The functional properties of proteins are governed by intrinsic properties; that is, their structural characteristics (e.g., size, charge, and surface hydrophobicity). These intrinsic properties are themselves affected by many extrinsic or environmental factors, such as pH, ionic strength, and temperature, and also by interactions between the proteins and other materials in the food system. The functional properties of milk protein products may be considered to be the consequence of the molecular structures and the interactions of milk proteins with other food components, such as fat, sugars, polysaccharides, salts, and flavor and aroma compounds. These interactions occur at two levels. First, the processing of milk into milk protein products alters the native structures and induces interactions of proteins that can exert a negative or positive effect on functional properties. Second, the milk proteins interact with other food components during the manufacture of prepared food products.

The functional properties of proteins may generally be classified into two main groups, hydrodynamic or hydration related, which includes water absorption, solubility, viscosity, and gelation. Functional properties such as emulsification, foaming, and film formation are related to the surface-active properties of proteins. Proteins usually exert several inter-dependent functional properties simultaneously in each food application. The functional properties of proteins vary with pH, temperature, ionic strength, and concentration of calcium and other polyvalent ions, sugars, and hydrocolloids, as well as with processing treatments.

Solubility

Protein–water and protein–protein interactions in aqueous systems are vitally important and control the dispersibility, viscosity, and solubility properties of proteins. A sensitive balance between repulsive and attractive intermolecular forces, which are, in turn, controlled by protein and water structures and affected by environmental factors, controls solubility. Generally, proteins are soluble in water when electrostatic and/or hydration repulsion between proteins is greater than the driving forces for hydrophobic interactions. Thus, the polar and ionizable groups of proteins largely confer water solubility.

The solubility of dried protein ingredients in aqueous systems over a range of pH, temperature, and protein concentration provides a good predictor of other functional properties, although this general rule may not always apply, particularly in the case of highly hydrolyzed milk proteins. Solubility is generally defined as the amount of protein in a sample that goes into solution or into colloidal dispersion under specified conditions and is not sedimented by low centrifugal forces. The most common methods for determining solubility involve preparation of a protein solution of known concentration (0.5–5.0%), centrifugation at a force ranging from 500 to 65 000 *g* for 5–40 min, and then protein analysis of the supernatant. The solubility of milk protein products depends on the chemical nature of the proteins in the product, processing treatments used, physical form of the powder, pH, temperature, and ionic concentration of the solution. In general, high-temperature treatments during the manufacturing process result in low solubility of the final product. Salts may enhance the solubility of protein up to a point and then reduce it. The pH affects

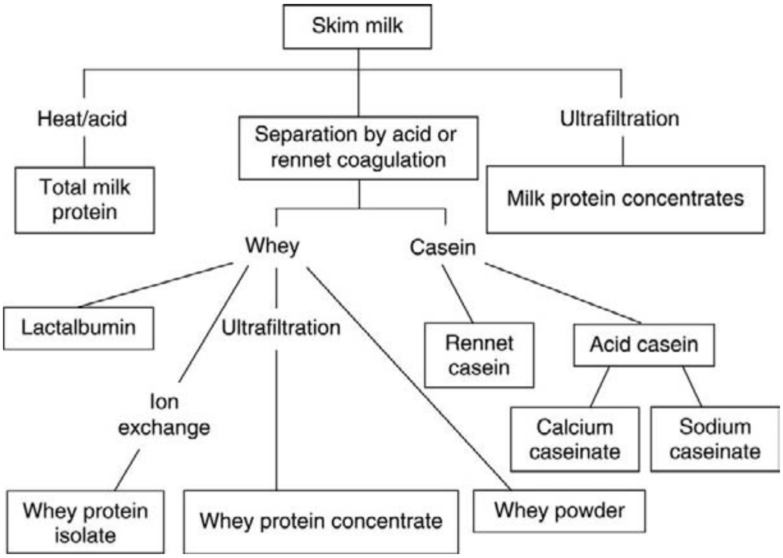

Figure 1 Functional protein products from milk.

Table 1 Functional properties of milk proteins in food systems

Functional property	*Food system*
Solubility	Beverages
Emulsification	Coffee whitener, cream liqueurs, salad dressings, desserts
Foaming	Whipped toppings, shakes, mousses, cakes, meringues
Water binding	Bread, meats, bars, custard, soups, sauces, cultured foods
Heat stability	UHT and retort processed beverages, soups and sauces, custard
Gelation	Meats, curds, cheese, surimi, yogurt
Acid stability	Acid beverages, fermented drinks

the charge and electrostatic interactions between protein molecules. Above and below the isoelectric point, proteins have a net negative or positive charge and enhanced solubility. At the isoelectric point, attractive forces predominate, causing protein molecules to associate, resulting in a loss of solubility.

Rennet and acid caseins, lactalbumin and coprecipitates are insoluble in water, and their food uses are limited to nutritive fortification or water binding. However, caseinates (Na, K, and NH_3) have excellent solubility at pH above 5.5; 10–15% sodium caseinate solutions can be readily prepared at pH 6.0–7.0. Calcium caseinate forms a coarse colloidal dispersion under these conditions. Caseinates are insoluble at the isoelectric pH (pH 4.0–5.0), but are also soluble at pH below 3.5, resulting in a U-shaped pH–solubility profile. Sodium forms of ‘conventional’ coprecipitates are less soluble than sodium caseinate, but the coprecipitates prepared from milk heated at alkaline pH values have solubility similar to that of caseinates. Enzymatic hydrolysis has been applied frequently to improve the solubility of caseinates in the isoelectric region.

Milk protein concentrates (MPCs), produced by ultrafiltration/diafiltration of milk, with up to 70% protein have good solubility at pH 7.0, but MPCs with a very high protein content (e.g., 85% protein) are generally known to have poor solubility upon reconstitution in water at 20 °C. The solubility improves at higher reconstitution temperatures but decreases with storage time at elevated temperatures. The major factor affecting the solubility behavior of MPC appears to be related to the rate of water transfer into the powder particle rather than to the thermal processes during manufacture. Various methods for manufacturing MPC with improved solubility in cold water have been proposed, involving the addition of a monovalent salt to the ultrafiltered retentate prior to drying or partial replacement (~30%) of the calcium content of ultrafiltered retentate by sodium ions.

Whey proteins show excellent solubility over the entire pH range, which enables them to be used in acid beverages. However, heat-induced denaturation renders them insoluble in the pH range 4–5. The level of denaturation and subsequent loss of solubility at pH 4.6 depends on heating temperature and time, whey pH, and ionic calcium concentration. Processing treatments used in the manufacture of whey protein concentrates (WPCs) and whey protein isolates (WPIs) may sometimes cause small amounts of denaturation, which tends to reduce their solubility. The solubility of whey proteins is generally not altered by ultrafiltration or spray drying, although pasteurization may cause up to 20% denaturation with a consequent loss of solubility.

In contrast to whey proteins, sodium caseinate is remarkably stable to heat treatments; a 5% solution at pH 7.0 can be heated at 110 °C for up to 8 h without loss of solubility. Calcium caseinate is less stable, and a 1% solution gels at 50–60 °C.

Viscosity

Milk protein products are widely used in a range of foods, such as soups, sauces, salad dressings, and dairy foods, to provide desirable viscosity and texture. Viscosity is related to quality attributes, such as physical appearance and mouthfeel, of food products. The viscosity of protein dispersions is governed by composition, size, shape, and charge of the protein molecules, which are influenced by environmental conditions, such as temperature, concentration, pH, ionic strength, and previous processing treatment history. The viscosity also reflects intermolecular interactions, resulting in the formation of weak and transient networks.

Different types of viscometers (e.g., 'Brookfield' viscometer, Ferranti-Shirley cone-and-plate viscosimeter, Haake coaxial cylinder viscosimeter, and Bohlin rheometer) have been used to study the viscosity of milk protein products. The values are usually expressed as relative or apparent viscosities.

The viscosity of sodium caseinate solutions increases exponentially with casein concentration; at concentrations >15%, caseinate solutions exhibit pseudoplasticity, which makes them difficult to process. In the temperature range 25–60 °C, the viscosity of a caseinate solution is logarithmically related to the reciprocal of the absolute temperature. Acidic casein solutions (pH 2.4–2.9) have higher viscosity than solution >pH 6 for the same protein concentration, and the solution viscosity decreases when the temperature is increased from 25 to 60 °C; at higher temperatures, the viscosity increases again. The apparent viscosity of sodium caseinate solutions is strongly dependent on pH with a minimum at pH 7.0. The addition of calcium causes considerable changes in the viscosity of sodium caseinate solutions, but the effect is dependent on pH, temperature, and protein concentration.

Calcium caseinate has a relatively low viscosity that decreases with increasing temperature and increases above pH 7.0. Solubilized coprecipitates tend to be more viscous than sodium caseinate.

Native whey protein solutions have very low viscosity compared with caseinates, and their viscosity decreases with increasing temperature between 30 and 65 °C. However, the viscosity increases at higher temperatures, due to denaturation and aggregation of the whey proteins. Solutions of WPC exhibit Newtonian behavior in the range 4–12% protein; at higher concentrations, more pseudoplastic behavior is observed.

Water Binding and Hydration

The ability of protein to hydrate and thus entrap or bind water is important in many foods, particularly when protein ingredients are used in viscous products, such as soups, custards, and doughs. The amount of water that can be retained by a protein matrix under a given set of conditions (expressed as g $H_2O\,g^{-1}$ dry protein) is referred to as its water-holding or water-binding capacity.

Water associates with protein in a number of ways. Bound water is not available as solvent, does not freeze, and has different physical properties from bulk water. This water is associated with proteins via hydrogen bonding to polar groups. Occasionally, non-polar groups are forced into water as a part of a specific protein structure. In addition, water may be held physically in capillaries within the product or trapped within the food structure by surface forces. In general, proteins that are completely soluble are less effective at water binding than those that are less soluble. An important aspect of protein hydration is the rate and extent of swelling.

Solution conditions, such as pH, ionic strength, and temperature, affect the hydration of proteins. Hydration capacity is minimal at the isoelectric point, where protein–protein interactions are favored over protein–water interactions. Low salt concentrations can also increase the hydration capacity of proteins.

Because a majority of the amino groups in globular proteins, such as whey proteins, are buried in the protein interior, the hydration capacity arises predominately from binding of water to amino acid residues on the protein surface. WPIs and WPCs are generally very soluble and thus do not bind large amounts of water in the native conformation. Hydration values determined for native individual whey proteins range from 0.32 to 0.60 g $H_2O\,g^{-1}$ protein. Heat treatment of the whey proteins causes them to unfold and to increase their water-binding capacity. Thus, most applications of whey proteins as water binders are in food systems, such as meat patties, sausages, breads, and cakes, that receive sufficient heat treatment to denature the proteins and increase the water-binding capacity. In yogurt and other similar products, whey proteins may be added to bind water that might be released during processing or storage. The rate and the extent of heating of these products are important variables in determining the effectiveness of water binding. They may be heated to a temperature that is high enough to denature the whey proteins without causing excessive aggregation and loss of water-holding capacity.

Casein micelles bind large quantities of water in their native state; values ranging from 2 to 4 g $H_2O\,g^{-1}$ protein have been reported. In contrast, sodium caseinate binds about 0.4 g $H_2O\,g^{-1}$ protein. A large amount of water in the micelles is largely due to entrapment of water in the micellar calcium phosphate–casein matrix and to binding by the hydrophilic surface of the micelles. It has been reported that acid casein, sodium caseinate, soluble low calcium coprecipitate, insoluble low calcium coprecipitate, and WPC absorbed 0.68, 2.50, 2.60, 0.75, and 0.65 g $H_2O\ g^{-1}$ protein, respectively.

Various techniques have been used to study water–protein interactions. These include sorption isotherms, nuclear magnetic resonance, dielectric dispersion, laser light scattering, X-ray scattering, intrinsic viscosity, and various spectroscopic techniques (e.g., infrared and Raman spectroscopy).

Emulsification

Milk proteins have excellent emulsifying properties and are therefore used in many food formulations as emulsifying agents. The manufacture of food emulsions, typically oil-in-water systems, is a highly energetic and dynamic process in which oil–water interfaces are created and are stabilized by the adsorption of surface-active materials. Caseins possess high surface hydrophobicity with a well-balanced distribution of hydrophilic and hydrophobic domains and possess a high degree of conformational flexibility, which allows them to interact strongly at the oil–water interface. Whey proteins also adsorb rapidly to, unfold and reorientate at the oil–water interface forming emulsions that are only slightly less stable than those formed with casein under the same conditions. The emulsifying ability of ‘aggregated’ milk protein products, such as MPC and calcium caseinate, is much lower than that of whey proteins or sodium caseinate (i.e., much higher concentrations of protein are required to make stable emulsions).

A wide variety of apparatus, including mixers, valve homogenizers, ultrasonic equipment, and several types of blenders, can be used to prepare emulsions. Two important fundamental properties, droplet size distribution and surface protein coverage, must be measured to characterize emulsions stabilized by proteins. The droplets in food emulsions are widely dispersed in size and may range from 0.1 to 10 μm in any one system. The state of the droplet size distribution reflects the emulsifying capacity of the proteins, the energy input during emulsion formation, as well as the effects of various factors (such as pH, temperature, ionic strength, and ratio of the two phases) on the surface activity of the proteins. In addition, the droplet size distribution influences markedly the properties of food emulsions, such as stability, viscosity, texture, and mouthfeel.

The surface protein coverage of emulsion droplets, usually expressed as milligrams of protein per unit area of the dispersed phase ($mg\ m^{-2}$), depends on the concentration and type of protein as well as the conditions used for emulsion formation. The factors that affect the surface protein coverage include protein concentration, volume of oil, energy input, state of protein aggregation, pH, ionic strength, temperature, and ionic calcium concentration. In emulsions formed with sodium caseinate or WPC, the surface protein concentration ($mg\ m^{-2}$) increases with an increase in protein concentration until it reaches a plateau value of about 2.0–3.0 $mg\ m^{-2}$. The surface protein concentration of emulsions formed with MPC is in the range 5–20 $mg\ m^{-2}$ depending on the protein concentration used in making the emulsions.

When caseinates or whey protein products are used as emulsifying agents, there is competition between individual proteins for adsorption onto the oil–water interface. A number of researchers have reported that β-casein is adsorbed in preference to α_{s1}-casein and other proteins in emulsions stabilized by a mixture of purified β- and α_{s1}-caseins, as it is the most surface active and hydrophobic. The preferential adsorption of the β-casein in sodium caseinate appears to be dependent on the concentration of protein used in making the emulsions. β-Casein is adsorbed in preference to α_{s1}-casein at low protein concentrations (<2.0%), whereas a larger amount of α_{s1}-casein than β-casein is present at the interface at high protein concentrations. When casein is in the highly aggregated form of casein particles, as in calcium caseinate or MPC, there is very little competitive adsorption and protein exchange. In these systems, the average surface composition is determined by the adsorption of protein aggregates of fixed composition.

It has been shown that preferential adsorption of caseinate over whey proteins occurs in emulsions made with caseinate and whey protein mixtures. No preferential adsorption between β-lactoglobulin and α-lactalbumin is observed. Once the adsorbed β-lactoglobulin molecules become partially unfolded and closely packed together at the interface, the slow intermolecular linking by disulfide bonds leads to the formation of a structured film, which continues to strengthen irreversibly with time.

The primary processes leading to instability of emulsions are creaming, flocculation, coalescence, and phase inversion. Creaming refers to the gravitational separation of emulsified droplets to form a densely packed phase without change in droplet size. Flocculation denotes the aggregation of droplets via interactions between adsorbed proteins. Although this generally modifies the physical properties of the emulsion, the particle size distribution remains unchanged and the ‘flocs’ can be dispersed readily as these interactions are usually weak. There are two kinds of flocculation, bridging flocculation and depletion flocculation, depending on the amount of protein available to cover the interface of oil/water droplets. Coalescence (i.e., an increase in droplet size) gradually results in separation of the oil and aqueous phases. Unlike creaming and flocculation, coalescence is always irreversible. Coalescence requires rupture of the stabilizing film at the oil–water interface, but this occurs only when the layer of continuous phase between the droplets has thinned to a certain critical thickness.

Emulsions stabilized by sufficient quantities of milk proteins are generally very stable to coalescence during prolonged storage, but they can be susceptible to different types of flocculation, which in turn leads to enhanced creaming or serum separation. When there is insufficient protein to fully cover the oil–water interface during homogenization, bridging flocculation and/or coalescence of droplets may occur during or immediately after emulsion formation. Bridging flocculation is commonly observed in emulsions formed with aggregated milk protein products, such as calcium caseinate or MPC, in which the droplets are bridged by casein aggregates or micelles. Optimum stability can generally be attained at protein concentrations high enough to allow full saturation coverage of the oil–water interface. However, at very high protein-to-oil ratios, the presence of excess, unabsorbed protein may lead to depletion flocculation in some emulsions. For example, sodium caseinate-based emulsions show depletion flocculation when the protein content is increased to above 3.0 wt.% in a 30% oil emulsion. This flocculation results in a marked decrease in creaming stability but is reversible by shearing or dilution with water. Emulsions formed with calcium caseinate, MPC, or whey proteins do not show depletion flocculation and are stable against flocculation, coalescence, and creaming for several weeks.

The methods used for evaluating the emulsifying properties of proteins can be separated into two categories. The first category, which includes the emulsifying capacity (EC) and the emulsifying activity index (EAI), provides direct information on emulsifying potential. The second category provides an estimation of the effects of proteins on the emulsion stability (ES). However, complete characterization of the emulsifying properties of proteins requires both of these approaches. In the EC test, the maximum amount of oil emulsified by a protein dispersion just prior to the inversion point is determined. The EAI is a rough estimate of the dispersed particle size of the emulsion, based on the interfacial area (calculated from turbidity) per unit of protein. The EAI measures the ability of the protein to disperse the oil phase. The ES can be evaluated by measuring the rate at which an emulsion creams or breaks. The rate of these changes can be measured by determining the distribution of oil droplets or by estimating the fat or water content in the upper or lower part of the emulsion. Other methods, measuring the dielectric constant of the upper part of the emulsion or the electrical conductivity of emulsions, have also been proposed. In addition, numerous methods for accelerating the separation process by centrifugation, heating, and so forth have been proposed to evaluate the long-term stability of emulsions. However, these methods should be used with caution because of the poor relationship between accelerated stability and storage stability.

Whipping and Foaming

As milk proteins are surface active, they have the ability to adsorb to the air–water interface during foam formation. Foams are most commonly formed by mechanically dispersing air into a solution containing surface-active agents. Essential for the formation of protein-based foams is a rapid diffusion of the protein to the air–water interface to reduce surface tension followed by partial unfolding of the protein. Further interactions between protein molecules at the interface lead to the formation of a cohesive film with a certain degree of elasticity, which stabilizes the foams. Milk proteins, in particular WPC and WPI, are capable of forming a cohesive structure surrounding the foam bubbles as well as providing excellent surfactant properties.

Foaming properties are commonly determined as foam volume (overrun) and foam stability. Caseinates generally give higher foam overruns but produce less stable foams than WPCs. The foaming properties are influenced by many factors, including protein concentration, level of denaturation, ionic strength, preheat treatment, and presence of lipids. Generally, overrun increases with protein concentration to a maximum value after which it decreases again; for WPC foams, this maximum is observed between 8 and 12% whey protein. Partial heat denaturation of the proteins improves the foaming characteristics of WPC, with the effect being greater on stability than on overrun. However, excessive denaturation and aggregation of the proteins have a detrimental effect on the foaming properties of WPCs. The presence of phospholipids and unsaturated fatty acids in WPCs can rupture the foam, as a result of their higher surface activity and their thinning effect on the protein film. Maximum overrun and foam stability have been observed at pH 4–5. This is attributed to the formation of a more cohesive protein film at the air–water interface, due to decreased electrostatic repulsions. Different ions vary in their effect on foaming properties. Partial hydrolysis of whey proteins with proteolytic enzymes increases the foam volume but reduces its stability. However, limited hydrolysis of WPC combined with heating at 55–70 °C gives excellent overrun and stability, provided the pH is between 7 and 8 before whipping.

Heat Stability

Heat stability, or lack of it, may be an important functional property in some food applications. Milk proteins vary in their susceptibility to heat-induced aggregation and precipitation. Casein micelles in milk or in MPC and aqueous solutions of sodium caseinate are remarkably heat stable; a 3% solution of sodium caseinate at pH 7 can be heated at 140 °C for 60 min, whereas skim milk is usually stable at 140 °C for about 20 min at pH 6.7. Calcium caseinate containing 1.5% calcium is not heat stable, with aggregation and coagulation occurring above 45 °C. Obviously, sodium caseinate or skim milk is very suitable for use in products where thermal stability is required, such as soups and sauces.

In contrast to caseins, whey proteins are readily denatured above 70 °C, followed by aggregation and precipitation. The susceptibility of whey proteins to heat denaturation is influenced by factors such as pH, total solids, ionic calcium concentration, protein concentration, and the presence of sugars and protein-modifying agents.

A common method for measurement of heat stability involves heating a protein solution of known concentration and pH in an oil bath for a given period of time at defined temperatures. Changes in free amino nitrogen, soluble ammonia, turbidity, and trichloroacetic acid (TCA)-soluble and pH 4.6-soluble amino nitrogen have been attributed to the effects of heating on protein solutions. The heat stability of a protein product can also be measured by assessing the ability of a reconstituted protein solution (5%) to withstand retort sterilization (121 °C, 16 min). However, a more appropriate approach is to measure the heat stability in a model food system simulating the final food application.

Gelation

Milk proteins have the ability to form rigid, heat-induced irreversible gels that hold water and fat and provide structural support. The ability of milk proteins to undergo gelation upon the addition of acid or rennet to milk is well known. Caseinates are rarely added to food products as gelling agents, but WPC and WPI products can provide gelation under a wide range of conditions.

The heat-induced gelation of whey proteins involves a series of steps, starting with the unfolding of protein molecules, followed by their aggregation in aqueous solution. A gel is formed when the extent of aggregation exceeds some critical level; a three-dimensional, self-supporting network that traps the solvent in the system is formed. When the extent of aggregation is below some critical minimum, soluble aggregates or a precipitate will form. Therefore, gel formation and the properties of the gel depend on the type and number of protein–protein interactions, which in turn are affected by variables such as type of protein, protein concentration, temperature, pH, ionic strength, and the presence of other ingredients, such as lactose.

The most outstanding microstructural feature of the gels formed from whey proteins is the presence of a homogeneous network of connected protein particles, usually referred to as 'fine-stranded' gels, or aggregates that form a three-dimensional matrix with the interstices filled by a liquid or aqueous solution, usually referred to as 'particulated' gels. β-Lactoglobulin, bovine serum albumin (BSA), and whey protein products are known to form either type of gel, depending on the pH and ionic strength.

Generally, heating a protein solution above the minimum denaturation temperature of the constituent proteins is required for gel formation. The strength of whey protein gels is affected by the concentration and purity of the protein. A protein concentration of 7.5% or greater is needed to form a strong gel from WPC at pH 7.0 upon heating for 10 min at 100 °C. Pure solutions of β-lactoglobulin and BSA can form gels at 5 and 4% protein, respectively, after heating for 15 min at 90 °C. As the protein concentration is increased, the number of potential interactions between molecules is enhanced, resulting in an increased gel strength, a reduced gelling time, and a finer gel network. When other factors are maintained, gel hardness increases with increasing heating temperature and time. Heating rate also affects the gelation process; slow heating allows the proteins enough time for unfolding and aggregation, resulting in much stronger gels.

Several investigators have found that opaque gels are formed on heating whey protein solutions at pH 4–6, whereas the gels are translucent above and below this pH range. Opaque gels have been described as soft and creamy, and they tend to lose water during compression. The transparent gels formed at pH below 4 are weak (low values for fracture stress) and brittle (low values for fracture strain), whereas those formed at pH above 6.0 are strong and rubbery, with high fracture stress and strain values. The variations in gel properties with pH are attributed to variations in electrostatic interactions and disulfide bonding.

It is well established that salts have a major effect on the properties of whey protein gels, especially at pH values far from the isoelectric point where the proteins carry a large net charge. Addition of NaCl or $CaCl_2$ to a dialyzed solution of WPC or WPI results in an increase in gel strength until maximum values are reached, and then the gel strength decreases at higher salt concentrations. A maximum in a gel property has generally been attributed to an optimum balance between protein–protein and protein–solvent interactions at a particular salt concentration. Calcium ions influence protein–protein interactions by shielding electrostatic repulsion and also by forming calcium bridges between protein molecules. In general, divalent calcium ions have a much greater effect on gel properties than monovalent sodium or potassium ions. This is due to the higher

Table 2 Key functional properties of different milk protein products

binding affinity of calcium to specific binding sites, specific conformational changes, and intermolecular bridging.

Calcium caseinate solutions at protein concentrations greater than 15% form reversible gels upon heating to 50–60 °C. The gelation temperature increases with protein concentration from 15 to 20% and with pH in the range 5.2–6.0. Upon cooling, these gels are changed into viscous liquids.

The heat-induced gelation of protein can be described as the gelation time, as observed visually, or the gelation temperature, measured as the temperature at which it is possible to invert a tube containing the protein solution without movement of the contents. The rheological and textural properties of gels are determined using small, non-destructive strain techniques (i.e., sample deformation) and destructive techniques (i.e., sample rupture). In the first case, rheological characteristics using small, non-destructive strain allow a dynamic measurement of rheological transitions. Changes in rigidity or shear modulus (stress/strain), storage modulus (G'), and loss modulus (G') can be measured as a function of time or temperature.

Table 2 summarizes the important functional properties of a wide range of milk protein products. The relative importance of nine key functional properties to each product is also indicated.

Introduction

The quality of milk may be evaluated by measuring the parameters that indicate both its suitability for consumption or processing into dairy products and the health status of the cow or herd producing the milk. The principal parameter routinely used internationally in this context is the somatic cell count (SCC) per milliliter of milk, which enumerates epithelial cells shed from the udder tissue and white blood cells (WBCs) from the blood. Milk SCC results are generally expressed as the number of cells per milliliter of milk, or converted to a log value. It is one of the main indicators of udder health in lactating animals and, in many countries, it is used in animal health programs as a criterion for bulk milk payment schemes.

Different types of milk samples may be analyzed for SCC (or any other quality parameter), depending on the reason for testing:

1. milk from an individual quarter of a single cow;
2. mixed milk from all four quarters of an individual cow;
3. milk from a farm bulk tank, containing a mixture of milk from all the cows in the herd.

For a sample from an individual cow, SCC directly reflects the migration of WBCs into the milk (transfer across the blood/milk barrier) and therefore reflects the health status of the cow, and in particular the occurrence of mastitis. Bulk milk SCC therefore gives an indication of the overall average health of the milk-producing herd.

The quality of milk may also be assessed through measurement of the microbiological population, by determining either the total bacterial count (TBC) or the presence of specific types of bacteria. Bacteria in milk may originate from the udder, the environment, milk-handling equipment, and farm personnel (*see* **Milking and Handling of Raw Milk**: Milking Hygiene). The primary concern regarding the presence of bacteria in milk unquestionably relates to the health of the consumer; it was due to the presence of pathogenic bacteria such as *Mycobacterium tuberculosis* in milk that pasteurization of milk was introduced almost a century ago (*see* **Plant and Equipment**: Pasteurizers, Design and Operation). However, the presence of nonpathogenic spoilage bacteria in milk (such as *Pseudomonas* species) may also have profound implications for the keeping quality of the liquid milk or dairy products made from milk, highlighting again the importance of routine testing of the microbiological quality of milk. Milk TBC is usually applied as a payment or rejection standard in parallel with milk SCC. A partial list of the most significant bacteria in milk is given in **Table 1**.

In this article, the methods by which SCC, udder health, and indices of milk microbiological quality are evaluated will be reviewed. In the accompanying article (*see* **Milk Quality and Udder Health**: Effect on Processing Characteristics), the relationships between some of these parameters and milk processability, and the quality of dairy products, will be discussed.

Table 1 Bacteria that may be present in raw milk and their significance

Bacterium	*Origin*	*Significance*
Bacillus cereus	Feed, soil, dirt	Spoilage bacterium[a]
Brucella abortis	Diseased cow	May have disease links
Campylobacter jejuni	Dung, water	Food poisoning
Clostridium botulinum	Soil, water	Causes botulism
Clostridium perfringens	Soil, dung, water	Food poisoning
Corynebacterium bovis	Udder	No major problems
Coxiella burtenii	Diseased cattle	Causes Q fever in humans
Escherichia coli	Fecal contamination	Food poisoning/spoilage
Lactobacillus spp.	Milk handling	Spoilage (souring)
Lactococcus spp.	Milk handling	Spoilage (souring)
Listeria monocytogenes	Soil, dung, feed	Causes meningitis
Mycobacterium tuberculosis	Diseased cow	Human pathogen
Mycobacterium avium subsp. *paratuberculosis*	Cow	May cause Crohn's disease
Pseudomonas spp.	Milk handling	Spoilage bacterium
Salmonella spp.	Dung, water	Food poisoning
Staphylococcus aureus	Diseased cow, skin	Food poisoning
Streptococcus agalactiae	Udder, milking parlor	Food poisoning/spoilage
Streptococcus dysgalactiae	Udder, milking parlor	Food poisoning/spoilage
Streptococcus uberis	Udder, milking parlor	Food poisoning/spoilage

[a]May produce toxins at very high levels (but milk will spoil before this point).

A number of other factors that are known to affect milk quality, such as variations in the composition, freezing point, and free fatty acid content of milk, may be rooted in on-farm handling practices or may be linked to the status of the cow. Internationally, dairy processors may include such quality parameters when considering the acceptability or value of milk. Furthermore, testing schemes operated by processors may routinely analyze milk for the presence of undesirable additives or contaminants, such as antibiotics or cleaning and sanitizing agents, which would have both public health and product quality implications. However, in this article, only tests for udder health and microbiological quality will be discussed in detail.

Somatic Cells in Milk and Mastitis

Somatic cells in milk comprise epithelial cells shed from the udder tissue and WBCs from blood. The basic function of the WBC in the mammary gland is defense against bacterial invasion. In normal bovine milk from noninfected quarters, the SCC is typically $<100\,000\,\mathrm{ml}^{-1}$, of which ~50% are epithelial cells and the others are WBCs including ~15% macrophages, 10% lymphocytes, and 25% polymorphonuclear leukocytes (PMNs). In other dairy animals such as goats or sheep, SCC in noninfected halves is typically higher and can be ~150 000 to $300\,000\,\mathrm{ml}^{-1}$.

Upon entry of bacteria into the mammary gland, the response of the bovine immune system depends on the invading species. For example, infection by Gram-negative bacteria such as *Escherichia coli* typically results in a rapid and massive influx of somatic cells, mainly PMNs (such that SCC exceeds $1\,000\,000\,\mathrm{ml}^{-1}$, of which >90% are PMNs, within 6 h). In contrast, Gram-positive bacteria such as *Staphylococcus aureus* and coagulase-negative staphylococci can 'hide' for several days in the mammary gland and then develop into a clinical and/or chronic infection manifested by a fluctuating moderate influx of SCC between ~500 000 and $>1\,000\,000\,\mathrm{ml}^{-1}$. In the latter case, the number of PMNs is lower and the number of lymphocytes, mainly T-CD8^{+}, is higher.

Mastitic infections may be classified as either clinical or subclinical. The former is defined by the International Dairy Federation (IDF) as udder inflammation characterized by visible abnormalities in the milk and/or udder, and cases may be subclassified as mildly, moderately, or seriously severe. Cows with clinical mastitis may exhibit swelling of the udder and apparent pain or discomfort, and their milk may contain flakes or clots. Subclinical mastitis is defined as inflammation that is not visible and requires a diagnostic test for detection, such as measurement of SCC along with bacteriology, and is the most prevalent form of the disease (15–40 subclinical cases for every clinical case today). Chronic mastitis refers to cases where the infection is of long duration and may show periodic clinical symptoms.

In general, although milk SCC is an indication of the presence or absence of infection, any estimate of SCC should be supplemented by microbiological analysis to determine the true cause and nature of any indicated infection. Rapid diagnosis of subclinical mastitis presents a particular challenge and depends on the analysis of milk from individual cows or quarters. While subclinical mastitis can always be diagnosed by bacteriological methods, such approaches are slow, and hence a number of more rapid methods for early and rapid identification of subclinical infection have been developed, as will be discussed later.

Overall, the SCC of milk is an extremely important parameter of milk quality, as it reflects the health status of a cow (or a herd), and is known to be an indicator of the quality and processing properties of milk; hence, SCC is widely used as a payment parameter by dairy companies, as will be discussed later in this article.

Measurement of Milk Somatic Cell Count: Total Counting

The oldest method for enumerating somatic cells in milk is direct microscopic counting, often combined with methylene blue staining, which, although slow and labor-intensive, remains in many instances the reference method against which other methods are calibrated.

Several methods are being used for on-farm ('cow-side') estimation of SCC and thus for diagnosis of mastitis. In the California mastitis test (CMT), a small sample of milk (from an individual cow or a quarter) is mixed with an alkaline detergent on a special mixing device, and the extent of subsequent formation of a gel is ranked on a simple scale, which relates gel formation to the number of somatic cells in the milk. A slightly more complex variation of the CMT, known as the Wisconsin mastitis test (WMT), is intended as a rapid milk quality test on receipt at dairies, and involves the extent of gel formation being read as the volume of sediment in a calibrated tube.

Several instrumental systems for measuring bulk milk SCC, such as the Fossomatic, Coulter, or Bentley cell counters, are available. Such instruments give SCC in number of cells per milliliter of milk, and provide, when calibrated against microscopic counts, accurate, rapid, and precise measurement of SCC, but are too complex and expensive to be applied routinely on a farm. An online cell counter (OCC) has, however, been invented that may provide a precise cell count for every cow at every milking. Coulter counters use electric counting of formalin-fixed somatic cells passing through an aperture, while Fossomatic systems label the nuclei of somatic cells using ethidium bromide and then count the stained nuclei as they pass through a thin film under a high-energy light source. The Bentley Somacount system uses laser-based flow cytometry, again combined with ethidium bromide staining of DNA. The above methods are generally and routinely used for analysis of large numbers of samples in a dairy testing laboratory.

An indirect instrumental method that gives a measure of the health status of the cow is the electric conductivity measurement, which takes advantage of the influx of ions into the alveoli owing to the opening of the tight junctions when inflammation commences. This can form part of a computerized milking system in modern dairy farms, as manufacturers of modern computerized dairy milking parlors have developed devices to measure electrical conductivity during milkings and compare that conductivity value to the precedent value. Differences in values between milkings can signal to the milker that an unusual increase/decrease in this measure was noted, and the cow must then be checked by other means for the presence of mastitis. The system is used with all models of automatic milking systems.

