e. Cystathionine γ-lyase (γ-elimination)

Due to its role as a coenzyme in amino acid metabolism (see below), vitamin B_6 has a broad range of functions in many systems of the body, including the immune system, the nervous system, gluconeogenesis, lipid metabolism, erythrocyte function, hormone modulation, gene expression, and niacin formation. In the immune system, for example, vitamin B_6 increases the immune response of critically ill patients and suppresses the nuclear factor-kappa B (NF-κB) reaction in lipopolysaccharide (LPS)-stimulated mouse macrophages, a well-established laboratory method to challenge the immune system. In the nervous system, PLP may cause neurological dysfunction, particularly epilepsy. On the other hand, there is no direct evidence for an influence on cognitive functions in people with either normal or impaired cognitive functions. An intensively investigated role is that of vitamin B_6 (with B_{12} and folate) in regulating homocysteine levels, with homocysteine levels playing a major role in

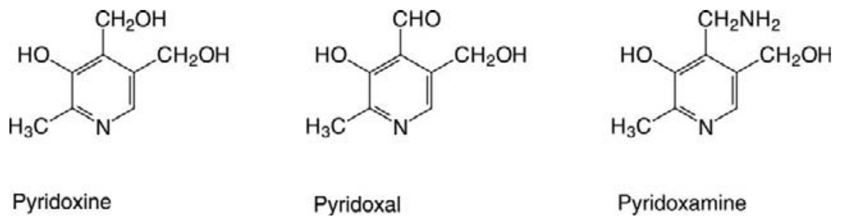

Figure 1 Structures of pyridoxine, pyridoxal, and pyridoxamine.

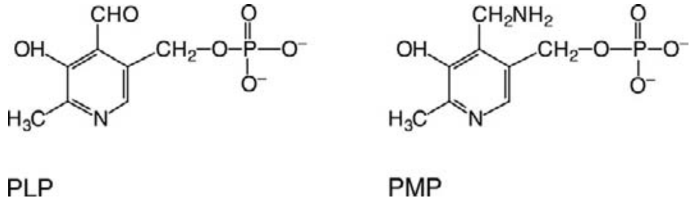

Figure 2 Structure of the coenzymes pyridoxal-5′-phosphate (PLP) and pyridoxamine-5′-phosphate (PMP).

cardiovascular diseases like atherosclerosis or endothelial dysfunction, and is also associated with the risk of hip fractures in the elderly. The benefits of vitamin B_6 supplementation during pregnancy (e.g., higher birth weight or reduced incidence of preeclampsia and preterm birth) could not be confirmed by a meta-analysis. Additional effects of B_6 include decarboxylation and transamination, inhibition of DNA polymerases and a couple of steroid receptors, and usefulness as an adjunct in cancer chemotherapy (see Further Reading).

Sources of Vitamin B_6

Tables 1 and **2** give an overview of the concentrations of vitamin B_6 in selected foods and dairy products, including the milk of different species that is used for human consumption. Regarding vitamin B_6 in cheese, most of the vitamin passes into the whey and the concentration decreases further during early maturation, while in later phases the concentration increases, especially on the surface (yeast and molds). Cheese types like Camembert and Brie have the highest vitamin B_6 concentration, followed by very hard, hard, semi-hard, and soft unripened cheese. **Table 3** presents recommended dietary uptakes.

Table 1 Vitamin B_6 concentration in foods

Food	*Concentration (μg per 100 g)*
Soybean, dry seed	1000
Salmon	980
Oats	960
Ox liver	877
Mackerel	630
Pig's liver	590
Lentil, dry seed	575
Pork	565
Chickpea, dry seed	550
Millet	519

Vitamin B_6 Deficiencies

The vitamin is essential for humans, most animals, and some microorganisms. Some recommendations concerning uptake relate the concentration of B_6 to protein uptake; the German Society for Nutrition, for example, recommends a minimum intake as shown in **Table 3** based on a quotient of 20 μg g^{-1} recommended protein uptake. Bioavailability is negatively correlated with the amount of glycosylated forms of vitamin B_6 in the respective food. The glycosylated form mainly appears in plant-derived foods but not animal-derived foods. As an estimation, the bioavailability of vitamin B_6 in a 'normal, mixed diet' is about 75%.

A specific vitamin B_6 deficiency in humans can hardly be detected, as the first symptoms resemble the symptoms of niacin and riboflavin deficiency (stomatitis, dermatitis like pellagra). Sometimes, in children, neurological problems occur, maybe due to changes in neurotransmitter metabolism (PLP functions as a coenzyme of an amino acid decarboxylase). Longer-lasting deficiency might lead to peripheral neuropathy (nerve demyelination and hypochromic anemia that cannot be cured by iron supplementation (vitamin B_6 functions in heme synthesis)), and also the risk of dementia is recently under discussion.

Some drugs, hydrazines, chelators, antibiotics, oral contraceptives, L-DOPA (L-3,4-dihydroxyphenylalanine), and alcohol, reduce vitamin B_6 concentration, especially when they are taken over an extended period of time (then vitamin B_6 status should be monitored.

Vitamin B_6 status is normally measured by

- PLP in plasma
- 4-Pyridoxic acid excretion in 24 h urine (short-term)
- Assessment of the activation coefficient of erythrocyte transaminase (long term)

PN is highly toxic when taken over an extended period of time. A dose of 150 mg day^{-1} over several months leads to (reversible) peripheral neuropathy with dysreflexia and insensibility. However, therapies with megadoses of vitamin B_6 showed high positive potential in the treatment of PN dependency (2–11 mg day^{-1}), cystathioninuria (400 mg day^{-1}), homocystinuria (250–1250 mg day^{-1}), primary oxalosis type I ('spine syndrome', 150 mg day^{-1}), and also isoniazid intoxication (1 g PN g^{-1} isoniazid). In some cases, beneficial effects have been described for carpal tunnel syndrome, premenstrual syndrome, and rheumatic diseases, although for the latter it is still unclear.

Thiamine

D Nohr and H K Biesalski, Universität Hohenheim, Stuttgart, Germany

E I Back, Novartis Pharma GmbH, Nürnberg, Germany

© 2011 Elsevier Ltd. All rights reserved.

This article is a revision of the previous edition article by H. K. Biesalski and E. I. Back, Volume 4, pp 2690–2694, © 2002, Elsevier Ltd.

Introduction

Thiamine or vitamin B_1 is a water-soluble vitamin and is unstable and loses its biological activity in alkaline solutions (pH >7) as well as in the presence of oxidants and radiation. The chemical name of thiamine is 3-[(4-amino-2-methyl-5-pyrimidinyl)methyl]- 5-(2-hydroxyethyl)-4-methylthiazolium; its coenzyme form is thiamine pyrophosphate (TPP; **Figure 1**).

In pharmaceutical and other preparations, thiamine is used in the form of water-soluble thiazolium salts (thiamine chloride hydrochloride, thiamine mononitrate); synthetic lipophilic derivatives (allithiamins) also exist. The latter can pass through biological membranes more easily and in an almost dose-related manner, thus offering a possibility to develop thiamine stores by supplementation, which are normally low and last for only 4–10 days.

In the presence of oxidizing agents and in strongly alkaline solutions, thiamine is converted into thiochrome, a fluorescent substance used to determine the thiamine content of feeds, foods, or pharmaceutical preparations.

Functions of Thiamine

A number of enzymes (pyruvate dehydrogenase complex; α-ketoglutarate dehydrogenase complex; branched-chain α-keto acid dehydrogenase complex) involved in intermediary metabolism and playing a role in the oxidative decarboxylation of α-keto acids require TPP as a coenzyme. Thus, metabolites from carbohydrate metabolism and keto analogues from amino and fatty acid metabolism are made available for energy metabolism. In addition, a TPP-dependent transketolase is involved in the formation of NADPH and pentose in the pentose phosphate pathway. Both metabolites play important roles in several other synthetic pathways. There are hints that the above-mentioned enzymes are also involved in neural functions; however, the exact mechanisms of action need to be elucidated further. Interestingly, a decrease of glutamate uptake in the prefrontal cortex of thiamine-deficient mice is described.

Sources of Thiamine

Tables 1 and **2** show the thiamine content of various foods. **Table 2** focuses on dairy products, including milk from different species, that are consumed by humans.

It has to be taken into account that heat treatment, as well as storage conditions, can lead to losses of the thiamine content of the foods:

- low pasteurization 3–4%
- boiling 4–8%
- spray-drying 10%
- roller-drying 15%
- pasteurization 9–20%
- condensed milk 3–75%
- sterilization 20–45%
- evaporated milk 20–60%

Fresh milk in dark bottles loses 24% of its initial thiamine content on storage for 24 h at 4 °C, 14% on storage at 12 °C, and 16% on storage at 20 °C. Evaporated milk loses 15–50% over periods >12 months; spray-dried whole milk shows no changes up to 12 months. Thiamine is lost during cheese manufacture mainly during drawing of the first whey; no significant changes occur during maturation.

UV light-induced inactivation of thiamine can, under certain conditions (cheese, fresh milk), be counterbalanced by thiamine-synthesizing microorganisms. Modern high-pressure-assisted thermal sterilization methods result in almost stable vitamins, although the decay in model solutions (acetate-buffered, pH 5.5) was about 30 times higher than in minced pork. Thus, a general deduction of the test results to routine food preparation needs further investigations.

The recommended daily uptake of thiamine given by the DGE (German Nutrition Society) is shown in **Table 3**.

Thiamine Deficiencies

Because of the relatively small and short-lasting thiamine stores, marginal deficiencies are quite common, but early symptoms are rarely recognized.

Symptoms of thiamine deficiency are cardiac failure, muscle weakness, peripheral and central neuropathy, and gastrointestinal malfunction. Reasons for deficiency besides a thiamine-free diet (e.g., parenteral nutrition) might be reduced absorption (gastrointestinal diseases), impaired transport, increased requirements (pregnancy, lactation, infancy, childhood, adolescence, increased physical activity, infections, trauma, surgery), or increased losses and impaired biosynthesis of TPP.

Clinically manifest deficiency appears in several forms of an illness called beriberi, which is nowadays mostly a problem in some regions of Southeast Asia, mainly because of the consumption of thiamine-free rice or raw fish (which contains thiaminase) or chewing of betel nuts or fermented tea leaves (which contain 'antithiaminic' tannins). Another risk group is chronic alcoholics who often consume low-quality meals, have poor appetite, and suffer from gastrointestinal problems and malabsorption. One can differentiate infantile beriberi (often lethal in sucklings fed by thiamine-deficient mothers) from two forms of adult beriberi: dry beriberi is characterized by peripheral neuropathy ('burning feet syndrome', exaggerated reflexes, diminished sensation, and weakness in all limbs, muscle pain, problems rising from squatting position, and, in severe cases, eventually seizures). Wet beriberi is characterized by cardiovascular symptoms (rapid heart rate, enlargement of the heart, edema, breathing problems, and ultimately congestive heart failure). 'Cerebral' beriberi mostly leads to Wernicke's encephalopathy and Korsakoff's psychosis, both together appearing as the Wernicke–Korsakoff syndrome, which is, however, not easily diagnosed but can be treated by thiamine supplementation.

Thiamine Supplementation

For the therapeutic treatment of diseases of the central (CNS) and the peripheral nervous system (PNS) and of exhaustion and during cytostatic treatment, doses of 50–200 mg thiamine day^{-1} are administered orally. Clinically manifest beriberi is treated by administering 50–100 mg day^{-1} subcutaneously or intravenously for several days, followed by the same dose orally for several weeks. Other than single cases of anaphylactic shock after intravenous application, no side effects of higher doses of thiamine (e.g., up to 200 mg day^{-1}) are known.

Riboflavin

D Nohr and H K Biesalski, Universität Hohenheim, Stuttgart, Germany

E I Back, Novartis Pharma GmbH, Nürnberg, Germany

© 2011 Elsevier Ltd. All rights reserved.

This article is a revision of the previous edition article by H. K. Biesalski and E. I. Back, Volume 4, pp 2694–2699, © 2002, Elsevier Ltd.

Riboflavin or Vitamin B$_2$

The chemical name for riboflavin is 7,8-dimethyl-10-(1′-D-ribityl)isoalloxazine; riboflavin exists in an oxidized and a reduced form (**Figure 1**), from which two coenzymes are formed: flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD; **Figure 2**).

The ending 'flavin' refers to its yellowish color (in Latin *flavus* means yellow).

Free as well as protein-bound riboflavin occurs in the diet, and milk in general is the best source. In cow's milk, the free form, with a higher bioavailability, is the major one (61% riboflavin, 26% FAD, 11% hydroxyethyl form, and others), whereas the protein-bound, and thus less bioavailable, form predominates in other foods. In human breast milk, approximately one- to two-thirds of riboflavin occurs as FAD.

Riboflavin is very heat stable but it is extremely photosensitive. It is photodegraded to lumiflavin (under alkaline conditions) or lumichrome (under acidic conditions), both of which are biologically inactive. Concentrations are significantly reduced in high-pressure low-temperature treated milk as compared to raw milk. UV light excites riboflavin to a high degree of natural fluorescence, which is used for its detection and determination in yogurt or non-fat dry milk.

Functions of Riboflavin

Riboflavin-dependent enzymes are called flavoproteins or flavoenzymes, because of their yellowish appearance. They catalyze hydroxylations, oxidative decarboxylations, dioxygenations, and reduction of oxygen to hydrogen peroxide, serving as electron carriers, mediators of electron transfer from pyridine nucleotides to cytochrome *c* or to other one-electron acceptors, and as catalysts of electron transfer from a metabolite to molecular oxygen. The two flavoenzymes, FMN and FAD, play major roles in the metabolism of glucose, fatty acids, amino acids, purines, drugs and steroids, folic acid, pyridoxine, vitamin K, niacin, and vitamin D.

The FAD-dependent enzyme, glutathione reductase, plays a major role in the antioxidant system by restoring reduced glutathione (GSH) from oxidized glutathione (GSSH). GSH is important in protecting lipids from peroxidation and in stabilizing the structure and function of red blood cells; it is the most important antioxidant in erythrocytes and in keeping lens proteins in solution (thus preventing cataracts).

The formation of FMN and FAD is ATP dependent and takes place mainly in the liver, kidney, and heart. All enzymatic steps are under the control of thyroid hormones.

- Flavokinase: riboflavin + ATP → r/FMN + ADP
- FAD pyrophosphorylase: FMN + ATP → /FAD + PP
- FAD + apoenzyme/protein → covalently bound flavins

Sources of Riboflavin

Tables 1 and **2** summarize dietary sources of riboflavin and its concentration, especially in the milk of various species and in dairy products.

Heat treatment has only negligible effects on riboflavin concentrations, whereas exposure of milk to sunlight results in the loss of 20–80% of riboflavin. Thus, storage in dark bottles, light-tight wax cartons, or special polyethylene terephthalate (PET) bottles is recommended.

Photo-degradation of riboflavin catalyzes photochemical oxidation and loss of ascorbic acid. Gamma radiation of 10 Gy destroys about 75% of riboflavin in liquid milk, whereas milk powder shows no losses even at higher doses.

Storage influences riboflavin concentration as follows: condensed milk loses 28% (33%) of its initial riboflavin content when stored at 8–12 °C for 2 years (10–15 °C for 4 years), ice cream loses 5% when stored at –23 °C for 7 months. No losses were found in fresh milk stored at 4–8 °C for 24 h or in milk powder stored for 16 months.

In cheese, most losses (66–88%) of the original riboflavin content of the milk appear to occur during whey

drainage, while ripening has almost no effects. However, in some cheese varieties, the concentration is higher in the outer layers due to microbial synthesis. High-pressure tests for thermal sterilization processes led to different results concerning the decay of the vitamin, depending on the matrix of the food tested.

Table 2 Riboflavin in milk, dairy products, and cheese

Food	*Concentration (μg per 100 g)*
Dried whole milk	1400

Riboflavin Deficiency

Riboflavin is essential for humans, animals, and some microorganisms. Among humans, seniors and adolescents seem to be at particular risk of deficiency; the recommended uptake is given in **Table 3**. In some cases, recommended

Table 3 Recommended daily uptake of riboflavin

	Riboflavin (mg day^{-1})	
Age	*Male*	*Female*
Sucklings <4 months	0.3	
Sucklings 4–12 months	0.4	
Children 1–4 years	0.7	
Children 4–7 years	0.9	
Children 7–10 years	1.1	
Children 10–13 years	1.4	1.2
Children 13–15 years	1.6	1.3
Adults 15–25 years	1.5	1.2
Adults 25–51 years	1.4	1.2
Adults 51–65 years	1.3	1.2
Adults >65 years	1.2	1.2
Pregnant		1.5
Breast feeding		1.6

uptake is related to energy intake, and 0.6 mg riboflavin per 1000 kcal is considered adequate. Milk and milk products (without butter) can contribute about 30% of the total riboflavin supply.

A major portion of riboflavin is bound to proteins and these flavoproteins have to be hydrolyzed before absorption by specialized transporters in the upper gastrointestinal tract. The amount that can be stored depends on the availability of proteins providing binding sites. Although a limited uptake makes sense in preventing accumulation in tissues, it increases the body's dependence on dietary supply. Under normal conditions, riboflavin stores last for 2–6 weeks, but in cases of protein deficiency, they last significantly shorter.