Measurement of Milk Somatic Cell Count: Differential Counting

While measurement of total milk SCC has been recognized for many years as a very useful index of udder health, recently there has been an increased interest in differential measurement of somatic cell types in milk comprising the total count. The relative numbers of specific cell types, such as PMNs, macrophages, and lymphocytes, were first studied using light or electron microscopy. These are slow and laborious methods. To automate and hasten the cell-sorting process, some researchers in the 1980s used Coulter counter equipment to differentiate counted particles (cells) on the basis of size into groups, which can be enumerated separately. Most recent studies on differential SCC have used flow cytometry, where cells stained by mixing milk samples with a nuclear stain, such as acridine orange, pass singly through a detector cell in a narrow stream of liquid, and are differentiated based on fluorescence properties or cell size and shape into clusters, which can be directly related to different cell types. However, a more accurate method that differentiates between specific cell types involves using monoclonal antibodies targeting specific receptors on the cell surface. This method also allows information about the cell condition and function to be gathered.

Using flow cytometry, it has been confirmed that of the WBCs, macrophages and lymphocytes represent the majority of cells in milk from noninfected udder, while PMNs are the predominant cell types in mastitic milk. On this basis, it has been suggested that PMNs may be a useful tool for diagnosing mastitis, although the complexity and expense of the technique may preclude its routine use for large numbers of samples in dairy testing laboratories. However, flow cytometry undoubtedly offers advantages for a detailed study of the immunological status of the udder. In an alternative approach, monoclonal antibodies against PMNs have been used for the development of an enzyme-linked immunsorbent assay (ELISA) for the enumeration of the level of these cells in milk, and studies are performed to determine the distribution of PMNs in bulk tank and individual milk samples, and PMN levels are correlated with total SCC.

It must be noted that, as with SCC, differential milk SCC may also be affected by factors such as stage of lactation, stress, age of cow, and milking frequency, which must be considered when interpreting data.

Standards for Milk Somatic Cell Count

When considering milk SCC, it is essential to distinguish between the SCC for individual cows, the SCC of milk from individual quarters of the udder of the same cow, and the SCC of mixed milk in the farm bulk tank (bulk tank SCC (BTSCC)), which comprises a weight-averaged SCC of all cows with accepted milk in the herd. While the first two measurements relate directly to the health of the individual cow, the last is a function of the number of infected cows in the herd and the extent of withholding of high-SCC milk. It has been shown that there is a linear relationship between the level of infection in a herd and BTSCC. BTSCC is widely accepted as an indicator of mastitis control practices on farms, herd health and the suitability of milk for processing, but has limitations as a diagnostic tool for measure the cause and etiology of mastitis within a herd. Thus, in cases of high BTSCC, it is necessary to have data for each individual cow in the herd in order to understand and deal with the problem.

Some processors may apply penalties for exceeding certain SCC on even one occasion. However, dairy companies frequently calculate penalties or bonuses applied to individual milk suppliers on the basis of a geometric mean BTSCC over a fixed time period, such as 3 months. The advantages of using geometric means include normalization of data, reduced variance in raw data, which are not normally distributed, and less tendency to penalize single violations.

An SCC for an individual cow >200 000 ml^{-1} is generally regarded as indicating that an inflammatory response is either in progress or has occurred recently. Interpretation of SCC data for individual cows must, however, be tempered by the acceptance that SCC is a dynamic parameter that can vary considerably even in noninfected animals, requiring multiple SCC measurements before interpretations may be offered, and should be accompanied by a bacteriological examination of individual quarters. While an SCC >200 000 ml^{-1} is generally regarded as abnormal and milk with an SCC <100 000 ml^{-1} is generally regarded as normal, the status of cows with an SCC between these limits remains unclear. In some cases, SCC may be corrected to account for the age and breed of the cow, stage of lactation, and milk yield.

Table 2 Current international standards for maximum acceptable SCC

Country	*SCC limit (cells ml^{-1})*
European Union	400 000
New Zealand	400 000
Switzerland	350 000
Australia	400 000
Canada	500 000
United States of America	750 000

SCC, somatic cell count.

There is a lack of international consensus on the value of SCC above which bulk milk should be considered abnormal. EU Directive 92/46 sets the maximum allowable SCC for manufacturing milk at 400 000 ml^{-1} (for a geometric average over 3 months, with at least one BTSCC measurement per month), but the US Pasteurized Milk Ordinance (2003) states that milk with an SCC up to 750 000 ml^{-1} may be accepted. The US limit for SCC is currently the highest in major developed dairy countries (see **Table 2** for a comparison of international standards for SCC).

International debate on SCC limits frequently concerns the distinction between the perception of SCC as an index of milk quality or of milk safety. Unlike the general position of the European Union, BTSCC is not regarded in the United States as being directly linked to food safety, as consumers do not become ill from drinking high-SCC milk. High-SCC milk is nevertheless generally accepted as having an increased risk of the presence of pathogenic bacteria or toxic products. This acceptance drives policy toward reducing the acceptable BTSCC, which should thus reflect a lower incidence of mastitis, milk of better processing quality, and better farm hygiene. A high BTSCC may also suggest a risk of potential use of antibiotic treatment at the herd level, with concomitant human health implications due to the development of antibiotic resistance among human pathogens. Sometimes, BTSCC is also regarded as an index of herd welfare; Scandinavian countries tend to regard herds with a BTSCC >400 000 ml^{-1} as having poor welfare and being unhealthy overall. In general, it is likely that the trend in the future, driven by pressure from consumers and scientists alike, will be toward lower SCC limits, in particular in the United States.

In many countries today, the average SCCs are far below the legal maximum (e.g., in Norway, the mean BTSCC in 2000 was 142 000 ml^{-1}, or a geometric average of 112 000 ml^{-1}). Local milk payment schemes may be targeted toward financial incentives for the production of milk of considerably lower SCC, with penalties imposed when the milk exceeds certain SCC limits. Thus, there are obvious incentives for farmers to produce milk of lower SCC, including the fact that a reduced BTSCC is closely correlated with increased herd milk yield.

A potentially significant question is whether milk SCC can be too low, in terms of the biological function of the 'background' SCC in milk in immune surveillance and protection of the mammary gland and in initiating the cellular response that attracts huge numbers of PMNs into the mammary gland. For example, could animals selected for excessively low SCC ($<15\,000$ cells ml^{-1}) be, in the long term, less resistant to infection? While the key issue today is obviously ensuring low infection rates, this specific aspect of SCC control programs may nonetheless be relevant.

Incentives and the pressure to reduce BTSCC to 200 000 cells ml^{-1} or below have achieved a reduction in the frequency with which milk from mastitic cows is included in bulk milk. However, maintaining this level is expensive for the farmer, owing to the need to cull or treat udder infection. Moreover, it is not clear how further lowering of SCC will benefit the dairy industry. It is important to note that average SCC of 200 000 cells ml^{-1} by itself cannot reflect the health of each individual cow in the herd that is milked into the bulk, since such an average could be the outcome of cows with SCCs as low as 15 000 ml^{-1} and numerous cows with SCCs over a million. Therefore, it is of continuing importance to define new parameters that could influence the quality of the milk supplied to the dairy industry and assure elimination of milk from infected udders.

Measurement of Other Parameters Related to Udder Health

A number of other parameters indirectly related to SCC have been proposed as useful indices of udder health. The enzyme *N*-acetyl-β-D-glucosaminidase (NAGase), for example, has been implicated as an indicator of tissue damage during mastitis, as large quantities are secreted in the mammary gland during inflammation. While it has been suggested to have an antimicrobial effect, the exact physiological function of this enzyme in milk is unclear. NAGase levels in milk are typically highly correlated with SCC, and have been reported to be a better predictor of the extent of protein breakdown in milk than SCC, being more highly correlated with the activity of the indigenous proteolytic enzyme plasmin than SCC. Several rapid methods have been developed for measuring NAGase activity in milk. The alkaline milk proteinase plasmin has been of significant interest as an index of milk quality, both because its activity in milk is very sensitively affected by physiological factors such as mastitis and lactation, and because its hydrolysis of the caseins can have a direct impact on milk and dairy product quality (e.g., negatively affecting rennet coagulation and cheese yield). However, while there are a number of assays available for measuring plasmin activity, it has not been widely considered as a routine test for milk quality, perhaps due to the complex nature of the plasmin system and its effects on milk.

As mentioned above, flow cytometry could differentiate between the various types of somatic cells, and a number of studies have correlated the cell distribution with the cause of inflammation and milk quality. At present, this method is expensive and is used only for research purposes. However, implementation of one or two of these specific cell types into the automated cell counters may improve the quality of information gathered about the bulk milk.

The electrical conductivity (or alternatively electrical resistance) of milk has also been studied as an index of milk quality. This index has the advantage of being amenable to online measurement at the point of milking, allowing automated and immediate identification of problematic cows (both at subclinical and clinical stages) and rapid response (*see* **Mastities Therapy and Control**: Automated Online Detection of Abnormal Milk). A number of rapid automated sensors of milk conductivity have been described in the literature. Changes in milk conductivity reflect changes in the ionic content of milk, such as increases in the levels of sodium and chloride ions during mastitic infections. Increases in milk conductivity have been reported to occur earlier than clinical signs, allowing early diagnosis and rapid treatment of infection. Differences in milk conductivity between quarters of the same udder are particularly useful for detecting subclinical infection. Measurements of the conductivity of milk taken at different points during milking (e.g., foremilk, main milking, and stripping fractions) may provide further information on the magnitude and location of the infection within the quarter. The sensitivity and specificity of online diagnostic techniques may be improved by combining the online measurement of electrical conductivity of milk with other parameters that, alone, would not directly act as diagnostic parameters, such as milk yield and the temperature of the milk.

Other milk parameters that have been studied as potential indicators of changes in udder health include milk pH and levels of lactose, sodium, potassium, bovine serum albumin (BSA), lactate dehydrogenase, antimicrobial enzymes such as catalase and myeloperoxidase, and the proteinase inhibitor α_1-antitrypsin. Recently, acute-phase proteins such as haptoglobin and serum amyloid A, the levels of which are elevated in cases of physiological stress such as mastitis, have been proposed and studied as potential biomarkers of mastitis and raw milk quality.

Comparison of Methods for Evaluating Udder Health

An ideal test for udder health status must be unaffected by any factor other than the infection status of a particular quarter, preventing false-positive identifications. However, almost all parameters, with the exception of specific measurement of individual microorganisms, are affected by some factors other than infection status. For example, milk from older cows may have a higher SCC and NAGase activity, while SCC, NAGase, sodium, potassium, and lactose levels vary with the stage of lactation.

Several investigators have attempted to discriminate between diagnostic power and usefulness of various predictors of mastitis. A number of studies have concluded that SCC or log(SCC) is the best indicator of infected versus noninfected status, while NAGase activity discriminates between infections caused by major (streptococci, *S. aureus*; *E. coli*) or minor (coagulase-negative staphylococci, micrococci) pathogens. NAGase activity decreases much more rapidly than SCC after clinical mastitis. Monitoring BTSCC generally provides a useful indication of the incidence of mastitis on farms suffering outbreaks of contagious mastitis, which causes gross alterations to BTSCC, rather than farms with infections due to environmental pathogens, particularly in the case of subclinical infections, where BTSCC may not be severely affected.

In terms of relating milk SCC to suitability of the milk for production of dairy products such as cheese, some recent studies have suggested that different bacterial types causing mastitis can result in different responses in terms of leukocyte distribution, and differing effects on proteolysis in milk and subsequent coagulation properties. Studies of acute-phase protein levels in milk samples of different SCC have shown detectable levels of haptoglobin and serum amyloid A in milk samples of elevated SCC, and that samples with detectable levels of such proteins had reduced casein levels and evidence of increased proteolytic activity.

The optimum threshold SCC for differentiating between milk samples from infected and uninfected cows or herds has been reported to vary between herds, at different stages of lactation, and even from cow to cow, as individuals respond differently to mastitis pathogens. These factors are crucial for small ruminants, due to the variability of breeds, management, and particularly the seasonality of milk production, which result in increased SCC in the milk of healthy animals toward the end of lactation.

The correlation between SCC and the level of infected quarters is quite low (∼0.6), indicating that many other factors influence milk SCC. Thus, it has been suggested that application of a universal SCC threshold for diagnosis of mastitis may be flawed, as the background SCC varies sufficiently to reduce the sensitivity of diagnosis. However, it is likely that SCC will continue to be regarded as a primary indicator of milk quality, providing information of importance to the farmer, the processor, and the consumer, and that limits for acceptable milk SCC will continue to decrease in the future.

Determination of the Microbiological Quality of Milk

A rapid indication of the microbiological status of milk can be provided by simple tests such as dye reduction methods, where the presence of a high number of bacteria in a milk sample reduces a dye such as methylene blue or resazurin, resulting in a color change. Other rapid tests to determine indirectly the presence of bacteria in milk, through their fermentative activities, include testing the stability of a milk sample to boiling or mixing with alcohol solutions, and measurement of the titratable acidity of milk.

However, the preferred measure of overall bacterial quality of milk is the TBC (sometimes also known as standard plate count (SPC) or total viable colony count (TVC)) of milk, which is an accepted index of both milk hygienic standard and the shelf life and quality of products made therefrom. TBC may be determined by standard plating techniques on a suitable nutrient agar, although standard incubation times before counting can be as long as 3 days. Recent modifications to standard plate counting techniques include use of cylindrical tubes instead of dishes for incubation, spiral plate inoculation instruments, and of preprepared nutrient media in convenient disposable units (such as the Petrifilm system).

To obtain critical information on milk quality more quickly, rapid methods, such as the direct epifluorescent filter technique (DEFT) and automated Bactoscan instruments, have been adopted widely for analysis of large numbers of samples. Both these methods employ automated counting of bacteria whose nuclei have been stained with agents such as acridine orange; in the case of the DEFT system, bacteria are removed and concentrated from trypsin-treated milk by filtration, while the Bactoscan uses centrifugation to achieve this.

Metabolic products of bacterial cells in milk may also be measured, for example by determining the pyruvate content of milk or by determining the bacterial adenosine triphosphate (ATP) content through bioluminescence measurements.

A high milk TBC may result from poor teat hygiene, poor milking machine operation, inadequate milk refrigeration, or mastitis. In cases of mastitis caused by certain bacteria, such as *Streptococcus agalactiae*, *Streptococcus uberis*, or *E. coli*, high numbers of bacteria may be shed in milk, leading to high milk TBC. As with SCC, TBC may be measured either for bulk tank milk samples, as a quality index, or for individual cows or individual quarters, principally to aid in the diagnosis of causative agent in cases of mastitis. In the latter case, samples for analysis must be taken with great care, to avoid environmental contamination. EU and US legislation sets maximum acceptable TBC for milk of 100 000 ml^{-1}. In general, however, TBC is not used as an index of mastitis, as it can be influenced by many factors not directly related to udder health. For example, a large proportion of the bacteria in refrigerated milk will probably be psychrotrophic bacteria. However, measurement of the presence of specific types of bacteria can provide critical information for diagnosis of the type of mastitis and its causative agent, and hence for determining treatment strategies.

Specific bacteria in milk, such as individual mastitis pathogens, may be measured using specific microbiological media. This is particularly important for determining, for example, what type of antibiotic treatment should be applied to treat cases of mastitis. Either bulk samples containing mixed milk from all four quarters or, for more detailed diagnosis, individual quarter milk samples may be analyzed. Microbiological characterization of mastitis pathogens is complicated by the fact that many different causative organisms may be involved, with over 100 different species, subspecies, and biovars having been isolated from infected udders.

The presence of specific types of bacteria may be studied using specific DNA-based technologies, for example polymerase chain reaction (PCR) technology to detect genes from specific mastitis pathogens such as staphylococci or streptococci. PCR tests have also been used to semiquantitatively detect somatic cells in milk, through detection of eukaryotic ribosomal RNA sequences. For such applications, however, PCR tests may have to be modified due to inhibition of the polymerase reaction by substances found in milk.

ELISA methods have been developed for specific bacteria in milk, such as *S. aureus*. Immunological agglutination tests have been developed for a number of mastitis pathogens, and some cow-side tests for specific bacterial types, such as Gram-negative species, have also been developed.

Conclusion

The most common methods used to measure udder health, through indices of the level of either somatic or bacterial cells, are summarized in **Table 3**. In recent years, the trend, in terms of analytical techniques designed for operation in quality control laboratories in milk processing factories, has been toward development of highly automated methods capable of giving rapid and reliable information about the quality of large numbers of samples. However, there is undoubtedly a requirement for rapid simple tests that could be applied on the farm itself, both for diagnostic purposes and to ensure that quality control is applied right through the production and processing chain.

Table 3 Summary of methods for analysis of udder health

Somatic cell count and related properties
Direct microscopic cell counting (total or differential)
Electronic cell counting (e.g., Fossomatic, Bentley, Coulter counters)
Rapid cow-side tests (e.g., California mastitis test)
Rapid dairy tests (e.g., Wisconsin mastitis test)
Differential somatic cell counter (flow cytometry methods)
Differential cell counting (immunological)
Chemical/enzymatic indices (e.g., *N*-acetyl-β-D-glucosaminidase, bovine serum albumin, haptoglobin, serum amyloid A)
Total bacterial count or other microbiological parameters
Microscopic counts
Rapid indicator tests (e.g., dye reduction tests, titratable acidity, clot-on-boiling)
Standard plate counts
Automated bacterial counters (e.g., Bactoscan, epifluorescence methods)
DNA/polymerase chain reaction analysis
Specific culturing techniques for individual bacteria

Introduction

The health of the udder can have a profound effect on the quality and processing characteristics of milk. The most widely used indicator of udder health is somatic cell count (SCC), a measure of the number of white blood cells, known as leukocytes, in milk. Many milk processing companies around the world have incorporated SCC as a key parameter in schemes that reward producers for producing milk of the highest quality.

An elevated SCC usually indicates the presence of mastitis. Mastitis is caused by pathogenic bacteria entering the mammary gland via the teat canal and multiplying within the udder sinuses or epithelia, or in the teat duct. This bacterial infection usually initiates a complex inflammatory reaction within the mammary gland as part of the cow's immune response. A key feature of this inflammation is an influx of leukocytes into the milk, which are sent to the site of infection to combat the invading bacteria.

Mammary inflammation during mastitis causes a range of physical, microbiological, and chemical changes in the milk. This includes changes to the chemical composition of milk, and because the different milk components have different functional properties, this leads to changes in the processing properties of the milk. Both subclinical mastitis (mastitic infection for which there are no clinical symptoms) and clinical mastitis can cause such changes.

Effects of Mastitis on Milk Yield

Mastitis reduces milk yield by 10–25% per cow. This decline in milk production is due to physical damage to the epithelial cells of the mammary gland, which limits the synthetic and secretory capacity of the gland. A reduction in the capacity of the mammary gland to synthesize and secrete lactose is important in this regard, given the role of lactose as the osmotic regulator of milk volume. A decline in milk yield can also result from blocked milk ducts or impairment of the blood supply of the precursors for milk production.

Effects of Mastitis on the Composition of Raw Milk

Mechanisms by Which Mastitis Affects Milk Composition

Changes to the chemical composition of milk associated with mastitis are shown in **Table 1**. These changes are brought about in three main ways:

1. Chemical mediators of inflammation (e.g., histamine, cytokines), along with toxins released by the invading bacteria, can damage the cells in the secretory tissue of the mammary gland. This leads to a reduction in the synthesis and secretion of most milk components synthesized in the udder.
2. Bacterial toxins can cause the junctions between the mammary epithelial cells to rupture, increasing the permeability of adjacent blood vessels. This allows leakage of blood constituents into milk, and of milk constituents into blood.
3. The activity of hydrolytic enzymes in milk is elevated during mastitis, leading to the postsecretory breakdown of milk constituents. These enzymes include those from bacteria and from the somatic cells themselves, but there is also an increase in the activity of the native milk proteinase, plasmin.

Milk Fat

The effect of mastitis on milk fat concentration is uncertain. A decline in milk fat concentrations during mammary infection is logical given the reduced synthetic and secretory ability of the mammary gland, and this is what some researchers have reported. It is possible, however, that in other studies the concentrating effect of a reduction in milk volume has offset any reduction in the synthesis and secretion of milk fat, resulting in either a negligible change or an increase in overall fat concentration.

Conditions within the infected mammary gland can increase the susceptibility of milk triacylglycerols to degradation by lipase, which leads to the release of free fatty acids. In turn, the presence of elevated quantities of free fatty acids can cause organoleptic defects, especially rancid flavors, in milk and dairy products. Free fatty acids also increase in milk during mastitis because of incomplete synthesis, as well as because of

Table 1 Effects of mastitis on milk composition

Milk Protein

Reports on the effect of mastitis on concentrations of total protein are conflicting. Overall, mastitis usually causes a decrease in casein coupled with an increase in whey protein, producing a negligible change in total milk protein concentration. The direction of the change, if any, can be influenced by factors such as the severity and type of infection.

Decreased casein concentrations in high SCC milk are partly due to lower synthesis and secretion of casein, as a consequence of physical damage to the mammary epithelial cells. They are also due to postsecretory degradation of the different casein proteins, especially β-casein, by a range of proteinases originating from bacteria, leukocytes, or the blood.

Increased concentrations of whey protein during mastitis are partly due to an influx of serum proteins from the blood, through ruptured tight junctions between mammary epithelial cells. Such proteins include immunoglobulin G and bovine serum albumin, as well as the lesser proteins transferrin and α_2-macroglobulin. Lactoferrin, though synthesized in the mammary gland, also increases in milk during mastitis, an occurrence probably associated with its bacteriostatic function.

The net result of a reduction in casein and a concurrent increase in whey protein concentration during mastitis is a decline in casein as a percentage of total protein, or casein number (**Figure 1**). This has important implications for the manufacturing potential of the milk, particularly, but not exclusively, for cheese manufacture. It is also of concern to manufacturers who pay for milk using systems based largely on total protein concentration.

Plasmin

Milk with an elevated SCC can have increased quantities of many different proteolytic enzymes. A major proteinase is plasmin, which can rapidly cleave β-casein into γ-casein and smaller polypeptide fragments that then diffuse into the whey fraction. Thus, a decrease in total casein concentration during mastitis is often accompanied by low β-casein and high γ-casein, as proportions of total casein. Hydrolysis of α-casein also occurs during mastitis, although the breakdown products are unknown. The precise effects of mastitis on κ-casein concentrations are uncertain.

The caseinolytic capacity of plasmin is important for several reasons:

- The optimum temperature for plasmin activity is about the body temperature of the cow, which facilitates almost immediate postsecretory casein hydrolysis.
- The enzyme is heat stable, and thus able to survive high-temperature treatments during processing. This can shorten the shelf life of subsequent milk products.
- The inactive precursor of plasmin is plasminogen, present in milk and at up to 9 times the concentration of plasmin. Plasminogen is converted to plasmin by 'plasminogen activators', which may be secreted by somatic cells. Thus, plasmin concentration may increase during mastitis due to greater influx from the blood, as well as through increased conversion from plasminogen (*see* **Enzymes Indigenous to Milk**: Plasmin System in Milk).

Lactose

Mastitis causes a reduction in the lactose concentration in milk. The changes in lactose concentrations during mastitis are unlikely to be due to reduced synthesis and secretion at the cellular level because lactose is the osmotic regulator of milk volume. Thus, water is drawn into the cells only in sufficient quantities to maintain osmotic equilibrium (during mastitis, less lactose in secreted and so less water is drawn into the cells, resulting in less milk). It is more likely that lactose leaks out of milk following the breakdown of the epithelial barrier, as shown by elevated concentrations of lactose in the blood and urine of cows with mastitis.

Mineral Balance and Milk pH

The concentrations of many minerals are altered during mastitis (**Table 1**), and this change in the ionic environment leads to an increase in the conductivity of the milk. For example, Na and Cl, found in the blood in high quantities, leak into the milk and consequently their concentrations increase. Conversely, potassium, the most abundant mineral in milk from healthy cows, leaks into the interstitial fluid through the ruptured mammary epithelia during mastitis, and its concentration decreases.

Most Ca in milk is associated with micellar casein, and so mastitis generally results in a decline in total milk calcium concentrations as a result of reduced casein synthesis. No consistent effect of mastitis on the soluble and insoluble fractions of calcium has been reported.

Milk pH generally increases during mastitis, because of the movement of blood components into milk. These changes to the mineral balance and pH of milk can play important roles in determining the manufacturing quality of the milk, particularly for cheese manufacture.

Bacterial Contamination

An effect of mastitis on milk quality that is often overlooked is the contamination of bulk milk with the causative bacteria when milk from cows with mastitis is not excluded. Bacteria from cows with subclinical mastitis contribute to the total bacterial count of bulk milk, but usually not more than 10 000 cfu ml^{-1}. On the other hand, milk from cows with clinical mastitis can have a bacterial load of up to 10 000 000 cfu ml^{-1}, and admitting this milk to the bulk supply markedly increases total bacterial numbers. This bacterial contamination can lead to changes in milk composition via the action of hydrolytic enzymes released by the bacteria and, if the microorganisms are psychrotrophic, increases the likelihood of spoilage of milk and dairy products.

Effects of Mastitis on Dairy Products

Cheese

Most studies of the effects of mastitis on the yield and quality of dairy products have investigated cheddar cheese. Of these, most have demonstrated that mastitis causes changes to milk composition that are deleterious to the cheese-making process (**Table 2**). Cheese making

Table 2 Summary of reported product defects associated with elevated somatic cell count

Product	*Effects*
Cheese	Reduced yields and yield efficiencies Elevated moisture content Increased rennet clotting time Soft cheese and textural defects Higher loss of solids in whey Inferior organoleptic properties
UHT milk	Accelerated age gelation
Pasteurized fluid milk	Reduced shelf life Organoleptic defects
Cultured products	Increased coagulation time Inferior organoleptic properties
Butter	Extended churning times Reduced shelf life Inferior organoleptic properties
Milk powder	Altered heat stability Reduced shelf life
Cream	Altered whipping properties

involves the coagulation of milk from a colloidal dispersion to a network of aggregated casein micelles, forming a gel that entraps moisture and fat. This gel provides the means by which the fat and casein can be concentrated, recovered, and preserved in the form of a cheese curd. Thus, any changes to milk composition that interfere with this coagulation process can potentially affect cheese yield and/or quality.

An elevated SCC can cause low recoveries of milk fat and protein in cheese, and a decline in the yield of cheese per kilogram of milk. This is partly because of a decrease in casein as a percentage of total protein, since it is mostly casein that is incorporated into the curd while the whey is expelled during syneresis. It is also because a suboptimal ratio of casein to fat leads to less fat becoming entrapped in the curd. This loss of cheese yield and cheese yield efficiency is a key economic driver for companies to reduce the SCC of their bulk supply.

Mastitis causes increases in cheese moisture contents (**Figure 2**). This is a serious cheese quality defect, and can place the cheese outside product specifications if high SCC milk is used. The increase in cheese moisture that occurs as milk SCC increases is caused by a slow, weak coagulation due largely to alterations in milk protein composition and mineral balance, combined with increased milk pH. These changes in milk composition interfere with the expulsion of water from the curd during syneresis.

In turn, elevated cheese moisture contents usually cause decreases in curd firmness, leading to a deterioration of the organoleptic properties of cheese. Textural problems, specifically soft, pasty cheese, occur as a result of the high moisture content of the cheese. Flavor defects can also occur, especially during ripening, as a result of the increased activity of hydrolytic enzymes.

For example, in a study using milks obtained from commercial dairy farms during late lactation in Victoria, Australia, actual and moisture-adjusted cheese yields decreased (by 5 and 10%, respectively), as SCC changed from 252 000 to 1 463 000 cells ml^{-1} (**Table 3**). Concurrently, cheese moisture contents increased (8%), and textural defects were observed in the cheese from high SCC milk.

Similar declines in the yield of cottage cheese occur when high SCC milk is used, again due to a decrease in the recovery of milk solids in the final product. Additionally, there are similar elevations in cheese moisture contents and there are also increases in proteolysis during storage when high SCC milk is used compared those with low SCC milk (*see* **Cheese**: Overview).

Other Dairy Products

The influence of mastitis on the yield and quality of dairy products other than cheese has not been investigated nearly so extensively. Of those that have been reported, most have been detrimentally affected as SCC increased (**Table 2**).

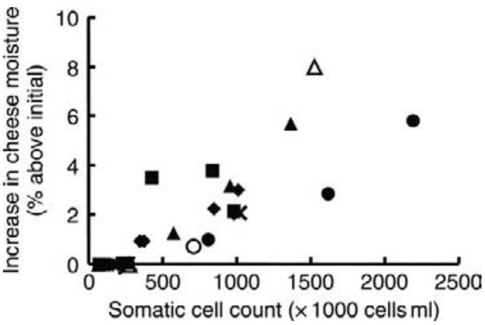

Figure 2 Effect of SCC on cheese moisture content. Data points represent the percentage increase in cheese moisture content above that for the milk with the lowest SCC used in each particular study. ■ Barbano DM, Rasmussen RR, and Lynch JM (1991) Influence of milk somatic cell count and milk age or cheese yield. *Journal of Dairy Science* 74: 369–388; ▲ Grandison AS and Ford GD (1986) Effects of variations in somatic cell count on the rennet coagulation properties of milk and on the yield, composition and quality of Cheddar cheese. *Journal of Dairy Research* 53: 645–655 (experiment 1); ● Grandison AS and Ford GD (1986) Effects of variations in somatic cell count on the rennet coagulation properties of milk and on the yield, composition and quality of Cheddar cheese. *Journal of Dairy Research* 53: 645–655 (experiment 2); △ Auldist MJ, Coats S, Sutherland BJ, Mayes JJ, McDowell GH, and Rogers GL (1996) Effects of somatic cell count and stage of lactation on raw milk composition and the yield and quality of Cheddar cheese. Cheddar cheese from farm bulk milk. *Australian Journal of Dairy Technology* 41: 12–14; ◆ Rogers SA and Mitchell GE (1994) The relationship between somatic cell count, composition and manufacturing properties of bulk milk. 6. Cheddar cheese and skim milk yogurt. *Australian Journal of Dairy Technology* 49: 70–74. (No studies reported decreases in cheese moisture content with increasing SCC).

For example, an elevated SCC in milk can cause an increase in the coagulation time of butter and yogurt cultures. The organoleptic quality of sweet cream butter made from high-SCC milk is also reduced, and the product deteriorates more rapidly during storage than butter made from low-SCC milk. A high SCC can also be associated with poor heat stability of full cream milk powder (*see* **Dehydrated Dairy Products**: Milk Powder: Physical and Functional Properties of Milk Powders).

Using high-SCC milk for the production of pasteurized fluid milk can decrease the shelf life of the product. This occurs via an increase in hydrolytic enzyme activity, which leads to organoleptic defects such as rancidity and bitterness (*see* **Liquid Milk Products**: Liquid Milk Products: Pasteurized Milk; Liquid Milk Products:

Table 3 Effects of somatic cell count (SCC) on cheese yield, coagulation times, and cheese moisture content

	Low SCC	*High SCC*

Super-Pasteurized Milk (Extended Shelf-Life Milk); Liquid Milk Products: UHT Sterilized Milks).

Somatic Cell Count Threshold Affecting Dairy Products

It is difficult to associate a particular SCC with the onset of defects in dairy products. Some researchers have reported that SCC begins to affect product as it increases above 100 000 cells ml^{-1}, while others have suggested that the threshold is closer to 500 000 cells ml^{-1}.

This large variation in the SCC at which the manufacturing properties of milk are affected is probably due to a number of factors. Whether an elevated bulk milk SCC is due to milk from a small number of cows with extremely high SCC being included with milk from a predominantly healthy herd, or to large numbers of cows with low-level subclinical infections, probably contributes to variation in the effects of SCC on dairy products. Additionally, some pathogens affect milk composition in different ways, irrespective of SCC. Similarly, there is evidence that some types of somatic cells can have greater effects on milk composition than others (see below).

It is also likely that other factors such as nutritional status and stage of lactation could affect the magnitude of the impact of mastitis on milk composition and dairy products, possibly through an influence on the immune system of the cow.

Effects of Type of Somatic Cell

Somatic cells in milk are primarily white blood cells, or leukocytes. There are many different types, with the predominant being polymorphonuclear neutrophils (PMNs), macrophages, and lymphocytes. During an infection of the mammary gland, most somatic cells are likely to be PMNs as these cells migrate to the site of infection to perform their function of engulfing and digesting invading bacteria.

Research in Ireland demonstrated that the percentage of PMN in milk can vary between quarters, between cows, and between herds, and that the number of PMN present is correlated with the SCC of the milk. For example, the amount of PMN as a percentage of total leukocytes in bulk herd milks can vary from less than 20% to more than 70%, although the percentage is generally lower in low-SCC milks.

The above observations are important because the effect of PMN on milk composition may be more severe than for other types of cells. This could be a major contributing factor to the large variation in reports of the threshold at which SCC begins to affect the manufacturing potential of milk. It also implies that measuring both the number and the type of somatic cells may be more accurate than measuring only the number of cells, when assessing the manufacturing quality of milk.

Conclusions

Mastitis induces changes in milk composition via a reduction in the synthesis and secretion of milk components, postsecretory breakdown of milk components by hydrolytic enzymes, and 'leakage' of blood constituents into milk. Some of these changes are detrimental to the manufacturing properties of milk, particularly cheese manufacture. Using milk with high SCC for cheese making results in increased coagulation times, elevated cheese moisture contents, decreased cheese firmness, lower recoveries of milk solids in cheese, and reduced cheese yield and yield efficiency.

Introduction

The salt fraction of milk consists of about 8–9 g of matter per liter of milk. It is composed of cations (calcium, magnesium, sodium, and potassium) and anions (inorganic phosphate, citrate, and chloride). These ions are more or less associated between themselves and with proteins. Depending on the type of ion, they are present in the aqueous phase or partially associated with casein molecules to form casein micelles (**Table 1**). The distribution of the ions and salts between aqueous and micellar phases is called salt equilibria.

Citrate is an organic molecule and not a mineral. However, as its contribution in the salt equilibria of milk and dairy products is considerable, it is necessary to take it into account in the salt fraction.

Soluble Salts and Micellar Calcium Phosphate – Milk Salt Equilibria

Table 2 shows the different ionic forms and salts present in milk. Their locations and forms of association are also indicated.

Salts in the Aqueous Phase

In the aqueous phase, ions are free or associated to form salts (**Figure 1** and **Table 3**).