Symptoms of a marginal deficiency are often nonspecific: weakness, fatigue, mouth pain, glossitis, stomatitis, burning and itching of the eyes, and personality changes. Signs of increased deficiency are cheilosis; angular stomatitis; seborrheic dermatitis at the mouth, nasolabial sulcus, and ears (later extending to the trunk and extremities); desquamative dermatitis with itching in genital regions; opacity of the cornea; cataract; and brain dysfunction. The major reasons for riboflavin deficiency are

- Insufficient dietary intake by seniors and adolescents (especially girls)
- Endocrine abnormalities, insufficient adrenal and thyroid hormones
- Drugs (psychotropic, anti-depressant, cancer therapeutics, anti-malarial)
- Alcohol intake interfering with the digestion and absorption of food flavins
- Agents that chelate or form complexes with riboflavin or FMN, affecting their bioavailability: copper, zinc, iron, caffeine, theophylline, saccharine, nicotinamide, ascorbic acid, tryptophan, urea.

As riboflavin (via FAD-dependent glutathione reductase) is involved in antioxidant mechanisms, riboflavin deficiency may considerably affect erythrocyte metabolism. However, several studies have reported protective effects of a deficiency against malaria infection. A study in the United States showed that the uptake of yogurt, milk, cereals, and also riboflavin was inversely correlated with homocysteine levels in plasma, which, in turn, seem to be positively correlated with a higher risk of developing atherosclerosis.

Assessment of the riboflavin (mainly by HPLC methods) status uses the following parameters:

- Erythrocyte glutathione reductase activity coefficient,
- Excretion in urine ($\mathrm{mg\,g^{-1}}$ creatinine to assess short-term effects), and
- Riboflavin in erythrocytes ($\mathrm{mg\,g^{-1}}$ hemoglobin).

Concerning supplementation, no case of intoxication has been described. Thus, riboflavin is regarded as safe even at high doses. Supplements are usually given to reverse deficiency symptoms or to support high-risk groups:

- Regular intake of drugs (e.g., anti-depressants, oral contraceptive)
- Malnutrition
- Patients after trauma
- Malabsorption
- Chronic alcoholics

Hyperbilirubinemia can be treated much quicker by phototherapy when 0.5 mg riboflavin per kg of bodyweight is given. Finally, persons with congenital methemoglobinemia might benefit from 20–40 $\mathrm{mg\,day^{-1}}$.

Properties of Water and Water Activity

Water is a well-characterized compound that exhibits physical and chemical properties that differ significantly from those of other compounds with a corresponding molecular structure. These include relatively high phase transition temperatures, heats of changes in phase, and other thermodynamic quantities. The latent heat of melting of ice at 0 °C, ΔH_m, is 334 J g^{-1} (6.012 kJ mol^{-1}), the latent heat of vaporization of water, ΔH_v, at 100 °C is 2255 J g^{-1} (40.63 kJ mol^{-1}), and the heat of sublimation of ice at 0 °C is 2826 J g^{-1} (50.91 kJ mol^{-1}). The solid, liquid, and gaseous states of water may coexist in equilibrium at the triple point, which is located at 0.0099 °C and a pressure of 610.4 Pa. Water may solidify in various forms of ice depending on the pressure. Water may also solidify as an amorphous glass. Vapor-deposited glassy water undergoes the glass transition with onset temperature, T_g, at −138 °C. The fundamental physical properties of water in dairy products are the main determinants of energy and temperature requirements as well as economics of all heat treatments and the evaporation and dehydration processes, in particular, in the dairy industry.

The purest forms of water in dairy products are crystalline ice and gaseous water vapor. The vapor pressure of water is lower in solutions as well as in dairy products than the vapor pressure of pure water at the same temperature. In ideal dilute solutions, vapor pressure is defined by Raoult's law:

$$p = xp_0 \qquad [1]$$

where p is the vapor pressure of water in the solution, p_0 is the vapor pressure of pure water at the same temperature, and x is the mole fraction of water.

Raoult's law defines that water in a solute–solvent system has a lower vapor pressure than that of pure water. This results in a lower freezing temperature and a higher boiling temperature than those of pure water at the same pressure. Real solutions, such as milk, do not obey Raoult's law, but an 'effective' mole fraction for the solutes can be defined. The effective mole fraction of water is often referred to as water activity, a_w. Water activity is equal to the equilibrium relative vapor pressure (RVP) of water in the surrounding atmosphere, i.e., a_w as the ratio of the vapor pressure in a solution to that of pure water at the same temperature:

$$a_w = \frac{p}{p_0} \qquad [2]$$

Therefore, the equilibrium or steady-state water activity is related to equilibrium relative humidity (ERH) corresponding to the equilibrium RVP of the surrounding atmosphere by

$$a_w = \frac{\text{ERH}}{100} \qquad [3]$$

Although water activity is a measure of water availability, it should be emphasized that water activity is a temperature-dependent property of water in a material, such as food. In most dairy products, temperature and pH are more important factors that control rates of deteriorative changes and the growth of microorganisms than water activity. This is because the average water content of milk is very high, 87.1%, and milk contains only about 8.9% of non-fat solids. The water activity of milk is, therefore, very high, 0.993. The pH of milk is close to neutral, about 6.7, which allows the growth of almost all microorganisms. Thus, in high-water, non-fermented dairy products, temperature is the main variable controlling microbial growth. In fermented milk products and in the water phase of butter, the pH is reduced, for example, to about 4.6 in ripened cream butter, which significantly reduces the growth of spoilage microorganisms. Water activity is, however, an important factor controlling the microbial flora in ripening cheese, and quality changes of some cheeses and dairy powders during storage. The reduction of water activity in these products affects the predominant microbial culture, and, in some cases, an increase in water activity improves shelf life due to reduced availability of water for microbial growth. The water activity of evaporated milk is 0.986 and a relatively rapid removal of water by dehydration or freezing results in supersaturation of soluble compounds. Evaporation of water also reduces the pH of milk to about pH 6, depending on the extent of concentration.

Water Sorption

Water sorption characteristics, as well as most other interactions of solids with water, are defined by the composition of the non-fat solids of dairy products. The water sorption properties are affected mainly by the component carbohydrates and proteins, which represent most of the non-fat fraction of milk solids, as well as by the physical state. The sorption properties may also be affected by time-dependent phenomena as a result of structural transformations and solute crystallization. Water sorption in low-water dairy products results from the difference between the vapor pressure of water in the material and the vapor pressure of water in the surrounding atmosphere. Water sorption occurs when the solids are exposed to conditions where the vapor pressure of water is higher than that within the solids. Therefore, the solids may sorb water until an equilibrium vapor pressure within the food and the surrounding atmosphere is reached. The sorption properties are strongly dependent on temperature. Moreover, sorption properties of low-water solids and desorption of high-water solids may differ resulting in water sorption hysteresis.

Sorption isotherms, which show the water content as a function of water activity at a constant temperature, are useful tools in describing the relationships between water content and steady-state RVP. Typical sorption isotherms of dairy powders, such as that of skim milk solids in **Figure 1**, with amorphous components, and milk and whey proteins are sigmoid curves and exhibit hysteresis. However, the amorphous lactose in dairy powders is unstable and it tends to crystallize during the storage of powder above a critical water content or water activity. Such crystallization is observed from time-dependent loss of sorbed water and a break in the sorption isotherm. The water sorption properties of the nonhygroscopic, crystalline lactose differ significantly from the water sorption properties of amorphous lactose. Therefore, crystallinity and crystalline forms of lactose may greatly affect sorption properties and one of the most significant differences between dairy powders with glassy or precrystallized lactose is the water sorption behavior. Amorphous lactose is very hygroscopic and it may sorb high amounts of water at low relative humidities. Crystalline lactose shows little sorption of water at low humidities and its water sorption becomes significant only at the higher relative humidities as a result of partial solubilization. In addition, differences in salt content may affect water sorption; for example, the presence of salts may increase water sorption by cheese and milk proteins.

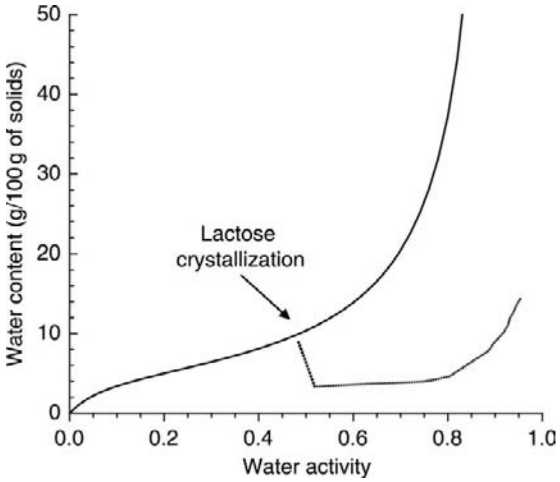

Figure 1 Sorption isotherm of skim milk solids (——). The break in the sorption isotherm resulting from crystallization of amorphous lactose is shown schematically (...).

Phase and State Transitions

Water-soluble milk solids often form amorphous, supercooled liquids or glasses as a result of dehydration or freeze concentration, for example in dairy powders and frozen desserts. The dominant component in defining the physical state is lactose. The formation of the non-crystalline, amorphous state of lactose results either from the rapid removal of solvent water by dehydration or from freeze concentration in freezing of water. In the amorphous solids, water behaves in a manner similar to plasticizers in synthetic polymers. Water plasticization is observed from a softening of the amorphous material, which is accompanied by increasing rates of quality changes. Plasticization may also result from an increase in temperature, or an increase in both temperature and water content. At a sufficient level of plasticization by temperature or water, the amorphous solids exhibit the glass transition. The glass transition occurs over a temperature or water content (water activity) range, and it can be observed from changes in heat capacity, dielectric properties, various mechanical properties, volume, and molecular mobility. The effect of water on the physical state of milk solids can be observed from decreasing glass transition with increasing water content (**Figure 2**) and structural changes that occur above a critical temperature, water activity, or water content, as the material suffers the glass transition.

The temperature–water combinations that support the various states or that result in state or phase transitions of amorphous solids and freeze-concentrated solutions can be described using state diagrams. State diagrams are simplified phase diagrams that describe the concentration dependence of the glass transition of solutes and relationships between ice formation and solute concentration at low temperatures. State diagrams are useful in the characterization of the physical state and physical properties of milk solids at various temperatures and water contents. The state diagram, as shown for lactose in **Figure 3**, shows the glass transition of the solids and the decrease in the glass transition temperature, T_g, with increasing water content. At sufficiently high water contents, ice formation before vitrification cannot be avoided, separating ice from the material with concurrent freeze concentration of solutes in an unfrozen water-solute phase. Therefore, the state diagrams often show the effect of ice formation on the phase and state behavior. A maximally freeze-concentrated solute has the glass transition at T'_g, which corresponds to a solute concentration of C'_g. Moreover, a full state diagram shows the onset temperature for ice melting in the maximally freeze-concentrated solution, T'_m, equilibrium ice melting temperature, T_m, curve, and the solubility curve. The solute concentration of maximally freeze-concentrated solute matrices, including non-fat milk solids, has been found to be about 80% (w/w).

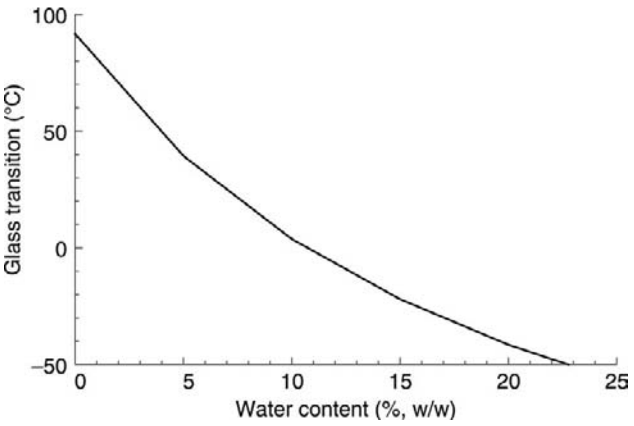

Figure 2 Glass transition temperature, T_g, of skim milk solids as a function of water content.

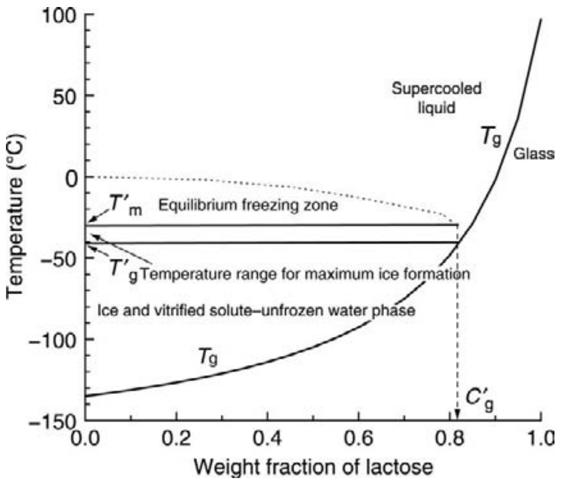

Figure 3 State diagram of lactose showing the decrease of the glass transition temperature, T_g, with increasing water content (—), the glass transition temperature of maximally freeze-concentrated lactose solutions, T'_g, and onset temperature for ice melting in the maximally freeze-concentrated state, T'_m. C'_g shows lactose concentration in the maximally freeze-concentrated, unfrozen solution. The equilibrium ice melting temperature, T_m, curve is shown schematically (---).

Water in Milk Solids and Dairy Powders

Stickiness and Caking

Various time-dependent structural transformations or changes in mechanical properties may occur in dairy powders at temperatures or water contents resulting in the glass transition. These transformations include stickiness and caking of powders, plating of particles on amorphous granules, and structural collapse of dehydrated structures, which are related to a rapid decrease in viscosity and increase in flow above the glass transition.

The main cause of stickiness is water or thermal plasticization of particle surfaces, which allows a sufficient decrease of surface viscosity for adhesion. Since viscosity is extremely high in the glassy state, the contact time must be very long for the occurrence of stickiness. A dramatic decrease in viscosity above T_g reduces the contact time and causes stickiness that can be related to the timescale of observation. A contact time of 1–10 s is sufficient at a surface viscosity less than 10^6–10^8 Pa s to cause stickiness. The decrease in viscosity is orders of magnitude over a fairly narrow water activity range, which results from the transformation of the solid material into the free-flowing liquid state. Obviously, water activity or storage relative humidity is often a more important indicator of stability than water content. The most common caking mechanism in food powders is plasticization due to water sorption and subsequent interparticle fusion. Caking of amorphous powders results from the change of the material from the glassy to the less viscous liquid-like state, which allows liquid flow and the formation of interparticle liquid bridges. The close relationships between collapse phenomena and glass transition suggest that the former occur above T_g with rates that are defined by the temperature difference, T–T_g.

Agglomeration is an important step in achieving instant solubility properties for dairy powders. The process is based on controlled thermal and water treatment of fine particles. Common agglomeration methods are based on rewetting of fine powders or on agglomeration during and after spray drying using a straight-through process. The straight-through process is accomplished by producing plasticized particles with a temperature and water content that allow sufficient plasticization of particle surfaces and the formation of interparticle liquid bridges. The plasticized agglomerates enter a vibrating fluidized bed dryer, which completes dehydration and allows sufficient cooling of the product with concurrent solidification and vitrification of the particle surfaces. Agglomeration by both the rewetting and straight-through processes requires that amorphous solids are allowed to exist for a sufficiently long time in the plasticized state at appropriate temperature–humidity conditions allowing controlled stickiness. The proper agglomeration conditions are defined by the T_g of the particles and their water plasticization properties.

Lactose Crystallization

Drying of milk and whey by spray drying or roller drying produces a glass that is composed of a noncrystalline mixture of α- and β-lactose. The existence of lactose in the glassy state and lactose crystallization due to increased molecular mobility have been confirmed by several studies, which have determined the physical state using polarized light microscopy, electron microscopy, differential scanning calorimetry (DSC), nuclear magnetic resonance (NMR) spectroscopy, and X-ray techniques. Crystallization of amorphous lactose in dairy powders may accompany the glass transition due to thermal or water plasticization and the increase in molecular mobility. Such crystallization is often detrimental to powder quality and it may significantly alter rehydration characteristics and reduce shelf life.

In general, the crystallization time of amorphous sugars above T_g depends on temperature and water content. The crystallization behavior of amorphous lactose is also temperature dependent. An increase in storage temperature shifts the break in the sorption isotherm, indicating loss of sorbed water, to a lower relative humidity. Typical DSC heating scans of milk powders with amorphous lactose show a glass transition followed by a crystallization exotherm. Lactose crystallization during water sorption may occur either into the anhydrous β-form or into α-lactose monohydrate. The crystalline form produced depends on relative humidity and temperature. Lactose crystallization occurs into the anhydrous β-form at relatively low water activities and the α-lactose monohydrate form often crystallizes at water activities above 0.57 a_w at room temperature. Crystallization into the anhydrous β-lactose crystals releases water associated with the amorphous lactose while the α-lactose monohydrate contains 5% water in the crystalline lactose phase. At higher temperatures, crystallization behavior may change according to the stability of the crystalline form at the crystallization temperature.

The kinetics of crystallization at a constant temperature above glass transition can be related to water content and water activity, which define the T–T_g. Therefore, lactose crystallization may occur above a critical water content or water activity at a constant temperature with a rate defined by T–T_g. An increasing relative humidity increases water sorption by amorphous lactose, which causes water plasticization and increases the temperature difference, T–T_g. Combined T_g and water sorption data have suggested that a water content of 7.6 g per 100 g non-fat solids depresses the glass transition to room temperature. The corresponding water content for pure lactose is 6.8 g per 100 g solids and the critical a_w is 0.37. This water activity or storage relative humidity of 37% RH is empirically known as critical to the stability of dairy powders, including milk and whey powders.

Milk powders with lactose hydrolyzed to galactose and glucose show no break in the sorption isotherm. Both the water sorption and crystallization behavior of these sugars differ significantly from that of lactose, and the behavior of the sugar mixture differs from that of typical skim milk solids. For example, component crystallization in the protein–glucose–galactose mixture is delayed in comparison to lactose crystallization in common dairy powders. Skim milk powders containing hydrolyzed lactose show a glass transition well below that of amorphous lactose. The glass transition of lactose-containing anhydrous skim milk powder has an onset at 92 °C. Anhydrous powder produced from skim milk with lactose hydrolyzed to galactose and glucose has the glass transition onset at 49 °C, and the critical water content that depresses the glass transition to room temperature is as low as 2.0 g per 100 g. The decrease in the T_g and the low critical water content are responsible for difficulties in the production of lactose-hydrolyzed dairy powders. These powders are extremely sensitive to temperature and water and they show hygroscopicity and stickiness during processing and storage.

Chemical Stability

Rates of deteriorative changes at reduced water activities are often related to water content and molecular mobility. Water as a plasticizer has a significant effect on molecular mobility above a critical, temperature-dependent water activity or water content. Molecular mobility is governed by the physical state and water plasticization of solids, and rates of several deteriorative changes are probably affected by diffusion. Diffusion below T_g may be assumed to be restricted, and a chemical reaction may become diffusion limited in a glassy matrix. Although diffusion of water occurs in glassy systems, the diffusion of larger reactant molecules is most likely to be affected by the glass transition. A significant increase in a reaction rate may occur as the material is transformed into the supercooled liquid state as a result of the glass transition. The temperature dependence of chemical changes often follows the Arrhenius equation, but kinetics may show deviations from Arrhenius kinetics at reduced water contents due to diffusional limitations.

Non-enzymatic browning is one of the most important, water content-related deteriorative reactions in low-moisture dairy foods. The non-enzymatic browning reaction is a series of condensations, but it may be considered as a bimolecular reaction. Browning rates in non-fat milk powder below the critical water activity (water content) are low, but the rate of browning is dependent on water content and it increases substantially above the critical water activity. In general, non-enzymatic browning occurs very slowly in glassy dairy products. However, above the glass transition, the rate of the reaction increases and a further increase often results from lactose crystallization and release of the sorbed water. Lactose crystallization must be prevented to avoid caking and impaired solubility. The loss of lysine is most rapid at water activities that allow lactose crystallization. It should also be taken into account that crystallization of amorphous lactose in closed containers or packages is more detrimental as the water released from amorphous lactose remains in the system, accelerating deterioration of the noncrystalline solids.

Diffusion of reactants is probably the main requirement for the occurrence and increasing rates of chemical reactions above some critical temperature or water content. In some cases, flow through pores may increase reaction rates. Such exceptions include oxidation of free fat in dairy powders. Oxygen may diffuse in the material and enhance oxidation on the pore membranes. Crystallization of lactose coincides with an increase in free fat, which presumably facilitates lipid oxidation. In powders containing amorphous lactose, milk fat is encapsulated within the amorphous lactose–protein matrix and it is protected from oxidation. Exceeding the T_g and subsequent crystallization releases the encapsulated lipids, which become accessible to atmospheric oxygen and undergo oxidation rapidly.

Frozen Dairy Products and Ice Cream

The freezing temperature of milk, about −0.53 °C, is relatively constant. At the freezing temperature, all ice formed at lower temperatures is melted into water. The initial ice formation in milk, dairy products, and in foods, in general, requires supercooling to below the equilibrium melting temperature and it is followed by further crystallization of water as the temperature is decreased. Freezing behavior of water, for example, in ice cream is significantly affected by the component compounds, and by sugars in particular. The main component affecting freezing behavior is lactose. Ice formation in a lactose solution, provided that no lactose crystallization is taking place, occurs at temperatures above −30 °C. At −30 °C, the maximum ice formation in the solution can be achieved and a highly viscous, freeze-concentrated lactose solution with approximately 80% lactose and 20% unfrozen water remains unfrozen, as described by the state diagram. During further cooling, this unfrozen solution suffers the glass transition. Such nonequilibrium ice formation is a typical phenomenon of carbohydrate solutions and probably the most common form of ice formation in frozen foods, including frozen dairy products.

The viscosity of a freeze-concentrated solute phase is an important factor that may affect time-dependent crystallization phenomena, ice formation and recrystallization, and material properties. At a sufficiently low temperature, the viscosity of a freeze-concentrated solute matrix becomes high enough to retard diffusion and delay ice formation. The ice formation in real time ceases at the T'_g, since the high viscosity of the freeze concentrated solute matrix prevents diffusion of water molecules to the surface of ice crystal lattice and crystal growth. Ice formation and the extent of freeze concentration are dependent on temperature according to the melting temperature depression of water caused by the solute phase. Maximum freeze concentration may occur at temperatures slightly below the onset temperature of ice melting, T'_m, in the maximally freeze-concentrated material.

The size of ice crystals that are formed during freezing depends on the freezing method and freezing rate. Rapid freezing at a low temperature produces a large number of small ice crystals, while slow freezing at a higher temperature results in the formation of relatively few large ice crystals. The ice crystals, which form during freezing, are not stable, and recrystallization is common at typical storage temperatures of frozen dairy products. Recrystallization is a temperature-dependent process, which is enhanced by temperature fluctuations. Recrystallization with a decrease in the number of crystals and an increase in the average crystal size is referred to as Ostwald ripening. Recrystallization by fusion of smaller crystals resulting in the formation of large ice crystals is also an important recrystallization mechanism in ice cream. Melt–refreeze crystallization, which involves melting of ice and refreezing of unfrozen water, may occur under fluctuating temperatures, especially at relatively high temperatures. An average ice crystal size of 40 μm with a distance of 6–8 μm between the crystals is acceptable. The critical size, which produces a grainy texture, is 40–55 μm. Recrystallization of ice in ice cream and other products that are consumed in the frozen state produces a coarse, icy, undesirable texture. In addition, solute crystallization in freeze-concentrated products can be retarded by the use of sugar blends and syrups.

Evaluation of kinetic data on ice recrystallization should consider the effect of ice melting above T'_m. The viscosity of the unfrozen matrix is increased by stabilizers, which decrease the rate of recrystallization. Recrystallization of ice, as well as lactose crystallization during frozen storage, can be reduced by using hydrocolloids, such as carrageenans, guar gum, or locust bean gum, as stabilizers. Polysaccharide stabilizers do not significantly alter the T'_g of ice cream mixes, but ice crystal growth in stabilized ice cream above T'_g is a function of kinetic properties of the unfrozen solute matrix and the mobility of water within the unfrozen matrix. An increase in the amount of unfrozen water increases the recrystallization rate, but stabilizers reduce the recrystallization rate.

Water and Microbiological Stability

Microbial growth requires a minimum amount of water in an environment supporting the growth of microorganisms. In dairy products, the effect of water on the growth of microorganisms is probably most important in the ripening, texture, and quality of cheeses. Water availability may also be an important factor in controlling mold growth in low-fat dairy spreads and butter. Water activities of milk products vary widely, from 0.1 to 0.3 for dried dairy products to above 0.99 for liquid milk and whey. Sweetened condensed milk with 0.77–0.85 a_w has an intermediate water activity, but most other dairy foods have high water activities supporting the growth of bacteria and other microorganisms.

The minimum requirement for microbial growth is a_w 0.62, which allows the growth of xerophilic yeasts. An increasing a_w allows the growth of molds, other yeasts, and finally bacteria at high water activities. The most important water activity value for the safety of food materials is 0.86, which is the limit for the growth of *Staphylococcus aureus* (**Table 1**). The water activity of various cheeses and processed cheeses varies between 0.86 and 0.99 (**Table 2**). There are also critical a_w values for the multiplication of bacteria used in cheese manufacture. For example, propionibacteria, which are responsible for eye formation in Swiss cheese, are very

Table 1 Minimum water activities (a_w) for the growth of selected pathogenic bacteria in dairy products

Pathogen	*Minimum* a_w
Bacillus cereus	0.930
Campylobacter jejuni	0.990
Clostridium perfringens	0.945
Escherichia coli	0.935
Listeria monocytogenes	0.920
Salmonella spp.	0.940
Shigella spp.	0.960
Staphylococcus aureus	0.860
Vibrio parahaemolyticus	0.936
Yersinia enterocolitica	0.960

Table 2 Typical water activity (a_w) of common cheeses at 25 °C

Cheese type	*Water activity*
Appenzeller	0.96
Brie	0.98
Blue	0.94
Camembert	0.98
Cheddar	0.95
Cottage cheese	0.99
Edam	0.96
Emmentaler	0.97
Gouda	0.95
Mozzarella	0.99
Parmesan	0.92
Tilsiter	0.96

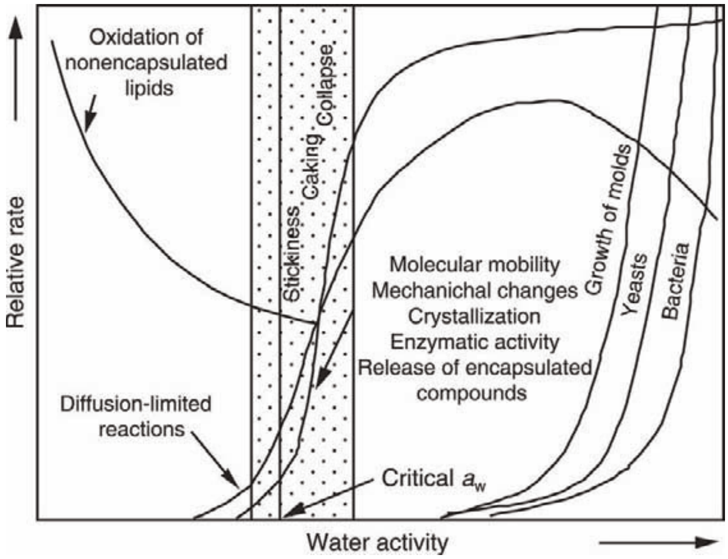

Figure 4 Food stability map showing the effect of water activity on the relative rates of various changes in food systems. The critical a_w refers to the water activity at which the glass transition occurs at the storage temperature.

sensitive to changes in a_w over the range 0.95–0.99. Water activity in cheese ripening may affect growth and CO_2 production.

Inhibition of the growth of most microbes in salted butter may be accounted for by the high concentration of salts in the water fraction and reduced water activity. The water activity of salted butter is 0.91–0.93, while that of unsalted butter is >0.99. In low-fat dairy spreads, a low pH with a reduced water activity is necessary to prevent the growth of pathogens and molds.

Stability Maps

The relative rates of deteriorative changes in food materials are traditionally related to water content and water activity on the assumption that stability at common storage temperatures can be maintained at a low water content. Structural transformations in milk solids may occur at temperatures above the glass transition, which corresponds to a water content that can be quantified. Such transformations include collapse of the physical structure, which reduces diffusion through pores and crystallization of amorphous lactose. Crystallization of amorphous lactose may also release encapsulated fat, which becomes susceptible to oxidation.

The effect of water activity on the relative rates of deteriorative changes is often described by stability maps, which are used to show the relative rate of enzymatic changes, non-enzymatic browning, lipid oxidation, microbial growth, and overall stability as a function of water activity (**Figure 4**). Various reactions rates may also be related to the physical state, molecular mobility, and water plasticization and glass transition of amorphous food solids. It is obvious that structural transformations, as well as diffusion-limited deteriorative reactions and those affected by lactose crystallization, occur at increasing rates with increasing water activity above the critical a_w.

Definition and Significance of Water Activity

Definition

Water activity of a system is a way of characterizing the potential energy of the contained water, which is thought to be related to the difficulty to remove it, for example, in drying, and to its availability to allow the functioning of living cells. It can be viewed, for instance, as the difference between the water vapor pressure measured over pure water and that measured over a food product (**Figure 1**(**a**)), or as the energy necessary to compensate for the osmotic pressure of a solution (**Figure 1**(**b**)). **Figures 2** and **3** show schematic views of water activity of dairy products as compared to their water content.

The chemical potential (μ_i, J mol^{-1}) of the component i in a mixture is defined as the partial derivative of the free energy, G, when the number of molecules of i (n_i) is varied, whereas the temperature, pressure, and total number of molecules in the system are kept constant.

$$\left(\frac{\partial G}{\partial n_i}\right)_{T,P,n} = \mu_i \qquad [1]$$

If the component considered is water, the subscript w will be used. For a process where the water concentration (expressed as the mole fraction X_w) is changed from X_w^0 to X_w, the change in free energy, ΔG, is

$$\Delta G = \mu_w - \mu_w^0 \qquad [2]$$

where X_w^0 and μ_w^0 concern a state of reference, namely, pure water under the temperature and pressure conditions of the system. As we will see later, ΔG can be calculated for various processes, for example, as the work corresponding to the upward motion of the piston if water is allowed to enter the concentrated solution in the system shown in **Figure 1**(**b**), or as the change in free energy as the pressure is changed from p_w^0 to p_w in the system shown in **Figure 1**(**a**).

If the system is a dilute solution, ΔG is observed to be proportional to the logarithm of the solvent molar fraction (Raoult's laws and van't Hoff's law):

$$\Delta G = \mu_w - \mu_w^0 = RT \ln X_w \qquad [3]$$

Solutions obeying eqn [3] are called 'ideal' solutions. For nonideal systems, X_w is replaced by a new characteristic named 'water activity' (a_w):

$$\Delta G = \mu_w - \mu^0{}_w = RT \ln a_w \qquad [4]$$

Comparing eqns [3] and [4], $a_w = X_w$ for ideal solutions. For nonideal solutions, a parameter, γ (activity coefficient), was introduced to represent the deviation from ideality:

$$a_w = \gamma X_w \qquad [5]$$

Water activity is a colligative property; that is, it depends on the number of solute molecules in the solution. The presence of solutes induces a disorder in the water structure, that is, an increase in entropy, which results in a reduced chemical potential. With small solutes, a_w is controlled mainly by X_w, that is, by the number of solute molecules. In the presence of macromolecules or hydrophilic surfaces (cell membranes), the mixing entropy plays a minor role in the depression of a_w (X_w remains high); low values of μ_w (and, in turn, of a_w) are attributed to interactions of the water molecules with the other constituents. When interactions occur between water and solutes (dipole–dipole, ionic interactions, or hydrogen bonds), or when the size of the solute is much larger than the size of the water molecule, $\gamma < 1$. When solute–solute interactions dominate over water–solute interactions, $\gamma > 1$ (remember, however, that a_w is always <1). **Figure 4** shows some examples of the a_w-lowering effect of dairy components.

If pure water is contained in a cylindrical capillary space (diameter d), the wall of which is perfectly wetted by water, the difference in chemical potential defined as in eqn [2] can be shown to be (Kelvin's law)

$$\mu_w - \mu^0{}_w \cong -V_w \sigma \frac{4}{d}$$

$$\ln a_w = -\frac{V_w \sigma}{RT}\frac{4}{d} \qquad [6]$$

where V_w and σ are, respectively, the molar volume and the surface tension of water. For a descending pore diameter range of 100–1 μm (and a surface tension of ~35 mN m^{-1} for a caseinate solution–air interface), eqn [6] predicts a_w in the range 1–0.999, that is, a very small lowering of a_w by capillary effects. If Kelvin's law can be assumed to be valid for a pore size approaching molecular dimensions ($d \approx 10$ nm), a_w could be lowered to ~0.90.

In products with intermediate or low water content, it is generally considered that water is retained by adsorption processes. The model most often referred to is the BET multilayer adsorption process, according to which a

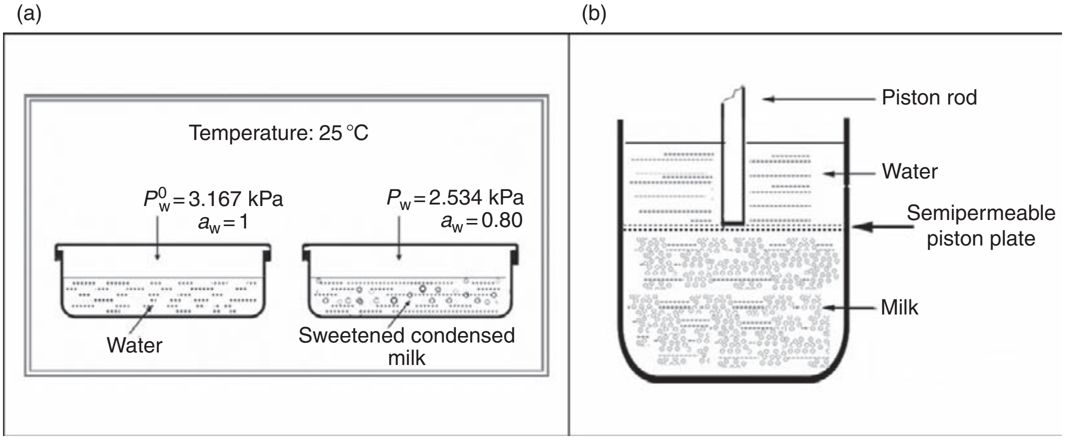

Figure 1 (a) Schematic representation of the difference in water vapor pressure above pure water and above a food product, measured at the same temperature (*T*). This difference may be known, either from a direct measurement of the partial water vapor pressures ($P^0{}_w$ (*T*), the saturated water pressure at *T*, above pure water, and P_w above sweetened condensed milk) or from the relative humidity (RH) in the headspaces. (b) Since the chemical potential of water in the concentrated milk is less than in pure water, there is a tendency for water to move into milk through the semipermeable plate. A downward pressure, $\prod$, on the piston is required to maintain it in place. Reproduced from Simatos D, Champion D, Lorient D, and Roudout G (2009) Water in dairy products. In: McSweeney PLH and Fox PF (eds.) *Advanced Dairy Chamistry-3. Lactose, Water Salts and Minor Constituents*, 3rd edn. In press.

first layer of sorbate (water) molecules would be formed on the surface of the solid, followed by a multilayer condensation of the sorbate onto the monolayer.