Quantitatively, the interactions between cations and anions in the aqueous phase depend on the values of the different constants of association and the solubilities of the salts. Globally, calcium is ionic (Ca^{2+}) and associated with trivalent citrate Cit^{3-} and, in lesser degree, with inorganic phosphate (as a mixture of $H_2PO_4{}^-$ and HPO_4^{2-}) and chloride. The solubility of calcium phosphate salt is very low and consequently its concentration in the aqueous fraction is less than 1 mmol l^{-1}. Sodium and potassium are present mainly as free ions. A small part of them is associated with citrate, inorganic phosphate, and chloride to form salts. Thus, at pH 6.6–6.7 and by taking into account these different associations, the milk aqueous phase is supersaturated with calcium phosphate and its ionic strength is about 80 mmol l^{-1}.

The Micellar Calcium Phosphate

In the micellar phase, the organization of ions is complex, heterogeneous, and not well defined. The micellar calcium phosphate (MCP) can be described as a mixture of calcium caseinate (containing organic phosphate present in the phosphoseryl residues of caseins) and calcium–inorganic phosphate complex. Concerning the chemical nature of MCP, hydroxyapatite, brushite, and tricalcium phosphate were proposed. These different propositions were not in total agreement and the subject was always controversial. As it is difficult to observe *in situ* the MCP and to isolate it without changing its structure, some experiments are performed to prepare 'experimental MCP'. This preparation is carried out with the phosphopeptide 1–25 of β-casein in the presence of different milk salts, especially calcium and inorganic phosphate. The insoluble calcium phosphate in interaction with phosphopeptide is formed during a

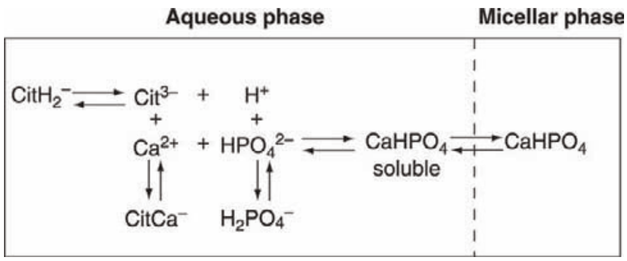

Figure 1 Phosphocalcic equilibria in the presence of citrate ions between aqueous and micellar phases at pH 6.75. In this figure, micellar calcium phosphate (MCP) was basically converted to $CaHPO_4$. Precisions concerning the composition of this MCP are reported in the text.

progressive increase of pH due to the enzymatic transformation of urea in ammonia. The nature, composition, and structure of this calcium phosphate, named nanoclusters, were studied in detail and it is claimed that the physicochemical properties of MCP and nanoclusters are relatively close. Chemically, X-ray absorption and infrared spectroscopy indicate that MCP is close to brushite (dicalcium phosphate). A modified dicalcium phosphate $Ca(HPO_4)_{0.7}(PO_4)_{0.2}$ was proposed after calculation of the apparent solubility product. In the model nanoclusters, it is reported that one casein chain containing four phosphoseryl residues (corresponding to the phosphopeptide 1–25 of β-casein) can bind 13.2 calcium ions. The precise

formula is $[Ca_{13.2}(P_i)_{6.5}Mg_{1.0}Cit_{1.3}SerP_4Cas]_{49}$. Physically and by using diffraction methods and high-resolution transmission electron microscopy, the MCP was determined as amorphous. By cryo-transmission electron microscopy and X-ray scattering, it is observed as small granules of high electron density with an estimated diameter of about 2.5 nm. In the different proposed structural models of the casein micelle, the MCP is an integral part of the casein micelle. Its presence probably contributes to the structure and stability of casein micelles. It is, at the same time, a cross-linking and a neutralizing agent of phosphoseryl residues. According to Holt, a typical micelle with an average radius of 108 nm, say, has a mass of 7.2×10^8 Da, corresponding to about 3000 polypeptide chains and, according to the model, contains 830 calcium phosphate nanoclusters. Caseins with more than one phosphate center per polypeptide chain are able, at least in principle, to cross-link the MCP particles and hence a substantial fraction of all the polypeptide chains.

Milk Salt Equilibria

Even without changes in the physico-chemical conditions, the milk salt equilibria are dynamic, and permanent exchanges of calcium and inorganic phosphate between aqueous and micellar phases exist. Depending on the location of calcium and inorganic phosphate ions in the casein micelles, three types of exchangeability are distinguished: slow, fast to exchange, and non-exchangeable. This last fraction could correspond to calcium and inorganic phosphate associated to the phosphoseryl residues of caseins.

Interspecies Comparison and Correlations between Various Salt Concentrations and Concentrations of Other Constituents

The comparison of the milk salt composition of several species (**Table 4**) to find different interrelationships between these ions is interesting to understand the behavior of this salt fraction.

Thus, it appears that the concentrations of calcium and citrate in the aqueous phase are positively correlated. On the other hand, the micellar concentrations of calcium, magnesium, and citrate are positively correlated with the concentration of MCP. The other correlations well known are between

- casein and calcium concentrations (positive);
- casein and lactose concentrations (negative);
- sodium and chloride (positive).

For milk of all species, the monovalent ions such as sodium, potassium, and chloride are mainly present in the aqueous phase.

All these positive or negative correlations are related to the mechanisms of formation and secretion of milk by the cells of mammary gland.

Variations in the Salt Equilibria as a Function of Physico-Chemical Conditions

The distribution of ions and salts between the aqueous and micellar phases are in equilibria (**Figure 1**). These equilibria depend on the physico-chemical conditions such as variations in pH (acidification or alkalinization), thermal treatments (increase or decrease in temperatures), and additions of different salts and chelatants (**Figure 2**). Theoretically, the modifications of salt equilibria are controlled by the solubility of the calcium phosphate salt in the aqueous phase. The consequences of these changes in the salt equilibria are modifications of the composition, structure, and stability of casein micelles.

Acidification

Acidification is a fundamental step in the manufacture of different dairy products like fermented milks, cheeses, and acid casein. Depending on the rate of acidification, casein molecules precipitate (fast acidification) or are organized to form a gel (slow acidification). During this pH decrease, the different acido-basic groups present in milk, like organic and inorganic phosphate, citrate, and carboxylic residues, bind the protons added or produced *in situ* by microorganisms. This binding of protons by these groups depends on their p*K*a values. The affinities of these different groups for protons are higher than the affinities for calcium ions. The decrease of pH is not linear because these groups, by binding protons, limit the pH decrease. This effect is named buffering capacity. During acidification, the MCP is dissolved (or solubilized) and the caseins are released into the aqueous phase. Up to pH 5.2, calcium and inorganic phosphate are transferred to the aqueous phase. The solubilization of one is strongly correlated to the second one. At pH 5.2, the totality of the inorganic phosphate initially present in the MCP is solubilized. This pH coincides with the maximal value of the buffering capacity of milk. At pH 5.2, a part of calcium is always associated to casein molecules. It is necessary to decrease the pH to 3.5 to observe its total solubilization. At this acid pH, calcium exists mainly as Ca^{2+} in the aqueous phase. The difference of pH required

Figure 2 Modifications of the composition of casein micelles as a function of different physico-chemical conditions.

to obtain the total solubilization of inorganic phosphate (pH 5.2) and calcium (pH 3.5) strengthens the hypothesis that calcium is associated in the casein micelles with inorganic phosphate and phosphoserine residues of casein molecules. During acidification, the anions associated to protons (e.g., chloride, nitrate, or sulfate in the case of acidification by hydrochloric, nitric, or sulfuric acids or lactate in the case of biological acidification) remain in the aqueous phase and contribute to the increase in its ionic strength.

These changes of salt equilibria are irreversible and the original MCP and casein micelles cannot be reconstructed after neutralization of the acidified milk.

Alkalinization

Alkalinization is not a common practice in the dairy sector. However, the consequences of this pH increase were studied to understand the milk salts equilibria. It is reported that alkalinization of milk induces an increase of viscosity and a decrease in its whiteness. The whiteness decreases from pH 8 and is minimal at pH 10. These modifications are related to changes in the structure and stability of casein micelles and especially of the salt fraction. From a mechanistic point of view, the pH increase induces modifications to the state of ionization of inorganic phosphate present in the aqueous phase and of amino groups of proteins. HPO_4^{2-} is transformed to PO_4^{3-}, which has a higher affinity for calcium compared to HPO_4^{2-}, and this triply ionized form reacts with calcium. Consequently, the calcium exclusively in interaction with the phosphoseryl residues of casein micelles is shifted toward the PO_4^{3-} to form calcium phosphate salt. As the calcium phosphate in the aqueous phase is saturated, the amounts of calcium and inorganic phosphate in the aqueous phase decrease, suggesting precipitation of this salt. The chemical and physical structures of the newly formed calcium phosphate are not well defined. The use of different microscopic studies has failed to observe and characterize these new salts of calcium phosphate. This result suggests a size of the order of a few nanometers. The initial calcium inorganic phosphate present in the micellar phase is not changed during alkalinization. The concentration of sodium from NaOH increases with the increase in pH. This ion remains in the aqueous phase and contributes to the increase in the ionic strength. In parallel to these changes in the salt equilibria, it is probable that the protein–protein and protein–water interactions are affected because the state of ionization of proteins is also affected by the increase in pH.

Thermal Treatments

Heat treatment is a common operation in the dairy industry. The most commonly used heat treatments are pasteurization (with low or high intensities), ultra high temperature (UHT) treatment, and sterilization. The aim of these treatments is to destroy pathogens to ensure a safe product. During heating, several biochemical reactions occur like denaturation of whey proteins, Maillard reactions, proteolysis, deamidation, destruction of some vitamins, and alterations of the salt equilibria. These modifications depend on the intensity of the heat treatment. Concerning the salt equilibria, it is known that when the milk temperature increases, the dissociation of inorganic phosphate present in the aqueous phase increases. Consequently, part of $H_2PO_4{}^-$ is transformed to HPO_4^{2-}, which has a higher affinity for calcium than $H_2PO_4{}^-$ and reacts with calcium to form a calcium phosphate salt. The aqueous phase being supersaturated in this salt, the concentrations in calcium and inorganic phosphate are reduced in this phase. The extent of these decreases depends on the intensity of the applied heat treatment. If the heat treatment is less than 95 °C for few minutes, the modifications of salt equilibria are reversible after cooling. If the heat treatment is severe (more than 100 °C for several minutes), alterations of the salt equilibria are irreversible. On the other hand, during intense heat treatments, casein molecules can be dephosphorylated. In these cases, the decreases of calcium and phosphate contents in the aqueous phase do not correspond to a simple precipitation of calcium phosphate. It is noteworthy that for severe heat treatment, some changes in the structure and composition of the MCP are observed. The newly formed phase is not clearly identified but it is related to the formation of crystalline β-tricalcium phosphate or hydroxyapatite.

Cooling

Inversely to the heat treatments, the dissociation of inorganic phosphate present in the aqueous phase decreases when the milk is cooled and part of HPO_4^{2-} is transformed into $H_2PO_4^-$ form. In this case, the solubility of calcium phosphate increases and the concentrations of calcium and inorganic phosphate increase in the aqueous phase, indicating that part of MCP (about 10%) is transferred to the aqueous phase. Simultaneously, β-casein is solubilized and the casein micelles become more hydrated. These changes are reversible and the previous partition may be re-established after re-warming.

Addition of Chelatants

It is known that the addition of chelatants of calcium like citrate, EDTA, oxalate, or cation-exchange resins to milk or to suspensions of casein micelles induces a decrease of lightness, an increase of viscosity, and an improvement of the heat stability. This last result is specially applied in the dairy sector. All these physico-chemical changes suggest a loss of the micellar structure. The explanations can be related to the modifications of the milk salt equilibria. Indeed, these different types of chelatants have high affinity for calcium present in the aqueous phase. Their affinity for calcium depends on their association constant. Consequent to this chelating action, the aqueous phase becomes less saturated in calcium phosphate and the salt equilibria are shifted from the micellar to the aqueous phase with increases of calcium and inorganic phosphate contents in the aqueous phase. At the same time, the pH of milk increases. This pH increase is probably due to a binding of free protons when the calcium is displaced from phosphate (organic or inorganic) toward the aqueous phase. The solubilization of calcium is positively correlated to those of inorganic phosphate, confirming the strong relation of both ions in the micellar structure. Indeed, these solubilizations are due to a disruption of the MCP causing a destruction of casein micelles.

Addition of NaCl

There are few industrial applications using the NaCl addition to milk but some scientific studies have been conducted to understand the changes of salt equilibria induced by NaCl addition. In these studies, the effects on the physico-chemistry of casein micelles were also studied. Globally, it is described that NaCl addition alters the salt equilibria and protein ion interactions and consequently the milk becomes more viscous. At the same time, the casein micelles become more hydrated suggesting some changes in the interactions between proteins and water molecules. At the same time, a reduction in pH is observed (a decrease of 0.1–0.3 pH units after addition of NaCl to more than 0.1 mol l^{-1}). At this level of NaCl, an increase in calcium concentrations in the aqueous phase is observed. From a mechanistic point of view, these changes are due to some exchanges between added sodium and (1) calcium bound to organic phosphate and (2) protons present in the casein micelles. To interpret this slight calcium solubilization, it is necessary to take into account the effect of the ionic strength which is increased. This increase reduces the activity coefficients and increases the dissociation of ion pairs. It is noteworthy that some authors report also a solubilization of inorganic phosphate and β-casein after NaCl addition.

Addition of Calcium

For nutritional and technological reasons, the calcium enrichment of milk and dairy products is often performed in the dairy industry. Depending on the physical and chemical nature of the calcium salts added, the salt equilibria are modified differently. If the salts added have low solubility like calcium phosphate, the salt equilibria and the casein micelles are not modified. If the calcium salts are soluble, like calcium chloride or calcium lactate, the physico-chemical characteristics of casein micelles are changed strongly. For example, it is reported that their zeta potential (casein micelles become less negative), hydration, and heat stability are reduced and the whiteness and turbidity of milk are increased. At the same time, the salt partitions between aqueous and micellar phases are altered. Thus, it is suggested that one part of the added calcium reacts with inorganic phosphate present in the aqueous phase, resulting in the formation of calcium phosphate with a release of protons, and the pH decreases (which can be regulated). Then, since the aqueous phase is saturated in this salt, the newly formed calcium phosphate is 'shifted' toward the casein micelles. The nature and the mode of association of this salt to the casein micelles are not known precisely. It is also important to note that part of the added calcium remains in the aqueous phase in the ionic form or associated to citrate molecules. The counter-ions of the added calcium salt (e.g., lactate or chloride) remain in the aqueous phase and increase the ionic strength. The intensity of these modifications depends on the concentration of the added salt, the eventual modification and regulation of the pH after calcium addition.

Analysis of Milk Salts

The determination of the total concentrations and the distribution of these different ions and salts between the aqueous and micellar phases of milk are often useful and interesting to control the biochemical and functional changes in dairy products during their manufacture. It is necessary to prepare the sample correctly and to use the correct analytical methods.

Preparation of Samples

Preparation for the determination of total ion content

Dry and wet ashing are the possible ways to destroy proteins, fat, and lactose before the determination of the ions contained in milk or dairy products. If the sample is milk, the micellar and aqueous phases are distinguished.

Dry ash is the material that remains after heating for several hours in the temperature range 400–800 °C. On the other hand, this mineralization induces the destruction of citrate and transforms organic phosphates (phosphate groups esterified to serine residues of caseins or to several small molecules) into inorganic phosphate. Chloride ions are volatilized if the dry ashing is performed at a temperature higher than 550 °C. After mineralization, the ash can be dissolved in dilute HCl or HNO_3 solution and one or several ions can be determined specifically. No specific reagents are required to do this dry ashing which can be applied to relatively large amounts of sample. Wet ashing corresponds to an acid digestion in a solution with the oxidation/destruction of organic matter. This preparation requires the use of various acid mixtures of HNO_3, H_2SO_4, and $HClO_4$ and is limited by the amounts of sample. However, to reduce the consumption of acids, it is possible to digest samples under high pressure in sealed and specific tubes. An alternative to obtain the total content is to perform an extraction with acid solutions. The acidification of milk to pH 3.0 causes the total transfer of calcium, magnesium, inorganic phosphate, and citrate from casein micelles to the aqueous phase and precipitates the caseins and whey proteins (if trichloroacetic acid is used). The determination of ions can be performed on the filtrate. It is noteworthy that during acid extraction, the organic phosphate corresponding to phosphoserine residues is not solubilized. To obtain this organic phosphate, enzymatic dephosphorylation by phosphatase is necessary.

Preparation for the determination of the concentration of ions in the aqueous phase

The aqueous phase can be recovered by ultrafiltration, ultracentrifugation, or rennet coagulation of milk.

For ultrafiltration, the molecular weight cut-off of the membrane should be close to 10 000 Da. Under this condition, the ions and salts present in the aqueous phase of milk pass through the membrane. The advantage of this preparation is that the aqueous phase obtained is free of protein. Ultrafiltration can be performed at a large range of temperature (between 4 and 50 °C) with a small volume of milk (2 ml minimum). However, as the filtration is frontal, a fouling occurs and can limit the recovery of a large volume of aqueous phase. Another disadvantage is that the units of filtration are often quite expensive. Depending on the supplier, some of them are for only one use and there is no problem of contaminating ions.

Typically, ultracentrifugation at 80 000 *g* for 2 h or 100 000 *g* for 1 h is performed to obtain the supernatant. In this case, the aqueous phase contains not only soluble ions and salts but also ions associated with serum proteins especially α-lactalbumin, which has in its structure one calcium ion per molecule. The concentration of this type of calcium corresponds to the concentration of α-lactalbumin in the aqueous phase of raw milk. The value is lower than 0.1 mmol l^{-1} which can be considered as negligible compared to the concentration of 10 mmol l^{-1} of calcium in the aqueous phase and to the sensitivity of the method used to determine the calcium concentration. This method requires an ultracentrifuge which is expensive. With this method, the use of ultracentrifugation tubes previously washed with acid solution and rinsed with demineralized water is obligatory.

For the recovery of the cheese whey, it is necessary to coagulate the milk by an enzyme like rennet, cut the gel, recover the whey, and filter it before the determination of minerals. This method is relatively rapid, simple, and not so expensive than ultrafiltration or ultracentrifugation. In this case, the aqueous phase obtained may contain serum proteins and casein micelles, which bind minerals, including calcium. Moreover, the enzymatic solutions used to coagulate the milk can contain sodium and chloride ions. This must be taken into account in the interpretation of results. It is noteworthy that the enzymatic action of rennet is very limited at low and high temperatures. At a low temperature (<20 °C), the activity is reduced, and at a high temperature (>50 °C), the enzyme can be denatured.

For connecting the concentrations determined in these different aqueous phases to the concentration existing in the milk, it is necessary to multiply the determined concentration by 0.96, which takes into account the excluded volume effect.

Analytical Determinations of Ions in Milk and Dairy Products

The concentrations of the main ions in milk are determined by different techniques which are classified according to their principles. Molecular absorption spectrometry, complexometric methods combined with titration, electrochemical methods (ion-selective electrode), atomic spectrometry, enzymatic methods, and separative methods (chromatography or capillary electrophoresis) are the most used and described (**Table 5**).

Table 5 Analytical methods for ion quantification in milk and dairy products. Depending on the sample preparation and the analytical method used, P can exist in different forms (**Table 2**)

	Ca	*Mg*	*Na*	*K*	*P*	*Cl*	*Citrate*
Atomic spectroscopic methods	x	x	x	x			
Titration	x	x				x	
Selective electrode	x		x			x	
Spectrophotometric method	x				x	x	x
Ionic chromatography	x	x	x	x	x	x	x
Capillary electrophoresis					x	x	x
Enzymatic method							x

Atomic spectroscopic methods

The atomic spectroscopic methods are rapid and accurate to determine the content of calcium, magnesium, sodium, and potassium in milk and dairy products. The best method is atomic absorption spectrometry but other techniques, like flame atomic absorption spectrometry, graphite furnace atomic absorption spectrometry, inductively coupled plasma atomic emission spectrometry, and inductively coupled plasma mass spectrometry, are available.

Titration

Calcium can be determined by its precipitation as calcium oxalate followed by titration of the excess of oxalate by a $KMnO_4$ solution. It is also possible to titrate calcium directly with the chelating agent, EDTA, in the presence of murexide that changes its color when it binds calcium. In a similar way, magnesium can also be determined by this method. In the case of a dairy mixture containing calcium and magnesium, the magnesium concentration is obtained as the difference between the two titrations, one with an indicator like murexide that measures calcium and the other with eriochrome black that detects both calcium and magnesium.

The method of Mohr is a classical method to determine chloride ions. It involves adding $AgNO_3$ to the dairy liquid to form a precipitate of AgCl. In dairy analyses, automatic equipments may be used to titrate automatically chloride ions with silver ions. When titration is complete, conductivity of the solution increases which can be sensed by electrodes causing the titration to stop. The instrument uses the elapsed titration time to calculate the chloride content.

Traditional methods for measuring sodium generally involve titration of chloride in the sample with silver nitrate with an indicator (potassium dichromate) for the end point. These methods are specific for chloride and indirectly measure sodium ion.

Ion-selective electrodes

They are used in conjunction with a reference electrode to form a complete electrochemical cell. The logarithm of the activity of a given ion in solution is correlated with the measured potential differences (ion-selective electrode vs. outer reference electrode potentials). Calcium, sodium, and chloride concentrations in milk and different dairy products (after adequate sample preparation) can be determined by these ion-selective electrodes.

Spectrophotometric methods

The calcium concentration can be measured in the presence of glyoxal-bis-(2-hydroxyanil), by forming a complex having an absorption maximum at 524 nm. This ion is also determined in the presence of *o*-cresolphthalein complexone and 2-amino-2-methylpropan-1-ol. The calcium–cresolphthalein complexone complex absorbs at 580 nm and pH 12.0.

The method of Briggs is a classical method to determine phosphorus concentrations. Under reducing conditions (presence of vitamin C or sulfite and hydroquinone), phosphorus reacts with molybdate (or vanadate) to form a blue complex, phosphomolybdate. This compound has a maximal absorption at 700 nm.

The content of citrate can be determined by measuring the absorbance of a product resulting from its reaction with pyridine in acetic anhydride. Another method for citrate determination is based on the complexation of Cu^{2+} by citrate. The complex formed absorbs at 280 nm. During enzymatic degradation of citrate in the presence of citrate lyase, malate dehydrogenase, lactate dehydrogenase, and NADH, H^+, the absorbance decrease of NADH, H^+ followed at 340 nm is proportional to citric acid concentration.

Ionic chromatography and capillary electrophoresis

The principal anions of milk and dairy products (chloride, inorganic phosphate, and citrate) can be separated by anion-exchange chromatography or by capillary electrophoresis. In both cases, the separation principle is based on differences in the charge-to-mass ratio of the ions analyzed. Their detected areas after elution are proportional to their concentration.

Theoretical Calculation of the Salt Equilibria

The different forms and location of ions and salts (**Tables 2** and **3**) in milk and dairy products are not all measurable experimentally and it is impossible, for example, to measure the amounts of calcium citrate and calcium phosphate in the aqueous phase. In this context, different research works were developed to calculate theoretically the salt equilibria. In the 1980s, calculation of the different ions and salts present only in the aqueous phase was described. Two studies proposed the theoretical calculation of the salt equilibria in milk by integrating the complexity of the micellar phase. The first study proposed by Holt in 2004 used a generalized empirical formula to calculate the composition of the nanoclusters containing calcium, magnesium, inorganic phosphate, and citrate in association with casein phosphorylated sequence named phosphate center. In addition, the mole fractions of the individual caseins not complexed to the calcium phosphate through one or more of their phosphate centers are included in the calculations. The calculated partition of salts between diffusible and non-diffusible fractions is well correlated with experimental values determined by other authors. The second model of calculation, proposed by Mekmene *et al.* in 2009, integrates

- affinities between cations (calcium, magnesium, potassium, and sodium) and anions (phosphoseryl residues and carboxylic groups of casein molecules, inorganic phosphate, chloride, and citrate) which contribute to the salt equilibria in milk and dairy products;
- pH;
- ionic strength of the aqueous phase; and
- solubility of calcium phosphate.

Good correlations between the calculated and experimental values are obtained. This second model offers the possibilities to calculate the distribution of ions and salts not only between aqueous and micellar phases in native milk but also under different physico-chemical conditions. These calculations constitute new and interesting tools to simulate salt equilibria in milk and dairy formulations containing different concentrations of minerals and caseins.

Conclusion

Research on the milk salt of milk has been conducted since the early 1900s and the knowledge concerning this fraction is gradually increasing. Today, and even if some questions are not totally resolved (chemical and physical nature of the MCP, its implication in the structure and stability of casein micelles), it can be considered that the salt composition and the salt equilibria are well described in native milk and also as a function of different physico-chemical conditions (pH and temperature variations, additions of supplementary salts). The use of different analytical methods to locate and quantify the different ions and salts present in milk and dairy products is probably a reason of this progress. This relatively good understanding of the milk salt equilibria is also confirmed by the good correlations found between the experimental determinations and values calculated theoretically.

This article is reproduced from the previous edition, Volume 3, pp 2007–2015, © 2002, Elsevier Ltd. with revisions made by the Editor.

Introduction and Definitions

The subjects of this article are the citrate (Cit), orthophosphate (P_i), and Cl^- salts of H^+, K^+, Na^+, Mg^{2+} and Ca^{2+}. These are the milk salts, though tradition also sanctions the use of the terms minerals or inorganic constituents for these components in spite of the fact that citrate salts are neither inorganic nor a mineral. The equilibria among these small ions cannot be considered in isolation because they interact strongly with other milk components, principally the Ca-sensitive caseins, β-, α_{S1}- and α_{S2}-caseins. For this reason, it is necessary to include some discussion of the structure of the colloidal particles in milk known as casein micelles.

Concentrations of the milk salts or individual ions are expressed here in units of mmol l^{-1} of skim milk, rather than in traditional units such as mg per 100 g milk because molar units form the basis for a thermodynamic treatment of the equilibria between the ions. Some aquatic mammals secrete milk with more than 50% fat so it is important to distinguish between whole and skim milk concentrations. Milk salts can be partitioned into diffusible and non-diffusible fractions by equilibrium dialysis or low pressure ultrafiltration across a membrane of suitable porosity. The concentrations in milk serum are denoted by a subscript s and non-diffusible or colloidal concentrations by a subscript c. Square brackets around a chemical symbol or anion abbreviation denote molar concentration and curly brackets, thermodynamic activity.

Secretory Mechanisms

Interrelationships of the Concentrations of the Monovalent Ions

Variations in the concentrations of the most osmotically important constituents of cows' milk show two different patterns of behavior. In healthy cows in mid lactation there is an inverse relation between lactose concentration, [L], and $[K^+]$ or $[K^+] + [Na^+]$ which is explained as a result of the drawing-in of water into milk to maintain a constant osmotic pressure during lactose synthesis. A notable result is the effect of insulin infusion of the goat that depresses lactose synthesis and reduces [L] in the milk while increasing [Casein]. A negative correlation of [L] and $[K^+]$ is found according to eqn [1] but $[Na^+]$ is unaffected.

$$[L] = 229.4 - 2.08(\pm 0.70)[K^+] \qquad [1]$$

On the other hand, at the end of lactation or during severe mastitic infection, the tendency is for $[Na^+]$ to be inversely related to [L] and $[K^+]$ and directly related to $[Cl^-]$. The observations can be explained as due to the mixing of the milk with an extracellular fluid rich in NaCl. Some examples of the two different patterns of interrelationships are shown in **Figure 1**.

Transcellular and Paracellular Routes of Secretion

The largely empirical knowledge of monovalent ion movements can be put into a wider physiological context of secretory mechanisms known as the transcellular and paracellular routes. According to a widely accepted scheme, $[K^+]$ and $[Na^+]$ will tend to attain electrochemical equilibrium across the apical membrane of the mammary secretory cell but in early or late lactation or during severe mastitic infection, the normally tight junctions between the mammary secretory cells become leaky and ions and other small molecules such as lactose can exchange with the NaCl-rich extracellular fluid. Since milk and blood have about the same osmolarity, Π, we can write:

$$\Pi = \text{constant} = \{L\} + \{Na^+\} + \{K^+\} + \{Cl^-\} + \cdots \text{smaller terms} \qquad [2]$$

so that $[K^+]$ is normally positively correlated with the other main ions and negatively correlated with [L], whereas, when the paracellular route overwhelms transcellular equilibration, $[K^+]$ becomes negatively correlated with $[Na^+]$ and $[Cl^-]$. Contrary to this theory, $[Na^+]$ and $[K^+]$ are uncorrelated with [L] in human milk but directly proportional to [Casein], which suggests that in high [L] milks, where serum salt concentrations are low, neutralization of net protein charge to achieve overall electrical neutrality becomes the dominant factor.

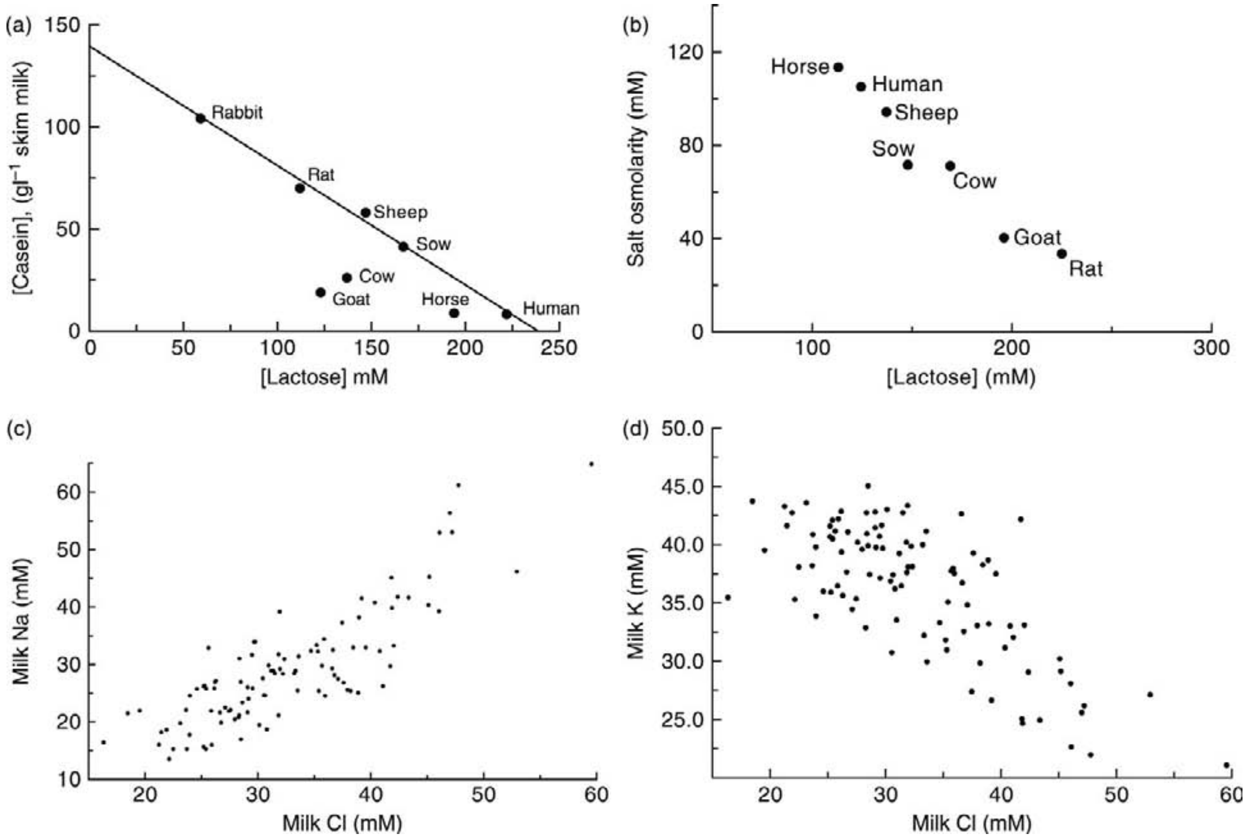

Figure 1 Direct and inverse correlations of the concentrations of lactose, casein and the monovalent ions. (a) Negative correlation of casein and lactose concentrations in the milks of eight species. (b) Negative correlation of calculated salt osmolarity with lactose concentration in milks of seven species. (c) Positive correlation of Na and Cl concentrations in the milk of individual Ayrshire cows at all stages of lactation. (d) Negative correlation of [K] with [Cl] in the milk of individual Ayrshire cows at all stages of lactation.

Lactose is synthesized in Golgi vesicles and transported to the apical membrane where exocytosis of the vesicle contents allows the aqueous phase of milk to accumulate in the alveolar lumen. This transcellular route is also followed by the great majority of the milk proteins and multivalent ions. Ca and P_i are concentrated in the vesicle by transport mechanisms that are far from clear and combine with caseins to form colloidal particles called casein micelles.

The sequestration of calcium phosphate by caseins is thought to provide a means by which this very insoluble material can be safely transported through the mammary gland, in high concentration in most species, without causing pathological calcification.

Vesicles appear to swell as they move toward the apical membrane. The swelling may be an osmotic dilution due, in eutherians, to lactose synthesis and the extent of swelling can be calculated from a simple theory which allows for a coupling of lactose synthesis to net anion transport through a coupling constant, ω. Assuming a constant concentration of casein in the unswollen vesicle, $[\mathrm{Casein}]_u$, the final concentration in milk is:

$$[\mathrm{Casein}] = \left(1-(1+\omega)\frac{[\mathrm{L}]}{\Pi}\right)[\mathrm{Casein}]_u \qquad [3]$$

which correctly predicts the negative correlation of [L] and [Casein] seen among 31 species. A maximum casein concentration of around $135\pm35\,\mathrm{g\,l^{-1}}$ is predicted.