The relations between a_w and water content are represented by sorption isotherms (SI) for dairy products and components, example of which are shown in **Figures 5** and **6**. SI have a sigmoid shape for products with a high content of biopolymers. Small-molecular-weight solutes, such as lactose, have a higher a_w than biopolymers at low water contents, and a lower a_w than biopolymers at high water contents. As illustrated in **Figures 5** and **6**, it is important to remember that important variations in SI may result not only from variations in chemical composition, but also from variations in the conditions of determination such as water content measurement, equilibration time, variations in structure resulting from the drying process, or from evolution during the sorption experiment (crystallization of lactose, physical aging of polymers). SI found in the literature should therefore be used only as a first approximation.

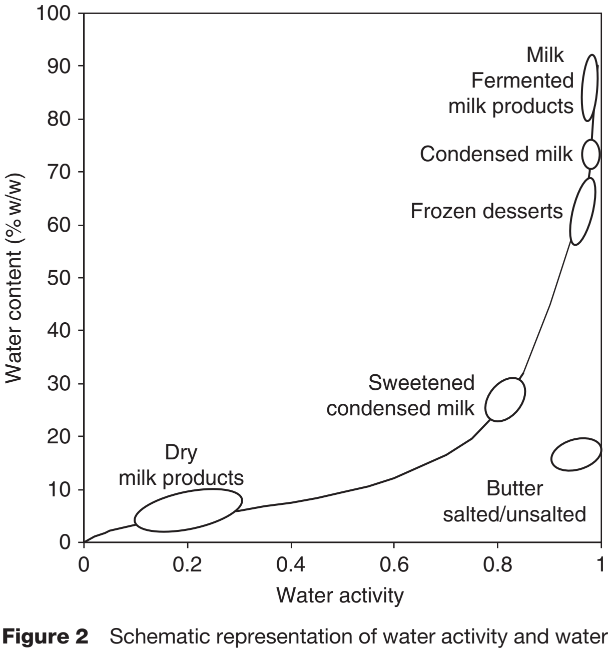

Figure 2 Schematic representation of water activity and water content of various dairy products (for cheese, see **Figure 3**).

One interesting aspect of a_w in food science and technology is that chemical potential must be the same in all phases of the system at equilibrium; this is important because food products most often comprise regions with different chemical compositions, physical states, or structures. A particular example of a multiphase system is frozen food products. As will be seen below, in a frozen product $a_w = p_{ice}/p_{supercooled\ water}$ and is, therefore, a function of temperature only. For instance, a food product with a water content high enough for the food to contain ice at −20 °C has (if at equilibrium) $a_w = 1.035/1.257 = 0.82$.

It must be remembered, however, that the definition of a_w and the derived expressions for its determination assume that the system is in a state of thermodynamic equilibrium. Hence, it is sensible to question the validity of their applicability to food products (Expert Panel, ISOPOW, 2000). Actually, solutions of small solutes, even if concentrated, can be considered to be at thermodynamic equilibrium, whereby the a_w concept is valid. For low-moisture or semi-moist solid food products, it is difficult to predict the actual status of the product, which will depend on (1) its position in comparison with glass

Note that the a_w of skim milk is very similar to that of lactose solutions in this a_w range. The large depression of a_W by NaCl is due to its low molecular weight and due to its dissociation into two 'active particles' (ions). Lactic acid has been considered as nondissociated by the authors.

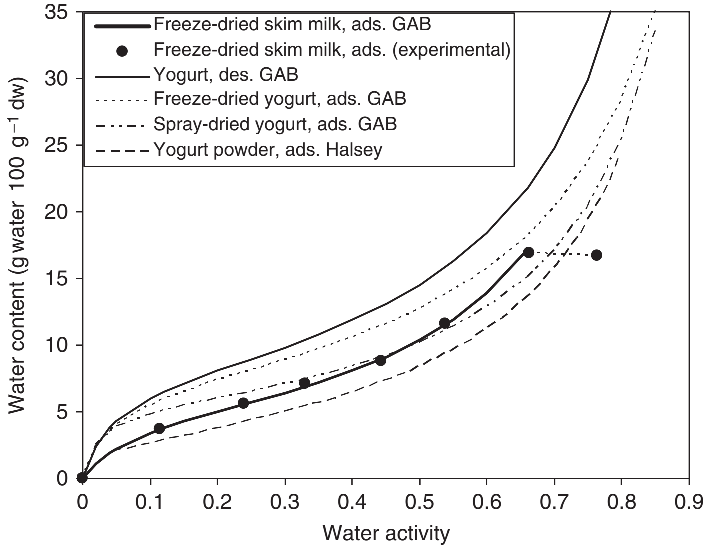

Figure 5 Water sorption isotherms for skim milk powder and yogurts. The experimental data for milk showing that the sorbed water amount remains constant (and even decreases) for a_W >0.66 indicate that lactose is crystallizing (crystals of β anhydrous lactose are able to adsorb much less water than amorphous lactose). The dry product (with a water content below ≈5%) is a glass at room temperature. If the ambient temperature is increased, or if T_g is decreased as a consequence of an increase in water content, the product becomes 'rubbery'. An increase in molecular mobility allows crystallization of lactose. The larger the distance of water content/temperature conditions to T_g, the shorter the delay, as indicated on the graph.

transition, as determined by its temperature and water content and (2) the duration of its stay under these conditions. A food material such as skim milk powder in the dry state is in a glassy state at room temperature (its glass transition temperature T_g is ~100 °C). When water is sorbed, the material is plasticized, that is, its T_g decreases to ~20 °C for a critical water content of ~8%. For a higher water content, the product is transformed into a viscoelastic material (supercooled liquid or rubber depending on the composition) (**Figure 7**). In the rubbery state, the product is in a metastable state: amorphous constituents (e.g., lactose) may crystallize; the more distant the product is from its glass transition, the faster the crystallization. In the glassy state, the product is out of equilibrium: it may undergo some evolution of its structure (physical aging); the closer the temperature is to T_g, the faster the evolution, but in practice it is always very slow. In both the rubbery and glassy states, the mobility of water remains rather high, and one may expect that equilibration of a_w will be usually accomplished within times of interest to the food technologist, as suggest some observations. In some situations, however, it must be recognized that what is measured is the relative humidity of the atmosphere in contact with the product, at best in a pseudo-equilibrium state. Hence it would be safer to use the term 'apparent water activity' (Expert Panel, ISOPOW, 2000).

Water Activity versus Bound/Free Water

Water activity is a way of measuring the energy status of water in a product. It gets depressed as a result of water structure being perturbed and due to interactions between water and solute molecules. Nevertheless, it does not allow one to define a fraction of bound water. The first point is the broad range of interaction energies between water and solutes: from the van der Waals interactions (~1 kJ mol^{-1}) to hydrogen bonds (10–40 kJ mol^{-1}) and ion–water interactions (50–100 kJ mol^{-1} for univalent ions and even more for multivalent ions). It can be noted that water–water and water–solute interactions that occur through H bonds have strength values of the same order; water molecules cannot therefore be viewed as strongly bound to solutes. Actually, spectroscopic observations and molecular dynamics simulations show that water molecules remain highly mobile, even when in direct contact with solute molecules. In liquid water at room temperature, water molecules tumble about with a reorientation time of ~2 ps (2×10^{-12} s). Although the properties (orientation, mobility) of some water molecules belonging to the primary hydration shell of ions are strongly modified, they still exchange with bulk water, albeit more slowly (e.g., lifetime ~10^{-9} s for Na^+). Similarly, molecular dynamics simulations of a sugar molecule in an aqueous solution show water molecules located at specific sites on the sugar molecule; however, within a few picoseconds, these molecules escape into the bulk water and are replaced by other water molecules. From spectroscopic methods, the ratio $\tau_s/\tau_{\mathrm{bulk}}$ of the rotational correlation time of water molecules in direct contact with the surface of solutes and that of bulk water is found to be in the range 1.0–2.5 at room temperature for free amino acids and other small organic molecules. For proteins in solution, only water molecules in direct contact with the protein surface are significantly perturbed, although they are still highly mobile, with mean residence times in the range 10–100 ps and the ratio $\tau_s/\tau_{\mathrm{bulk}}$ averaging around 5.5. Only water molecules buried within the protein have residence times longer than 1 ns (in the range 10^{-8}–10^{-4} s at room temperature). It is estimated that reduction of the mobility of water molecules in contact with proteins is not due to the interaction with the protein *per se* but rather due to their physical entrapment within the protein matrix.

Even in low-moisture solid products, water molecules appear to have a relatively high freedom of motion. The translational diffusion coefficient of water in a hydrated polysaccharide (pullulan with 20% water) has been estimated at $5 \times 10^{-12}\,\mathrm{m}^2\,\mathrm{s}^{-1}$ at 0 °C, that is, 1000 times lower than in liquid water, whereas the viscosity of the system in this glassy state (~50 °C below the glass transition temperature) would be 10^{15} times higher.

Based on the multilayer adsorption process, mathematical expressions have been derived to describe sorption isotherms (**Table 1**). The BET expression correctly describes the experimental curves of food materials for $0.2 < a_w < 0.5$; the GAB expression, which is derived from the BET expression, can be fitted satisfactorily to experimental data up to a_w ~0.9. The fitting parameters of these expressions are commonly used to calculate the water content corresponding to the monolayer and sorption energies, which are supposed to give information about the interactions of water with the material components. However, this use of the BET and GAB expressions is very questionable. First, the hysteresis observed between sorption and desorption points to the non-equilibrium character of the isotherms. Moreover, it is increasingly being admitted that the basic assumptions of the BET model are not fulfilled in the case of water sorbed on polar materials (energy equivalence of all sites on the sorbing solid surface). In the end, the plastifying action of water on the solid certainly plays a role in determining the form of the sorption curves. A plausible view would be that the sorption process changes at glass transition: in the glassy state, where the conformation is 'frozen', an adsorption model (such as the Freundlich model, assuming a distribution of independent sorption sites with different energies) would be suitable, whereas in the supercooled state, the isotherm could be based on the Flory–Huggins theory of polymer solutions.

Water Activity versus Food Quality and Food Processing Operations

In the 1960s, water activity became the favored parameter to characterize the availability of water to control the physical, chemical, or biological evolutions in foods. This originated in observations showing that the a_w values of media generally correlated well with the potential for growth and metabolic activity of microorganisms. Stability maps were produced, indicating a_w thresholds and a_w ranges corresponding to the maximal rates of chemical and biological evolutions. In the late 1980s, the value of a_w as a predictive index of food stability was questioned, first because most food products are not in a state of thermodynamic equilibrium, as discussed before; moreover, emphasis was placed on the importance of molecular mobility, namely in connection with the glass transition phenomenon. The respective relevance of both approaches, a_w and glass transition, has been discussed vigorously. Currently, a consensus appears to have become established, to recognize that both may have an essential role, in a particular domain, depending on the type of product or the objectives.

Microbial cells cannot be considered to behave as true osmometers; other parameters, such as pH, nature of the solutes in the medium, and mobility of the metabolites, must also be taken into account. Glass transition concepts, however, do not provide any better alternatives than a_w as a predictor of microbial behavior. Water activity is now generally recognized as an essential parameter for all aspects of microbial activity: germination and growth, and production of toxins and aroma. As regards texture, water content seems a better predictor than a_w; for instance, the texture of cheese was found to be better correlated to water content (coefficient of correlation with an extrusion force = −0.867) and fat content than to a_w (coefficient of correlation = −0.548). Crystallization (e.g., of lactose in milk powder) is a good example of evolution, the kinetics of which are controlled by water content and temperature, in connection with glass transition. With regard to chemical and biochemical reactions, the implication of water is complex: besides being a reactant for many reactions in foods and being necessary for the establishment of the appropriate conformation of enzymes, it constitutes the usual solvent for reactants and imparts the necessary mobility to reactants and reaction products. Water activity does not seem to be directly involved in the control of reaction kinetics; the observation that a reaction (e.g., non-enzymatic browning) occurs, in various food products, with a maximum rate in a characteristic a_w range most likely can be explained by these products having similar sorption isotherms and similar T_g values (e.g., because of a high content of biopolymers). Actually, if mobility is increased in these products, through the addition of a liquid fat or of a

plasticizer such as glycerol, the a_w range for maximal reaction rate can be shifted widely. However, a_w continues to serve as a useful guide for chemical stability because it allows prediction of the water content of the product in a given environment (so long as the specific sorption isotherm of the product is known). More generally, a_w is an essential tool in food technology, because it allows description of the gradient that will determine the transfer of water between two compartments having different initial relative vapor pressures in a multidomain food system, or between a food product and its environment during drying or osmotic dehydration, or during storage.

Principles of Measurement

Physical Properties to Be Measured

Water activity cannot be measured directly, but eqn [4] allows derivation of relations between a_w and some physical properties (**Table 3**), which lead to measurement methods.

Water vapor pressure

When the pressure of water vapor is changed from p^0 to p (**Figure 1(a)**), the change in free energy can be calculated from basic thermodynamics (and assuming that water vapor behaves as a perfect gas) to be $\Delta G = RT\ln p/p^0$. Then

$$a_w = \frac{p}{p^0} \qquad [7]$$

$100 \times p/p^0$ (%) defines the relative humidity (RH) of the atmosphere in equilibrium with the product, and a_w can be obtained from the measurement of p by various methods and calculation using the known p^0 values at the temperature of measurement.

- *Direct measurement with a manometer*: The air must be evacuated from the apparatus; drying of the sample during this operation must be kept at a negligible

Table 3 Relations between water activity and physical properties

(1) Equilibrium relative humidity	$a_w = \dfrac{p}{p^0} = \dfrac{\mathrm{ERH}}{100}$	p = partial water vapor pressure (Pa) p^0 = saturated water vapor pressure (Pa) at temperature T ERH = equilibrium relative humidity
(2) Freezing point depression	$\ln a_w = \dfrac{\Delta H_m}{R}\dfrac{T - T_0}{TT_0} + \dfrac{\Delta C_p (T - T_0)^2}{2RT^2}$	T_0, T = temperature of freezing of pure water and of the sample (K) ΔH_m = melting enthalpy of ice at T_0 (= 6 kJ mol^{-1}) ΔC_p = difference in the specific heat of ice and liquid water (= 37.697 J K^{-1} mol^{-1}) R = 8.314 J K^{-1} mol^{-1}
(3) Osmotic pressure	$\ln a_w = -\Pi \dfrac{V_w}{RT}$	$\prod$ = osmotic pressure (Pa) V = molar volume (8^{10-6} m^3 mol^{-1}) T = temperature (K) R = 8.314 J K^{-1} mol^{-1}

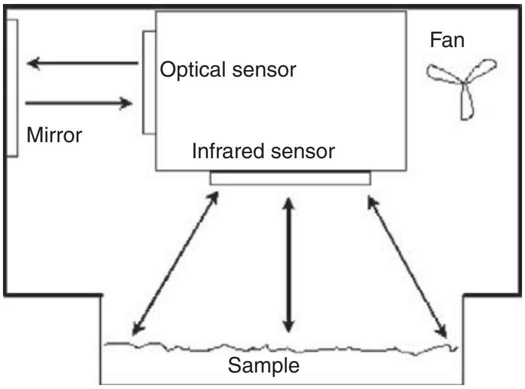

Figure 8 Schematic diagram of a dew point cell. The mirror is cooled progressively (e.g., via a Peltier device). The optical sensor emits light onto the mirror and detects the reflected light. When condensation occurs, the temperature of the mirror is recorded (giving the value of p_W). The temperature of the sample is recorded via the infrared sensor (giving the value of $p^0{}_w$). Diagram from Decagon.

level, for instance, by freezing it. This method is not suitable for products containing volatiles. Moreover, because of its technical requirements, its use is restricted to the laboratory as a standard method.

- *Dew point temperature*: **Figure 8** shows the experimental setup for measuring dew point temperature. As the mirror is progressively cooled, condensation occurs when its temperature is that for which the saturated vapor pressure is equal to p. Commercial instruments claim a measurement range of 0.030–1.000 a_w with an accuracy of ±0.003 a_w.

Freezing point

The second equation in **Table 3** is derived from thermodynamics. ΔC_p is assumed to be independent of temperature in the range T–T_0. This assumption does not result in any significant loss of accuracy. Considering that chemical potential must be equal in both the phases present in a frozen solution, that is, ice and the concentrated solution resulting from the separation of ice, the vapor pressure at equilibrium with the frozen product is p_{ice}. The reference vapor pressure (p^0) is the vapor pressure of supercooled water at the same temperature (T). Then

$$a_w = \frac{p_{ice}}{p^0} \qquad [8]$$

Both expressions give very similar results, confirming the validity of both. The measurement of T, where the first ice crystals are formed, by a classical cryoscopic measurement, gives accurate values of a_w (up to ±0.001 a_w) in the range 0.80–1. Actually, what is measured is a_w of the product at T. The differences with a_w at 25 °C are shown to be not more than ~0.01 a_w. The values may be corrected to obtain more accurate ones at the desired temperature.

Mechanical/electrical properties varying with RH

Unlike the preceding methods, which can be absolute measurements, these methods require calibration of the sensor. The sensor can be a thread-like material (a hair or a synthetic polymer) the length of which, when exposed to a force of given strength, depends on its water content and is measured. The sensor can also be a material the electrical conductivity or dielectric constant of which depends on the water content and which is measured.

Sorption isotherms

Water activity can be determined from SI of the product after measurement of the water content. In this case, it is more practical to have a mathematical expression of the SI, allowing interpolations. Besides the ones cited before, many expressions have been proposed to describe SI, a few examples of which are given in **Table 1**. For milk products, as for other foods, GAB expression was shown to be fitted satisfactorily to experimental data up to $a_w \approx 0.90$. To create SI, representative food samples that are initially dried (for adsorption isotherms) or hydrated (for desorption) are placed in controlled humidity chambers at constant temperature and are weighted periodically until a constant weight is reached. In the static desiccators method (**Figure 9**), different levels of RH are obtained using

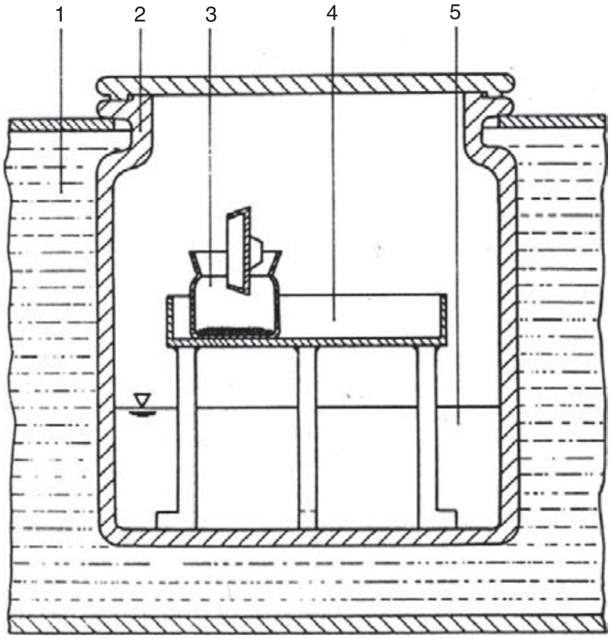

Figure 9 Sorption device as standardized for the COST Project 90 (Wolf W, Spiess WEL, and Jung G (1985) Standardization of isotherm measurement (COST Project 90 and 90 bis). In: Simatos D and Multon J-L (eds.) *Properties of Water in Foods*, pp. 661–679. Dordrecht: Martinus Nijhoff Publishers). 1. water bath, 2. sorption container (1-l glass jar, with a vapor-tight lid), 3. weighing bottle with a ground-in stopper, 4. Petri dish on trivet, 5. saturated salt solution.

saturated salt slurries that have known a_w values. Commercial devices control RH by mixing wet and dry gas streams and continuously monitor weight changes of the samples.

Equilibrium

The issue of equilibrium has already been mentioned concerning the internal moisture equilibrium of the product; equilibration of water vapor pressure between the sample, headspace of the measurement chamber, and the probe is also an important practical problem. Theoretically, the equilibration process is slowed as vapor pressures come closer, and equilibration time is infinite. Practically, therefore, the rate of change of RH is monitored continuously and the measurement is ended when the rate of change falls below a chosen limit. Equilibration of most products typically requires 45–60 min and can take as long as a couple of hours. Gentle ventilation in the measuring chamber may reduce equilibration time by 50%. For the generation of SI by the desiccators method, reducing the total pressure in the containers also reduces the equilibration time by a factor of 2–3. The volume and geometry of the sample are important parameters. Increasing its surface area (possibly by grinding) will reduce equilibration time; care should also be taken to ensure that the amount of sample is large enough, as compared to the headspace volume of the chamber (and to the surface area of the dew point mirror), so that the water lost by the sample will not significantly decrease its water content.

Several commercial instruments designed to generate SI change the controlled RH in a stepwise progression; some another instruments uses only air saturated with water (for adsorption) or dry air (for desorption), and continuously monitor weight changes and RH in the chamber with a dew point sensor. While the SI obtained with the former devices may be considered to represent equilibrium states, the latter are expected to provide information on the evolutions (glass transition, crystallization) occurring in the sample during sorption (**Figures 10** and **11**).

Temperature

Water activity of a product shows only small variations with temperature. For ideal solutions, a_w, being identical to X_w, is independent of temperature; even for nonideal systems, changes are small. SI of various dairy powders show no obvious temperature dependence between 4 and 38 °C; only at 50 °C the amounts of sorbed water are lower. Similarly, the a_w measured for six different cheeses between 5 and 30 °C showed no significant temperature dependence.

The temperature of a sample, however, is an important concern for a_w measurements. For methods relying on the measurement of p_w (direct measurement of p_w, dew point), an error in the sample temperature measurement will result in an error in $p^0{}_w$ and consequently in a_w. Between 20 and 25 °C, a 1 °C error in the sample temperature measurement represents a 6% error in $p^0{}_w$ and a_w. Similarly, to achieve an accuracy of ±0.003 a_w within the range of 0.800–1.000 a_w, the temperature of a dew point sensor is to be measured with an accuracy of ±0.05 °C. Because the temperature dependence of a_w is small, the actual temperature need not to be known precisely with apparatus measuring RH, so long as both temperatures of sample and of sensor are the same.

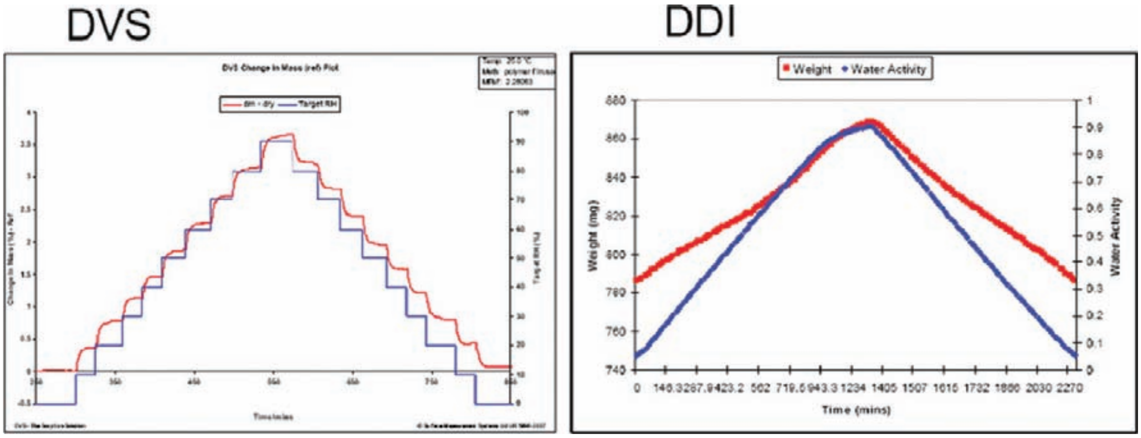

Figure 10 Two dynamic methods of sorption isotherm generation: dynamic vapor sorption (DVS): change in mass (blue) and change in target RH (red) versus time; dynamic dewpoint isotherm (DDI): sample weight (red) and measured RH (blue) versus time. Carter B (Decagon), personal communication.

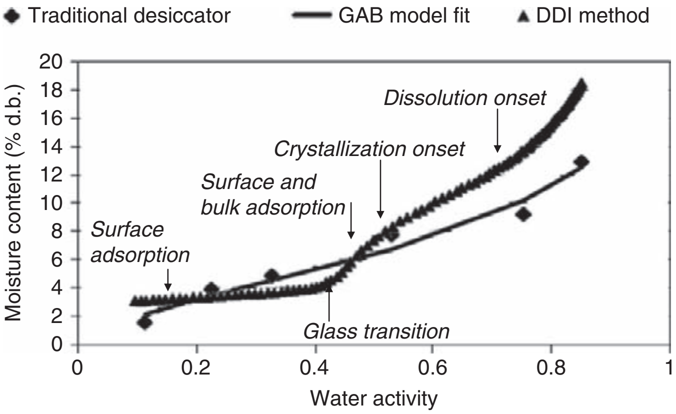

Figure 11 Sorption isotherm of milk powder (adsorption) obtained by continuously changing RH above the sample (DDI method), as compared to that obtained with the desiccators method. As water is adsorbed by the dry product, the temperature of glass transition is lowered to the working temperature; the glassy product is plasticized, water is then more easily adsorbed in the bulk of the sample. With the increase in molecular mobility,crystallization of lactose develops. Redrawn from Carter B (Decagon), personal communication.

WELFARE OF ANIMALS, POLITICAL AND MANAGEMENT ISSUES

This article is reproduced from the previous edition, Volume 4, pp 2735–2739, © 2002, Elsevier Ltd.

Introduction

Since World War II, a major revolution in social concern with the welfare and moral status of agricultural animals has emerged. The animal rights movement has arisen from old ideas but with new philosophies, emphasizing moral and ethical standards for how human beings should treat animals.

Public policy establishing the animal welfare movement began in the United Kingdom with the passage of an act in 1835 to "consolidate and amend the several laws relating to the cruelty and improper treatment of animals". In 1911 the UK Parliament passed the Protection of Animals Act which is still in force. It was established on the principle that, although human beings are free to subjugate animals, it is wrong for people to cause animals to suffer unnecessarily. The cultural and social evolution of animal protection in Europe has led to changes in the United States.

Terms Defined

Animal protection refers to all efforts to prevent cruelty, improve humane treatment, reduce stress and monitor research with animals.

Animal welfare generally describes the philosophy espoused by those who support the humane treatment of all animals without concern for their ultimate use. An 'animal welfarist' believes that human beings have the right to use animals so long as suffering is reduced or eliminated. Those who believe in animal welfare work for the reform of abusive or neglectful situations to alleviate animal suffering. Farmers have historically been perceived as strong supporters of animal welfare because they believed that animals raised under humane conditions and practices would be the most productive and profitable.

The animal rights philosophy, encompassing animal liberation, includes some fundamental differences from animal welfarism. It involves the idea that nonhuman animals are sentient beings – that they have the capacity consciously to experience pain and pleasure, among other things. Accompanying this belief is the notion that animals have certain inalienable moral rights which humans should not violate.

Philosophers, Activists and Political Action

Ruth Harrison, an English homemaker, initiated much of the public concern for the welfare of farm animals under modern production methods when her book *Animal Machines* was published in 1964. Following publication of her book, the UK Parliament called for an investigation. In 1965, the Brambell Committee, a group of scientists and concerned citizens, issued their report calling for certain mandatory standards that would conform to good husbandry in agricultural/animal production systems.

The political dimension of the animal rights and animal welfare movements involves individual and group efforts supporting or opposing specific issues. The methods include campaigns to influence legislation through letter-writing and other direct contacts; seminars and media events to influence members of legislative bodies and public opinion; demonstrations to draw public attention to what activists see as improper treatment; inviting sympathetic legislators and government officials to speak or receive awards at meetings and other special events; and securing sponsorship of bills in various legislative bodies. The participating activists may be classified as reformists or abolitionists.

Political action by animal rights and animal welfare advocates covers many issues from many different perspectives. However, four phases in these movements to influence political action can be identified: (1) identifying the problems of animal mistreatment; (2) developing appropriate ideology to cover the principles and concerns; (3) understanding how change occurs; and (4) developing explicit standards of ethics for advocating change.

Although intensive methods of animal production, which use more capital and less labor than traditional methods do, have improved production efficiency, they have at times put milk and meat producers in defensive positions because animal activists have branded certain ones of these contemporary methods as 'factory farming'. Producers adopted high-technology, intensive production systems because they would allow them to produce more product by substituting capital for labor to achieve lower cost per unit product.

Critics, however, see intensive animal agriculture differently because their views are based on philosophical thinking, feelings or opinions, often with little exposure to or understanding of the economics, the science or the actual practice of agricultural/animal production.

Dairy Cattle, Animal Welfare and Management Issues

A British report in 1983 identified animal protectionists' major animal welfare concerns for dairy animals:

- reduction of quality and quantity of individual attention in larger herds
- dehorning of calves with caustic chemicals with or without anesthetic
- prolonged stanchion tying of cows, especially without exercise
- need for separation of cow and calf
- neglect of unwanted bull calves
- raising replacements in individual hutches rather than in groups
- confinement of veal calves in small crates
- failure to employ welfare-related research knowledge
- production-related susceptibility to disease and metabolic disorders
- transportation of injured and sick animals to slaughter.

All of these issues continue to be mentioned to this day (but much progress has been made in correcting those issues that deserved attention). In addition another issue has come on the scene – docking cows' tails.

Several of these issues have been addressed by scientists and government officials around the western hemisphere in the intervening two decades. The UK Ministry of Agriculture, Fisheries and Food (now the Department of the Environment, Food and Rural Affairs) issued its codes of recommendations for the welfare of cattle emphasizing avoiding discomfort or distress and allowing the animals to fulfil their 'basic needs'. The recommendations called for these provisions to be considered: comfort and shelter, readily accessible fresh water and a diet to maintain full health and vigor; freedom of movement; company of other animals, particularly of like kind; and opportunity to exercise most normal patterns of behavior. Specific recommendations were identified for buildings, fire and other emergency precautions, ventilation and temperature, lighting, mechanical equipment and services, space allowance, feed and water and management.

Recommended codes of dairy cattle and veal calf husbandry practices also have been published in Canada.

Guidelines for the care of dairy cattle and veal calves have been published by dairy-industry stakeholders and scientists in the United States.

With respect to some of the issues listed above, much progress has been made, and general consensus currently stands as follows:

1. Cow behavior and care in large groups can be satisfactory.
2. Dehorning is beneficial, and its conduct has been refined to make it more humane.
3. Very few dairy cows are stanchioned for long periods nowadays.
4. Separating calf from cow very soon after birth is justifiable in terms of the dam's udder health so long as the calf receives an adequate dose of appropriate colostrum the first day after delivery. If a calf is to be weaned early, in terms of minimizing the stress of separation and loss it should be done as soon after birth as possible.
5. Dairy farmers are being educated as to the necessity of ensuring that surplus bull calves (to be finished as veal calves or dairy beef) be cared for just as heifer calves being kept as herd replacements, especially with respect to receiving an adequate dose of colostrum the first day after birth.
6. Individual outdoor hutches – in terms of calf sanitation, health and performance – are preferable to group housing for calves for the first 2 months after birth. This is so, regardless of the nature of the local climate. Benefits of the opportunity to socialize with other calves are outweighed by vices and other practical problems associated with group-rearing of young calves.
7. Although there have been numerous studies in many places seeking a suitable alternative to the conventional veal-calf stall, no alternative has emerged. Applied discovery research continues along this line.
8. There remains in the industry a strong tendency to follow economic dictates rather than ethical ones when the two are in conflict. Some of the reasons for this seem to be that, unfortunately, the correspondence of high animal state-of-being with high animal performance rate has not been adequately demonstrated by scientists, so the whole economic situation in such cases may be neither understood nor considered. Ironically, criticism and charges by animal protection advocates have probably dampened the support resources the industry and the governments of the various nations have devoted to such research, the results of which would probably for the most part be 'win–win' for agriculturists and animal protectionists alike.

9. Simply put, with modern animal production systems come the smouldering, multifactorial production diseases characterized by long-term, moderate morbidity and low mortality. But on balance the overall health of the animals is roughly the same in intensive production systems as in extensive systems. In the latter systems, the animals are more likely to suffer from parasitic diseases and the acute infectious diseases characterized by short-term, severe morbidity and high mortality.
10. Most abattoirs nowadays refuse to permit nonambulatory animals to be off-loaded at their docks, so most nonambulatory cows (which became nonambulatory at the farm) are not on-loaded and transported in the first place.
11. A consensus regarding tail-docking of dairy cows is now forming. On balance the practice seems to have few, if any, advantages but several disadvantages.

Policy and Legal Aspects

Calls for regulation of agricultural/animal care practices have been more successful in western Europe than in North America. The US House of Representatives did conduct hearings on the issues of veal calf husbandry and handling and transportation of nonambulatory animals in the late 1980s and early 1990s, but so far no legislation regulating these matters has been passed and signed into law. Some European countries, however, have set legal standards for animal husbandry on farms, although these standards often differ among nations.

In 1986 the European Communities Council issued its directive for protection of animals used for 'experimental and other scientific purposes'. The directive was designed to provide guidelines for uniform laws in the member countries. The objectives were to reduce the use of animals for experimental purposes to a minimum, ensure that they were adequately cared for, and avoid or minimize pain, suffering, distress and harm.