Total Concentrations

Interspecific Variation

Our knowledge of the composition of milks is very sketchy. Of the 4000 or so extant species of mammals, the milk composition of only 200–300 has been reported in outline and only 30–40 have been sampled from three or more females. A nearly complete picture of the total and serum concentrations of the main salts is available for only about a dozen, common, domesticated or laboratory model species, and humans. Even in this small sample, the pattern of change from early to copious milk secretion is sufficiently diverse to make generalization dangerous. For example, a rise in citrate concentration seen in the early lacteal fluid of goats, cows, and women is the harbinger of copious milk

Table 1 Total concentrations (mmol l^{-1} skim milk) of salts in the milk of seven species

	Rat	*Sow*	*Sheep*	*Goat*	*Cow*	*Mare*	*Human*
Ca	80.5	49.6	56.8	23.1	30.1	16.5	7.3
Mg	8.8	4.1	9.0	5.0	5.1	1.6	1.4
P_i	54.2	24.4	39.7	15.6	20.9	6.7	2.2
Cit	0.06	8.4	4.9	5.4	9.8	3.1	2.2
Na	38.3	14.4	20.5	20.5	25.5	5.7	4.7
K	43.6	31.4	31.7	46.6	36.8	11.9	15.2
Cl	36.1	28.7	17.0	34.2	30.3	6.6	6.2
Casein[a]	2.97	1.75	2.46	0.80	1.11	0.35	0.41

[a] Assumed relative molecular mass of 23 600.

secretion but the rise occurs well before parturition in the horse and does not occur in either sows' or sheep milk. **Table 1** gives a summary of total concentrations of salts in seven species, representing a substantial part of the whole range of variation of composition in the few eutherian species that have been examined in sufficient detail.

The total milk concentrations are not arbitrarily determined because they are constrained by the secretory mechanism and physicochemical principles. In eutherians, [L] and [Casein] are negatively correlated because lactose synthesis draws water into the Golgi vesicle to dilute the proteins. [Casein], [Ca] and [P_i] are all positively correlated because they are largely present as a definite chemical substance, micellar calcium phosphate.

Variation in Cows' Milk

The variation in cows' milk is smaller than that seen among other species and occurs mainly in early and late lactation. In an individual, healthy cow throughout the greater part of lactation, milk salt composition is nearly constant, though there are consistent differences between animals. **Table 2** gives average values for total salt concentrations in the milk of Ayrshire cows in early, middle and late lactation and in milk from cows with sub clinical mastitis.

Table 2 Average values for pH and total salt concentrations in the skim milk of Ayrshire cows in early, middle and late lactation and from cows with sub-clinical mastitis[a]

	Early	*Middle*	*Late*	*Mastitic*
Ca	33.2	29.4	32.1	29.4
Mg	5.7	5.0	5.4	4.9
P_i	19.4	20.9	18.4	19.0

Serum Concentrations

Inter- and Intra-specific Differences

In cows' milk about one-third of the Ca, half the P_i, two-thirds of the Mg and over 90% of the Cit are in the milk serum but the proportions vary between species. However, in all species the K^+, Na^+, and Cl^- are nearly all in the serum. Total and serum [Cit] vary from virtually zero in the rat or mouse to more than 10 mmol l^{-1} in some ruminant species and the rabbit. In Scotland and some other countries, cows' milk citrate shows a seasonal variation associated with the 'spring flush' when the cows first go out to grass. The temporary depression by up to 1–2 mmol l^{-1} for about a month is probably directly related to steady state levels of citrate in the cytosol and the need for NADPH in fatty acid synthesis. **Table 3** gives some representative serum concentrations for seven species.

Interrelationships of the Serum Multivalent Ion Concentrations

There is a close positive correlation of $[\mathrm{Cit}]_s$ with $[\mathrm{Ca}]_s$ and generally also with $[\mathrm{Mg}]_s$, for variations among and within species, as shown in **Figure 2**.

The correlations of $[\mathrm{Ca}]_s$ with $[\mathrm{Cit}]_s$ shown in **Figure 2** are generally improved if $[\mathrm{Ca}]_s - [\mathrm{Ca}^{2+}]$ is plotted on the ordinate. The reason is that there is a pH dependence to $[\mathrm{Ca}^{2+}]$, caused by equilibria with the micellar calcium phosphate. The pH-related correlations for cows' milk are shown in **Figure 3**.

Multiple Ion Equilibria in the Serum

The multivalent ions and H^+ interact strongly in milk serum and this is why $[\mathrm{Ca}^{2+}]$ is normally less, and sometimes much less, than $[\mathrm{Ca}]_s$. The principal equilibria in cows' milk are the following:

$$\mathrm{Ca}^{2+} + \mathrm{Cit}^{3-} \rightleftharpoons \mathrm{CaCit}^- \qquad [4]$$

$$\mathrm{Mg}^{2+} + \mathrm{Cit}^{3-} \rightleftharpoons \mathrm{MgCit}^- \qquad [5]$$

Table 3 Serum concentrations of milk salts for seven species

	Rat	*Sow*	*Sheep*	*Goat*	*Cow*	*Mare*	*Human*

$$\mathrm{H}^+ + \mathrm{HPO}_4^{2-} \rightleftharpoons \mathrm{H_2PO}_4^- \qquad [6]$$

$$\mathrm{Ca}^{2+} + \mathrm{HPO}_4^{2-} \rightleftharpoons \mathrm{CaHPO}_4 \qquad [7]$$

The formation of a strong and soluble complex of the divalent cations with citrate is the reason for the positive correlations shown in **Figure 2**. It is possible to construct a full model of all the important ion equilibria in milk serum and, using appropriate ion activity coefficients, convert the derived activities to concentrations. **Table 4** summarizes one such calculation of the main ion species for a typical serum for cows in mid lactation.

The explanation for the correlations in **Figure 3** is quite involved but to a reasonable approximation can be obtained in the following way. The complex $\mathrm{CaHPO_4}$ is a weak one but of very limited solubility. Essentially, it goes on to form micellar calcium phosphate and the serum activities of the ions are constrained by a phase equilibrium condition:

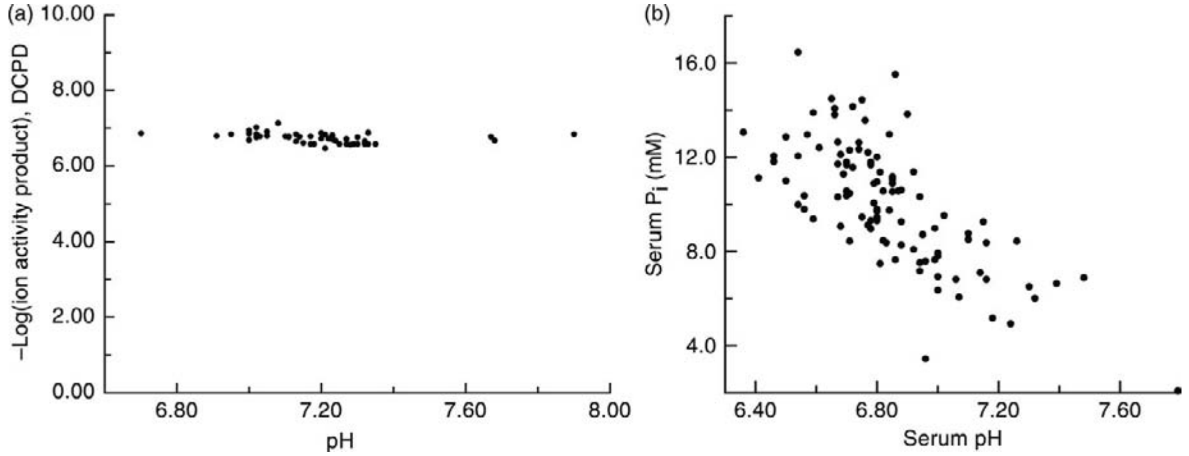

Figure 3 The pH related correlations of milk salt concentrations in cows' and human milk serum. (a) Apparently invariant ion activity product for a dicalcium phosphate salt in human milk sera. (b) Dependence of serum P_i concentration on pH in cows' milk.

Table 4 Summary calculation of the concentrations (mmol l^{-1}) of the main ion species in a typical milk diffusate[a] from cows in mid-lactation

		Cation complex			
Anion	*Free ion*	*Ca^{2+}*	*Mg^{2+}*	*Na^{+}*	*K^{+}*
Cit^{3-}	0.26	6.96	2.02	0.03	0.04
H_2PO^{4-}	7.50	0.07	0.04	0.10	0.18
HPO_4^{2-}	2.65	0.59	0.34	0.39	0.52
Cl^{-}	30.9	0.26	0.07	0.39	0.68
Free ion		2.00	0.81	20.92	36.29

[a] [Ca], 10.2; [Mg], 3.4; [Na], 22.0; [K], 38.0; [Cl], 32.3; [Cit], 9.4; [P_i], 12.4; [Glucose-1P], 2.6; [SO_4], 1.2; [CO_2], 0.44; [RCOOH], 3.1; pH, 6.70; Γ/2, 73 (calculated).

$$K_s = \{Ca^{2+}\} \times \{HPO_4^{2-}\} \qquad [8]$$

where K_s is an ion activity or solubility product. An invariant ion activity product of the form of eqn [8] is shown in **Figure 3(a)** for human milk. Similar relationships have been found in cows', goats', and sows' milk.

Since

$$[P_i]_s \approx [HPO_4^{2-}] + [H_2PO_4^{-}] \approx \{HPO_4^{2-}\} + \{H_2PO_4^{-}\} \qquad [9]$$

and

$$K_{H_2PO_4^-} = \frac{\{H_2PO_4^-\}}{\{HPO_4^{2-}\}\{H^+\}} \qquad [10]$$

the combination of eqns [8], [9], and [10] gives:

$$p\{Ca^{2+}\} \approx pK_s + p\left(1 + K_{H_2PO_4^-}\{H^+\}\right) - p[P_i]_s \qquad [11]$$

The precise form of the solubility relationship is more complex than eqn [8] but it is close enough to illustrate why, in eqn [11], natural variations in $[Ca^{2+}]$, pH and $[P_i]_s$ are interdependent, as shown in **Figures 3(a)** and **3(b)**.

Colloidal Concentrations

Interspecific Differences

Some values of colloidal concentrations for seven species can be readily derived by subtraction of the serum values in **Table 3** from the corresponding total concentrations in **Table 1**.

Interrelationships of the Concentrations of the Multivalent Ions

Both interspecific variations and intraspecific natural variations in the milk of cows, goats, and women show positive correlations of $[Ca]_c$, $[Mg]_c$, $[P_i]_c$, and [Casein] (**Figure 4**). Although comparably detailed data on the partition of milk salts are not available for many other species, the positive correlation between [Ca] and [P] in a number of other milks suggests that the micellar calcium phosphate is the predominant form of Ca in most milks, apart from primate, equine, and rhinoceros milks, where the casein concentration is quite small. The $[Ca]_c$, $[Mg]_c$, and $[P_i]_c$ also show positive correlations with intraspecific natural variations of $[Cit]_c$ in the cow and goat but not in womens' milk where the smaller concentrations give large errors in the determination of $[Cit]_c$. Moreover, inter-specific correlations of $[Cit]_c$ with any of the other colloidal components tend to be rather poor.

Some examples of the correlations of colloidal constituents both within and among species are shown in **Figure 4**.

Calcium Phosphate Nanoclusters and Micellar Calcium Phosphate

Calcium phosphate nanoclusters are nanometer-sized particles with a core of calcium phosphate and a shell of

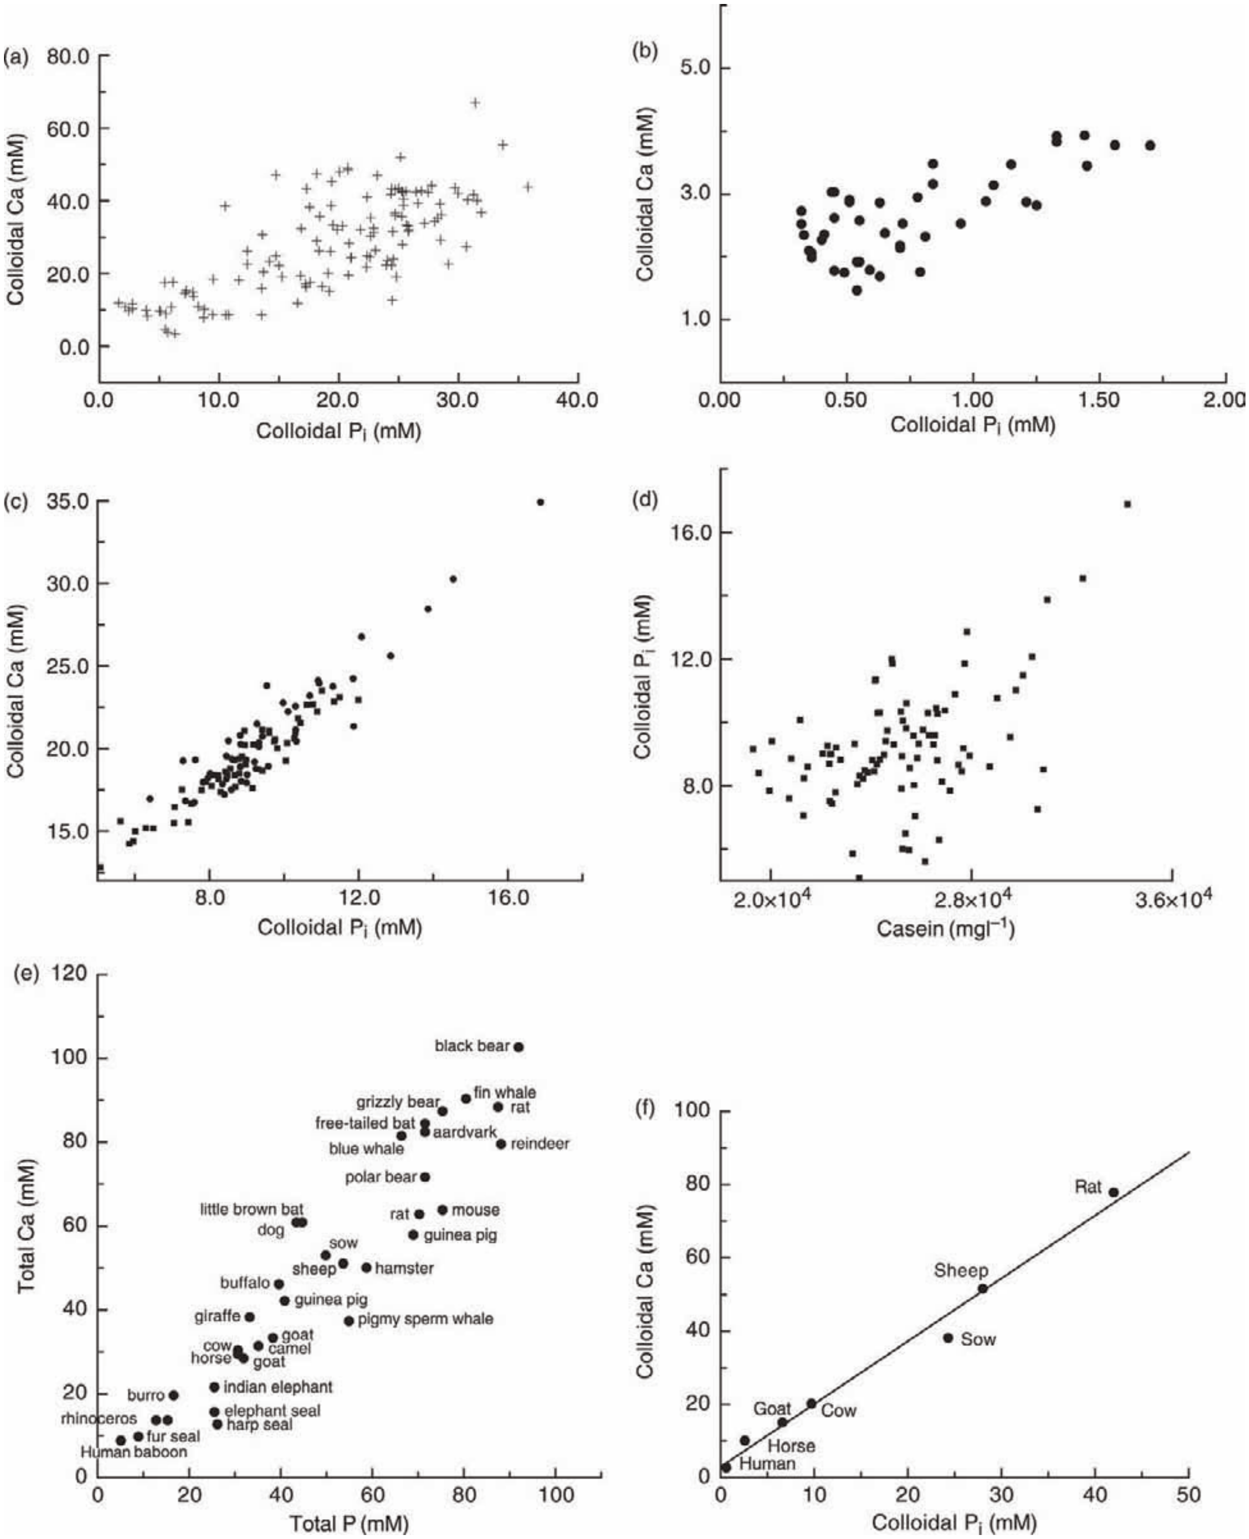

Figure 4 Some examples of the positive correlations of colloidal constituents, both within and between species. (a) $[Ca]_c$ and $[P_i]_c$ in sows' milk before, during, and up to 9 days after farrowing. (b) $[Ca]_c$ and $[P_i]_c$ in human milk. (c) $[Ca]_c$ and $[P_i]_c$ in cows' milk. (d) $[P_i]_c$ and [Casein] correlation in cows' milk. (e) Total Ca and P in 37 species. (f) $[Ca]_c$ and $[P_i]_c$ in seven species.

casein phosphopeptide. They form spontaneously from a solution containing 1.6 mmol l^{-1} phosphopeptide from the N-terminal region of β-casein, β-casein 4P (f1–25), together with milk salts at about the same concentrations as in cows' milk. The partition of salts in the nanocluster solution at pH 6.7, close to the natural pH of the milk, is essentially the same as in cows' milk and, in all other respects, the properties of the calcium phosphate in the nanoclusters closely approximate the known properties of the natural micellar calcium phosphate in cows' milk. The chemical formula of the nanoclusters is relatively invariant:

$$\left[\mathrm{Ca}_{13.2}(\mathrm{P_i})_{6.5}\mathrm{Mg}_{1.0}\mathrm{Cit}_{1.3}\mathrm{Casein}_{1.0}(\mathrm{SerP})_4\right]_{49} \qquad [12]$$

that is, there are 13.2 Ca ions per casein chain and the chain has 1 phosphate centre containing 4 phosphoserine (SerP) residues. A general formula for the composition of micellar calcium phosphate can be derived:

$$\left[\mathrm{Ca}_{13.2}(\mathrm{P_i})_{6.5}\mathrm{Mg}_{1.0}\mathrm{Cit}_{1.3}\mathrm{Casein}_{1/\bar{F}_b}(\mathrm{SerP})_s\right]_{49} \qquad [13]$$

where $\bar{F}_\mathrm{b}$ (≈1.6 in cows' milk) is the functionality or the average number of phosphate centers on Ca-sensitive caseins that are directly bound to the calcium phosphate through one or more of their phosphate centres. Equation [13] can be used to calculate the concentration of all the colloidal salts from a measurement of any one of them. The theoretical basis of the calculation derives from a simple model of casein micelle structure in which the micellar calcium phosphate is bound to a mol fraction, α, of all the phosphate centers in the caseins. The assumption is that micellar calcium phosphate has a defined and constant chemical formula as specified by the stoichiometric coefficients in eqn [13]. The concentration of unbound phosphate centers is then $(1-\alpha)\bar{F}_w[\mathrm{Casein}]$, where $\bar{F}_w$, (≈ 1.4 in cows' milk), is the number average functionality of whole casein. These unbound functionalities can then act as binding sites for small ions in competitive equilibria to give, principally, the isotherm functions $\bar{v}_\mathrm{Ca}$, $\bar{v}_\mathrm{Mg}$, and $\bar{v}_\mathrm{H}$ in units of mol ion per mol phosphate center. For example, the total colloidal concentrations of Ca and Mg are given by:

$$[\mathrm{Ca}]_\mathrm{c} = \bar{F}_\mathrm{w}[\mathrm{Casein}](13.2\alpha + (1-\alpha)\bar{v}_\mathrm{Ca} \times (\mathrm{pH}, \{\mathrm{Ca}^{2+}\}, \{\mathrm{Mg}^{2+}\})) \qquad [14]$$

$$[\mathrm{Mg}]_\mathrm{c} = \bar{F}_\mathrm{w}[\mathrm{Casein}](1.0\alpha + (1-\alpha)\bar{v}_\mathrm{Mg} \times (\mathrm{pH}, \{\mathrm{Ca}^{2+}\}, \{\mathrm{Mg}^{2+}\})) \qquad [15]$$

Within the range of natural variation, α is almost 1 so the term containing the binding isotherm is usually small enough to be neglected and the estimate of the colloidal concentration can be derived from the first term alone.

Such an analysis is shown in **Figure 5** for colloidal salts in the milks of seven species, where calculated values of $[\mathrm{Ca}]_\mathrm{c}$ and $[\mathrm{Mg}]_\mathrm{c}$ are compared with experiment.

As can be seen, the fitted lines for $[\mathrm{Ca}]_\mathrm{c}$ and $[\mathrm{Mg}]_\mathrm{c}$ have a slope close to unity and an intercept close to zero, as required by the theory. Not surprisingly colloidal citrate is poorly predicted by eqn [13], indicating that it is neither an invariant nor an essential component of the micellar calcium phosphate.

Conclusions

Milks are diverse in their composition, both quantitatively and qualitatively, and exhibit a multitude of patterns of change with respect to diet, season, and stage of lactation. Nevertheless, underlying the apparent complexity are patterns of change seen in the interrelationships of concentrations. Our understanding of the milk salts has advanced to the point where precise, physicochemical models give good predictions of the partition of salts in milk and account quantitatively for the interrelationships that occur as a result of natural variation.

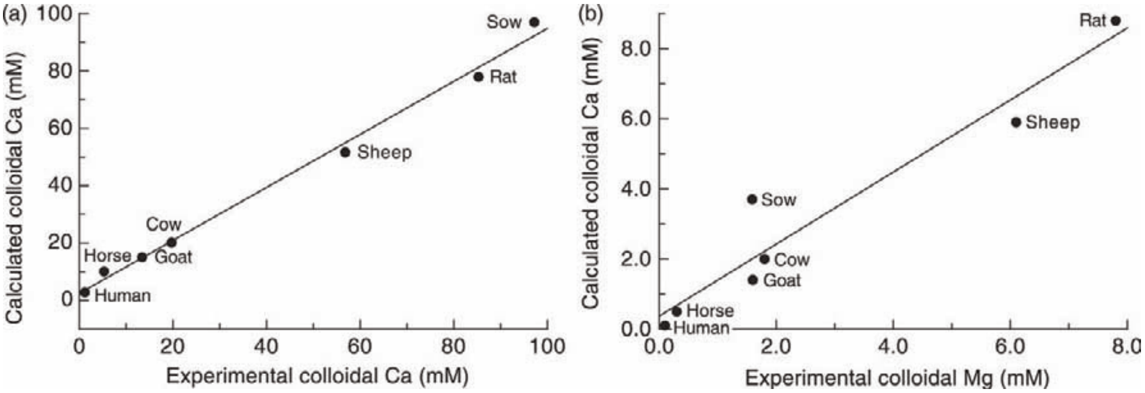

Figure 5 (a) Calculated and experimental values of $[\mathrm{Ca}]_\mathrm{c}$ for seven species. The regression equation shown has a slope of 0.924 ± 0.034 and intercept 2.4 ± 1.8 mM Ca. (b) Calculated and experimental values of $[\mathrm{Mg}]_\mathrm{c}$. The regression equation shown has a slope of 1.02 ± 0.13 and intercept 0.37 ± 0.49 mM Mg.

Macroelements, Nutritional Significance

K D Cashman, University College, Cork Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

In this article the term 'minerals' refers to those mineral elements that are of nutritional significance and, though the term may be chemically inaccurate, it is a commonly used and widely accepted terminology in the field of nutrition. Mineral elements occur in the body in a number of chemical forms, such as inorganic ions and salts, and constituents of organic molecules such as proteins, fats, carbohydrates, and nucleic acids. They serve a wide variety of essential physiological functions, ranging from structural components of body tissues to essential components of many enzymes and other biologically important molecules.

This article, in conjunction with another article within this Encyclopedia (*see* **Milk Salts**: Trace Elements, Nutritional Significance), outlines the nutritional roles, recommended intakes, and hazards of deficiency or excess of the 20 minerals that are considered to be nutritionally essential for humans, all of which occur in milk. In this article, 'milk' refers to cow's milk unless otherwise stated. The content, chemical form, bioavailability, and nutritional significance of these minerals in milk and dairy products are discussed.

The 20 minerals considered essential in the human diet are sodium, potassium, chloride, calcium, magnesium, phosphorus, iron, copper, zinc, manganese, selenium, iodine, chromium, cobalt, molybdenum, fluoride, arsenic, nickel, silicon, and boron. The essential minerals are sometimes classified into two groups: the macroelements (also known as the macrominerals) and the trace elements. The macrominerals (sodium, potassium, chloride, calcium, magnesium, and phosphorus) are present in the body in amounts larger than ~0.01% by weight, whereas the trace elements (the remaining 14 essential minerals) occur in the body at much lower levels and are required in the diet in amounts smaller than ~100 mg day^{-1}. The nutritional aspects of the former class of minerals will be discussed in this article, whereas the nutritional aspects of the latter class will be dealt with elsewhere (*see* **Milk Salts**: Trace Elements, Nutritional Significance).

Although the minerals are treated separately, it is important to realize that interactions of the minerals with each other, with other constituents of milk, and with other food constituents occur, and that such interactions are assuming an increasing importance in nutrition.

Content and Chemical Form of Macrominerals in Milk and Dairy Products

Mineral Content

The mineral content of milk is not constant but is influenced by a number of factors such as stage of lactation, nutritional status of the animal, and environmental and genetic factors. Reported values in the literature for the concentration of many minerals show a wide variation, which is due partly to these factors, but also partly to analytical errors and contamination during milk collection and from processing equipment and procedures. Representative values for the average macromineral content of milk are presented in **Table 1**.

Sodium, Potassium, Chloride

Particularly high levels of sodium occur in cow's colostrum, but the level decreases within a few days to the value shown in **Table 1**. The sodium content of milk is not influenced by dietary sodium intake within the normal range. Sodium concentration in milk tends to be higher at the end of lactation when milk yield is low. Removal of milk fat has little effect on milk sodium content. In contrast to most other minerals, potassium concentration in cow's colostrum is lower than that in mature milk, but increases to normal values within the first 2–3 days of lactation and is independent of potassium intake. The chloride concentration in milk decreases from higher levels in colostrum to lower levels in mature milk but increases sharply toward the end of lactation and is independent of dietary intake. The sodium, potassium, and chloride contents of other dairy products are shown in **Tables 2–5**. Levels of sodium (and also chloride) in cheese are dependent on the amount of added salt. Levels of potassium are no higher in cheese than in milk. In general, the concentration of macrominerals decreases as the fat concentration increases in milk and dairy products (**Table 3**).

Calcium, Phosphorus, Magnesium

The mean calcium and phosphorus contents of cow's milk are 1120 and 890 mg l^{-1}, respectively. In cow's milk, calcium concentration is slightly elevated in colostrum and at the end of lactation but varies little with feeding or

Table 1 Mean concentrations of macrominerals in cow's milk

Mineral	*Content (mg l^{-1})*
Sodium	430
Potassium	1550
Chloride	890
Calcium	1180
Phosphorus	930
Magnesium	110

Data from Food Standards Agency (2002) *McCance & Widdowson's. The Composition of Foods*, 6th edn. Cambridge: Royal Society of Chemistry.

season. There is little variation in the phosphorus content of milk throughout lactation.

The mean concentration of magnesium in milk is 110 mg l^{-1} and is unaffected by fat removal. Magnesium concentration in colostrum is 2–3 times that in mature milk and decreases to the level in mature milk within the first 1–3 days of lactation, remaining relatively constant thereafter. The concentration of magnesium in milk is unaffected by dietary intake of magnesium.

The calcium, phosphorus, and magnesium contents of other dairy products are shown in **Tables 2–5**. Levels of calcium and phosphorus are generally highest in hard cheeses (Parmigiano, Gouda, Edam, and Cheddar), that is, up to 10 times that in milk, followed by mold cheeses (Brie, Stilton), that is, 4–5 times that in milk (**Table 5**). The lowest levels are found in cream and cottage cheese types. Levels of magnesium are ordered similar to calcium but only around 5 times higher in hard cheeses and 2–3 times higher in mold types.

Chemical Form of the Macrominerals

The chemical form of a mineral is important because it may influence intestinal absorption and utilization (the process of transport, cellular assimilation, and conversion into a biologically active form) and thus bioavailability.

Sodium, Potassium, Chloride

Sodium, potassium, and chloride are believed to be present in milk almost entirely as free ions. Practically all the sodium, potassium, and chloride in milk is absorbed in the

gastrointestinal tract, although much of what is absorbed is not retained.

Calcium, Phosphorus, Magnesium

In cow's milk, 99% of the calcium is in the skim milk fraction, which explains why the calcium content is not affected by fat removal. Two-thirds of the total calcium occurs in colloidal form associated with the casein micelles, either as a calcium phosphate salt (about half of total milk calcium) or as calcium ions bound to phosphoserine residues (about one-sixth of total calcium); the remaining one-third is soluble. Ionized calcium in the soluble phase accounts for ~10% of the total calcium, and most of the remaining soluble calcium occurs as calcium citrate. A small amount of calcium (0.15%) is bound to α-lactalbumin.

Of the total phosphorus in cow's milk, 20% occurs as organic phosphate esterified to casein with the remainder occurring as inorganic phosphate. About 44% of the inorganic phosphate is associated with casein micelles as calcium phosphate and 56% is soluble, mainly as free phosphate ions.

In cow's milk, 98–100% of the magnesium is in the skim milk phase, where 65% of the magnesium is in a soluble form (40% as magnesium citrate, 7% as magnesium phosphate, and 16% as free magnesium ion), and the remainder is colloidal and is associated with the casein micelles (about one-half associated with colloidal calcium phosphate and the other half bound directly to phosphoserine residues in caseins).

Nutritional Significance of Macrominerals in Milk and Dairy Products

A simple and useful evaluation of the nutritional significance of macrominerals (as well as trace elements) in milk can be obtained by comparing the amounts of the different elements provided by 1 l of milk (**Table 1**) with the recommended daily intakes for these elements (**Table 6**). Another useful impression of the nutritional significance of milk and other dairy products can be obtained by computing, from data on dietary surveys, the actual contribution made by dairy products to the total intake of macrominerals and trace elements.

Sodium, Potassium, Chloride

Sodium is the principal cation in extracellular fluids and is the primary regulator of extracellular fluid volume. It is

important in the regulation of osmolarity, acid–base balance, and the membrane potential of cells, as well as in active transport across cell membranes. Chloride is the principal extracellular anion and is essential in the maintenance of fluid and electrolyte balance. Potassium is the principal intracellular cation, occurring in the cell at a concentration more than 30 times its concentration in extracellular fluid. Extracellular potassium contributes to the transmission of nerve impulses, to the control of skeletal muscle contraction, and to the maintenance of blood pressure.

Under normal circumstances, dietary deficiency of sodium, potassium, or chloride does not occur, but the body can be depleted of sodium and chloride under extreme conditions, for example, heavy perspiration, chronic diarrhea, or renal disease. Depletion of potassium can occur in the body under conditions where there are large alimentary or renal losses.

Minimum requirements for sodium, potassium, and chloride (e.g., 500, 2000, and 750 mg day^{-1}, respectively, in adults) have been established. Actual intakes of sodium and chloride are considerably higher than the minimum requirements in many populations and, given the evidence of a relationship of high salt intake to hypertension, it has been recommended that sodium intake be limited to 2.4 g day^{-1}. Similarly, considering the possible beneficial effect of potassium in hypertension, increasing potassium intake beyond the minimum requirement has been recommended.

Cow's milk contributes little to the dietary intake of sodium (7% in the United Kingdom), but some dairy products such as cheese and butter contain added salt and can be significant sources of sodium in some countries (e.g., ~13% of total sodium intake in the United Kingdom). It has been estimated that milk and dairy products provide 20% of total sodium and 24–29% of total potassium in the diet in Ireland and the United Kingdom.

The concentrations of sodium, potassium, and chloride in milk are of physiological importance in the feeding of the young infant, and clinical problems may arise if there is an excessive intake of these nutrients. The kidney of the young infant, as compared to that of the adult, has a limited capacity to concentrate solids, and the renal solute load exerts a major effect on water balance. Renal solute load is determined mainly by sodium, potassium, chloride, phosphorus, and protein (which gives rise to urea). Cow's milk has a much higher potential renal solute load (~300 mosmol l^{-1}) than human milk (~93 mosmol l^{-1}). The high renal solute load resulting from ingestion of cow's milk may be of relatively little significance in most circumstances because the kidney merely excretes a more concentrated urine. However, it does lead to a smaller margin of safety against dehydration, which can occur in conditions of diarrhea, fever, and low water intake, and for this reason it is recommended that the upper limit of potential renal solute load in formulae for young infants be ~220 mosmol l^{-1}. Recommended concentrations of sodium, potassium, and chloride in infant formulae are in the ranges 133–403, 534–1338, and 369–1360 mg l^{-1}, respectively. Cow's milk-based infant formulae currently in use fall comfortably within these guidelines.

Calcium

The adult human body contains ~1200 g of calcium, which amounts to ~1.5–2% of the body weight. Of this, 99% is found in bones and teeth, where it is present as calcium phosphate, providing strength and structure. The remaining 1%, found in extracellular fluids and intracellular structures and cell membranes, is responsible for a number of regulatory functions such as maintenance of normal heart beat, blood coagulation, hormone secretion, integrity of intracellular cement substances and membranes, nerve conduction, muscle contraction, and activation of enzymes.

Cow's milk and milk products, such as cheese and yogurt, are very good sources of dietary calcium. The contribution of dairy products to total calcium intake has been estimated as 75% in The Netherlands, 55% (dietary intake data) to 72% (food disappearance data) in the United States, 60% in the United Kingdom, and 52% in Ireland.

In the absence of milk and dairy products from the diet, calcium intakes in excess of 300 mg day^{-1} are difficult to achieve. This is far below the typical recommended intakes for calcium. For example, the recently established adequate intake (AI) values for calcium in the United States are 1000 mg for adults, 1200 mg for older adults, and 1300 mg for adolescents (**Table 6**). On this basis, it might be considered that consumption of dairy products is very important in order to achieve an adequate calcium intake. However, there is still considerable disagreement on human calcium requirements, and this is reflected in the wide variation in the recommended adult dietary intakes for calcium (400–1200 mg) that have been set by different authorities. The dietary reference value for calcium is currently under review in the United States, and the new recommendations will be released in Summer 2010.

In recent years, considerable attention has been focused on the bioavailability of calcium in milk. Evidence from studies on experimental animals suggests that essentially all of the calcium in human milk, cow's milk, and cow's milk-based infant formulae is potentially available for absorption in the gastrointestinal tract. In addition, it has often been suggested that the bioavailability of calcium is higher in human milk than in cow's milk or cow's milk-based infant formulae. This arises from the findings that calcium is absorbed more efficiently by human infants from human milk than from cow's milk or a cow's milk-based formula containing 738 mg Ca l^{-1}. However, the absolute amount of calcium absorbed is higher from cow's milk and formulae, and calcium absorption from cow's milk formulae with lower calcium contents (363–458 mg l^{-1}) is similar to that from human milk. Similarly, the efficiency of calcium absorption from human milk by weanling Rhesus monkeys has been reported as being significantly higher (72%) than from cow's milk-based infant formulae (45–53%), but the absolute absorption from human milk and formulae were similar due to the higher calcium concentration in the formulae. Moreover, bone mineralization in infants fed with cow's milk formula has been reported to be as good as, if not slightly better than, in infants fed with human milk.

Mean calcium absorption from cow's milk by healthy human adults has been variably reported in the range 21–45%. Calcium absorption has been reported as being similar from milk and from $CaCO_3$ by pregnant women at 36–47%, but calcium absorption from cow's milk by postmenopausal women has been variably reported in the range 5–41%. Calcium absorption from cow's milk by β-galactosidase-deficient subjects has been reported as being higher (36.2% of dose) as compared to a β-galactosidase-sufficient group (25.7%), and it has been suggested that this reflects lower habitual calcium intake owing to reduced milk consumption by the β-galactosidase-deficient subjects. It has been reported that calcium from various dairy products (including whole milk, chocolate milk, yogurt, Cheddar cheese, processed cheese) is absorbed equally well.

Thus, though it appears that all of the calcium in human milk, cow's milk, and cow's milk-based infant formulae is potentially available for absorption, the absolute amount of calcium absorbed by animals or humans is determined by physiological factors such as the efficiency of calcium absorption mechanisms in the gastrointestinal tract, which may be influenced by calcium needs, vitamin D status, and age, as well as by the calcium concentration in milk. In addition, some components of milk (lactose, phosphopeptides) may enhance calcium absorption.

There is strong evidence that lactose promotes intestinal absorption (particularly in the ileum) and body retention of calcium in rats. This effect of lactose is independent of vitamin D, but the mechanism by which it occurs remains unresolved. It has been suggested that undigested lactose reaching the ileum interacts with the brush border membrane, increasing its permeability to calcium. Lactose also appears to increase calcium absorption in human infants. For example, calcium absorption has been reported to be significantly higher from a soy-based infant formula containing lactose (48%) than from a similar formula in which the carbohydrate source was a mixture of starch hydrolysate and sucrose (33%). However, studies on the effect of lactose on calcium absorption by human adults have produced conflicting results. One study found no significant difference in calcium absorption from milk or lactose-hydrolyzed milk by either β-galactosidase-deficient or β-galactosidase-sufficient subjects, whereas another study reported that calcium absorption was similar from milk (21.4%) and lactose-free milk (lactose replaced by glucose) (26.8%) by healthy adult subjects, but lactose increased calcium absorption by β-galactosidase-deficient subjects. Overall, it is likely that lactose, at the level normally present in milk, does not have a significant effect on calcium absorption in healthy adults consuming normal diets. It is possible that lactose affects the non-saturable paracellular pathway for calcium absorption in the gut and its effect is most likely to occur in vitamin D deficiency, or when elevated levels of calcium are fed.

It has been suggested that phosphopeptides formed during the digestion of bovine caseins may be involved in promoting calcium absorption. Such phosphopeptides have the capacity to chelate calcium and to prevent the precipitation of calcium phosphate salts and may help to maintain a high concentration of soluble calcium in the intestinal lumen. There is evidence that phosphopeptides are present in the lumen of the small intestine of rats and pigs after a casein-containing meal; purified phosphopeptides have been shown to enhance the absorption of calcium in rats and chicks. The observation that calcium absorption in rats is enhanced by high-casein meals is consistent with this. However, the nutritional significance of these phosphopeptides in humans consuming milk remains unclear.

Age-related osteoporosis, a common bone disease and a major cause of disability in Western countries, is characterized by reduced bone density resulting in increased bone fragility and susceptibility to fracture. The condition is particularly common in elderly women, especially in Caucasians. It has been estimated that osteoporosis afflicts 10 million Americans (half of the women over 45 years of age and 90% of the women over 75 years of age).

Osteoporosis is a multifactorial disorder, but there is increasing evidence that inadequate calcium intake, particularly during early life, is a contributory factor. Adequate calcium intake is required in early life in order to develop maximum bone mass at maturity (during the third decade of life), and there is evidence that the amount of bone mass present at maturity is an important factor influencing fracture susceptibility in the elderly. Peak bone mass at maturity appears to be related to the intake of calcium during the years of bone mineralization. Inadequate dietary intake of calcium during the critical growth and building periods may result in failure to reach peak bone mass, causing osteopenia, osteoporosis, decreased skeletal integrity, and increased risk of fracture in later life. Many believe that the most promising nutritional approach to reduce the risk of osteoporosis in later life is to ensure a calcium intake that allows the development of each individual's genetically programmed peak bone mass during the formative years, that is, throughout childhood to the age of 25 years. In this regard, the prevalence of lower-than-recommended calcium intake among adolescent and young adult females in many countries, for example, in the United States and Europe, is of particular concern.

In recent years, evidence has been presented for a protective role of dietary calcium against hypertension, hypercholesterolemia, diabetes mellitus, and colon and rectal cancer. Dietary calcium has also been proposed to help regulate and maintain body weight. However, consensus on the role of calcium in these conditions is lacking and further research is required.

Phosphorus

Phosphorus is an essential nutrient for humans and serves a number of important biological functions. Phosphorus occurs as organic and inorganic phosphates in all body tissues and fluids; is an essential component of many biological molecules, including lipids, proteins, carbohydrates, and nucleic acids; and plays a central role in metabolism. As calcium phosphate, it is a major structural component of bones and teeth. Because almost all foods contain phosphorus, dietary phosphorus deficiency does not usually occur. The recently revised recommended dietary allowances (RDAs) for phosphorus are shown in **Table 6**.

Cow's milk and milk products, such as cheese and yogurt, are good dietary sources of phosphorus, and the contribution of milk and dairy products to total phosphorus intake has been reported as 30–45% in Western countries.

In the first few weeks of life, the infant's ability to regulate plasma calcium concentration is not fully developed, and hypocalcemia may result in neonatal tetany, which used to occur more frequently in artificially fed than in breast-fed infants. Excessive phosphorus intake contributes to this condition, and feeding unmodified cow's milk, which has a high content of phosphorus, increases serum phosphorus and lowers serum (ionized) calcium in the newborn infant. For this reason, it is recommended that the calcium-to-phosphorus ratio in artificial infant formulae be higher than that in cow's milk (~1.2:1) and more similar to that in human milk (~2.2:1).

In experimental animals, a high intake of phosphorus or a low calcium-to-phosphorus ratio in the diet could lead to bone loss. However, it is generally agreed that wide variations in phosphorus intake or in the calcium-to-phosphorus ratio in the diet do not adversely affect bone mass in adult humans.

Magnesium

Magnesium has an essential role in a wide variety of physiological processes, including protein and nucleic acid metabolism, neuromuscular transmission and muscle contraction, bone growth and metabolism, and regulation of blood pressure, and it acts as a cofactor for many enzymes.

There is little information from human studies on the bioavailability of magnesium from milk. Metabolic-balance studies in infants showed that 16–43% of magnesium is absorbed from cow's milk-based infant formulae and that lactose enhances the absorption of magnesium. Cow's milk and milk products contribute 16–21% of the total magnesium intake in Western countries.

Dietary deficiency of magnesium is uncommon except in conditions of severe malnutrition and certain disease states. There is evidence that many young adults, especially women, in various European countries and in the United States fail to achieve the recommended intakes of magnesium and this raises the issue of possible adverse effects of lower-than-recommended intakes. Scientists have attempted to demonstrate that suboptimal intake of magnesium (i.e., below the RDA, but not frank deficiency) is a contributor to the development of chronic maladies such as cardiovascular disease, hypertension, disorders of skeletal growth and osteoporosis, and diabetes mellitus. However, the results of studies in this area are ambiguous. The fact that the RDA for magnesium has been raised recently for most groups (**Table 6**) reflects nutrition scientists' belief that there is a negative consequence to suboptimal magnesium intake. Additional research is needed to fully justify this concern.

Conclusion

Even though the nutritional roles, requirements, and metabolism, and the quantitative relationship between dietary intakes and health for a number of macrominerals have been more clearly defined in recent years, there are still considerable deficiencies in our understanding of these issues, for example, the significance of calcium and magnesium in the etiology and treatment of osteoporosis and hypertension.

Reliable information on the content, and the principal factors affecting it, of most of the macrominerals in cow's milk is now available. The contribution of cow's milk and milk products to the diet in Western countries is significant for sodium, potassium, chloride, calcium, and phosphorus.

Sodium, potassium, and chloride are believed to be almost totally absorbed from milk and infant formulae. Though the bioavailability of calcium in milk has received considerable attention in recent years, there is little information on the bioavailability of magnesium in milk and infant formulae. In addition, there is a paucity of data regarding the bioavailability of macrominerals from other dairy products. Factors affecting the bioavailability of minerals are still poorly understood, and the role of possible enhancers (e.g., lactose, phosphopeptides) or inhibitors (e.g., proteins, calcium, phosphate) of macromineral absorption in milk and dairy products remains unclear. However, milk does not appear to contain substances that are strongly inhibitory to mineral absorption, such as phytate or polyphenols contained in foods from plants.

Finally, understanding the nutritional significance of macrominerals in milk and dairy products will also benefit from the improvement in our knowledge of fundamental aspects of minerals, such as their nutritional roles, requirements, and metabolism, and the quantitative relationship between dietary intakes and health.

Trace Elements, Nutritional Significance

K D Cashman, University College Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

There are 20 minerals that are considered to be nutritionally essential for humans, and these are sometimes classified into two groups: macroelements (also known as the macrominerals) and trace elements. The macrominerals (sodium, potassium, chloride, calcium, magnesium, and phosphorus) are present in the body in amounts larger than ~0.01% by weight, and the nutritional aspects of these minerals are dealt with elsewhere (*see* **Milk Salts**: Macroelements, Nutritional Significance). The trace elements (the remaining 14 essential minerals) occur in the body at much lower levels and are required in the diet in amounts smaller than ~100 mg day^{-1}. The nutritional aspects of these minerals will be discussed in this article.

The 14 trace elements considered essential in the human diet are iron, copper, zinc, manganese, selenium, iodine, chromium, cobalt, molybdenum, fluorine, arsenic, nickel, silicon, and boron. Although some of these, for example, arsenic, nickel, silicon, and boron, have not been shown to be essential for humans, they are essential for experimental animals and probably are also essential for humans. A number of other elements occur in milk, for example, lithium, bromine, aluminum, strontium, silver, lead, tin, vanadium, mercury, cadmium, rubidium, and cesium. These are not nutritionally essential and are not discussed here; moreover, many of them are toxic. However, their concentrations in milk are normally well below toxic levels.

This article outlines the nutritional roles, recommended intakes, and hazards of deficiency or excess of the 14 trace elements considered to be nutritionally essential for humans, all of which occur in milk. In this article, 'milk' refers to cow's milk unless otherwise stated. The content, chemical form, bioavailability, and nutritional significance of these trace elements in milk and dairy products are considered. In addition, in view of the widespread use of infant formulae based on cow's milk, some nutritional aspects of trace elements in these formulae are discussed.

Although the trace elements are treated separately, it is important to realize that interactions of trace elements with each other, with macrominerals, with other constituents of milk, and with other food constituents occur, and that such interactions are assuming an increasing importance in nutrition.

Content and Chemical Form of Trace Elements in Milk and Dairy Products

Mineral Content

The trace element content of milk is not constant but is influenced by a number of factors such as stage of lactation, nutritional status of the animal, and environmental and genetic factors. Reported values in the literature for the concentration of many trace elements show a wide variation, which is partly due to these factors, but also partly to analytical errors and contamination from milk collection and processing equipment and procedures. Representative values for the average trace element content of milk are presented in **Table 1**.

Iron, zinc, and copper

Although several investigations have reported lack of a developmental pattern for iron in milk, at least one study has reported that iron concentration decreases by 35–50% during the first 3 days of lactation and remains relatively constant thereafter. The iron content of milk is resistant to changes in dietary iron intake. Contact with metal containers can increase the concentration of iron in milk.

Mean zinc concentration in milk is 3.9 mg l^{-1}, but large variations in the zinc content of milk (2.0–6.0 mg l^{-1}) have been reported. There is a large decrease (50%) in the concentration of zinc in cow's colostrum during the first 3 days of lactation, with little change thereafter. Dietary zinc supplementation increases the zinc concentration in milk only slightly.

The concentration of copper in milk decreases by up to 50% during the first 3 days of lactation; it can be increased by dietary copper supplementation or by contact with metal containers and processing equipment.

Manganese, selenium, and iodine

The concentration of manganese is higher in colostrum (100–160 μg l^{-1}) than in mature milk (20–50 μg l^{-1}) and a decrease of over 50% has been reported to occur during the first 3 days of lactation. Oral supplementation of manganese to cows can increase the manganese content of milk, provided that large doses are administered over a long period.

Table 1 Mean concentrations of trace elements in cow's milk

Trace element	*Content (l^{-1})*
Iron (mg)	0.3
Zinc (mg)	4.0
Copper (mg)	0.09
Manganese (μg)	30
Iodine (μg)	100–770
Fluorine (μg)	20
Selenium (μg)	10
Cobalt (μg)	0.5
Chromium (μg)	2.0
Molybdenum (μg)	50
Nickel (μg)	26
Arsenic (μg)	20–60
Silicon (μg)	3000
Boron (μg)	500–1000

Adapted from Flynn A and Cashman K (1997) Nutritional aspects of minerals in bovine and human milks. In: Fox PF (ed.) *Advanced Dairy Chemistry*, Vol. 3, pp. 257–301.
London: Chapman & Hall and updated with data from Food Standards Agency (2002) *McCance & Widdowson's the Composition of Foods*, 6th edn. Cambridge: Royal Society of Chemistry.

The mean selenium concentration in cow's milk samples from 15 countries was reported as 10 μg l^{-1} (range 3–40 μg l^{-1}). The concentration in milk depends on dietary intake, and in areas such as New Zealand and Finland, where the selenium content of the soil and plants is low, concentrations as low as 3–5 μg l^{-1} have been reported. It has been shown that the selenium content of milk increased linearly from ~30 to 55 μg l^{-1} when dietary selenium was increased from ~2 to 6 mg day^{-1}.

Summarized data from various countries on the iodine content of milk indicate mean values of 100–770 μg l^{-1} and a wide range of individual values from 20 to >4000 μg l^{-1}. The concentration of iodine in milk is influenced by season and is closely related to dietary intake, and feeding winter rations containing mineral supplements results in considerable increases in milk iodine. High concentrations of iodine in milk have been related to the addition of excessive amounts of ethylenediamine dihydriodide (EDDI) to dairy cow rations.

The use of iodophors for teat disinfection increases the iodine content in cow's milk. In addition, use of iodophors for the disinfection of containers, milking machines, and processing equipment can also cause contamination of milk with iodine. Standardization of mineral feed supplements and supervised and restricted use of iodophor disinfectants have been recommended as measures to reduce the iodine content of milk and milk products.

Chromium, cobalt, molybdenum, and fluorine

The mean concentrations of chromium and cobalt in milk are 2 μg l^{-1} (range 0.2–3.6 μg l^{-1}) and 0.5 μg l^{-1} (range 0.4–1.1 μg l^{-1}), respectively. Dietary supplementation with cobalt increases the concentration of cobalt in milk, but does not increase the vitamin B_{12} content of milk unless the diet is cobalt-deficient. The concentration of molybdenum in milk has been shown to be dependent on dietary intake, increasing over fivefold when cows were supplemented with ammonium molybdate. The mean fluorine content in milk is 20 μg l^{-1} (range 10–140 μg l^{-1}).

Arsenic, nickel, silicon, and boron

Reported concentrations of these elements in milk are presented in **Table 1**. Little is known about the influence of stage of lactation, maternal nutritional status, and environmental and genetic factors on the content of these trace elements in milk.

Trace Element Content of Dairy Products

The contents of selected trace elements in other dairy products are shown in **Tables 2–5**.

Chemical Form of the Trace Elements

The chemical form of a trace element is important because it may influence intestinal absorption and utilization (the process of transport, cellular assimilation, and conversion into a biologically active form), and thus bioavailability.

Table 2 Mean concentrations of selected trace elements in concentrated milks

Iron, zinc, and copper

In milk, 14% of the iron occurs in milk fat, where it is associated with the fat globule membrane. About 24% of the iron is bound to caseins, probably to the phosphoserine residues of caseins, whereas 29% is bound to whey proteins and 32% is associated with a low-molecular-weight fraction.

Most of the zinc in milk is in the skim milk fraction, with only 1–3% in the lipid fraction. Of the zinc in the skim milk fraction, over 95% is associated with the casein micelles, with a small proportion (5%) associated with a low-molecular-weight compound that has been identified as citrate. Within the casein micelles, one-third of the zinc is loosely bound to casein phosphoserine residues and two-thirds is more tightly bound to colloidal calcium phosphate. The distribution of copper in milk has been reported as 2% in the fat fraction, 8% bound to whey proteins, 44% to casein, and 47% in a low-molecular-weight fraction.

Manganese, selenium, and iodine

In cow's milk, manganese distribution is 67% bound to caseins, 1% to the milk fat globule membrane, 14% to whey proteins, and 18% to a low-molecular-weight fraction. About 12% of the selenium in milk has been estimated to be incorporated in the enzyme glutathione peroxidase (EC 1.11.1.9).

Most (80–90%) of the iodine in milk is in the inorganic form, mainly as iodide and is in the water-soluble fraction, and 5–13% is bound to proteins through either covalent bonds or loose physical associations, with less than 0.1% bound to fat.

Molybdenum, chromium, and fluorine

All the molybdenum in milk is considered to be associated with xanthine oxidase (EC 1.1.3.22). The chemical form of chromium in milk is unknown, although chromium in foods is generally in the trivalent state.

Table 5 Mean concentrations of selected trace elements in some cheese varieties

About 46–64% of the fluorine in milk occurs as free fluorine ions, with the remainder bound to proteins.

Cobalt, arsenic, nickel, silicon, and boron

Little is known about the chemical form or distribution of these trace elements in milk and dairy products.

Nutritional Significance of Trace Elements in Milk and Dairy Products

A simple and useful evaluation of the nutritional significance of trace elements (as well as macrominerals) in milk can be obtained by comparing the amounts of the different elements provided by 1 l of milk (**Table 1**) with the recommended daily intakes for these elements (**Table 6**). During the last two decades, great progress has been made in our knowledge of the trace element nutrition of infants, particularly in the area of bioavailability.

Iron

Iron is an essential trace element that acts as a catalytic center for a broad spectrum of metabolic functions. Iron, as a component of heme in hemoglobin, myoglobin, cytochromes, and other proteins, plays an essential role in the transport, storage, and utilization of oxygen. It is also a cofactor for a number of enzymes. Deficiency of iron, resulting in anemia, afflicts about 30% of the world's population and occurs in Western countries as well as in developing countries.

The recently revised recommended daily allowances (RDAs) for iron in the United States are shown in **Table 6**. Milk and milk products are very poor sources of iron, and milk contributes little to the total iron intake.

Bioavailability of iron to the infant from human milk has been reported to be in the range 49–70%. Considerably lower absorption efficiency of iron from cow's milk by human infants has been reported, usually ~10–34%. To compensate for the relatively low bioavailability of iron in cow's milk, infant formulae are often supplemented with iron. Iron absorption by infants from cow's milk formulae containing 12 mg l^{-1} iron as ferrous sulfate is about 4–7%, but because of the much higher concentration of iron in such formulae, the absolute amount of iron absorbed is considerably larger than that from human milk.

The reason for the exceptionally high bioavailability of iron in human milk is not understood. It has been suggested that it may be related to the high concentration of lactoferrin (a glycoprotein in milk that can bind two ferric ions per molecule of protein) in human milk, but evidence for a role for lactoferrin in iron absorption is conflicting. Others have suggested that the apparent higher bioavailability of iron in human milk compared to cow's milk could be due to a number of possible factors, including a lower concentration of proteins, calcium, and phosphorus (potential inhibitors of absorption), and higher concentrations of lactose and ascorbate (enhancers of iron absorption) in human milk. However, studies on suckling rats, which have a very high capacity for iron absorption, have shown that a very high and similar proportion (90%) of iron is absorbed from human milk, cow's milk, and an iron-supplemented cow's milk-based formula, suggesting that there are no unabsorbable iron complexes in these milks. It is likely that the lower concentration of iron in human milk may be a contributory factor to the higher absorption efficiency of iron from human milk in infants, as iron absorption is subject to homeostatic control and small amounts are absorbed more efficiently than large amounts.

Iron deficiency is one of the most common nutritional deficiencies in infancy and childhood owing to rapid growth and marginal supply of iron in the diet. It has been suggested that the iron stores of a breast-fed infant 4–6 months of age may become compromised if they are not replenished from dietary sources, and dietary iron supplementation has been recommended at not later than 4 months of age for full-term infants and not later than 2 months of age for premature infants. Iron-fortified cow's milk-based formulae are effective in preventing iron deficiency, which may be partly attributable to the fact that ascorbate is also added to formulae at levels that markedly enhance the absorption of added iron.

Zinc

Zinc is essential for growth and development, sexual maturation, and wound healing, and it may also be involved in the normal functioning of the immune system and other physiological processes. It is a component of the hormone insulin and aids in the action of a number of hormones involved in reproduction, as well as being required for the synthesis of DNA, RNA, and proteins and as a cofactor for many enzymes involved in most major metabolic processes. Zinc deficiency in humans was first reported in the Middle East in the early 1960s, giving rise to dwarfism, impaired sexual development, and anemia. Mild deficiencies of zinc, although difficult to detect, have been shown to occur in Western countries, particularly in infants and young children, giving rise to low hair zinc levels, suboptimal growth, poor appetite, and impaired taste acuity.

The recently revised RDAs for zinc in the United States are shown in **Table 6**. Dairy products such as milk, cheese, and yogurt are moderately good sources of zinc, and it has been estimated that in Western countries milk and dairy products contribute between 19 and 31% of the total zinc intake.

A number of lines of evidence suggest that the bioavailability of zinc in human milk is higher than in cow's milk. Human milk (but not cow's milk) has a therapeutic value in the treatment of acrodermatitis enteropathica, a hereditary zinc malabsorption syndrome. The plasma zinc concentration of breast-fed infants has been reported to be significantly higher than that in infants fed a cow's milk-based formula containing 1.8 $\mathrm{mg\,l^{-1}}$ zinc. Studies on human adults using extrinsic labeling with ^{65}Zn with whole-body counting showed that zinc absorption from human milk (41 ± 9%) was significantly higher than from cow's milk (28 ± 15%) or cow's milk-based infant formulae (31 ± 7%). Short-term studies on human adults, pigs, and suckling rats have shown that zinc is absorbed more rapidly from human milk than from cow's milk or cow's milk-based infant formulae.

Two main theories have been proposed to explain the higher bioavailability of zinc from human milk compared with cow's milk:

1. Binding of a significant fraction of the zinc in human milk (but not in cow's milk) to a low-molecular-weight zinc-binding ligand (e.g., citrate) may enhance zinc absorption.
2. Binding of a large fraction of zinc in cow's milk to casein (present at about 10 times its concentration in human milk), which may result in the entrapment of zinc in casein curds formed in the stomach and thus render a significant proportion of the zinc unavailable for absorption.

However, studies on suckling rats, which have a high capacity for zinc absorption, showed that a very high and similar proportion of zinc (85–95%) was absorbed from human milk, cow's milk, and cow's milk-based infant formulae, suggesting that there are no unabsorbable forms of zinc in either human or cow's milk. It is likely that the lower concentration of zinc in human milk may be a contributory factor to the higher absorption efficiency of zinc from human milk by infants, as zinc absorption is subject to homeostatic control and small amounts are absorbed more efficiently than large amounts.

Copper

Copper is an essential element for a wide range of animal species. It is required for iron utilization and is a cofactor for enzymes involved in the metabolism of glucose and synthesis of hemoglobin, connective tissue, and phospholipids. Dietary deficiency of copper is uncommon except in conditions of severe malnutrition.

The recently established RDAs for copper in the United States are shown in **Table 6**. Milk and milk products are considered poor sources of copper, and cow's milk contributes little to the total dietary intake of copper.

Copper deficiency is rare in breast-fed infants, but has been reported in formula-fed infants in some countries. Feeding infant formulae containing 0.03 or 0.4 $\mathrm{mg\,l^{-1}}$ of copper has been shown to yield normal parameters of copper status similar to those of breast-fed infants.

Knowledge of copper absorption from milks is very limited. In a study on suckling rats, copper absorption was 83% from human milk, 76% from cow's milk, and 86–87% from cow's milk-based formulae, suggesting that there are no unabsorbable forms of copper in these milks.

Manganese

Manganese is an essential element for every animal species studied. It is a specific cofactor for glycosyltransferases that are involved in mucopolysaccharide synthesis and a nonspecific cofactor for a wide variety of other enzymes. There are two known manganese metalloenzymes: pyruvate carboxylase (EC 6.4.1.1) and superoxide dismutase (EC 1.15.1.1). Manganese is widely distributed in foods, and dietary deficiency is not known to occur in humans.

The recently established adequate intake values for manganese in the United States are shown in **Table 6**. Cow's milk is a poor source of manganese and contributes little (1–3% in Western countries) to the total dietary intake of this mineral.

Very little is known about the bioavailability of manganese in milks. One study reported that manganese absorption in healthy adults from human milk (8.2 ± 2.9%) was significantly higher than from cow's milk (2.4 ± 1.7%), whereas absorption from cow's milk-based infant formulae was 1.7–5.9%. However, the absolute amount of manganese absorbed from cow's milk and formulae was larger than from human milk due to the higher manganese concentrations in these milks. Studies with suckling rats showed that absorption of manganese from human milk (81%) was not significantly different than from cow's milk (89%) or cow's milk-based formulae (80%), suggesting that there are no unabsorbable forms of manganese in these milks.

Selenium

Selenium is an essential component of the enzyme glutathione peroxidase, which occurs in many human tissues where, together with vitamin E and the enzymes catalase (EC 1.11.1.6) and superoxide dismutase, it functions as an antioxidant, protecting cells against oxidative damage. In areas of China where the concentration of selenium in the soil is low, selenium deficiency causes Keshan disease, a cardiomyopathy that affects primarily young children and women of child-bearing age. Low selenium status has also been reported in New Zealand and Finland, countries where the concentration of selenium in the soil is also low.

The recently revised RDAs for selenium in the United States are shown in **Table 6**. The contribution of dairy products to daily dietary intake of selenium has been estimated as 5 μg (8% of the total intake) in the United Kingdom; 13 μg (10%) in the United States; 13 μg (21–26%) in Finland; and 11 μg (39%) in New Zealand.

Selenium intake of full-term infants fed on non-fortified, milk-based formulae has been shown to be near or below the RDA, whereas infants in the United States fed breast milk have a selenium intake meeting or exceeding the US RDA. Moreover, some studies have reported that the selenium status of milk-based formula-fed infants was lower than that of breast-fed infants. The finding that unsupplemented infant formulae have a lower selenium concentration than that in breast milk has meant that selenium is now being added to some infant formulae.

Iodine

Iodine is an essential component of the thyroid hormones thyroxine and triiodothyronine, which are important in controlling the rate of basal metabolism and in reproduction. Dietary deficiency of iodine causes enlargement of the thyroid gland and goiter, whereas a large excess of iodine in the diet reduces the uptake of iodine by this gland and also produces signs of thyroid deficiency (thyrotoxicosis). Worldwide, 1.6 billion people (30% of the world's population) are at risk of iodine deficiency. Of these, some 655 million have goiter. While the highest prevalence of iodine deficiency is in the less-developed regions of the world, it persists in parts of the industrialized world, too, in countries such as Germany and Luxembourg. Iodine is the only trace element for which there has been any suggestion of excessive amounts in cow's milk. Excessive addition of EDDI and use of iodophors for disinfection purposes have certainly contributed to the increased iodine content of milk in past years. However, there is evidence of a decline in the concentration of iodine in milk in the United States in recent years, although the situation in other countries is less clear.

The recently revised RDAs for iodine in the United States are shown in **Table 6**. The contribution of milk and dairy products to the daily dietary intake of iodine has been estimated as 37% of the total intake in the United Kingdom and only 6–7% in Germany.

Molybdenum

Molybdenum is an essential component of several enzymes, including xanthine oxidase, aldehyde oxidase (EC 1.2.3.1), and sulfite oxidase (EC 1.8.3.1), where it occurs in the prosthetic group molybopterin. It is not known whether the human requirement is for molybdenum *per se* or for molybopterin (or a precursor). Although molybdenum deficiency has been reported in a patient on long-term total parenteral nutrition therapy, dietary deficiency of molybdenum has not been observed in humans.

The recently established RDAs for molybdenum in the United States are shown in **Table 6**. Milk may contribute substantially to the intake of molybdenum (36% of total molybdenum intake).

Chromium, Cobalt, Fluorine, Arsenic, Nickel, Silicon, and Boron

Chromium is regarded as an essential nutrient for humans, and the earliest detectable effect of deficiency is an impairment of glucose tolerance. The only known function of cobalt in humans is its presence as an essential component of vitamin B12. Fluorine accumulates in the hard tissues of the body (bones and teeth), and although it is not strictly an essential element, it is regarded as beneficial for humans because of its protective role against dental caries.

The recently established adequate intake values for fluorine and chromium in the United States are shown in **Table 6**. As there is no evidence that the intake of cobalt is ever limiting in the human diet, no RDA is necessary.

There is substantial evidence to establish the essentiality of arsenic, nickel, silicon, and boron in animals, and it is likely that these trace elements are also essential for humans. However, the nutritional functions of these elements are still unclear and there are no reliable data on which to base estimates of human requirements.

Milk and dairy products do not contribute significantly to the intake of fluorine, arsenic, silicon, and boron. Milk may make a significant contribution to the intake of chromium (21%) and nickel (11%).

Conclusions

There is much less information on the nutritional aspects of some trace elements than those of others, and a considerable amount of current research is being carried out to clarify the roles of such minerals in nutrition.

Reliable information on the content of at least some of the trace elements in milk and the principal factors affecting it is now available. However, for the other trace elements there is still a wide variation in reported values in the literature, which is due, at least in part, to analytical difficulties. The contribution of cow's milk and milk products to the diet in Western countries is significant for zinc and iodine.

Although the chemical forms of the some of the trace elements (iron, zinc, copper, manganese) in milk are fairly well defined, the forms of many of the trace elements are unknown. Studies are required to characterize the chemical forms of a number of trace elements in milk.

Iodine is believed to be almost totally absorbed from milks and infant formulae. The bioavailability of some other trace elements (e.g., iron, zinc) in human milk appears to be very high (generally higher than in cow's milk), but the reason for this remains unclear. There is little information on the bioavailability of copper, manganese, selenium, fluorine, or other trace elements in milks, formulae, and dairy products. Factors affecting the bioavailability of minerals are still poorly understood and the role of possible enhancers (e.g., lactose, ascorbate, citrate, phosphopeptides, lactoferrin) or inhibitors (e.g., proteins, calcium, phosphate) of absorption of minerals from milks remains unclear. However, milk does not appear to contain substances that are strongly inhibitory to mineral absorption, such as phytate or polyphenols in foods from plants.

Finally, understanding the nutritional significance of trace elements in milk and dairy products will also benefit from the improvement in our knowledge of fundamental aspects of minerals, such as their nutritional roles, requirements, and metabolism, and the quantitative relationship between dietary intakes and health.

History

The oldest recorded evidence of domestication of the dairy cow appears to date from about 3100 BC. A relief frieze from Al-Ubaid, Iraqi Museum, Baghdad, provides verification of this. Since then, for a period of several hundred years, reliance on hand-milking has prevailed. The first record of an attempt to circumvent the sphincter muscle of the teat of the cow was in Egypt in about 400 BC. The first devices used were straws or tubes fashioned from quill feathers, which were introduced into the teat duct. Subsequently, mechanical milking was developed from three principles of milk extraction:

1. the use of a catheter inserted into the teat duct allowing the milk to drain from the udder
2. the use of the pressure principle to duplicate the technique of hand-milking
3. the use of vacuum (suction) to imitate the sucking action of the calf

The development of these principles did not follow in chronological order and there was much overlapping of these principles by the introduction of many devices. The major countries to actively develop these principles were the United Kingdom, Sweden, Australia, New Zealand, and the United States.

The Catheter Principle

The issue of mechanical milking next received attention in the early 1800s, when a small metal tube apparatus for insertion into the cow's teat was patented by Blurton in England in 1836 (**Figure 1**). In 1875, Sylvester A Smith of Letts, Iowa, patented a method of extracting milk from the udder of the cow, which consisted of inserting a tube into each teat; the tube was closed by a valve at the lower end. Milk ran into a pail when the simple sliding valve was opened (**Figure 2**). The idea of the milk tube persisted for many years and the Moreton automatic milker was advertised in England as late as 1916. The failure of this approach was no doubt due to the spread of udder diseases via the catheter and the injury to the sphincter muscle of the teat. It was reported that after using this treatment for a few months, milk dribbled from the teat continuously.

The Pressure Principle

Many devices were employed using the application of pressure on the teat in an attempt to duplicate hand-milking – plates, bars, belts, or rollers – and these were mechanically, hydraulically, or pneumatically driven. The Crees Lactator (**Figure 3**) is a notable example of this type of device patented in 1881. The Beyer and Rohde machine patented in 1886 (**Figure 4**) illustrates the complexity and crudeness of this method. In 1892, a Danish machine patented by Jens Neilson was another clumsy, complicated, hand-powered attempt at a pressure device (**Figure 5**).