The farm animal welfare policies and regulations in the United Kingdom are developed in line with European Union (EU) directives and have led the way for other European countries. The major issues around which all European animal welfare policies have evolved focus on housing, rearing, feeding, transporting, marketing and killing. In 1996 the EU Commission proposed that French, Italian and Dutch farmers could continue to use crates for raising veal calves until the year 2008, but new crates would be banned after 1998.

The UK Department of the Environment, Food and Rural Affairs (DEFRA) recognizes that both ethical and scientific issues play a part in this issue. For advice and counsel on animal welfare matters, DEFRA looks first to the Farm Animal Welfare Council (FAWC), comprised of scientists, educators and producers.

The FAWC is expected to combine the use of appropriate new technology with efficient use of available resources and adequate provision for the welfare and behavioral needs of animals. More practices requiring a veterinary surgeon are spelled out. Citizens who believe a livestock owner is not following the welfare guidelines can file a complaint, and government inspectors then determine whether violations have occurred.

In Sweden the 1988 Animal Protection Act established the most detailed and comprehensive laws dealing with animal welfare in any country. Livestock buildings had to have windows and provide space so all animals could lie at once and be able to move freely. Milk cows had to be sent out to pasture in the summer.

In Switzerland, veal calves must receive iron and roughage in their rations.

Differences within the EU exist on animal welfare policies. The northern countries tend to be more sympathetic to welfare policies than the southern countries. Eastern European countries are in transition, and animal welfare policies have much lower priority than other economic and social concerns.

Producer attitudes toward animal welfare regulations in the western hemisphere have changed in recent years. Many now recognize that public opinion cannot be ignored if they are to maintain a market for their products.

The development of welfare-oriented regulations for production practices is only part of the evolution of government influence. Along with concerns for the humane treatment of animals is the concern for the quality and safety of products and the environment. Production regulation also involves pollution controls, manure disposal, dead-animal disposal and the use of medicines and feed additives that could affect the safety of the processed animal product.

Producers are consulted as new animal welfare regulations are developed, but in their minority position they must accept the final policy decision. Many of the regulatory guidelines simply represent good management practices that any considerate producer would follow.

In Europe the policies and regulations established are primarily welfare-oriented, with less noticeable activism for animal rights *per se* than is observed in the United States. There is a growing consumer interest and awareness in Europe and North America about how food is produced. Although the primary concern is food safety, the humane treatment of animals is second and interest is growing. The rising profile of animal welfare in public awareness is contributing to growing demands for food that is labeled as having been produced under certain standards.

The legal framework regarding animals in the United States has focused on concerns that they should be treated humanely. Successful legislative efforts fall into these categories: (1) humane treatment of animals in slaughter plants, in research facilities and in transit; (2) protection of endangered animal species; (3) protection of fish, marine mammals and wildlife; (4) establishment of standards for conducting research with laboratory and other animal species; (5) protection of pets; and (6) control of terrorism. Dairy cattle owners have the most concern with categories (1), (4) and (6).

One of the oldest federal laws deals with livestock transportation. The act applies to the transport of animals and requires a respite period unless the vehicle itself provides feed, water and space.

In the United States, many bills dealing with animal protection have been introduced but none has been enacted. Those that would target dairy animals included bills attempting to identify humane animal husbandry practices for livestock, to establish a farm animal husbandry committee to investigate all aspects of intensive farm animal husbandry and to mandate diets and accommodations for veal calves.

In 1989 the US House of Representatives Agriculture Subcommittee on Livestock, Dairy and Poultry held a hearing on a bill (HR 84) that attempted to prohibit certain practices in raising veal calves. Testimony revealed support for the bill from the Humane Society of the United States, Humane Farming Association and other animal rights/welfare groups. Veal producers, the US Secretary of Agriculture, and members of Congress with major producer constituencies opposed the bill. The bill failed to receive a favorable vote in committee.

In the United States, advocates of a humane ethic for animals are gaining momentum based on a philosophy regarding the sacredness of life. Animal-welfare advocates emphasize that animals are sensing, living beings capable of feeling fear and pain and that they must be respected as such. Some members of Congress recognize the emotional commitment of animal-welfare advocates.

However, the US animal industry's strong public support, the close ties between trade associations and government agencies and the rapport between producers, state legislators and members of the US Congress provide major advantages over organizations and individuals' philosophies that would disrupt the economically sound management practices used on dairy, livestock and poultry farms.

Introduction

Whey, the greenish translucent liquid obtained from milk after precipitation of casein, has been viewed until recently as one of the major disposal problems of the dairy industry. The biological oxygen demand (BOD) of whey is very high ($40\,000\,\mathrm{mg\,kg^{-1}}$ or more), constituting a major ecological burden if disposed off as a waste material. Thus, the disposal practices of the past, including drainage into waste treatment facilities or spraying onto fields, are currently seldom practiced. Use of whey as cattle or pig feed is still one of the significant alternatives to utilization in the human food chain, now being predominantly favored due to the economic opportunities provided by some of the milk nutrients contained in the whey.

Whey Types and Composition

There are several types of whey, depending mainly on the processing sequence resulting in casein removal from fluid milk. The type of whey most often encountered originates from the manufacture of cheese or certain industrial casein products, where the processing is based on coagulating the casein by rennet, an industrial casein-clotting preparation containing chymosin or other casein-coagulating enzymes. Since the rennet-induced coagulation of casein and the subsequent whey drainage occur at a pH value of approximately 6.5–6.0, this type of whey is referred to as sweet whey. The second basic whey type, acid whey, results from processes using fermentation or addition of organic or mineral acids to coagulate the casein as in the manufacture of fresh acid-coagulated cheeses (e.g., Cottage cheese or quark) or most industrial acid casein.

The main components of both sweet and acid wheys, after water (which constitutes approximately 93% of the whey on an ‘as is’ basis), are lactose (approximately 70–72% of the total solids), whey proteins (approximately 8–10%), and minerals (approximately 12–15%). **Table 1** gives a more detailed breakdown of these components of the two basic whey types. The main differences between the two whey types are in the mineral content, the acidity, and the composition of the whey protein fraction (WPF). Although these differences are relatively minor on an ‘as is’ basis, they can have a profound effect on the technological as well as nutritional properties of the wheys and must be taken into consideration in applications of the various whey processing technologies now available to whey processors. The acid coagulation approach (using conversion of some of the lactose in milk to lactic acid by lactic acid bacteria and/or addition of acidulants such as glucono-δ-lactone or various acids such as sulfuric, phosphoric, hydrochloric, citric, or lactic acid) results in substantially increased acidity (final pH approximately 4.5) necessary for casein precipitation. At this low pH, the colloidal calcium contained in the casein micelles in normal milk is solubilized and partitioned into the whey. On the other hand, rennet clotting produces a fragment of the κ-casein molecule, termed glycomacropeptide (GMP), which ends up in the whey. Thus, the GMP constitutes approximately 20% of the WPF of sweet, rennet-based wheys but is not found in acid wheys unless use of rennet was included in the fresh cheese manufacturing process (as sometimes happens in the Cottage cheese manufacture for increased firmness) in addition to the acid coagulation.

Various technological steps used in the pretreatment of milk before the main processes (such as various thermal treatments before the casein-clotting operation) may also influence the composition of the whey resulting from such

Table 1 Typical composition of sweet and acid whey (g l^{-1} whey)

Component	*Sweet whey*	*Acid whey*
Total solids	63.0–70.0	63.0–70.0
Lactose	46.0–52.0	44.0–46.0
Protein	6.0–10.0	6.0–8.0
Calcium	0.4–0.6	1.2–1.6
Phosphate	1.0–3.0	2.0–4.5
Lactate	2.0	6.4
Chloride	1.1	1.1

Illustrative data compiled from various sources.

milk. Typically, the composition of the mineral fraction may be altered slightly and the content of heat-labile whey proteins may be reduced; these changes may result in further alterations in the technological properties of such wheys.

New technological alternatives for processing of dairy fluids, including membrane processing by ultrafiltration (UF) of milk in cheese manufacture or fractionation of the various wheys into various whey-based products, produce a whey-like residue termed UF permeate. The main difference between UF permeates and the various whey types is typically the virtual absence of whey proteins from the permeate. Although technically UF permeate does not fit the definition of whey, it is referred to in this article where appropriate, as its processing and utilization often present similar challenges and opportunities as for whey.

Industrial Technologies Used in the Processing of Whey and UF Permeates

As a general rule, about 9 l of whey is obtained for every kg of cheese produced; thus, the volume of whey to be processed, originating from just one typical large-scale cheesemaking operation, can exceed $1 \times 10^6 \, l \, day^{-1}$. Most of the technological alternatives used in specialized whey-processing plants are thus large-scale operations, some with a capacity to handle up to 10^7 l of whey daily.

The simplest technology for the conversion of whey to industrially valuable products is drying. Typical traditional whey-drying operations consist of evaporation in multistage vacuum evaporators, followed by spray-drying. The equipment used does not differ greatly from other such dairy plant installations but the evaporation and drying conditions must be adjusted to accommodate the specific properties of the whey. In particular, the differences between evaporation or spray-drying of skim milk and whey include the need to precrystallize the lactose in whey before the drying step to minimize the problems of hygroscopicity, as well as careful manipulation of the heat conditions to minimize problems related to heat sensitivity of whey proteins. Dried whey powders can differ rather substantially in composition and technological properties, depending on various pretreatment operations used to handle the original milk or the original whey. Some of the typical dried whey products are listed in **Table 2**. Partial (70%) or almost complete (90%) demineralization of the whey is an important pretreatment process differentiating many of the whey powders (*see* **Whey Processing**: Demineralization).

Table 2 Typical composition of major types of dried whey products (%, w/w)

Product type	*Total protein*	*Lactose*	*Minerals*
Regular whey powder	12.5	73.5	8.5
Demineralized (70%) whey powder	13.7	75.7	3.5
Demineralized (90%) whey powder	15.0	83.0	1.0
Ultrafiltration permeate powder	1.0	90.0	9.0
Whey protein 'concentrate' (skim milk replacer)	35.0	50.0	7.2
Whey protein concentrate	65.0–80.0	4.0–21.0	3.0–5.0
Whey protein isolate	88.0–92.0	< 1	2.0–3.0

Illustrative data compiled from various sources including data from manufacturers.

Dried whey powder can be produced also by roller (drum)-drying; although roller-drying of whey is not easy, the process is much cheaper than spray-drying and the lower quality of the resulting powder may not be detrimental for all applications. Whey, or nowadays more importantly UF permeate from milk or whey, is the principal raw material for the crystallization of lactose (*see* **Lactose and Oligosaccharides**: Lactose: Chemistry, Properties; Lactose: Production, Applications); the residual, partially or more substantially delactosed whey ('mother liquor') constitutes yet another dried whey product differing in composition from the basic dried unmodified whey. Finally, UF permeates are also being dried with increasing frequency, giving yet another modified dried whey product consisting primarily of lactose and whey minerals but almost devoid of protein. Until recently, spray-drying was the only technique used for the production of dried permeates; however, due to the very low market value of these powders, the spray-drying of permeates is uneconomical. Several novel technological approaches to drying of milk or whey permeates have been described in the literature and are available to the industry. In principle, these technologies are based on the production of concentrates with very high total solids content (about 76%) combined with additional moisture removal by alternative means, for example, by specially designed screw conveyors allowing additional evaporation of water while inducing lactose crystallization. The final drying step is accomplished in a fluidized bed, thus avoiding the need for the costly spray-drying.

The levels and forms of whey proteins are important factors differentiating the various dried whey protein products. In contrast to the processes described above, the WPF can be removed (selectively or totally) from raw whey and concentrated by using various membrane processes (see Membrane-based fractionation) giving rise to whey protein concentrate (WPC), whey protein isolate (WPI), or WPF products (*see* **Milk Protein Products**: Whey Protein Products). Although products with as little as 35% protein (produced by partial removal of lactose through crystallization or by using simple UF and intended for replacement of skim milk powder in certain applications) are included under the term WPC, the more valuable WPC products have at least 65% protein and the production technology does not involve any step involving lactose precrystallization. The highest quality WPI and WPF products are manufactured using various technologies including diafiltration, electrodialysis, ion exchange, nanofiltration, or their combinations. For the production of almost all whey protein products, the final step is spray-drying, which should be controlled carefully to minimize heat damage of the thermally sensitive whey proteins. Both spray-drying and especially evaporation can cause heat damage resulting in loss of solubility and other functionality defects. Thus, as a preconcentration step, especially for the production of WPC, WPI, and WPF products, reverse osmosis or freeze concentration can be viewed as viable alternatives to traditional thermal evaporation. The use of reverse osmosis to increase the capacity of conventional whey evaporators, or even for preconcentrating large amounts of whey before transportation to a central whey processing facility, is quite common in the whey processing industry.

Utilization of Whey in Industrially Processed Foods

The preceding discussion focused on industrial large-scale processes resulting in an array of technological and functional whey ingredients or whey protein products, used commonly in many processed foods such as spreads, sauces, dry soups, beverage and similar mixes, cookies and other bakery products, ice cream, and a myriad of other industrial food items. Dried whey is a very suitable 'bulking' food ingredient due to its bland taste compatible with many food processing applications. The heat sensitivity of whey proteins could pose problems in heated liquid food applications, but in most solid foods this is of no concern. Similarly, the limited solubility of lactose must be kept in mind when using dried whey in applications leading to development of supersaturated lactose solutions, for example, the unfrozen fraction of ice cream. The well known – but nowadays rarely seen – sensory defect called sandiness can occur more readily when dried whey is used as a portion of nonfat milk solids in ice cream formulation. The various higher value dry whey-based products, listed in **Table 2**, are increasingly being used as nutritionally important components in special dietary products for infant, geriatric, or sport nutrition. Large amounts of whey are being processed for use in the various infant nutrition products, with demineralized whey, lactose, and modified whey protein products being especially important in this application. Some of the unique technological properties of whey protein (in particular the acid solubility, heat-gelling, and foaming) make the various whey-based high-protein products ideal for use in acid beverages, foamed dairy desserts, yogurts, and similar dairy and nondairy products. A heat-denatured whey protein powder termed 'traditional lactalbumin' has a very high water-holding capacity and thus has been shown to be preferable to the undenatured whey protein in applications such as protein enrichment of pasta dough. In general, it has been estimated that of about 10 million tonnes of dried whey solids produced annually worldwide, over 50% is being utilized in human foods, with the rest finding less attractive valorization in animal feeds.

However, liquid unprocessed whey can also be a raw material for the production of some traditional foods destined for direct consumer markets. Two such product classes, whey cheeses and whey beverages, represent the traditional uses of whey on a small scale, practiced long before the industrial approach became feasible, and are still important in some parts of the world.

Whey Beverages

The drinking of whey for therapeutic applications was already advocated in ancient Greece by Hippocrates. This and other similar anecdotal comments concerning the use of whey as a beverage (including even in the rhyme Little Miss Muffet...) illustrate one of the most obvious, but least industrially advantageous, uses of whey as a drink, logically paralleling the use of milk, buttermilk, and other fluid milk products as beverages.

In general, whey beverages have not been overly successful with the sophisticated modern consumer, save for a few rather exceptional instances. Minimally processed unflavored or modified raw whey is sold in health-food stores in various countries, especially in Europe, where the current organic food movement may result in increased opportunities in this regard. Occasional reports on whey-based beverages marketed for special occasions (e.g., an 'official Olympic Games drink' in 1984 in Sarajevo) can be found in the literature. Local markets often feature whey beverages produced by dairy companies looking for new outlets for their surplus whey; unfortunately, these attempts are typically short-lived, often due to the lack of any serious product development effort that is necessary preceding the launch of any such new product. The rather unpleasant flavor of raw whey, the origins of which have never been satisfactorily explained, is a major deterrent limiting the acceptance of these products by contemporary consumers, especially in view of the fierce competition of other flavorful and inexpensive thirst-quenching beverages.

The only whey beverage with a record of lasting success is the Swiss product Rivella, which in fact uses highly modified whey as only a minor ingredient at 33% total volume (the remaining 67% being added water). Other locally successful products have existed on some European national markets (Austria, Finland, The Netherlands, and Switzerland) for some time; however, several known international marketing attempts with these products have failed. The most typical approach to whey beverage development is combination with fruit juices, especially citrus fruits, which are most compatible with the flavor characteristic of whey. This is especially true in the case of acid whey, which is more suitable for this application due to its high content of lactic acid and calcium in comparison to sweet whey. Some of the fruit flavors used in commercial whey beverages include mango, passion fruit, grapefruit, lemon, orange, pear, or their combinations. Other approaches documented in the literature include the production of yogurt drinks containing a substantial whey component, or fermentation of liquid WPCs from sweet whey to produce a 'thin sour milk', as the stability of the whey protein at low pH does not lead to the clotted appearance of traditional sour milk products. Milk or whey UF permeates are suitable for the production of isotonic sport drinks or beverages destined for replenishment of the mineral balance after vigorous physical activity; several such products have been described in commercial product surveys.

Attempts to produce whey beverages with high whey protein content have been recorded in the literature and are often seen in various food trade exhibitions, with little or no indication of commercial viability. It may be that with the presently increasing reputation of whey proteins as nutraceutically important food components, the development of such products will be intensified. The heat sensitivity of whey proteins is one important problem encountered in manufacturing these products with a demand for extended shelf life. However, since the resistance of whey proteins to heat-induced coagulation in the absence of casein increases dramatically at pH below 3.9, it may be possible to formulate high whey protein drinks, even for ultra-high temperature (UHT) processing. Alternatively, various nonthermal processes now being studied actively for various food processing uses can be considered. Whey beverages offered as liquid concentrates or as dry powders for home reconstitution can be occasionally found on regular market shelves, including even suitably flavored plain dry whey powder. Various "miracle protein" milk shake formulae based on isolated – even hydrolyzed – whey proteins are commonly marketed as products for body builders, active sport enthusiasts, and other health-food applications.