The Ljungström and Dalén milking units were two similar machines using the pressure principle. Frederick and Birger Ljungström obtained a patent for their machine in 1902. Later, the Dalén machine, patented in 1908, utilized compressed air to drive pistons against the teat in a futile attempt to duplicate hand-milking (**Figure 6**). Two more pressure-type machines of a similar nature, the Omega, the forerunner of the Manus machine, appeared in 1909–10. Compared with

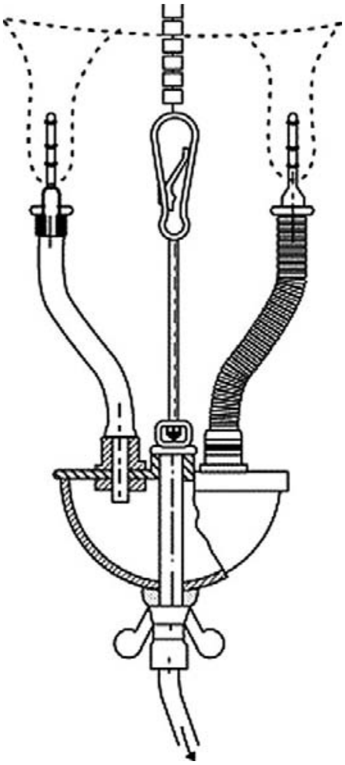

Figure 1 Catheter device patented by Blurton in England (1836).

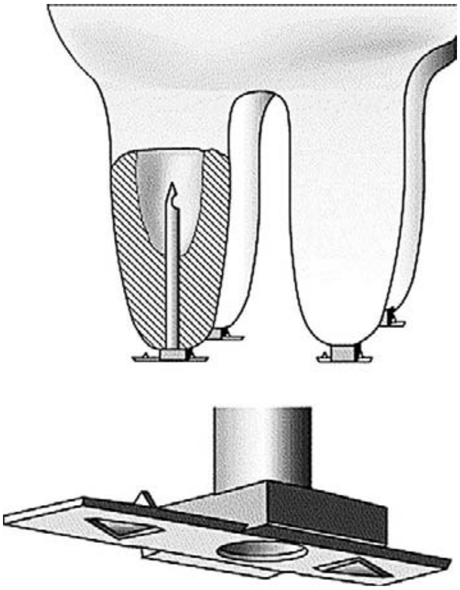

Figure 2 Milk tube with slide valve patented by Sylvester Smith, USA (1875).

hand-milking, these pressure-type machines milked at a slower rate, gave a lower milk yield, caused teat injuries, and required a high degree of operator skill. With such definitive conclusions, failure of this principle became inevitable.

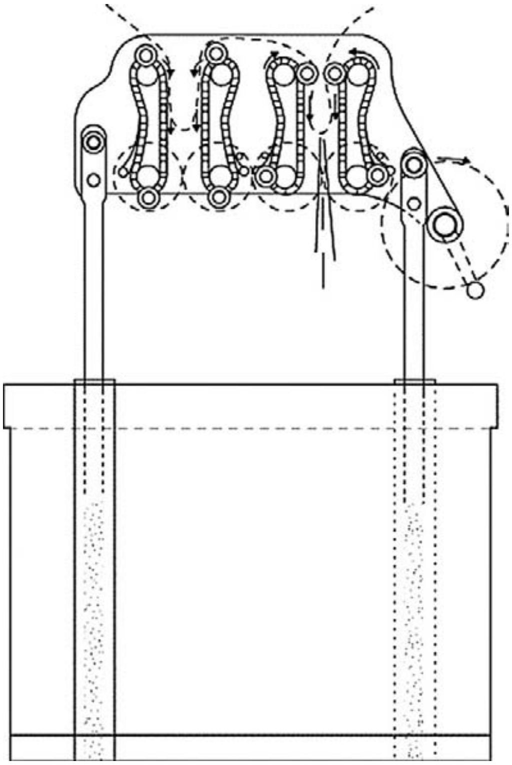

Figure 3 The Crees Lactator, patented in England (1881).

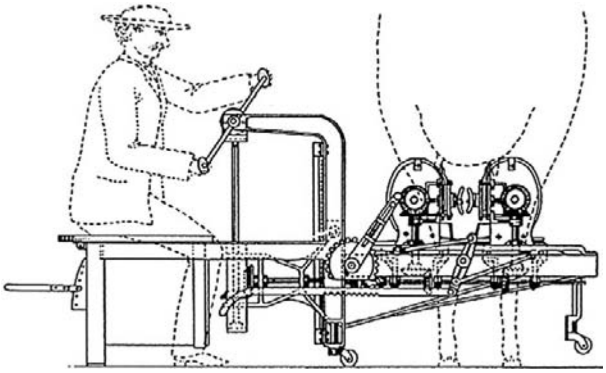

Figure 4 Complicated device by Beyer and Rohde, Wisconsin (1886).

The Vacuum Principle

In the meantime, there was increasing interest in the use of the vacuum principle. The initial idea of using a vacuum to extract milk from a cow is attributed to two British inventors, Hodges and Brockenden, in 1851. The L. O. Colvin hand-operated vacuum milker (United States) patented in 1860 utilized handles, which were moved back and forth by the operator to create a vacuum (**Figure 7**). Anna Baldwin of the United States made use

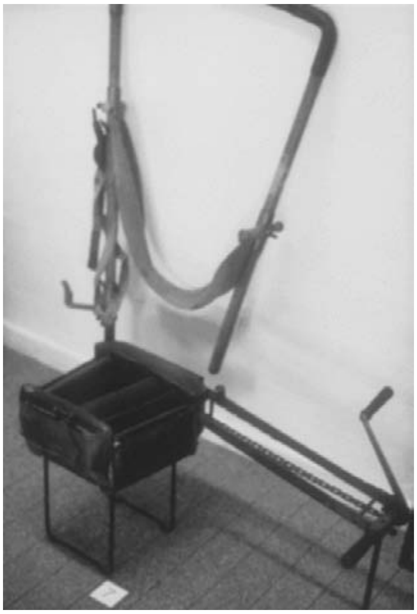

Figure 5 Hand-powered pressure device by Jens Neilson, Denmark (1892).

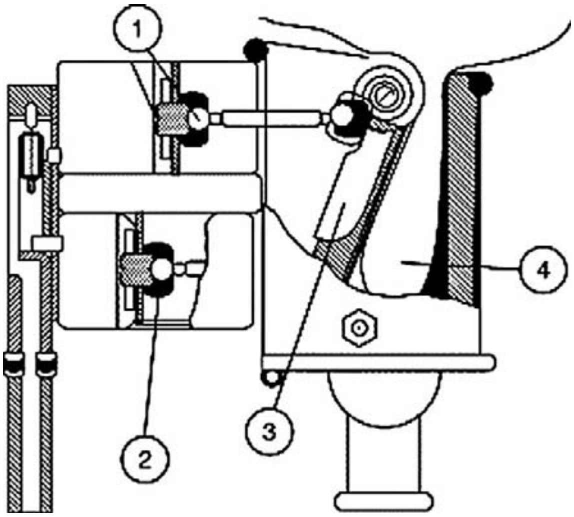

Figure 6 Compressed air-operated machine by Dalén (1908). Pistons 1 and 2 are driven by compressed air. The upper piston pushes forward the upper edge of the rubber plate (3), thereby closing the teat (4). Then the lower piston (2) presses the lower part of the rubber plate onto the teat and presses out the milk. The pistons retract together.

of the hand-operated water pump to create vacuum to milk (**Figure 8**). A foot-powered machine patented in Maryland, USA, in 1895 had limited success for several years (**Figure 9**). The Murchland teat-cup (**Figure 10**) had a rubber mouthpiece, which was later extended to form an open lining. Murchland also had the idea of piping the milk under vacuum to a central collecting point.

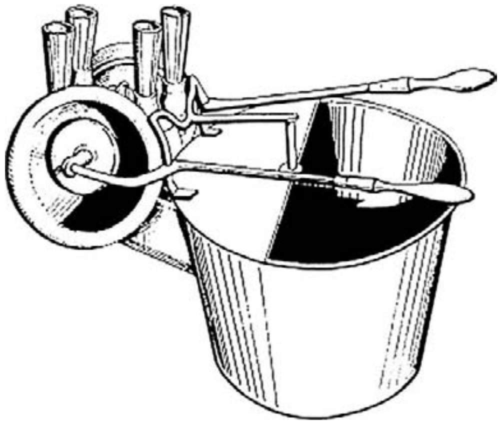

Figure 7 L. O. Colvin vacuum milker, USA (1860).

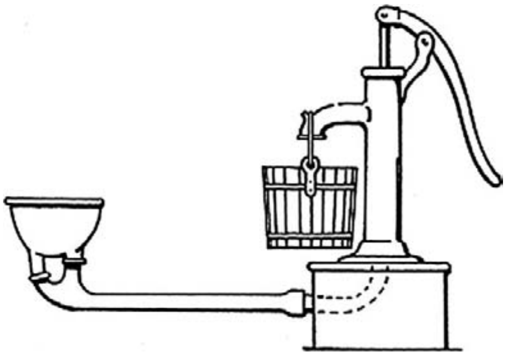

Figure 8 Utilization of a water pump to create vacuum by Anna Baldwin (USA, 1878).

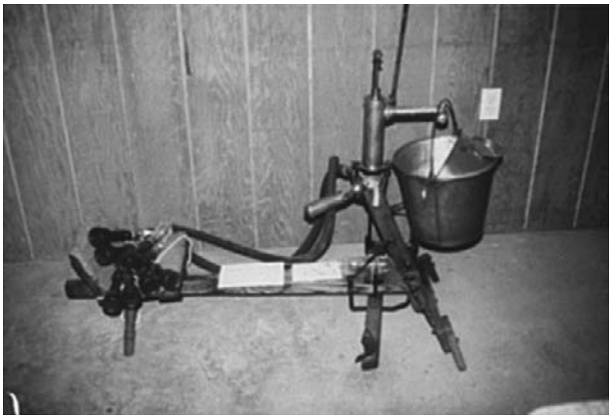

Figure 9 The foot-powered Mehring milker, Maryland (1895).

The first ‘pulsator’ was used by Dr. Shields of Glasgow (Thistle Mechanical Milking Machine Company). His idea was to relieve the stress on the teats of a constant vacuum by oscillating the vacuum on the teat. The single-chambered teat-cups were ‘pulsated’ at pressures between 50 and 15 kPa to form what was to become known as the ‘swinging vacuum’ machine.

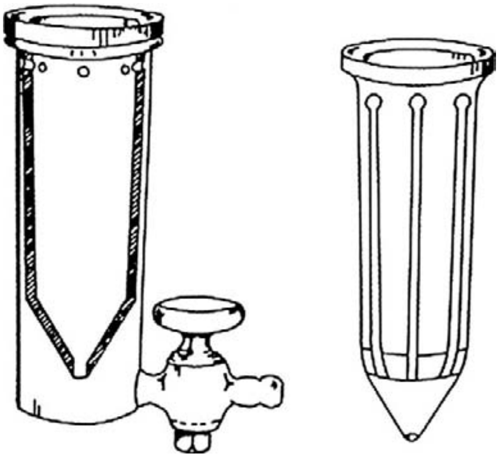

Figure 10 The Murchland teat-cup, Scotland (1889).

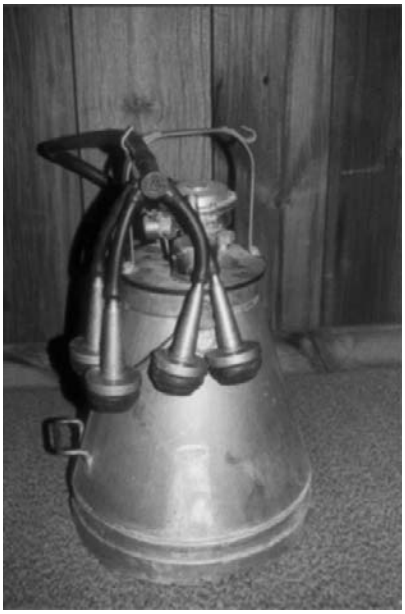

Figure 11 Burrell–Lawrence–Kennedy machine (1897). A US version of Lawrence–Kennedy machine, England).

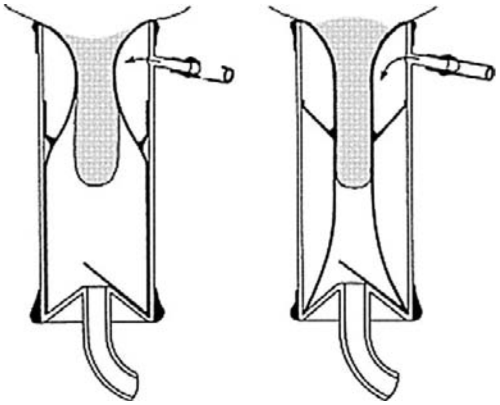

Figure 12 Double-chambered teat-cup by Struthers and Weir, Scotland (1892).

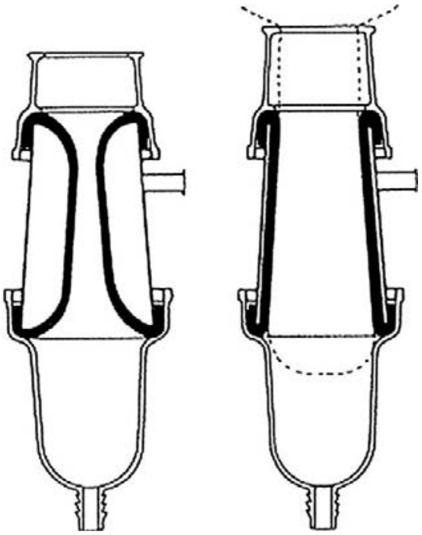

Figure 13 Double-chambered teat-cup by Harnett and Robinson, Australia (1893).

Patents for his ideas were recorded in 1895 and 1896. The Thistle Mechanical Milking Machine Company failed, but one of its directors, Robert Kennedy, joined up with a Glasgow engineer, William Lawrence, to produce the Lawrence–Kennedy machine in 1897. This machine was based on a single-chambered teat-cup with an intermittent vacuum (**Figure 11**). This machine is considered to be the first successful commercial milking machine.

Meanwhile, the first stages of the development of the double-chambered teat-cup were taking place. A patent was granted to Struthers and Weir of southwest Scotland in 1892 for a machine with a teat-cup made up of an outer shell with an inner liner of rubber (**Figure 12**). This advance does not appear to have had any commercial development. However, 1 year later, Harnett and Robinson, working independently in Australia, were granted a patent for a very similar invention (**Figure 13**). These devices were claimed to produce an intermittent pressure on the teat using a rubber diaphragm to 'counteract the influence of vacuum on the teat'. It is ironic that the Harnett patent included a device that 'automatically destroyed the vacuum in the tubes of the milking machines when the animal is sufficiently milked'. It took another 50 years before the principle of automatic cluster removers (ACRs) was incorporated into the design of milking machines.

In the same year (1902), an Australian dairy farmer by the name of Alexander Gillies patented a teat-cup

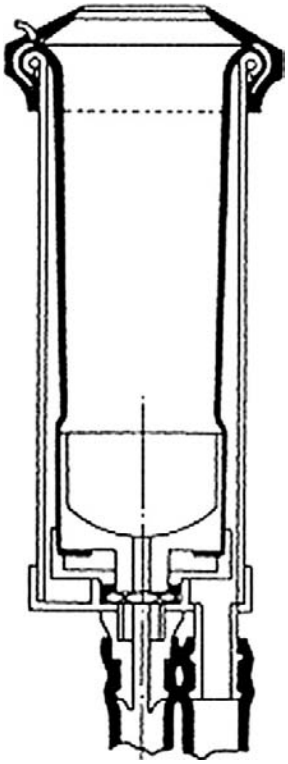

Figure 14 Teat-cup with a flexible mouthpiece by Alexander Gillies, Australia (1902).

consisting of a rigid rubber casing with a thin flexible lining (**Figure 14**). A second patent by Gillies in 1903 indicated that the assembly could be dismantled easily, along with an air bleed to move the milk more readily to the receiver. Thus, the basic principle(s) of the milking machine was born, and is used to this day.

Basic Milking Machine Function

The milking process consists of two phases of a pulsation cycle. Pulsation is defined by the International Standards Organization (ISO) as movement of the liner wall. The internal liner moves to an open position known as the milking phase and then to closure or the rest phase (**Figure 15**). A partial vacuum furnishes the energy to remove milk from the udder. At the interface of the teat and liner, the partial vacuum performs four basic functions:

1. The mouthpiece and barrel of the liner form a vacuum seal and friction on the teat, which offset the gravitational forces of the cluster weight.
2. The application of vacuum to the teat creates a pressure differential across the streak canal to remove milk from the teat during the milking phase of the pulsation cycle.

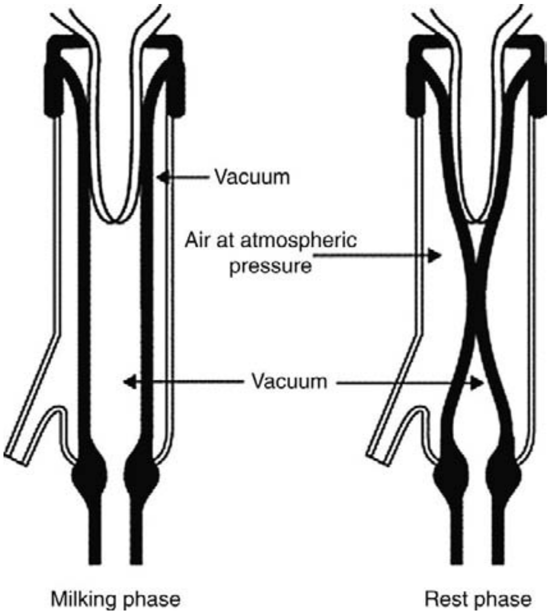

Figure 15 Basic operation of a milking machine showing liner in open and closed positions.

3. The partial internal vacuum within the liner closes the liner on the teat as atmospheric air is admitted between the liner and the shell. A compressive load is applied to the teat by the collapsing liner, which restores the streak canal to near its original diameter with each pulsation cycle so that milk can be removed effectively at the subsequent liner opening.
4. Liner opening is achieved by the application of a vacuum to the liner–shell chamber area.

In milking technology, vacuum is measured as gauge pressure expressed in kilopascal (kPa). Gauge pressure is referenced to atmospheric pressure, with vacuum expressed as a negative value relative to the atmosphere. The standard unit of force is the newton (N) and the standard unit of area is the square meter (m^2). Thus, pressure (P) is force per unit of area ($N\,m^{-2}$) and the derived unit is the pascal (Pa). The pressure unit used for milking is the kilopascal (kPa), which is equal to $1000\,N\,m^{-2}$ or 1000 Pa.

Vacuum has additional functions in machine-milking, such as transporting milk within tubes and pipes. In addition, it is the force used in cleaning complex piping systems without disassembly.

The ideal operating vacuum has not yet been established. The operating vacuum on the system varies among and within manufacturers. In general, the range tends to be between 40 and 50 kPa. Usually, some allowance is made for the height of the milk pipe above or below the cow platform, with increasing vacuum on high pipelines. In some cases, an allowance is made for the liner, depending on the collapse resistance of the liner. Operating vacuum influences milk flow rate, with yielding higher vacuum higher flow rate. Lower vacuum levels also increase the slip rate of most liners. As vacuum is increased, the postmilking strippings also increase, making the choice of operating vacuum a compromise. Excessively high vacuum (<50 kPa) has been shown to increase hyperkeratosis, or formation of callus-like tissue at the teat end, as does overmilking.

Vacuum Pumps

Electrical energy, which is normally used, is transformed to a pressure less than atmospheric pressure in a closed system by a vacuum pump. Until recently, the most popular type of vacuum pump has been the rotary vane. Its operation is depicted in **Figure 16**. The lobe-type pump is currently very popular (see **Figure 17**). The use of variable-frequency drive (VFD) systems in conjunction with vacuum pumps has resulted in energy savings and reduced noise levels. VFD turns the pump at the required rpm to equal the vacuum requirement. Regulation of milking vacuum is done electronically by the variable-speed drive; however, sometimes, a standard regulator is installed as an emergency measure in case of an electronic control failure.

The milking cluster airflow allowance is from 60 to 70 l min^{-1}, depending on pulsator rate and pulse tube dimension and length. This requirement consists of 20–30 l min^{-1} per milking cluster for the incremental component of effective reserve, pulsator consumption of 30 l min^{-1}, and cluster air admission of 10 l min^{-1}. The other major requirement variables during unit application and liner slips and falloffs. A falloff is the most severe usage requirement due to its sudden and large volume air admission. The minimum allowance for a falloff for each plant is 1000 l min^{-1}. An even greater allowance is indicated if the long milk tube of the cluster exceeds 16 mm in diameter. The cluster application requirement is then covered by the falloff allowance in the basic effective reserve. The final allowances for a newly installed system should allow for system leakage, pump wear, and regulation losses. Thus, the final allowances for the basic pump capacity are

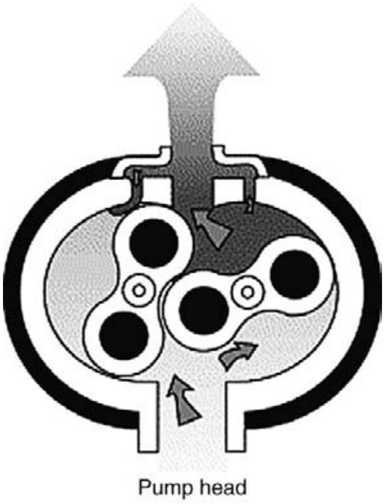

Figure 17 Lobe-type vacuum pump operation.

$$(1000 + 85n)\ \text{minl}^{-1}$$

where n is the number of milking clusters.

Milk Pump or Releaser

Milk pumps or mechanical releasers serve to remove milk from under vacuum to atmospheric conditions of a bulk tank. They are found in conjunction with the pipeline receiver or milk accumulator. Mechanical releasers have given way to milk pumps due to their low capacity. Milk pumps must be sized to the maximum flow rate of the total milk flow from the milking units and/or washing requirements. Liquid level controls are necessary to keep the milk pump from mixing air and milk, which causes an off-flavor in the milk. Recently, milk pumps have the option of being operated by VFDs. This is especially helpful when used in conjunction with a plate cooler or other type of inline cooling. The VFD improves cooling efficiency over start/stop operation of the milk pump by providing continuous milk flow at a lower flow rate than start/stop operation.

Air trapped and being carried to exhaust port
Air being expelled through port

Figure 16 Vane-type vacuum pump operation.

Regulators

The regulator serves the function of maintaining a preset vacuum level by admitting excess air into the closed system. In the event that there is insufficient pump capacity to meet the vacuum usage, the vacuum level falls since the regulator only admits air in excess of the vacuum requirement.

There are many types of vacuum regulators. The early types of regulators were usually spring loaded or of the weighted type. The weighted types were lever-operated, deadweight, or deadweight compensated. Both the spring-loaded and weight-type units have been found to be flow rate sensitive, that is, the vacuum level changes as the airflow varies through the regulator opening. More recently, the type of regulator of choice has been the diaphragm type. This regulator maintains a more constant vacuum and is much less sensitive to vacuum change as airflow through the valve opening varies. It is generally accepted that constant vacuum (±2 kPa or less) is the desired operating condition for milking systems. A constant vacuum during milking is essential, since irregular vacuum fluctuations have been shown to increase the new infection rate of the udder.

The regulator controlling the VFD pumps is an electronic transducer. This device signals the frequency drive to change the rpm of the pump motor to meet the vacuum needs of the system. When installed and tuned properly, the VFD vacuum systems can maintain vacuum within the prescribed limits.

The Milking Cluster

The cluster consists of the liner, the shell, and the clawpiece or a manifold; the clawpiece connects the short milk tubes of the liners to a common long milk tube. The long milk tube is connected to a vacuum source. The clawpiece may also serve as a mounting device for the pulsator spreader. Each teat-cup has a short pulse tube connecting to the clawpiece spreader. The spreader connects to the long pulse tube(s), which is then connected to the pulsator. **Figure 18** shows the milking machine cluster.

The ideal capacity for the clawpiece has not been established; however, one study indicated that capacities of greater than 300 ml had no particular advantage. The clawpiece is equipped with an air vent to move milk away from the clawpiece, by breaking up the milk column. Air admission is normally 5–20 l min^{-1}. Basically, the air vent reduces the claw vacuum to a level lower than the source vacuum, thus moving the milk away from the clawpiece due to the difference in pressure (vacuum). The resulting admission of air increases the air-to-fluid ratio in a two-phase flow system and reduces hydrostatic head. Sometimes, the air venting is done in the short milk tubes. An air vent of proper size is an important consideration since inadequate venting may cause a substantial increase in claw vacuum in low-line or tunnel parlors due to hydrostatic head. Conversely, excessive air admission may adversely affect milk quality by activation of the free fatty acids of the milk, resulting in an off-flavored product.

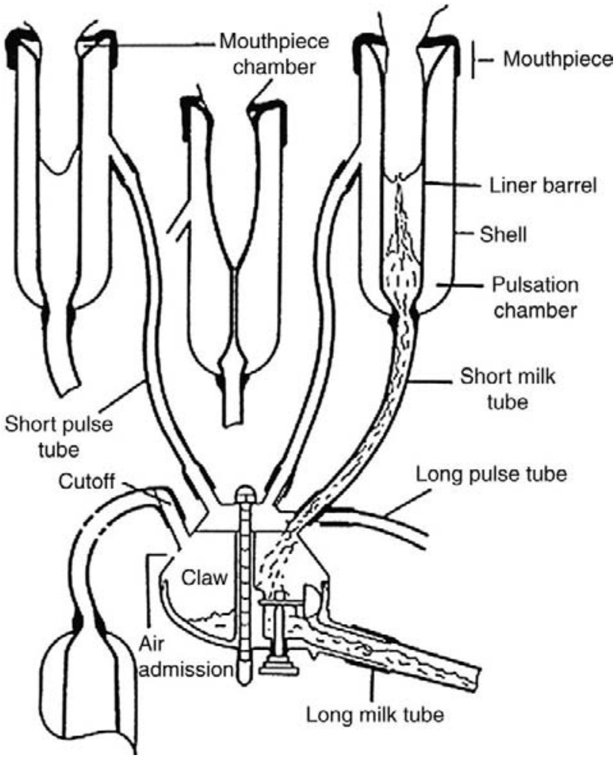

Figure 18 The milking machine cluster.

Automatic Cluster Removers

ACRs have become very popular on dairy farms. They serve to permit the operator to operate more units safely and prevent overmilking. Machine-on times can also be reduced, thereby resulting in faster throughput and reduced labor. Teat health may also be improved by reducing the number of liner closures on the teat. Excessive liner closures on the teat may exacerbate the condition of hyperkeratosis.

There are several means to determine the end point of milking, including the use of load cells, volumetric types, and mechanical and electronic flow rate sensors. Initially, the typical end point setting was when flow rate reached 0.23 kg min^{-1} and the delay time for removal was about 30 s. Recently, there is emphasis on increasing the flow rate setting and reducing the delay time for unit removal. Recent studies indicate that flow rate settings greater than 0.9 kg min^{-1} reduces milk yield. Unit removal set times may be as low as 3.0–5.0 s at the present time.

Shells

Teat-cup shells form a chamber around the barrel of the liner. This chamber is sealed at the top and bottom by the liner. The chamber can then be placed under vacuum or, alternatively, air admitted to this chamber to control liner wall movement or pulsation. The shell is fitted with a nipple in order to be connected to the spacer on the clawpiece with the short pulse tube. The location of the nipple is not important with respect to the influence upon the liner. Shells are normally constructed of stainless steel in a cylindrical form; however, some are molded in plastic. The vacuum changes in the shell–liner chamber are usually measured on the short pulse tube connecting the spacer and the shell. The resulting vacuum tracings are used to evaluate pulsator performance **Figure 19**.

Liners

The liner is a flexible tube made of natural, synthetic, or silicone rubber. The synthetic liners are currently the most popular option. The use of silicone is increasing in popularity and there is a decreasing use of natural rubber. However, most synthetic liners contain some natural rubber. There are many different liner designs in use. They are either molded or extruded into the desired shape for placement into the shell. They are normally under some tension in the shell to seal them at either end to prevent the entrance of moisture and soil. The tension also increases milking rate, but, if excessive, shortens liner life.

The classic opening and closing of the liner as shown in **Figure 15** is due to the imposed pressure differences across the wall of the liner as the pulsator operates. By definition, the movement of the liner wall is termed 'pulsation'. As the liner begins to close, this is known as the buckling pressure or the critical collapsing pressure difference (CCPD). Typical CCPD is 17–27 kPa, but liners with a barrel wall that is shaped other than round (oval, square, or triangular) will have a lower CCPD. Barrel wall thickness and tension affect the CCPD markedly, while rubber compounding has a relatively minor role in influencing CCPD.

A second measure of liner characteristics is its touch point pressure difference (TPPD), sometimes known as the 'inflection point'. This is the pressure difference at which the walls of the liner touch as the liner is in the process of closing. The liner continues to close beyond the touch point; however, measurement of the continuation of closure is not a repeatable measure. The major factor affecting the TPPD is the barrel wall thickness of the liner. TPPD may typically range from 30 to 45 kPa.

Liner slippage is related to an increase in the new infection rate of the udder. Operating vacuum influences liner slip, with higher vacuum having fewer slips. Liner slips are also influenced by udder shape, teat location, proper cluster adjustment, and teat preparation. Clusters applied to wet teats slip more frequently.

The mouthpiece chamber vacuum of the liner is quite variable but important with regard to milking characteristics. Wide-bore liners have a higher mouthpiece vacuum than narrow-bore liners. This is due to a combination of the teat seal on the liner barrel and air leakage of the mouthpiece of the liner. At the onset of milking and

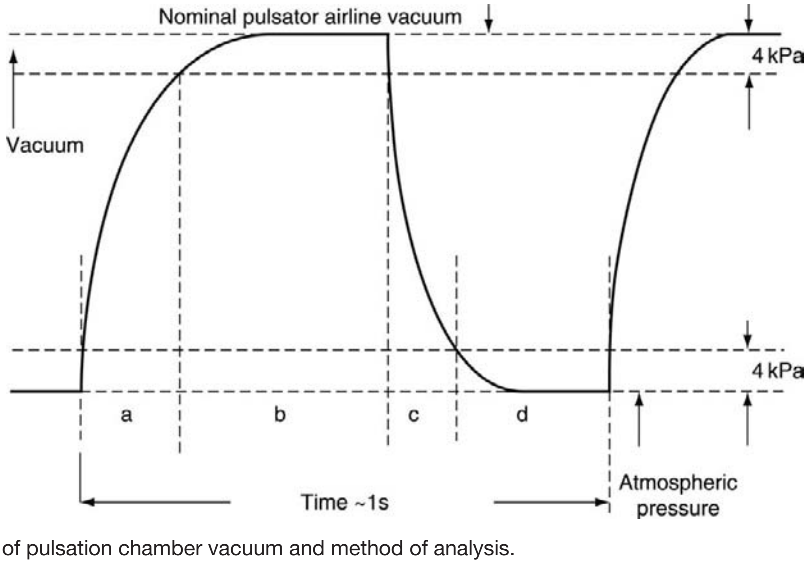

Figure 19 Waveform of pulsation chamber vacuum and method of analysis.

during milk flow, vacuum is relatively low and stable in the mouthpiece. As the teat milks out, vacuum generally increases and vacuum variability dramatically increases in relation to pulsator frequency. Teat penetration into the liner also influences mouthpiece chamber vacuum. Pulsator ratio has little effect on this characteristic.

High mouthpiece vacuum is associated with an increased frequency of tissue stress rings at the base of the teat, a greater risk of mastitis, increased discomfort to the cow, and a higher frequency of discolored teats. Mouthpiece vacuum is an excellent indicator of when the quarter has milked out due to the rather sudden increase in vacuum and vacuum variability.

Liner life is influenced by many factors such as rubber compounding, number of cow milkings, and number of washings. In the United States, liner life is usually recommended as 1000–1200 milkings, while in Europe, the typical recommendation is 2500 milkings. The difference is due to compounding requirements of regulatory agencies. A satisfactory method to determine the effective life of the liner remains an enigma to the industry, although peak milk flow rate appears to be the most sensitive indicator of liner age.

Pulsators

The purpose of the pulsator is to change the pressure conditions between the liner and the shell (pulse chamber) from atmospheric pressure to vacuum in an alternating manner (see **Figure 15**). The pulsator is basically an air valve, switching the pulse chamber pressure. By changing the vacuum to atmospheric pressure in the pulse chamber, the pulsator causes ‘pulsation’ or liner wall movement. The rate of change is known as the pulse rate. This rate is usually within the range of 50–60 min^{-1}, although greater ranges have existed from as low as 40 min^{-1} to as high as 180 min^{-1}. Generally, pulse rate has a small influence upon milking rate. The pulsator rate for small ruminants is usually higher than that for dairy cows, normally about 90 pulsations per minute.

Another pulsator characteristic is known as ratio. This term relates to the relationship between the milking phase of the pulsation cycle and the resting phase of the cycle. When the milking phase is equal to the resting phase, the ratio is 1:1 or 50% in the milking phase to 50% in the resting phase. Ratios as wide as 70% milking to 30% closed have been shown to be safe to the cows. The ratio has a definite influence on milking rate. Wider ratios milk faster; a 70:30 ratio reduced machine-on time by 1 min per cow compared to a 50:50 ratio in a US study. ISO specifies that the ‘b’ phase of the pulsation cycle shall be 30% or greater and that the ‘d’ phase shall not be less than 15% or 150 ms (see **Figure 19**).

Pulsation can be applied to the teats in different sequences. It is known as simultaneous pulsation when all four liners open and close at the same time (4 × 0). This is usually accomplished with a single long pulse tube and a four-way spreader at the clawpiece. When two liners are closed and the opposite two liners are open, it is known as alternating pulsation (2 × 2). Alternating pulsation can be applied in different patterns, including side to side of the four quarters, front to rear of the four quarters, and diagonal quarters. The last configuration is seldom used. A dual pulse tube is required for alternating pulsation. It is also possible to operate the milking unit sequentially, with each liner operated independently. Since sequential pulsation requires four pulse tubes, the flexibility of the milking unit is compromised, and this method is seldom employed.

Technically, pulsation is liner wall movement (ISO 3918). The method of defining the pulsator waveform is shown in **Figure 19**. While the liner wall generally follows the pressure changes in the pulse chamber, the waveform of the pulse chamber does not match the position of the liner. This relationship is shown in **Figure 20**.

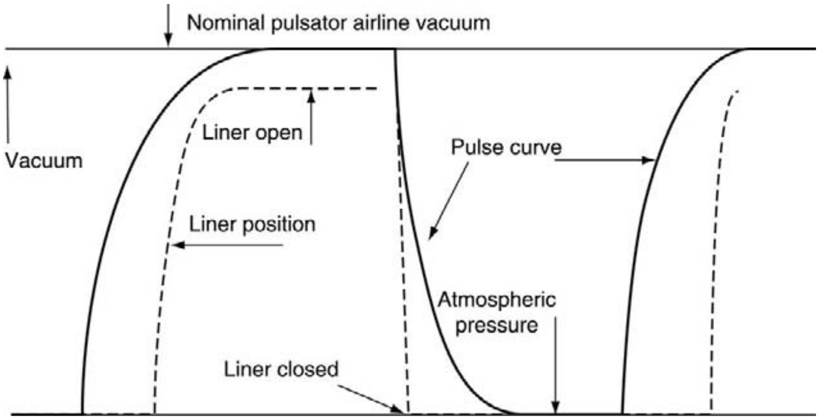

Figure 20 Waveform of pulsation chamber vacuum and the relative position of the liner wall.

Each liner design tends to have its own characteristic movement since it responds to the difference in pressure between the walls of the liner barrel.

Several types of pulsators are available. The pneumatic pulsator operates from the vacuum of the system, with each pulsator operating independently. While this type of pulsator does essentially the same function as an electronically controlled one, it is generally not quite as reliable due to fouling, temperature fluctuations, and humidity changes.

There are also several forms of electronic pulsators. Magnetic units may be centrally controlled by a make-and-break DC current. Some types of electric pulsators operate from a low-voltage AC current. Other types may be controlled from a master pulsator to a series of slave units located strategically in the milking area and operated by a pulse tube or pipe from the master. Whatever the type, they must perform the function of applying vacuum and atmospheric air to the pulse chamber. Pulsation failure has consistently been shown to increase the new infection rate of dairy cows.

Recent research indicates that a rapid pulsator 'c' phase decreases milking performance. The longer the milking times, the lower the peak and average flow. Yield in 2 min is lower while total yield is unchanged. Thus, a minimum 'c' phase of 12% (120 ms) is indicated. The effect appears to be due to the rate of liner wall closure. A fast moving liner (>120 ms) applies a greater pressure at a faster rate to the teat.

Supplementary Equipment

Milking machine components are generally assembled into a system on the dairy farm. The basic system may consist of a milking unit attached to a bucket with vacuum furnished from the vacuum pump via a vacuum piping system. Milk is then carried to a collecting point and ideally cooled prior to collection. Cooling is essential to prevent bacterial growth in the product.

Pipeline systems are more complex and have sanitary piping systems to transport milk from the cow to the collecting or cooling point. Sanitary piping systems are constructed of stainless steel or glass. Proper size in relation to degree of slope is given in **Table 1**. Piping systems are configured to be cleaned-in-place (CIP). Specialized cleaning compounds are circulated through the system after each use to prevent the accumulation of milk soils. Automatic cleaning controls are available to circulate solutions. Proper cleaning requires an adequate supply of potable hot water, and solution contact with all milk contact surfaces. Piping systems are cleaned most readily by a combination of air and cleaning solution in a slug formation completely around a circuit. Slug velocity should be kept between 6 and 10 ms, otherwise the slug may dissipate and no longer effectively contact the surfaces to be cleaned.

Table 1 Recommended milk pipeline size in relation to number of units per slope

Units per slope				
	Slope (%)			
Milkline diameter (mm)	*0.8*	*1.0*	*1.5*	*2.0*
50	2	3	4	5
64	6	6	9	10
75	11	13	16	20
98	27	30	38	45

Adapted from ASAE (American Society of Agricultural Engineers) S518.2. Jul 96

The pulsator side of the vacuum system may be constructed of iron pipe, stainless steel, or PVC. Pipe sizing should be adequate so that the difference in vacuum within the system does not exceed 2 kPa and the action of the pulsators does not influence vacuum by more than 2 kPa. Bucket systems should be provided with a means to clean vacuum supply pipes periodically.

A releaser or sanitary milk pump accomplishes circulation and removal of milk from under vacuum conditions. A liquid level control system or, more recently, VFD controls the rate of removal of fluid from the receiver. During milking, it is important to keep the milk level above the pump intake to prevent cavitation. Introduction of air by a starved milk pump leads to a serious flavor defect by the release of free fatty acids in the milk.

Milk recording of individual cows is possible with the use of recorder jars or milk meters. Glass recorder jars collect the milk yield of the cow at each milking and are calibrated to determine the amount of milk the cow has produced. Milk is released once each cow has been milked. Milk meters may be of the portable type or may be permanently installed. When permanently installed, electronic types of meter may collect the data and aid the dairy farmer in management decisions.

ACRs are popular adjuncts to milking systems that remove the milking units from the cow when a specified low milk flow condition is achieved. Typically, activation of the takeoff sequence is initiated when milk flow drops to 0.25–0.9 kg min^{-1}.

The most recent development in milking machines involves the use of robotic equipment to milk the cows on a voluntary basis without the attendance of an operator. The feasibility of using this equipment to milk cows has been amply demonstrated. The adoption rate and economic implications under a wide variety of conditions have not yet been established for this technology.

Robotic Milking

Introduction

The main reason for starting the development of automatic milking systems (AM systems) was the need for improved labor efficacy due to the growing costs of labor in many dairy countries. Milking continues to be a time-consuming activity on many dairy farms, requiring about 25–35% of the annual labor demand, so milking contributes substantially to the costs of the farm enterprise. Apart from substituting manual labor by technology, robotic milking affects the whole farming operation. The farmer's presence at regular milking times is no longer required. The nature and organization of farm labor change such that manual labor is partly replaced by management and control activities. Regular visual checks of cow and udder health during milking are taken over by automated monitoring. Satisfactory cleaning of cows and teats, as well as milk analysis and separating abnormal milk, is required. An AM system is in use for 24 h a day, which requires a high reliability of the AM systems as well as the adaptation of cleaning and cooling systems. Permanent access to the milking system may require specific cow routing within the barn and is likely to affect the possibilities of grazing, although many AM farms are able to apply grazing. Reduced labor demand and better social circumstances for the dairy farmers are the attractive benefits of AM systems. Other potential benefits are improved animal health and well-being and increased milk yields.

Technical Aspects

The development of AM systems started with the development of equipment for automatic attachment of the teat cups. After the development of the milking machine, parlors, and automatic cluster removers, automatic attachment of the teat cups was the only missing step in the complete automation of the milking process. However, automatic milking requires more than automatic teat cup attachment. An AM system has to take over the 'eyes, hands, and partly brains' of the milker and therefore these systems have electronic cow identification, cleaning, and milking devices and computer-controlled sensors to control the milking process and to detect any abnormalities in both animals and milk.

An AM system has six main modules:

- milking stall,
- teat-cleaning system,
- teat detection system,
- robotic arm device for attaching the teat cups,
- control system including sensors and software, and
- milking machine.

The Milking Stall

AM systems can be divided into one- and multistall systems. The one-stall systems have a milking stall with an integrated milking machine and a robot device for attaching the teat cups. The multistall systems have up to five stalls and a mobile robot device, which moves from one stall to another to attach the teat cups. All AM systems are equipped with electronic ID reading systems to identify the cow's ID tag in order to decide if the cow has to be milked or not. AM systems have a concentrate dispenser to make the cow's visit to the system more attractive. Furthermore, the milking stall is equipped with a gate system to control cow traffic from barn to AM system and vice versa.

Teat-Cleaning System

The purpose of cleaning the teats is primarily to remove dirt and other particles that can contaminate the milk. Automatic cleaning is also necessary to meet (inter)national legislation and hygiene rules from the dairy industry. Research and practical experiences at conventional milking systems suggest that if udders and teats are clean, teat washing can be suspended without affecting milk quality. However, current AM systems do not have sensors to detect the amount of dirt at the teats, so the cleaning system should be based on more or less dirty teats. Efficient cleaning is of particular importance with high levels of spores in the environment of the cow. The teat-cleaning system should also aim at minimizing the risk of transferring udder pathogens from teat to teat or from cow to cow. To prevent residues in milk, teats should be free from disinfectants before attaching the teat cup.

There are several principles of teat cleaning with AM systems:

- sequential cleaning by brushes or rollers,
- cleaning with water in the same teat cup as used for milking, and
- cleaning by a separate 'teat cup-like' device.

Generally, plain water is used for the cleaning of the teats. Sometimes, the cleaning devices are flushed with plain water or disinfected between consecutive cleanings. The efficacy of the cleaning devices in cleaning the teats seems to be sufficient, although the results are not as good as manual cleaning by the herdsman in conventional milking systems. Extra attention to the hygiene conditions in the barn is essential to safeguard cleanliness of the udders. Besides cleaning the teats, automatic cleaning devices also stimulate the milk letdown process. Stimulation of the milk ejection reflex is necessary for efficient milking. The different teat cleaning methods do not differ with respect to the intensity of the milk ejection reflex; moreover, it is clear that the way of pretreatment in AM systems before each milking is very repeatable compared with conventional milking, which is seen as a positive effect.

Teat Detection System

The udder shape and teat position will differ substantially from cow to cow and besides breed and genetic merit are dependent on milk production, milking interval, deformation of the udder shape due to cows lying in the cubicle, and stage of lactation. Moreover, cows, although they are locked up, can move in the milking stall and so the position of the teats will change. AM systems have active teat detection systems to localize the four teats. This technically quite difficult process has been solved by using different techniques, like ultrasonic sound, laser techniques, and charge-coupled device (CCD) camera systems. All these techniques are used to find the position and place of the teats in reference to a fixed point at the robot arm. In fact, the system creates a three-dimensional view, so the robot arm knows where to attach the teat cup to the teat. The environment where these techniques have to operate is quite rough with moisture, dust, and manure, and special attention has to be paid to these circumstances to maintain good performance.

Robotic Arm

Different types of robot arms are used. Some robot arms imitate conventional milking by using an arm with a gripper, which picks up the teat cup from a storage rack at the side of the stall. The four teat cups are attached in succession. Some robot arms also take care of maintaining the position of the teat cups during milking and after milking for spraying and disinfection of the teats. Another system uses a robot arm with a fixed milk rack integrated with the robot arm. Each teat cup is attached separately, starting with the teat cups for the hind teats and finishing with the front teats. The robot arm is fixed to the milk stall, so each stall has its own robot arm.

In the multibox AM systems, a movable robot arm is used. In such a situation, the teat cups are positioned in a special teat cup holder close to the cow or the teat cups are mounted on a special milk rack. The robot arm moves from one stall to another, picks up the milk rack and teat cups, and starts the attachment process. After finishing the attachment, the milk rack stays in the same position and the robot arm is disconnected and can be moved to the next stall to start teat cup attachment for the next cow.

Control System and Sensors

AM systems need sensors to observe and to control the milking process as the milker is doing. AM systems therefore are equipped with a variety of sensors. These sensors are the 'eyes' of the AM system and their task is to monitor the technical functioning of the AM system, like cow identification, teat cup attachment, vacuum level, and start of the milk letdown process. The control unit in fact acts as the 'brains' of the AM system. In the case of deviations, the control system decides to cancel or to restart the milking process. Moreover, the control system takes care of an alert message to the end user. Modern AM systems are equipped with sensor technology to control the quality of the milking process, for example, check on abnormalities in the milk, milk yield, electrical conductivity (udder health), temperature of the milk, hormones in milk, feed intake, activity of the animal, and body weight of the animal. Sensors controlling milk quality like somatic cell counts (SCCs) and electrical conductivity are used to detect abnormal milk. If necessary, abnormal milk will be diverted automatically.

All measurements are automatically stored in the control system database and the accompanying management program is used to analyze these data and to control the settings and conditions for the cows to be milked. Attention lists and performance reports are presented to the farmer by screen or printer messages. In urgent cases like a breakdown or severe problems with a cow, the system immediately warns the herdsman by sending text messages to his mobile phone.

The Milking Machine

The milking machine is more or less similar to the milking systems in conventional milking parlors, except for the cluster. AM systems lack a milking cluster and are based on individual quarter milking. For each quarter, a teat cup, milk and pulse tube, and shutoff valve are used to control the milking of the individual quarter. The milk is kept separate till milk of the four quarters enters the central milk meter or the receiver. Although the basic technology is quite similar, in general milk tubes will be much longer than those applied in conventional milking, resulting in a considerable vacuum drop below the teat end during milking.

Barn Layout, Management, and Milk Production

Since AM systems largely depend on voluntary attendance, a well laid-out free stall barn is essential for a successful operation. Cows should have easy access to the milking stall and selection gates: long alleys, steps, and other obstructions should be avoided. A central location of the AM system in the barn minimizes walking distances of the cows. However, in many countries, regulations require that the AM system has to be located close to the milking room and accessible via a clean route. After visiting the milking system, the cow should have access to the feeding area. In 'forced cow traffic' systems, the cow has to pass the milking system in order to get access to the feeding area. In 'controlled-traffic' systems, one-way gates, with cow identification and selection capabilities, restrict cows from going directly to the feeding area only when the interval since the last milking exceeds the preset minimum. In 'free cow traffic' systems, access to the feeding area is unrestricted and only the concentrate fed in the AM system is used to attract cows. Grazing is also possible; however, long walking distances will negatively affect the visiting behavior of the cows to the AM system.

Changing over from a milking parlor to automatic milking will lead to big changes for both herdsman and cow and can cause stress to both. However, it can be concluded that cows in general adapt themselves quite easily to an AM system. Culling rate of cows, because they are not suitable for automatic milking, is reported to be less than 5%. These figures are comparable to those associated with the introduction of milking machines in the 1950s and milking parlors in the 1960s. More important is the introduction and learning period, during which cows should be handled quietly and consistently, to train them to adapt themselves to the new surrounding and milking system.

Automatic milking places emphasis on the cow's motivation to visit the AM system to be milked voluntarily. Cows can more or less decide themselves when to visit the AM system. The main underlying motive for a cow to visit the AM system is the supply of concentrate; therefore, all AM systems are equipped with concentrate dispensers. In the transition from conventional to automatic milking, cows have to learn to visit the AM system at other times than before. This needs special attention, and in the first days or week, human assistance will be necessary. Especially heifers with no history of conventional milking adapt themselves very easily to the conditions of automatic milking.

A large variation in milking intervals can be observed from cow to cow (**Figure 1**). In practice, the number of milkings per day varies from 2.5 to 3.0, but rather big differences in the milking intervals are reported from commercial farms. Cows that fail to visit the AM system voluntarily within the maximum set milking interval have to be fetched by the herdsman. These cows will not show any increase in yield or may even experience production losses. By changing the milking parameters of the AM system, it is quite easy to prevent cows from being milked at too low yields or too short intervals. But it is more difficult to prevent cows from being milked at long intervals. This means it will be necessary to manage the

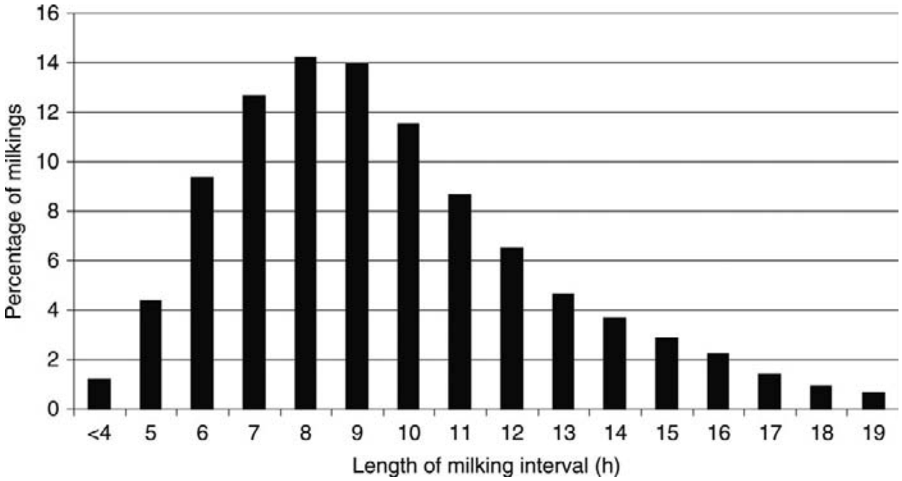

Figure 1 Frequency distribution of the intervals between milkings (2-year period, high-tech farm at Waiboerhoeve, The Netherlands).

intervals by fetching cows that have exceeded a maximum interval. Usually, this is done several times per day when other tasks such as cleaning and bedding have to be done.

The effect of automatic milking on labor requirement depends largely on the management approach, barn layout, and herd characteristics. On average, a 20–30% reduction in labor requirement is reported, but results show large variations. It is obvious that the character of the labor will change from manual work to managerial activities and observations of the cows and their behavior. Therefore, management is without doubt one of the key factors in the successful application of automatic milking.

Capacity

The capacity of an AM system is often expressed as the number of milkings per day. This number will largely depend on the configuration of the AM system, like the number of stalls and the use of selection gates, milking frequency, machine-on time, and herd size. Increasing the number of milkings per cow per day does not necessarily contribute to a high output capacity in kg of milk per day. This is due to the more or less fixed handling time of the AM system per milking and the decreasing amount of milk per milking. The challenge is to maximize the capacity of an AM system in terms of kg milk produced per day in order to minimize the costs per kg of milk produced.

Handling Time and Machine-On Time

A milking visit to the AM system consists of several activities. The cow walks to the AM system, is identified, and if it is allowed to be milked, the process starts. First the udder preparation and teat cleaning take place. The teat positions are detected and the four teat cups are attached. Then the milking process starts. After the teat cup takeoff, the teats are disinfected and the cow is allowed to leave the milking station. The milking visit ends when the entrance gate is opened again to allow the next cow to enter the AM system.

In fact, each milking visit can be divided into two main parts: the handling time of the AM system and the machine-on time covering the milking process. The handling time consists of the time for cow traffic (walking in and out of the system), identification, udder preparation, attachment of teat cups, and teat spraying. The handling time depends mainly on the AM system and on the time to attach the teat cups. Handling times between 2 and 4 min are reported from various studies. The machine-on time depends largely on the yield and flow rate of the individual cow. Between herds and between cows, the average flow rates will differ from 1.5 to 3 kg min^{-1} due to the yield per milking and genetic differences.

Daily Capacity

The maximum number of milkings per day and the capacity in kg per day can be calculated for the one-stall AM systems by using the handling time per milking visit, the machine-on time per visit, and the occupation rate of the AM system. For example, an occupation rate of 80% means that the AM system operates for 19.2 h day^{-1}. The remaining 4.8 h include time spent in rinsing and cleaning of the milking machine, refused milking visits, and the idle time, that is, the time spent by the AM system waiting for the next cow to be milked. In **Table 1** the results are presented for different yields per milking. Increasing the average yield per milking will result in less milkings, but in an increased capacity in kg per day. The results can also be used to predict the potential milking frequency of a herd. For example, 166 milkings per day divided by 60 cows in the herd will result in a milking frequency of 2.8 times per day.

The results show large differences in the number of milkings per day between the three flow rate groups (**Figure 2**). The minimum number of milkings will be 123 milkings per day for the low flow rate group at 15 kg yield per milking, and 230 milkings per day for the high flow rate group at an average yield of 7 kg per milking. Short intervals will result in a lower yield per milking and therefore an increased number of milkings per day. Increasing the yield per milking will result in less milkings per day, but in a higher daily production of the AM system. So milk flow rate and yield have a large impact on capacity in kg per day. By changing the milk criteria for

Table 1 Flow rate, machine-on time, number of milkings per day, and capacity in kg per day at an occupation rate of 80%

Yield (kg)	*7*	*9*	*11*	*13*	*15*
Flow rate (kg min^{-1})	2.27	2.37	2.47	2.58	2.68
Machine-on time (min)	3.08	3.79	4.45	5.04	5.60
Handling time (min)	2.50	2.50	2.50	2.50	2.50
Stay per milking visit (min)	5.58	6.29	6.95	7.54	8.10
kg per day	1444	1647	1825	1985	2134
Number of milkings per day	206	183	166	153	142

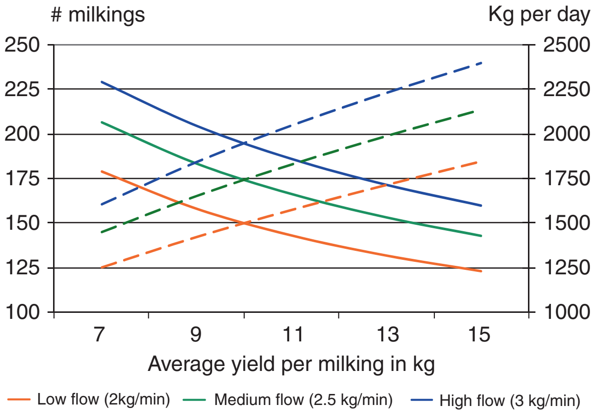

Figure 2 The calculated number of milkings per day and production per day at different yields and flow rates for a one-stall AM system.

Table 2 Global capacity in number of milkings per day for one- and multistall AM systems expressed in herd size

AM system	*Herd size (cows)*	*Number of milkings*
One stall	55–65	150–200
Multistall systems		
Two stalls	90–115	270–320
Three stalls	135–150	400–450
Four stalls	160–190	475–525

individual cows, the AM system can be optimized to realize a maximal capacity in kg per day. **Table 2** presents some global figures for the capacity of one- and multistall AM systems. Each extra stall will show a relatively smaller capacity due to extra walking distances and transport time of the robot arm.

Milk Quality

Milk quality is without doubt one of the most important aspects of milk production on modern dairy farms. Milk payment systems are based on milk quality, and consumers expect, besides food safety, a high quality level of the milk products they buy. Although automatic milking has more or less the same milking principles as conventional milking systems, there are some big differences. The AM system is in use for 24 h continuously. Visual control during the milking process is not possible, which implies both the milk and cleaning of teats. Cows will visit the AM system more or less voluntarily and this will result in a large variation in the milking frequency from cow to cow. All these aspects may influence the quality of the milk produced.

SCC and total bacterial count (TBC) are, respectively, measurements of the number of white blood cells and the total number of bacteria present in a milk sample. A high SCC might indicate reduced udder health due to mastitis (udder infection) and implies a lowered milk quality. The cleaning process and cleaning frequency of the milking equipment and the cooling of the milk seem to be the most important factors regarding the increase in TBC. In general, herds milked by AM systems consistently show slightly higher SCC and TBC values than conventionally milked herds, although differences are relatively small and far within the requirements of the dairy industry (**Table 3**).

Free Fatty Acids

It is generally known that the content of free fatty acids (FFA) in milk will increase with shorter milking intervals, all the more if the yield per milking is rather low. All studies with AM systems show a significant increase in FFA levels for AM systems. This increase cannot be explained solely by the shorter intervals, because the increase in FFAs with AM systems is even larger than with conventional milking parlors milking 3 times per day. Another explanation might be the increased air inlet by attachment of teat cups, during milking and at takeoff. Also the cooling process and a negative energy balance of the cow might play a role.

Economical Aspects

AM systems are more expensive than traditional milking systems. An AM system with two stalls requires an investment that is about 2 times greater than that

Table 3 Milk quality results for farms before and after the introduction of AM system

	Conventional milking		*Automatic milking*	
	Two times milking	*Three times milking*	*Before*	*After*
Bacterial count ($\times 1000\,\text{ml}^{-1}$)	8	8	8	12
Cell count ($\times 1000\,\text{ml}^{-1}$)	181	175	175	190
Freezing point (°C)	−0.520	−0.521	−0.521	−0.516
Free fatty acids (meq per 100 g fat)	0.44	0.54	0.41	0.59

From http://www.automaticmilking.nl;

required for a 2 × 8 automated herringbone milking parlor. These differences imply that total annual costs of milking with an AM system will be higher. However, more milk will be produced per cow and per herd with less labor than before. More milk means that the costs of milking per kg of milk will decrease. The same applies to the labor costs per kg milk. Theoretically, with an AM system more cows can be kept with the same labor force compared with the traditional milking system. But then also, additional investments have to be made for buildings, land, or feed, and for milk quota. On a farm with more than one full-time worker, the possibility exists to reduce labor input and thus costs. However, quite often, that does not happen and the time saved as a result of lower labor requirement will be used for personal activities: sports, family life, and other activities. Without doubt, milking with an AM system instead of a traditional milking parlor will have significant economical and social consequences.

Several simulation models are used to calculate the economical consequences, which will differ for each farm. The room for investment (RFI) model takes these differences into account. The RFI value equals the amount of money that can be invested in an AM system on a farm, without any change of the net return compared with the conventional milking system. The model accumulates the annual returns from increase in milk yield, annual savings in labor costs, and annual savings in not investing in the conventional milking parlor, and then divides this total by the annual costs of the AM system. The model is explained in **Table 4**. With this model, farm-specific factors and circumstances can be used to calculate the RFI value.

Table 4 Calculation of room for investment in €

Annual costs of conventional milking parlor	13 500
Labor saving using AM system	7750
Increase in milk yield	10 250
Total	31 500
Annual costs of AM system	25%
Room for investment	126 000

In **Figure 3**, the results of a combined sensitivity analysis are presented. The figure clearly shows that increase in milk yield and labor savings are essential factors regarding the economy of AM systems. The RFI value for the basic farm with 10% increase in milk yield, 10% labor saving, medium automated milking parlor, and 25% annual costs of the AM system amounts to € 134 000. The differences between the extremes are rather large, almost equal to the investment of a single-stall AM system. The lowest RFI value (0% yield increase, 0% labor saving) is € 83 000 and the largest value (15% yield increase, 30% labor saving) is € 194 000.

Economical results from commercial farms show that the use of AM systems in general is profitable, highly depending on the extra milk yield and labor savings. A Dutch case–control study of farms with AM systems and farms with conventional milking systems showed no differences in margin, although fixed costs for the AM farms were higher. AM farms saved 29% labor, and therefore when economical results were transformed to full-time equivalents (FTEs), AM farms in the case–control study had greater revenues, margins, and gross margins per FTE than the farms with conventional milking systems. So when deciding between investment in an AM system and in a conventional milking system, dairy farmers must weigh decreased labor needs for the AM system against the increased fixed costs of milking with an AM system. Therefore, in many cases, adoption of an AM system is for many dairy farmers a socioeconomic decision, rather than just a purely economic decision.

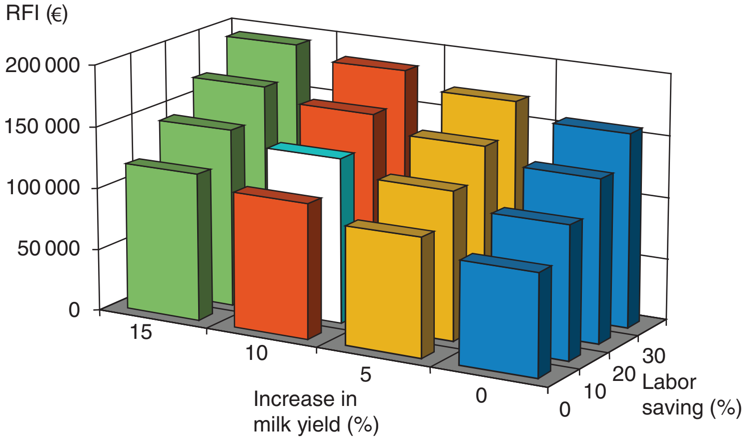

Figure 3 Room for investment (RFI) due to labor saving and increase in milk yield with annual costs for AM system of 25%.

This article is a revision of the previous edition article by D. J. Reinemann, Volume 3, pp 2045–2051, © 2002, Elsevier Ltd.

Introduction

A milking parlor is part of a building where cows are milked on a dairy farm. Cows are brought to the milking parlor to be milked and are then returned to a feeding and/or resting area. Cows may also be milked in their housing area using bucket milkers or a pipeline milking system. Automatic, or robotic, milking systems usually operate without someone being present to supervise the milking process and have been in use for the past decade on commercial farms (see **Milking Machines**: Robotic Milking). The main advantages of a milking parlor when compared to milking cows in their housing area are that it increases labor efficiency, provides ergonomic advantages, and reduces the risk of injury, both traumatic and repetitive stress related. This article presents an overview of milking parlor design concepts. The major types and components of contemporary milking parlors and common forms of milking parlor automation are described. Milking parlor efficiency and hygiene are also discussed.

Design Considerations

The area where cows are milked (milking parlor) is usually part of a larger complex known as the milking center, which contains supporting structures and equipment for the parlor. A milking center typically contains the following use areas:

- Holding area – a pen for collecting cows before milking.
- Milking parlor – the location containing the milking equipment, milking stalls, cow platform, and operator's work area.
- Milk room – a room housing equipment for cooling and storing milk and for cleaning and sanitizing the milking and milk storage equipment.
- Utility room – a room that houses equipment such as vacuum pumps, refrigeration compressors, and water heaters.
- Supply area – a room or area for storing chemicals, drugs, towels, milk filters, and other supplies necessary for the milking operation.

As the size of the farm increases, it is common to incorporate other work areas and animal treatment areas into the milking center (*see* **Dairy Farm Layout and Design**: Building and Yard Design, Cool Climates; Building and Yard Design, Warm Climates). Milking centers may also contain the following additional use areas:

- Office – for record keeping and herd record storage. In some cases, office facilities for the entire farm operation are maintained at the milking parlor.
- Wash/drip pens – areas where the underside of a group of cows may be washed with floor-mounted sprinklers and then allowed to drip-dry before entering the holding area and/or milking area. Wash pens are used only in very dry climates.
- Herd health facilities – a central area for herd health needs on the farm to restrain animals for treatment or breeding, and to store veterinary and breeding supplies and equipment. Simple restraint facilities might be included in the milking parlor return lane if the milking parlor is not in use for extended periods.
- Hospital area – an area for isolation and convalescence of cows that cannot be kept with the milking herd.
- Worker comfort areas – areas for workers to wash, eat, relax, and so on.
- Maternity area – a housing area for cows ready for calving and a clean, isolated area for calving. In hot climates, the maternity area is usually separate from the milking parlor complex.
- Calf area – an area or room with hot and cold water for mixing calf rations. In hot climates, the calf area is usually separate from the milking parlor complex.
- Animal loading facilities – a ramp or dock for loading and unloading animal trucks or trailers.

The milking parlor and milking center house equipment for harvesting, cooling, and storing milk (*see* **Milking and Handling of Raw Milk**: Effect of Storage and Transport on Milk Quality) and must be designed to accommodate the special needs of these equipment (*see* **Milking Machine**: Principles and Design). The most important of these design criteria is that the milklines must be sloped toward a central receiver jar. Increasing the slope greatly increases the carrying capacity of milklines. All other pipelines in the milking system must also be sloped to drain point and generally conform to the slope of the milklines. The location of the milkline and dimensions of ancillary equipment, such as milk meters and pulsators, determine the required clearances between the floor of the operator's area and the cow platform. As a general rule, the total length of pipe and number of fittings in the milking machine should be kept to a minimum to reduce the cost of the system as well as improve milking and washing performance.

A well-designed milking parlor also allows easy and efficient disposal of waste milk and wastewater. Floors should be sloped with drains located to eliminate standing water that can create slippery or icy surfaces. The milking center is often the focus of activities on a dairy farm and the first stop for visitors to the farm. The location and layout of the milking parlor and milking center should facilitate desired activities and discourage entry into milking and milk handling areas except when necessary. Farmsteads should be arranged to minimize animals, vehicles, and people movement and interference. Seemingly minor design details, like floor plans that use a milk room for the main entrance to the milking center, can result in the accumulation of manure, debris, and extraneous materials.

Construction Methods

The various parts of the milking center require special construction materials and methods for ease of cleaning, moisture protection, ventilation, heating, fire protection, noise control, illumination, and so on. An understanding of the activities performed in the various use areas is required to specify the building materials and methods used for each.

Proper design, selection, and installation of electrical systems for milking parlors are crucial to using electricity safely and efficiently. Inferior wiring and equipment cause hazardous conditions for humans and livestock and often result in higher insurance premiums, increased maintenance costs, and greater risk of fire. Milking parlor equipment is washed regularly with chemicals, creating a wet and corrosive atmosphere. Corrosive gases, moisture, and dust hasten deterioration of electrical components. Wiring methods and materials that minimize this deterioration and maintain electrical safety and equipment function under these conditions are necessary for milking parlors. Consult relevant local codes and standards for the specific requirements for electrical equipment and materials suitable for use in the wet and corrosive environment found in milking parlors.

A basement can be built under the operator's area or milking areas to house milklines, pulsator airlines, milk meters, pulsators, receiver, and other equipment. This design can be used with herringbone, parallel, parabone, or side-open stall types. Milking equipment is protected from mechanical damage as well as excessive dirt and moisture. The operator's area is less cluttered, easier to keep clean, and quieter. The basement option generally has a higher building cost than a similar parlor without a basement.

Environmental Control

Environmental control is an important but often neglected component in milking parlor design and operation. Demands on the environmental control systems differ for the various areas of the milking center. Control of temperature, humidity, and odors can be accomplished through ventilation and heating and cooling systems that are properly designed, installed, and managed for each area. Ventilation systems must remove moisture, odors, and excessive heat from the milking parlor and holding area. Mechanical ventilation is typically used in parlors and milk rooms, while natural ventilation is most commonly used in holding areas. In cold regions, some type of heating system will be required in the milking parlor and offices. It is also common to have separate ventilation systems in the milking parlor for cold weather (to remove moisture and add heat) and hot weather (primarily to remove excess heat).

Parlor Types

Milking parlors are classified according to whether the cows are elevated above the person doing the milking (flat parlor vs elevated parlor), the type of stall used to confine cows during milking, and cow entry and exit methods. A description of the main parlor types follows.

Herringbone: In herringbone (or fishbone) parlors, cows stand on elevated platforms on either side and at an angle of about 45 ° to the edge of the operator's area (**Figure 1**). This orientation allows the operator access to the side of the udder for cow preparation and unit attachment. In larger parlors, the two rows of stalls may be arranged in a

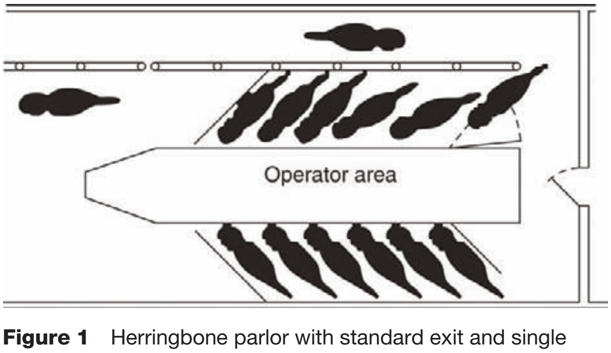

Figure 1 Herringbone parlor with standard exit and single return lane.

wedge or 'V' configuration, resulting in a wider operator area on the end away from the parlor animal entrance. This improves the visibility of units and cows from the other side of the operator area. Cows enter the milking stalls in groups according to the number of milking stalls on each side of the parlor. The rear portion of a herringbone stall is usually shaped in an 'S' pattern to position the rear end of the cow in close proximity to the milking unit. The front end of herringbone stalls can be stationary or fitted with indexing stalls (see definition in the next section) and can use either standard or rapid exit. In small herringbone parlors, it is common for cows on one side of the parlor to cross over to a common exit lane on the other side of the milking area. In larger parlors, an exit lane is provided for each side of the parlor (dual return).