Whey Cheeses

Whey cheeses have suffered a somewhat similar lack of international marketing success; however, in a few localities, whey cheeses belong among the most traditional and most important foods. Two types of whey cheeses are recognized in the textbooks and by the International Dairy Federation. The main differences between the production technologies for these two products are illustrated schematically in **Figure 1**. The more widespread of the two is the Italian-type whey cheese Ricotta; similar products are also popular in Portugal, Turkey, and other localities. These products are essentially a heat–acid-coagulated whey protein paste, sometimes referred to as 'whey quark' (*see* **Cheese**: Acid- and Acid/Heat Coagulated Cheese). The processing technology is quite simple, consisting of heating whey (often mixed with up to 25% added skim milk) to at least 90 °C for a few minutes, resulting in heat-induced coagulation of whey proteins (and any caseins if present due to the added milk); the coagulum is then separated by suitable mechanical means. The traditional batch manufacturing procedures are cumbersome and involve much

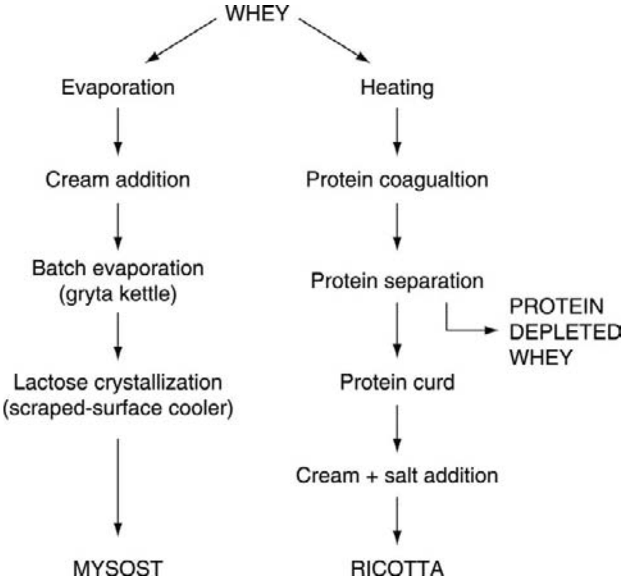

Figure 1 Alternative processes for manufacturing whey cheeses.

hand labor, in particular in the separation of the heat-coagulated, fragile whey protein curd. Mechanized and automated continuous systems are now in existence and these result in increased economy, improved shelf life, and better sensory qualities of the final product.

In contrast to the Ricotta-type whey cheese involving primarily the protein fraction of whey (and thus not offering a solution to the whey disposal problem, which is especially pressing for the small-scale cheese manufacturers), the Norwegian-style whey cheese Mysost utilizes all the whey components and leaves no residue other than water vapor. The principle of the Mysost cheese process is even simpler than that for the manufacture of Ricotta, as Mysost is essentially highly concentrated whey to which some other components (such as milk fat, cream, or goats' milk in the most traditional version) have been added (**Table 3**). The main technological problem encountered in the manufacture of Mysost cheese is the crystallization of lactose in the highly concentrated whey-based paste related to the low solubility of lactose. Thus, a 'controlled crystallization' step, consisting of rapid cooling of the hot paste with intensive stirring, from about 95 °C (the temperature of the last phase of the evaporation process) to below 65 °C, is the most essential aspect of the otherwise routine evaporation process carried out in two steps. After preconcentration in traditional dairy evaporators, the final operation involves a special kettle, 'gryta', in which batch evaporation is carried out at an elevated temperature needed to reduce the viscosity of the thick paste. This high temperature tends to minimize the uncontrolled crystallization of lactose and is the main reason for the typical brown color of the product due to the pronounced Maillard reaction. The subsequent rapid cooling step in scraped-surface agitators/coolers promotes formation of very small lactose crystals, thus minimizing the development of pronounced grittiness/sandiness of the final product. There are two basic types of Mysost – sliceable or spreadable – available in Norway, its country of origin and still the only significant market for these products; the two main types are differentiated principally by the moisture content and encompass further variations differing in the fat content, inclusion of some goats' milk for a stronger taste, intensity of the brown color development, and sometimes inclusion of sweetening agents or other nondairy ingredients such as hazelnuts or chocolate.

Table 3 Compositional characteristics of whey cheeses (%, w/w)

Cheese	*Moisture*	*Fat*	*Protein*	*Lactose*
Ricotta				
Whole milk	72.2	12.7	11.2	3.0
Whey	82.5	0.5	11.3	1.5
Mysost				
Sliceable	17.4	28.3	11.5	36.2
Spread	26.6	3.6	7.7	46.2

Illustrative data compiled from various sources.

Because the relatively simple Mysost process technology leaves no residue other than the evaporated water, its principle is much more useful than that of the Ricotta process as a means of whey disposal, particularly for small cheese manufacturers. However, significant product development efforts would be necessary to modify the sensory profiles of the basic Norwegian products to suit the tastes of markets outside Norway, as demonstrated in several consumer studies conducted in Canada and elsewhere.

Utilization of Whey as a Fermentation Substrate for Food or Nonfood Applications

Although whey and whey-like UF permeates originate from milk and contain about 50% of valuable milk nutrients, the profitable utilization of these materials for human nutrition continues to be a problem because of the sheer volume of these by-products of conventional or modern cheesemaking. In numerous research reports and several major industrial projects, whey – due to its suitable content of a fermentable carbohydrate, lactose – was used as a medium for the production of various food-grade or nonfood products using microbial fermentations. Among the most successful current uses of whey in this regard are the plants producing food-grade or industrial alcohol in New Zealand, the United States, Ireland, and possibly other countries; one of the best examples of such use is the Original Bailey's Cream Liqueur from Ireland or most of the liqueurs produced in New Zealand. In the past, whey was an important substrate for conversion into *Torula* spp. yeast biomass used in animal feeds, or for other fermentation-based, lactose-derived products such as antibiotics, lactic acid, or other microbial metabolites. The current preoccupation with organically produced foods and natural food ingredients may signal a possible opportunity for revitalization of some of these processes, abandoned in the past due to unfavorable economic feasibility in comparison to direct chemical synthesis or using other fermentable substrates. Use of whey for the propagation of lactic cultures for cheese manufacturing is well established in many countries. Whey can be used also for the generation of biogas; several such installations where biogas is used as an energy source in the same cheese plant at which whey is produced are in operation in Switzerland and possibly other countries. More recently, whey or whey permeates have been shown to be suitable fermentation substrates for the production of bacteriocins such as nisin, or for other valuable food ingredients using specific strains of various lactic acid bacteria.

Lactose is not fermented by many microorganisms, necessitating careful selection of the cultures for many of the possible fermentation applications. Uses of whey as a raw material for the production of alcoholic beverages, such as whey wine or whey beer, have been described in the literature, but because lactose is not fermented by common yeasts without special pretreatments, as well as other reasons, these attempts at profitable whey utilization have not resulted in lasting success. However, since the key to new approaches to utilization of whey is to find new avenues for conversion or other utilization applications of lactose, the fermentation route will undoubtedly continue to be explored. One of the currently active industrial research topics is the conversion of lactose to oligosaccharides, either by fermentation with whole microorganisms or by applications of crude enzymatic extracts of suitable bacterial cultures. Similarly, production of exopolysaccharides from lactose is increasingly being used in the production of yogurt; it is likely that this route could be explored in large-scale whey fermentations as well.

Nutritional and Nutraceutical Aspects of Whey Utilization

The new approach to developing technically and economically feasible uses of whey and whey-like products lies in finding some unique properties of at least some of the main whey components. The current trend in the food field, focusing on the health-promoting aspects of traditional or novel foods, has opened up new possibilities for whey-based products. Whey contains many minor milk components that are known (or thought) to have physiologically important functions. Some of these compounds are found especially among whey proteins; these include minor whey protein components such as lactoferrin or lactoperoxidase, the immunoglobulins, and even major constituents of the WPF such as the GMP or bovine serum albumin. Some of the mineral compounds, especially the calcium phosphate complex, are now also being marketed as 'natural' milk-based food ingredients. Even lactose is being reexamined for its unique nutritional properties, including the purported enhancement of calcium absorption or its unique disaccharide composition, thus serving as a raw material for the production of prebiotic compounds such as galacto-oligosaccharides (*see* **Lactose and Oligosaccharides**: Lactose: Galacto-Oligosaccharides) or heterooligosaccharides. The limited sweetness of lactose can be enhanced by hydrolysis into the two lactose monosaccharides, glucose and galactose. Most of the industrial lactose hydrolysis processes developed for the production of sweetening syrups for food uses (such as in ice cream) using immobilized β-galactosidase enzyme reactors have failed mainly because of the high cost of such technology. Alternative low-cost processes, based, for example, on the use of mechanically disrupted common dairy bacteria producing high amounts of β-galactosidase, or on other principles, continue to be investigated. In general, the lactose hydrolysis process, which seems to be grossly underutilized by the industry today, could have a major impact on expanding the dairy markets for lactose- intolerant consumers not only for the processing and utilization of whey, but also for uses in other dairy and especially nondairy foods (*see* **Enzymes Exogenous to Milk in Dairy Technology**: β-D-Galactosidase, **Lactose and Oligosaccharides**: Lactose: Chemistry, Properties; Lactose: Production, Applications).

The main focus of interest regarding the nutritional/nutraceutical properties of whey is currently centered on the WPF. Today, whey protein products are the main ingredients in most protein formula supplements used by bodybuilders and active athletes worldwide. Whey protein products have been one of the principal ingredients in infant feeding formulae for some time, often requiring additional treatments such as enzymatic hydrolysis to minimize the allergenicity potential of some of the components such as β-lactoglobulin. Most recently, whey protein and/or its main fractions have been investigated for many unique health-enhancing or disease-combating properties, including immunopotentiation through increased intracellular glutathione synthesis; role in reducing cancer cell proliferation; counteracting the wasting syndrome in HIV-positive individuals; antimicrobial properties of some of the minor whey proteins; and other effects. WPIs advertised to supply some of these benefits are now being marketed even as dietary supplements at highly inflated prices. Hydrolysates of whey proteins have been shown to contain bioactive peptides effective in blood pressure reduction, and several industrial products are now on the market.

Extraction of some functional components from whey has become a major industrial activity for specialized whey processors, although in most cases, the physiological functionality in human subjects still awaits confirmation from well-controlled clinical trials. Of course, manufacture of any such isolated functional product from the liquid whey will not alleviate requirements for further processing of the residual by-product. As many of the components with documented or proposed unique functionalities are present in the whey in very minute amounts, the need to process the bulk of the residual whey stream will remain a major challenge accompanying any such novel development.

Surprisingly, by far the most abundant whey component, water, seems to have been neglected in the innumerable research attempts to find new profitable uses of whey and/or its components. The only well-known use of whey water is as a condensate from the evaporators, mainly for rinsing and equipment washing purposes, but not for productive economically advantageous applications. As one potential such use suggested in the past, the adjustment of the mineral content of the whey water by suitable membrane processing could lead to various pharmaceutical uses for cleansing solutions mimicking the human body fluids.

The approach to whey processing and utilization has changed in the recent past, from considering whey a bothersome waste to capitalizing on the opportunities that the whey and whey-like products present for the innovative technically advanced processor. However, for traditional cheese manufacturers, the problems of dealing with large volumes of whey or whey permeate continue to pose difficulties, determining the overall success of their main industrial activity. Nowadays, industrial processing of whey is a highly specialized, technologically advanced segment of the dairy industry requiring up-to-date knowledge and focused attention.

Introduction

In order to make nonhygroscopic whey powder as well as to make whey powder a suitable ingredient for certain foods, a reduction of the mineral content is needed. Typically, whey contains 8–10% minerals on a dry weight basis. This can be problematic when processing whey, especially when concentrating, crystallizing lactose, and spray-drying whey. It is also a problem when using whey and whey powders as food, especially for infant formulas, where a 90–95% reduction in minerals is needed. This is necessary in order to mimic the mineral composition of human milk. Critical ions for the preparation of infant formulas are Na^+, K^+, Cl^-, and PO_4^{3-}. For example, for ice cream applications, in order to reduce the salty taste of ordinary whey powder, a 50–70% overall reduction in minerals is often enough. Addition of less demineralized whey powder is always a possibility. It should be remembered that instead of using a specific demineralization process, like ion exchange or electrodialysis, ultrafiltration in combination with pure lactose is an alternative for the manufacture of infant formulas. The necessary composition of macrocomponents can thus be reached in many different ways. This article will focus on three main technologies for whey demineralization, that is, electrodialysis, ion exchange, and nanofiltration (NF). Combination of these processes will also be mentioned.

Electrodialysis

Electrodialysis is defined as the transport of ions through semipermeable membranes under the driving force of an electric field caused by an applied direct current (DC) source. The membranes used have both anion and cation exchange functions, making electrodialysis capable of reducing the mineral content of a process liquid, for example seawater or whey. **Figure 1** is a schematic representation of an electrodialysis unit. It consists of a number of compartments separated by alternate cation and anion exchange membranes, which are spaced about 1 mm apart. The end compartments contain electrodes. There can be as many as 200 cell pairs between each pair of electrodes. The two electrodes at each end of the cell stack have separate rinse channels, through which a separate acidified stream is circulated to protect the electrodes from chemical attack. For whey treatment, the whey feed and acidified brine pass through alternate cells in the stack.

Operating Principle

Alternate cells in the electrodialysis stack act as concentration and dilution cells, respectively. Whey is circulated through the dilution cells and a 5% brine carrier solution through the concentration cells.

When DC is applied across the cells, cations attempt to migrate to the cathode and anions to the anode, as shown in **Figure 1**. However, completely free migration between the cells is not possible because the membranes act as barriers to ions of like charge. Anions can pass through an anion membrane but are stopped by a cation membrane. Conversely, cations can pass through a cation membrane but not an anion membrane. The net effect is depletion of ions in the whey (depletion) cells. The whey is thus demineralized, to an extent determined by the ash content of the whey, residence time in the stack, current density, and flow viscosity.

The electrodialysis plant can be run either continuously or in batches. A batch system, which is often used for demineralization levels above 70%, can consist of one membrane stack over which the process liquid, for example, whey, is circulated until a certain ash level is reached. This is indicated by the conductivity of the process liquid. The holding time in a batch system can be as long as 5–6 h for 90% demineralization at 30–40 °C. Preconcentration of the whey to 20–30% dry matter (DM) is desirable for maximum utilization of installed membrane area and low electric power consumption. The whey concentrate should be clarified before it enters the electrodialysis unit.

The high process temperature means that there is a risk of bacterial growth in the product. A bacteriostatic compound such as hydrogen peroxide is therefore often added to the whey, when allowed. The process liquid heats up during the process, so cooling is needed if it is necessary to maintain process temperature. In a

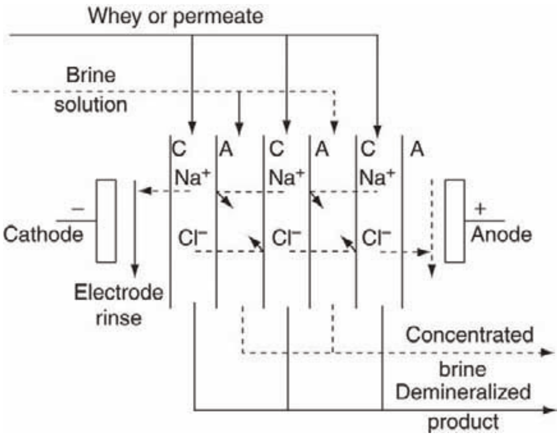

Figure 1 Schematic layout of an electrodialysis stack.

continuous plant, consisting of, for example, five membrane stacks in series, the holding time can be reduced to 10–40 min. The maximum demineralization level of such a plant is 60–70%. In relation to capacity, the installed membrane area is much larger in a continuous plant than in a batch plant.

An electrodialysis plant can easily be automated and furnished with a programmed clean-in-place (CIP) system. The cleaning sequence normally includes water rinse, cleaning with an alkaline solution (maximum pH 9), water rinse, cleaning with hydrochloric acid (pH 1), and a final water rinse. A typical cleaning program takes about 100 min.

Power Supply and Automation

DC is used in the electrodialysis plant, which should have facilities for regulating current in the range of 0–185 A and voltage in the range of 0–400 V. Flow rates, temperatures, conductivity, pH of process water and product, product inlet pressure, pressure difference between the stacks, and current and voltage over each membrane stack are monitored and controlled during production.

Limiting Factors in Electrodialysis and Processing Costs

A major limiting factor for using electrodialysis in dairy processing is the cost of replacing membranes, spacers, and electrodes, which constitute about 35–40% of the total running costs of the plant. Replacement is necessary due to fouling of the membranes, which in turn is caused by (1) precipitation of calcium phosphate on the cation exchange membrane surfaces and (2) deposition of protein on the anion exchange membrane surfaces.

The first problem can be handled by proper flow design over the membrane surface and regular acid cleaning. The second problem, with adsorption of protein, is the main factor shortening the lifetime of the anion membrane. The theoretical background to this problem is as follows. At the normal pH of whey, the main whey proteins are negatively charged (anionic character) and move as such under the influence of the electric field in the stack. These molecules, which are too big to pass through the anion exchange membranes, are deposited as a thin protein layer on the face of the anion exchange membranes in the whey compartments. Techniques such as polarity reversal can be used to dislodge these deposits.

Although frequent cleaning at high pH removes most of the deposits, at least in older plants, disassembly of the stack for manual cleaning is recommended at intervals of 2–4 weeks. The processing cost of electrodialysis depends very much on the degree of demineralization. Increasing the demineralization level in steps from 50 to 75 to 90% doubles the processing cost per step, as a rule of thumb.

Water treatment, electric power, chemicals, and steam account for the operating costs of a demineralization plant. Wastewater treatment is a particularly expensive item. During production, lactose leaks through the membranes to an extent of as much as 5–8% at 90% demineralization. The phosphate removed from the whey accumulates in the waste stream. The cost of electric power amounts to 10–15% of the processing cost, while the chemicals used in the process, mainly hydrochloric acid, account for 5%. The cost of steam used for preheating the product and cost of cooling for controlling the process temperature are 10–15%, depending on the demineralization level.

Ion Exchange

Industrial application of ion exchange often means pumping the process liquid to be treated through a fixed-bed column filled with polymeric beads loaded with ions that are exchangeable with the ions in the process liquid. The capacity of the process is limited by the amount of ions on the resin in the fixed bed. After the ion exchange capacity has been used up, the adsorbed ions must be removed by regeneration of the column by an appropriate regeneration solution. After that, the flow of process liquid through the column can be resumed.

Modern ion exchange resins are macromolecular porous plastic materials formed into beads with a diameter in the range of 0.3–1.2 mm for technical applications. Chemically, they act as insoluble acids or bases, which when converted to salts remain insoluble. The main characteristic of ion exchange resins is their capacity to exchange the mobile ions (counterions) that they contain for ions of the same charge sign contained in the solution to be treated. The exchange reactions are equilibrium reactions governed by a constant. The concentration of ionic species is an important factor for the driving force in the exchange reaction. The functional groups of ion exchange resins for demineralization purposes vary. First of all, a distinction between anion exchangers and cation exchange resins can be made and within these groups there are both weak or strong base and acid varieties, respectively. The group to which the specific ion exchange resin belongs depends on the functional group. Strong cation exchange materials often have sulfonic groups bound to the matrix. This group is ionized throughout the pH range 0–14, and therefore active for exchange reactions to take place. The most common weak acid exchange material has a carboxylic acid functionality. This group is ionized at pH values above the isoelectric point, typically above pH 5–6. Strong base functionality is based on quaternary amine groups. These groups are dissociated throughout the pH range. Weak base ion exchange functionality is often based on tertiary amine groups, which are active in the pH range 0–7.

From the point of view of ease of regeneration, it is beneficial to use weak resins whenever possible. They can be regenerated with acid or alkali in excess in comparison with the theoretical need of just 10–50%. Strong resins need 200–400% excess of regenerant to be fully converted to the active form.

For demineralization according to the classical procedure, a strong cation exchanger in the hydrogen ion form is often combined with a weak base anion exchanger working in the free base (hydroxyl) form. The whey passes through the cation exchange column before the anion exchange column. It is not possible to use a weak acid cation exchange resin instead of a strong one, because of pH and the carboxyl functionality of the weak cation exchange resin. The equilibrium constant for the exchange reaction to occur is unfavorable.

Other important characteristics of ion exchangers that are not further discussed are (1) ion exchange capacity, (2) swelling properties, (3) mechanical strength, (4) fluidization during backwashing of the bed, (5) pressure drop, (6) flow velocity restrictions, and (7) water rinse requirement after regeneration.

Conventional Ion Exchange for Demineralization

A simple demineralization plant based on ion exchange is shown in **Figure 2**. The whey enters the strong cation exchanger, loaded in the hydrogen ion form, and continues to the weak base anion exchanger in its free base form. The ion exchange columns are rinsed and regenerated separately with dilute hydrochloric acid and sodium hydroxide (or ammonia). Once a day, the columns are disinfected by rinsing with water containing active chlorine. The following net reactions take place during demineralization (NaCl is used to illustrate the salts of whey and R represents the insoluble resin exchange site):

$$\text{cation exchange:} \text{R-H} + \text{Na}^+ + \text{Cl}^- \rightleftharpoons \text{R-Na} + \text{H}^+ + \text{Cl}^-$$

$$\text{anion exchange:} \ \text{R-OH} + \text{H}^+ + \text{Cl}^- \rightleftharpoons \text{R-Cl} + \text{H}_2\text{O}$$

The above reactions illustrate that by the ion exchange process the whey salts are exchanged for water.

The flow program in the ion exchange process includes the following steps:

1. exhaustion: 10–15 bed volumes of whey can be treated per regeneration cycle. The bed volume refers to the volume of the cation exchanger;
2. regeneration;
3. displacement of whey from the columns by water;
4. backflushing;
5. contact with regeneration solution; and
6. water rinse.

A typical cycle time is about 6 h: 2 h for exhaustion and 4 h for regeneration. The ion exchange vessels are often

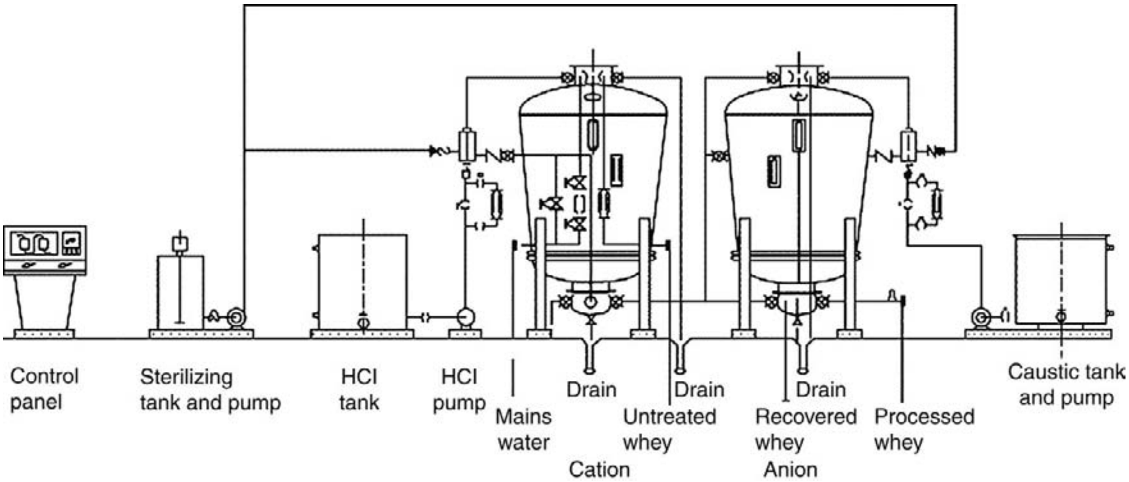

Figure 2 Schematic diagram of an automatic whey demineralization plant.

made of rubber-lined mild steel to avoid corrosion problems. A conical shape is used specially for the anion exchanger to allow for swelling of the bed during transformation from the free base to the salt form. It is common practice to regenerate the cation column in upflow (countercurrent to exhaustion). This system reduces the consumption of regeneration chemicals by as much as 30–40%. The plant can easily be automated. Two or three parallel ion exchange systems are needed for a continuous flow of whey.

Process Limitations and Costs

Whey is a liquid with a high ash content, which means short runs between regenerations with high consumption of regeneration chemicals. These facts lead to a high salt load in the wastewater from both the whey and from the surplus of regeneration chemicals. Consumption of rinse water is also high, especially from washing out excess sodium hydroxide from the weak anion exchange resin.

Losses of whey proteins occur due to adsorption phenomena, primarily on the anion exchange resin. Consumption of regeneration chemicals accounts for 60–70% of the operating costs. The process is primarily designed for 90–95% demineralization but any level can be chosen if a bypass system is used.

An Alternative Ion Exchange Process

In order to reduce the consumption of regeneration chemicals and thus also create a better waste situation for a demineralization plant, the R&D Department of the Swedish Dairies' Association, SMR, developed an alternative ion exchange process. In this process, several different unit operations are linked together, namely, ion exchange, evaporation, distillation, and absorption in order to recover the regenerant, NH_4HCO_3, as illustrated in **Figure 3**. In this process, the whey is first treated with the anion exchange resin regenerated in the bicarbonate form. During anion exchange, the anions of whey are exchanged for HCO_3^-. After this, the whey enters the cation exchange column regenerated in the ammonium form. During the passage of the whey through this column, the cations in the whey are exchanged for NH_4^+. Thus after the process, the whey salts are exchanged for ammonium bicarbonate, NH_4HCO_3. The reactions can be summarized as follows:

$$\text{anion exchange: R-HCO}_3 + \text{Na}^+ + \text{Cl}^- \rightleftharpoons \text{R-Cl} + \text{Na}^+ + \text{HCO}_3{}^-$$

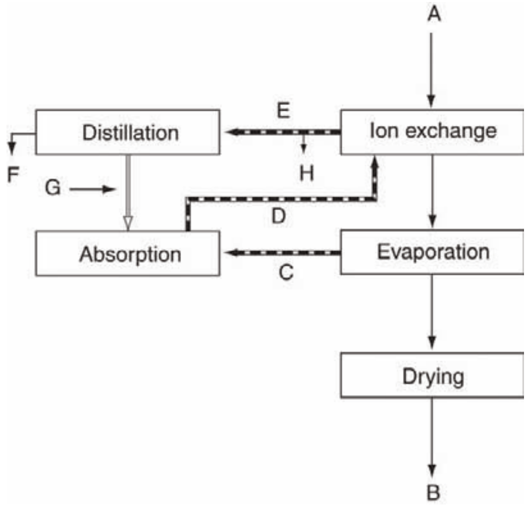

Figure 3 The SMR process for demineralization. A, whey; B, demineralized whey powder; C, condensate with NH_3 and CO_2; D, new regeneration solution; E, spent regeneration solution; F, whey salts; G, NH_3 and CO_2; H, precipitate of $MgNH_4PO_4$.

$$\text{cation exchange: R-NH}_4 + \text{Na}^+ + \text{HCO}_3{}^- \rightleftharpoons \text{R-Na}^+ + \text{NH}_4{}^+ + \text{HCO}_3{}^-$$

NH_4HCO_3 is a thermolytic salt (sometimes used as baking powder), which decomposes to NH_3, CO_2, and H_2O when heated. This happens during the subsequent evaporation of the whey, offering the possibility of recovering the NH_3 and CO_2 vaporized from the whey to make new regeneration solution (NH_4HCO_3). Part of the used regeneration solution after passing the columns, containing surplus of regeneration salt (about 100% of theoretical need is used during regeneration), is collected for vaporization in a distillation tower. **Figure 4** shows the industrial layout of the SMR process. The description of the flow arrangement is given below. The whey first enters the anion exchange column regenerated in bicarbonate form and then the cation exchange column in ammonium form. This is in reverse order compared with the classical ion exchange demineralization procedure.

In practical design, the ion exchange systems are paired, one working on whey while the other is being regenerated. With two pairs of columns, an uninterrupted flow of whey is obtained. The cycle time is 4 h (2 h for ion exchange and 2 h for regeneration). After passing through the ion exchange unit (1) the cool whey is used for heat recovery in the absorption tower and as cooling medium in the condenser (9). Then, the whey enters the evaporator (3) and finally the demineralized whey concentrate is spray-dried (10). The condensate from evaporator stage 2, which is especially rich in ammonia, is separated from the other condensate streams and continues to the absorption

tower (4), where it forms the liquid base for the new regeneration solution. The condensates from evaporator stages 1, 3, and 4 are used to rinse off the ion exchangers, giving further recovery of ammonia in these condensates. The recovery of ammonia is 75–80% in the process. Most of the CO_2 stripped off during evaporation is recovered in gaseous form from the mechanical vacuum pump of the evaporator. This gas flows directly into the bottom of the absorption tower, where it is almost completely absorbed in the synthesis of NH_4HCO_3. Overall recovery of CO_2 is more than 90%. To compensate for losses of NH_3 and CO_2 in the process, fresh quantities of NH_4HCO_3 are injected into the circulation flow of the absorption tower (4). The part of the regeneration solution which is rich in NH_4HCO_3 is collected in a tank (8), where the phosphate from whey is precipitated by addition of $MgCl_2$. When the precipitate of magnesium ammonium phosphate ($MgNH_4PO_4$) has settled, the supernatant liquid is pumped to the top of the distillation tower (9) and at the same time preheated in a plate heat exchanger (not shown in the figure) using the bottom liquid in the distillation tower as the heating medium. About 10% of the liquid is stripped off as vapor, which in turn is condensed by using the whey after ion exchange as cooling medium (2).

In summary, the SMR process has the following characteristics:

1. low running costs due to recovery of the regeneration chemicals;
2. low losses of whey solids and only half of the salt discharge compared to the classical ion exchange process;
3. small variations in pH of the whey (6.5–8.2), resulting in minimum losses of denatured whey proteins due to adsorption on the columns;
4. high demineralization efficiency (more than 90%);
5. low operating temperature (4–6 °C), enhancing the microbiological status of the end product;
6. high yield of whey solids compared to classical ion exchange and electrodialysis; and
7. optimum heat recovery.

Process Limitations and Costs

In most cases, depending on the cost of chemicals, the operating cost of the SMR process is 30–70% lower than that of the classical ion exchange process. The equipment for plant design of an SMR plant includes more components than the classical ion exchange process. Therefore, the capital costs are somewhat higher. For optimum profitability, a plant greater than 100 m^3 is needed.

Nanofiltration

An interesting alternative to electrodialysis and ion exchange is NF. NF is a membrane pressure-driven process in between reverse osmosis and ultrafiltration. It is named after the mean pore diameter, which is approximately 1 nm. Thus, the separation area for molecules, especially charged monovalent ions like Na^+, K^+, and Cl^-, lies in the molecular range of 100–1000 Da. The normal operating pressure is typically 2–3 MPa.

Apart from steric exclusion and considering the low value of pore diameter, the membrane separation characteristic is to a large extent determined by electrostatic forces in the membrane matrix because of the electric charges of its carboxyl groups; this causes ions to avoid regions of low dielectric constant. Moreover, the role of the retention of multivalent co-ions (salts and/or proteins) in the facilitated transmission of monovalent ions has been demonstrated.

In the case of sweet whey (membrane negatively charged), the retention of polyvalent anions leads to the presence of higher amounts of negative charges in the retentate, which results in an increased transmission of Cl^- and an increased retention of Na^+ and K^+ and Ca^{2+} in order to maintain the electroneutrality. The demineralization efficiency is thus almost restricted to removal of monovalent ions.

For a volume reduction ratio of 4–5 during filtration of whey, an ash removal from whey of 40–60% is obtainable. It corresponds to 70–80% for monovalent co-ions (which are Na^+, K^+, and H^+ for acid whey and Cl^- and OH^- for sweet whey) and 40–70% for monovalent counterions (which are Na^+, K^+, and H^+ for sweet whey and Cl^- and OH^- for acid whey). Divalent ions are reduced in the range of 3–20%.

Partial demineralization is often needed in various situations when manufacturing dairy ingredients, for example, various whey protein concentrate products, in order to adjust the mineral composition.

Another effect of NF is the concomitant concentration of the whey up to a DM of 20–22%, which helps to economize the evaporation costs.

By combining with water dilution of the NF retentate and renewed filtration (diafiltration), the ash reduction can be driven from 35–50 up to 60–70% but at the expense of increased cost, water utilization, and by-product (nanofiltrate) production. In contrast, in newer types of NF membranes, the loss of organic molecules has been improved, especially lactose.

Indeed the loss of lactose and the loss of nonprotein N and protein in NF are today lower than those found in electrodialysis or ion exchange, making retentate more valuable and leading to a permeate with lower biological oxygen demand (BOD).

Urea does leak quite extensively. Also, organic acids like lactic and acetic acid can pass through the membrane to a large extent, presenting the possibilities of deacidification of acid whey. Corresponding salts of these acids are strongly retained by the membrane.

The benefits of NF are low investment costs and simple installations, which are easy to run. Moreover, the amount of effluents is greatly reduced in comparison with the other demineralization processes, and the generated effluents have a lower BOD. Demineralization by electrodialysis and ion exchange is usually known to generate high amounts of effluents. Moreover, it has been demonstrated that the running costs of these demineralization techniques are 25–55% higher than NF, due to their combination with evaporation concentration.

NF is a fast-growing technology in the dairy world today for different application purposes.

Combination of Processes

For large demineralization installations, that is, those processing more than $400\,m^3\ day^{-1}$ of whey, investment in combined technologies may be of interest. The combinations used are electrodialysis or NF in combination with the classical ion exchange process. The benefits are reduced costs of chemicals but the capital costs are higher and more complicated processes are more difficult to run.

Many modern demineralization plants are combinations of classical ion exchange with NF. By doing this, the ionic load on the ion exchangers is reduced by about 30% in combination with lower volumes to treat. The size of the columns can be reduced by the same figure, in principle.

When electrodialysis and classical ion exchange are combined, the whey first passes the electrodialysis step to about 50% demineralization level. After that, the whey passes on to the ion exchange plant.