Parallel: In parallel or side-by-side parlors, cows stand on elevated platforms at an angle of 90 ° to the operator area (**Figure 2**). Access to the udder for cow preparation and unit attachment is between the cows' rear legs. The cow platform in a parallel parlor is shorter but wider than that in a herringbone parlor. It is not possible to fit parallel stalls with arm-type cluster removers because of the limited access to the udder. Head chutes at the front end of the stall are used to position cows. Parallel stalls are commonly fitted with indexing front ends and rapid exit with dual return lanes. When compared to herringbone parlor types, the parallel configuration results in a shorter operator's area, which reduces the distance walked by operators.

Parabone: Parabone stalls place the cow at an angle of about 70 ° to the operator area (**Figure 3**). The entrance and exit features and positioning method of this stall design are similar to the herringbone type. The sharper cow angle makes the operator's area shorter, and units are commonly attached between the cow's back legs as in a parallel stall.

Side open or tandem: In side opening or tandem stalls, cows stand in an end-to-end configuration during milking, and units are attached from the side (**Figure 4**). This parlor type is less affected by variations in individual cow milking times than herringbone or parallel parlors as cows are moved one at a time rather than in groups. This parlor type also gives the maximum view of and access to cows by the operator during milking. It is ideally suited to situations in which individual cow care is done in the milking parlor. Entrance of cows may be automated.

Exit area

Figure 3 Parabone milking parlor with standard exit with fixed breast rail (bottom) and adjustable breast rail (top).

Rotary or carousel: In rotary (or carousel) parlors, cows walk onto a rotating milking platform one at a time (**Figure 5**). The cows move past an operator where cow preparation and unit attachment is performed. A second operator is positioned near the exit to remove milking units if detachers are not used and to apply postmilking

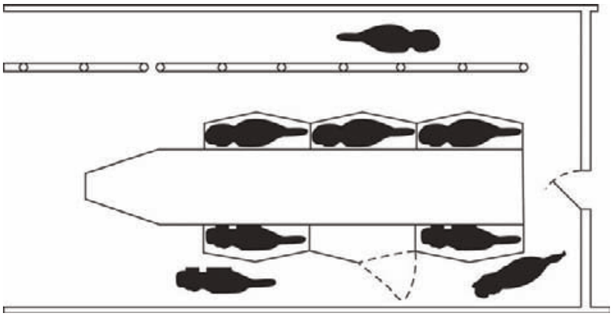

Figure 4 Side-open or tandem milking parlor with single return lane.

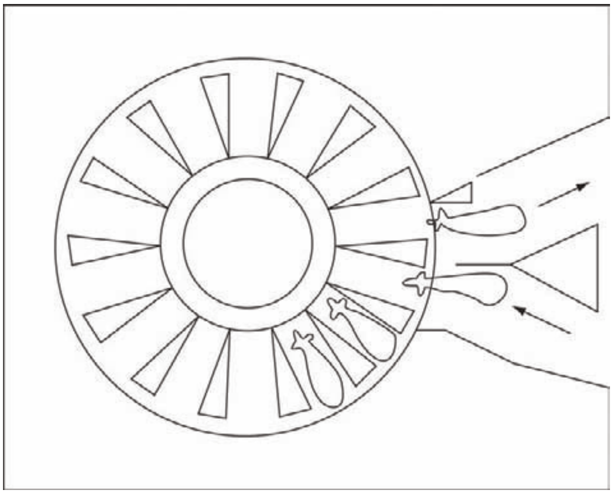

Figure 5 Rotary parlor with face-in cow platform and outside operator area.

teat sanitizer. A third operator may be employed to tend to unit slips and falloffs and other special cow needs during milking. The number of stalls in rotary parlors can range from 10 to 90. Although rotary parlors have gained popularity for large herds during the past decade, they still make up a relatively small percentage of parlors in the world.

Other Milking Parlor Design Elements and Support Equipment

Swing-over: The swing-over or swing configuration can be used on herringbone or parallel parlors but is most common with the parabone stall configuration (**Figure 6**). Stalls on either side of the operator's area share milking units. When milking is completed on one side of the parlor, the milking units are removed and 'swung' to the stall immediately across the operator's area. This configuration reduces the number of milking units required to reduce the initial cost of the parlor. Swing-over parlors usually milk slightly fewer cows per hour per stall but more cows per hour per milking unit compared to parlors with one milking unit per stall.

Flat parlors: In flat parlors, the milking area and the operator's area are at the same or similar elevation (**Figure 7**). Various stall designs are used, from simple stanchions in which the cow must back out of the stall after milking to more complicated gates that cows walk through after milking. Flat parlors can be inexpensively fitted into existing stanchion or tie-stall barns with highline milking equipment as a method to improve labor efficiency. They are not, however, as labor efficient or worker friendly as elevated parlors.

Indexing stalls: Both herringbone and parallel parlors may be fitted with movable or indexing stall fronts. The stall front is moved forward as cows enter to widen the stall area and facilitate rapid cow movement. When milking is ready to commence, the stall front is moved rearward to position the cows as close as possible to the milking unit and operator. This reduces the reaching distance required to prepare cows and attach units and also reduces cow movement during milking.

Entrance/exit gates: Entrance and exit gates to milking stalls may be manually operated or powered by pneumatic cylinders. Controls for both entrance and exit gates should be located at both ends of the operator's area and in intermediate locations in large parlors. The standard exit configuration for herringbone, parallel, and parabone stalls is a single exit gate located at the exit end of the stall row. In these configurations, cows walk out of the milking stalls in single file. Rapid exit stalls allow for all cows to exit the front end of each stall simultaneously. Methods used include raising, lowering, or rotating the entire stall front or opening a series of gates in front of each cow simultaneously. Rapid exit stalls require a wider exit area on the milking platform and a return lane on each side of the parlor. Rapid exit stalls improve performance in parlors with more than 8–10 stalls per side.

Automatic cluster removers (ACRs): ACRs or automatic detachers sense the end of milk flow and then shut off the vacuum to the claw and remove the milking unit from under the cow. ACRs improve labor efficiency primarily by removing the need for operators to observe the end of milking for each cow and, secondarily, by eliminating the detachment task, allowing one operator to handle more milking units. ACRs typically reduce milking time by reducing the amount of overmilking. With arm-type units, the milking unit is attached to a retractable arm that removes the unit from under the cow at completion of milking. With rope or chain ACRs, the milking unit is attached to the rope or chain. At completion of milking, the rope is retracted to remove the unit from the udder and lift it away from the cow. Arm-type units are more ergonomically friendly because they support the weight

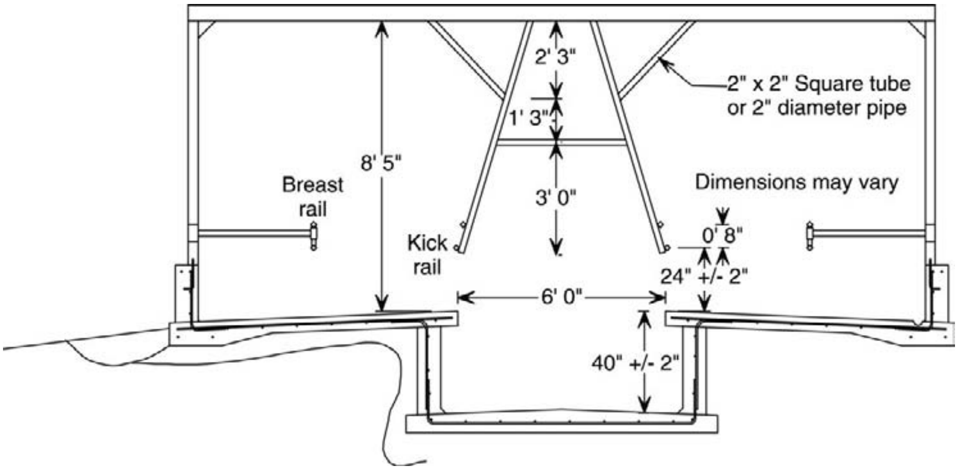

Figure 6 Cross section of a swing-over parlor.

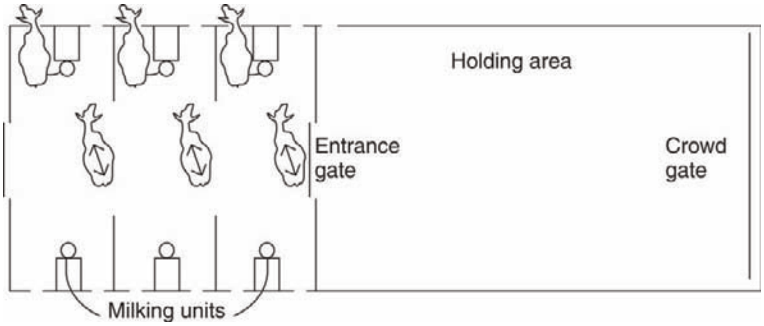

Figure 7 Flat parlor with back-out stalls.

of the cluster and hoses during unit attachment. They also offer superior support for the long milk and pulse tubes resulting in better balance of the milking unit on the udder, and prevent the milking unit from lying on the platform in the event of a cluster falloff.

Crowd gates: Power-driven crowd gates reduce the size of the holding pen as cows move into milking stalls. A bell or other signal device can be fitted to the crowd gate to alert cows to the movement of the gate. Crowd gates can also be fitted with controls to stop the drive unit automatically when the gate senses a cow. Some gates can be raised over a group of cows in the holding pen to return to their starting position, thus allowing a new group to be loaded in the holding pen while milking of the earlier group is being completed. Electrically charged wires on any crowd gate make cows nervous and are not recommended. The proper use of a crowd gate improves labor efficiency by eliminating the need for operators to leave the operator area during milking in order to encourage cows to enter the milking stalls.

Animal identification and data collection/records systems: Automatic animal identification systems read information from a transponder affixed to individual cows. Additional systems are available to automatically collect a variety of data for the identified animal, including milk yield, milking time, milk conductivity, activity level, and weight (*see* **Mastitis Therapy and Control**: Automated Online Delection of Abnormal Milk). These data are sent to a central collection point where they are organized, analyzed, and stored by a computer-based records system. Records systems help to identify animal health problems and determine reproductive status. Cow identification and performance data can also be used to automatically sort animals as they enter or leave parlors equipped with automatic sorting gates and pens and to control automatic animal feeding systems.

Work Routines and Labor Efficiency

A milking parlor is a tool that facilitates implementation of proper and consistent milking techniques (*see* **Milking and Handling of Raw Milk**: Milking Hygiene) while improving the efficiency, safety, and comfort of milking personnel. A worker-friendly facility will also help to attract and retain milking labor. The working posture in an elevated milking parlor should be as close as possible to an erect stance with arms and hands in a natural working position. The dimensions of the parlor and location of milking stations and stalls must be designed to accommodate good working postures. An adjustable height of the floor will make it possible for milkers of different heights to have a correct ergonomic position in the parlor. A primary reason for investing in a milking parlor is to improve labor efficiency. The milking facilities can comprise from 20 to 60% of the total capital investment in a dairy. Milking can make up more than half of the labor expended on a dairy farm. Proper planning, construction, and operation of the milking facilities can thus have a significant influence on the labor and economic efficiency and general work environment of a dairy enterprise. Parlor planning should always begin with a thorough economic analysis of the various options for the specific situation on each farm.

Labor efficiency in automated side-open, herringbone, and parallel milking parlors typically ranges from 40 to more than 80 cows milked per person per hour, depending primarily on the efficiency of work routines and tasks other than milking that may be performed in the parlor. These parlors typically are designed with 6–12 milking stalls per operator (3–6 stalls per side) when not automated and with 12–20 stalls per operator (6–10 stalls per side) when automated. The typical turnover rate ranges from 3 to 5 filling and emptying (turns) per hour for these parlor types, with larger parlors typically having a lower turnover rate. Rotary parlors typically range from 4 to 5 turns per hour with 2–4 operators.

The steps used in premilking udder preparation and the efficiency of work routine have a much larger effect on labor efficiency than does parlor type. Several recent analyses have shown that multiple small parallel and herringbone parlors are more labor efficient and have higher economic values than a single large parlor with the same number of milking stalls.

Hygiene

It is important to clean the exterior surfaces of milking and milk handling equipment to avoid contaminating milk during milk harvest and transport (*see* **Milking and Handling of Raw Milk**: Milking Hygiene). Parlor equipment should be cleaned after every milking and at least 3 times per day in large parlors milking around the clock. A milking parlor should be fitted with equipment to easily clean exterior surfaces of milking and milk handling equipment. This is typically accomplished with a combination of manual cleaning with a brush and cleaning solution and a rinse with water under medium or high pressure. The walls and floors are typically cleaned using a combination of manual scraping or brushing and then a rinse using hoses with water under medium or high pressure.

Some parlors are also fitted with devices to automatically clean the floor of the parlor and/or holding area during milking. This may be accomplished by periodic application of water under pressure or by a flush system in which a large volume of water is released to create a wave of water on floor surfaces that will carry manure and urine to a collection pit. Care must be taken in the design of flushing systems so that flush water does not contaminate milking units (*see* **Milking and Handling of Raw Milk**: Milking Hygiene).

Introduction

Molecular genetics (MG) is a scientific discipline concerned with the structure and function of genes at the molecular level and encompasses the technique of genetic engineering, which can be defined as the direct manipulation of an organism's genome through the introduction of foreign DNA, or any artificial (not natural) modification that alters the structure and characteristics of the organism's genes. MG has enormous potential and will continue to contribute to the production of high-quality dairy products through advances such as the design of 'tailor-made' starter cultures used in the production of fermented dairy foods, for the selection of genetically elite animals (i.e., within the farm gate) and the generation of improved transgenic livestock (i.e., outside the farm gate). The objective of this overview is to briefly discuss the contribution of MG both within and outside the farm gate toward the production of dairy products, as well as discuss ongoing and future research in this discipline.

From Gene to Protein

Structure of DNA

DNA or deoxyribonucleic acid is the central molecule in almost all living organisms that serves as the carrier of genetic information. It is composed of chemically linked sequences of subunits; each subunit (collectively referred to as a nucleotide) contains a base molecule (adenine, guanine, thymine, or cytosine), a pentose sugar called deoxyribose (ribose in RNA), and a phosphate group. The double-stranded DNA helical molecule results from the pairing of adenine with thymine via two hydrogen bonds, and cytosine with guanine via three hydrogen bonds, while the sugar and phosphate group form the backbone of the molecule (**Figure 1**(**a**)). Three adjacent nucleotides encode for an amino acid, the building blocks of proteins (e.g., ATG codes for the amino acid methionine). The four nucleotides can be arranged in sets of three in 64 different ways, which is more than sufficient to code for the 20+ required amino acids. A gene is thus a segment of DNA containing a specific sequence of nucleotides that carries the information responsible for producing one particular protein. The simplicity of the structure of DNA makes it amenable to genetic engineering. Basically, the DNA strand can be cut with special enzymes called restriction endonucleases, which recognize short specific DNA sequences, and can be rejoined by the action of other enzymes called ligases, enabling the fusion of different DNA molecules. The polymerase chain reaction (PCR) enables the amplification or synthesis of several thousand copies of a desirable DNA sequence, which can also be fused with other DNA molecules. During the cloning process, the sequence of interest is ligated to a vector molecule, which is in essence an extra-chromosomal circular DNA molecule. These vectors are often derived from bacterial plasmids, which are naturally occurring extra-chromosomal DNA molecules but have been modified to harbor other genes to aid the cloning process.

Transcription and translation

In order to produce a protein, two processes must occur, namely transcription and translation (**Figure 1**(**b**)). During the process of transcription, messenger RNA (mRNA) is synthesized by the enzyme RNA polymerase, representing a single strand of the DNA. Transcription begins when the enzyme binds to a special sequence on the DNA called the promoter at the start of a gene and continues until it reaches a terminator sequence, generating a transcription unit (**Figure 1**(**b**)). A transcription unit may include more than one gene. Proteins/polypeptides are then generated from the mRNA by the process of translation whereby a ribosomal RNA (rRNA) moves along the mRNA strand while transfer RNAs (tRNAs) concomitantly deliver the correct amino acid to the rRNA for the growing polypeptide chain depending on the genetic code in the mRNA sequence.

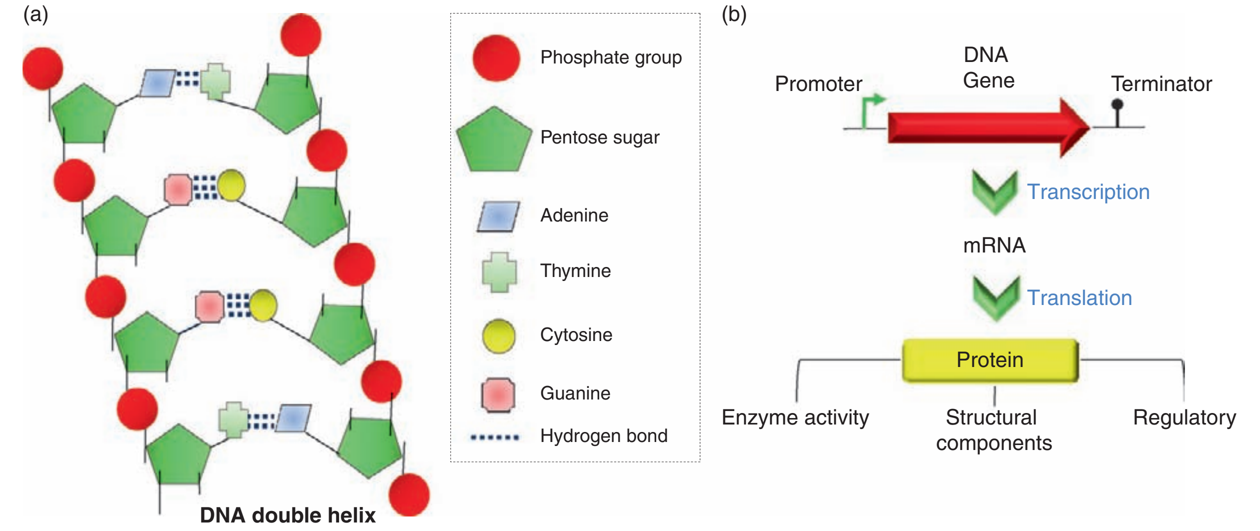

Figure 1 (a) Diagrammatic representation of the DNA double helix. In this diagram, the sequence of DNA is read as AGGT. (b) Sequence of events involved in transcription and translation. The gene is represented by the red arrow. The small green arrow before the gene represents the promoter sequence and the terminator sequence is represented by the black ball and stick at the end of the gene.

DNA Sequencing in the Twenty-First Century

A major advantage to MG has been the unprecedented upsurge in DNA sequencing in the last decade, from viruses and bacteria right through to mammals. The sequencing of the human genome was completed in May 2006 through the Human Genome Project (HGP). Indeed, a new proposal has now been launched called Genome 10K (G10K), which aims to obtain whole-genome sequence data for 10 000 vertebrate species. Projects of this nature are now becoming more feasible as new DNA sequencers promise ultra-fast and inexpensive delivery of DNA sequence information. With regard to the dairy industry, genome sequences are now available for a number of lactic acid bacteria (used in food manufacture and as probiotics) and their bacteriophages (bacterial viruses), many of which are fundamental to the dairy industry. In 2009, the first full genome sequence of a female Hereford cow, named L1 Dominette, was released by the Bovine Genome Sequencing Project, making her the first ever livestock animal to be completely sequenced. The vast quantity of sequencing data generated is handled and sorted by computer technology through the scientific discipline of bioinformatics. The benefits of an available genome sequence are vast in that it provides the entire genetic blueprint of an organism. With regard to livestock, available genome sequence data will lead to more accurate diagnosis of disease and to the production of healthier and more productive animals through animal transgenesis and strategic animal breeding programs, as discussed later. Genome sequences of dairy bacteria are providing information on the genes that encode fundamental traits such as production of flavor compounds, bacteriocin production, and resistance to bacteriophage infection, as well as providing genetic machinery for the development of improved genetic tools. Moreover, the availability of the genome sequence has pioneered the twenty-first-century science, systems biology, which aims to understand biological systems in their entirety through multidisciplinary approaches. It combines a range of modern technologies beginning with the annotated genome sequence and includes transcriptomics, the study of the complete set of transcription units in a cell under a particular set of conditions; proteomics, which involves the study of the protein complement produced by an organism; metabolomics, which describes the metabolite profile; and interactomics, which is the study of complex molecular interactions in cells, alongside mathematical modeling techniques to build models for biological interpretation and ultimately prediction of behavior.

Molecular Genetics Outside the Farm Gate

Gene Technology: Tailor-Made Cultures

MG has been used to generate ‘tailor-made’ bacterial cultures with many applications in the dairy food industry. For example, metabolic engineering has been applied to starter cultures to increase the production of various desirable flavor compounds. Diacetyl is an important flavor compound with the characteristic butter aroma and is produced by the dairy starter culture *Lactococcus lactis* subsp. *lactis* biovar *diacetylactis* via metabolism of citrate. Diacetyl production in *Lc. lactis* via metabolism of lactose (the main sugar in milk) instead of citrate was achieved either by disruption of the enzyme lactate dehydrogenase (LDH) or by over-production of NADH oxidase. High diacetyl production levels were achieved by combining the above strategy with the disruption of α-acetolactate decarboxylase. In another example, the carbon flux of *Lc. lactis* was rerouted toward the production of alanine, an amino acid with a sweet flavor, by expressing the *Bacillus sphaericus* alanine dehydrogenase gene. Moreover, expression of alanine dehydrogenase in an LDH-deficient strain permitted the production of alanine as the sole end product (homoalanine fermentation).

Bacteriophage infection of starter cultures during fermentation is a constant issue that can result in quality defects that affect the flavor, texture, and even safety of dairy products. A number of phage-resistance mechanisms have been identified and characterized, particularly in *Lc. lactis* (*see* **Lactic Acid Bacteria**: *Lactococcus lactis*). It has been possible to clone these phage-resistance mechanisms, mainly genes involved in restriction modification and abortive infection, into dairy starter cultures including *Lc. lactis* and *Streptococcus thermophilus*, producing superior cultures that are resistant to phage infection.

Bacteriocins are polypeptides produced ribosomally by bacteria and can have a bactericidal or bacteriostatic effect on other bacteria. The application of MG to the study of bacteriocins has resulted in the development of novel starter cultures with an inbuilt antimicrobial mechanism, thus endowing the fermented dairy product with an innate immunity to foodborne pathogens such as *Listeria monocytogenes*. One such example is nisin, a well-known bacteriocin produced by *Lc. lactis*. The genetic machinery encoding for nisin production has also been harnessed to develop specialized cloning vectors that enable controlled expression of the cloned gene. These vectors, termed the nisin-controlled expression (NICE) vectors, contain the promoter of the *nisA* gene, which encodes the bacteriocin nisin. In the natural situation, extracellular nisin acts as the signal for transcriptional activation of its own structural gene (*nisA*) and several other biosynthetic and immunity genes. The gene of interest is therefore cloned directly after the *nisA* promoter in the expression vector. The level of expression can be controlled by the amount of nisin used for induction and it has been reported that recombinant protein synthesis can reach levels up to 60% of the total protein. This system has been used for the efficient expression of many heterologous enzymes in *Lc. lacti*s. For example, the system has been exploited for the over-production of exopolysaccharides (EPSs) in a transgenic derivative of the probiotic strain *Lactobacillus paracasei* 338 (**Figure 2**). EPSs play a major role in the production of a number of dairy products such as yogurt, where their viscous nature enables them to contribute to texture, mouthfeel, taste perception, and stability of the final products, and in some cases EPSs have also been associated with beneficial health effects.

Lactococcus lactis has also been engineered to synthesize various therapeutic molecules for delivery to the gastrointestinal tract, many of which are already in advanced stages of preclinical and clinical development. For example, recombinant human interferon-β that exhibits antiviral activity was expressed in

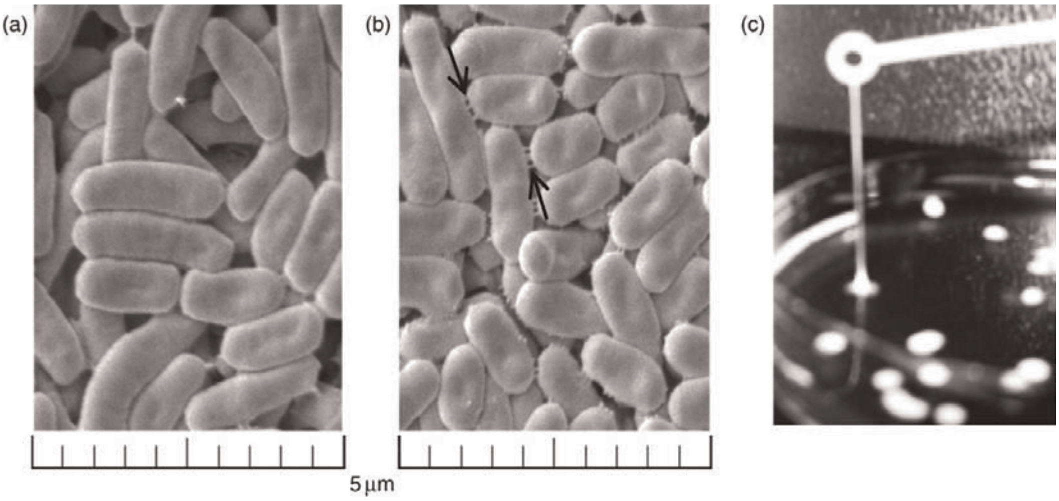

Figure 2 Scanning electron micrograph (5 μm) of *Lactobacillus paracasei* 338 (control) (a) and transgenic derivative *Lb. paracasei* 338 that contains the gene for producing exopolysaccharides (EPSs) (b) after growth in 7% glucose. Arrows indicate EPS production. (c) EPS production in transgenic derivative demonstrated by the loop touch test of a colony, where over-production of EPS causes a ropy phenotype. Adapted from Stack, H. M., Kearney, N., Stanton, C., Fitzgerald, G. F., Ross, R. P. (2010). Association of beta-glucan endogenous production with increased stress tolerance of intestinal lactobacilli.*Applied and Environmental Microbiology* 76: 500–507.

Lc. lactis. Another promising application for engineered *Lc. lactis* is its use as an antigen delivery vehicle for live mucosal vaccines. Indeed, a wealth of bioactive molecules from both microbial and eukaryotic backgrounds can be expressed in lactococci providing a food-grade vehicle for oral delivery of such compounds. Generation of dairy products using these genetically modified strains could create a whole new niche in the market; dairy foods with targeted medicinal benefits. Such foods would be distinctly separate from the highly popular functional foods, which aim to exert a positive effect on human health, most often linked to the presence of probiotic organisms or their metabolites.

Gene Technology: Transgenic Animals

One of the key breakthroughs of MG in dairy animals has been the ability to endow transgenic animals with traits that could not be achieved through standard breeding strategies. However, the time required to create transgenic livestock is approximately 5–7 years. A typical example has been the creation of transgenic dairy cows that express the antimicrobial protein lysostaphin in the mammary gland and consequently secrete the protein into milk. This protein is particularly active against the mastitis pathogen *Staphylococcus aureus*, and has been shown to protect the transgenic cattle in a dose-dependent manner. Mastitis is a disease of the mammary gland, affecting almost every dairy farmer globally at some stage and is estimated to cost $2 billion in losses annually in the United States alone. Robert J. Wall and coworkers from the US Department of Agriculture USDA, Maryland, who have pioneered this work, are also looking into the possibility of using other antimicrobial proteins with a broader spectrum of antimicrobial activity. Such strategies could also protect against other unwanted microbes, thus extending the shelf life of milk. The human antimicrobial protein lactoferrin has also been expressed in four transgenic cows at a concentration of up to $2\,\mathrm{mg\,ml^{-1}}$ milk. Human lactoferrin has demonstrated antibacterial, antifungal, and antiviral properties and could be important in defense against pathogens in infants.

Transgenic cows have also been created to produce milk that is more suitable for cheese manufacture. In this approach, the genes encoding β- and κ-caseins were cloned in cows, which resulted in the over-expression of both proteins in milk. Increased κ-casein has been linked to a reduction in micelle size and can improve the heat stability of micelles, all of which favor cheese production. Milk protein allergy is a common problem, particularly in children. Intolerance to the major protein allergen β-lactoglobulin has been addressed in transgenic cows through the inactivation of the β-lactoglobulin gene.

Public Concerns Regarding Genetically Modified Organisms

The US Food and Drug Administration (FDA) recently issued a formal risk assessment declaring food products from cloned cattle, pigs, and goats safe for human consumption, while the European Food Safety Authority (EFSA) issued a draft ‘Opinion’ with the same conclusion. While this may seem promising, cloned animals in essence do not contain genetically modified DNA and are thus different from transgenic animals. However, despite the efforts of the FDA and the EFSA, other groups such as the USDA and the European Group of Ethics do not agree for the moment that cloned animals should enter the food chain. Additional challenges clearly exist for the acceptance of transgenic animals. However, it is worth noting that recently a human-use anticoagulant (trade name ATryn) derived from the milk of genetically modified goats became the first approved pharmaceutical product having received FDA approval for use in patients with hereditary antithrombin deficiency. However, apart from the United States and Canada, the public view toward genetic manipulation is largely one of uncertainty. Those in favor of genetically modified organisms (GMOs) believe that the products of GMOs are generally safe and beneficial, and that the technologies used to generate them are well understood and can be managed and controlled by modern science. Those on the opposing side view this technology as unnatural and do not believe that perceived benefits outweigh the risks associated with food safety, animal welfare, as well as possible impacts on ecosystems and the environment, which cannot be controlled once the technology is introduced. It is worth noting, however, that the research field of biosafety was created recently to manage the ecological impact of GMOs. Concern is also expressed regarding the intent behind the research into genetic modification, particularly if the focus is on the creation of commercial products and maximization of corporate profit. Indeed, one of the major issues to date is that few if any genetically modified products exist that actually benefit the consumer directly. The availability of products such as foods that improve human health alongside studies evaluating the impact and safety of GMOs should play a significant role in increasing the acceptance of this technology.

Molecular Genetics within the Farm Gate

Exploitation of MG within the farm gate is through the identification of genetically elite parents of future generations. The interest in MG in animal breeding stemmed from the limitations of traditional, quantitative methods of genetic evaluation, which ignore the effect of individual genes but instead evaluate animals based on their entire complement of genes. Quantitative genetics is not without its weaknesses, in particular the long time period and resources required to obtain accurate estimates of the genetic merit of an animal. These estimates of genetic merit are generally termed estimated breeding values (EBVs) in animal breeding.

The potential in animal breeding of tools generated through advances in MG relies on the ability to identify the causative mutation giving rise to a difference in phenotype (i.e., the performance of the animal as observed in the field), or to identify a linked genetic marker, and to use this marker in a breeding program with the appropriate breeding goal. The end objective of this approach, as for any breeding program, is to effectively and efficiently disseminate the superior genetics into the commercial population. Possibly one of the greatest benefits of genomics in animal breeding is that genomic DNA is available from an animal at any age as well as from both genders. Knowledge of the 'ideal genotype' and the genotype of every animal can facilitate increased genetic gain through a combination of mainly altering accuracy of predicted EBVs and the time from birth to the realization of an accurate estimate of genetic merit.

Marker-Assisted Selection

One of the motivations for exploring the use of MG in animal breeding was that causative mutations, or linked genetic markers, could be included in a breeding program, an approach referred to as gene- or marker-assisted selection (MAS). The regions of the genome associated with performance are called quantitative trait loci (QTLs). Many different types of genetic markers exist but the markers of choice nowadays are single-nucleotide polymorphisms (SNPs). An SNP is a variation at a single-nucleotide position of the DNA sequence of individuals of the same species. The shift toward the widespread use of SNPs was to more readily facilitate automation and scoring of genotypes. Several SNPs have been shown in many studies to affect milk quality. For example, a dinucleotide polymorphism in the acyl CoA:diacylglycerol acyltransferase gene has been shown to be associated with milk fat and protein composition. Similarly, SNPs in the casein and lactoglobulin genes have been associated with milk quality.

Although MAS, using information generated from MG, theoretically has huge potential, such as the ability to increase the accuracy of predicted genetic merit at a very young age, it also has, like traditional quantitative approaches, its shortcomings. Disadvantages of MAS are (1) it is often difficult and resource-intensive to find the causative mutation or a genetic marker tightly linked to the causative mutation, (2) the QTL effects are often overestimated, and (3) the QTL(s) rarely explain all of the genetic variance and therefore polygenic or remaining genetic effects still need to be accounted for in the analysis.

Genomic Selection

One of the main shortcomings of MAS is that currently, and for the foreseeable future, identified QTLs are not likely to explain all the genetic variance in quantitative traits, that is, that multiple genes at different locations in the genome contribute to a particular phenotype. An alternative to identifying and selecting based on a limited number of QTLs is to select based on all genetic markers simultaneously. Genomic selection is based on the simultaneous selection for many thousands of genetic markers that densely cover the entire genome and is essentially a large-scale version of MAS made possible by the development of arrays with many thousands of SNPs for fast genotyping throughput. The success of genomic selection is based on exploitation of linkage, often called linkage disequilibrium, between the genetic markers and the causative mutation and this association is assumed to persist across the population. Therefore, dense marker coverage is vital to ensure that all causative mutations are tightly linked with a genetic marker.

The process of genomic selection follows two broad steps: (1) estimation of marker effects in a reference or training population and (2) prediction of EBVs of animals with no phenotypes. The first step is the most difficult since it requires the estimation of thousands of effects usually from a data set with considerably less records. Nevertheless, several statistical approaches are possible to estimate genomic EBVs using genome-wide dense marker maps. Genomic selection will soon become the method of genetic evaluations in most countries across a large proportion of agricultural species and MG was key to achieving this.

Future Requirements for Molecular Genetics in Animal Breeding and Food Processing

Explaining the 'missing heritability' will be arguably one of the most challenging areas for animal breeding in the future. Heritability is the ratio of genetic variance to phenotypic variance after excluding the variance attributable to systematic environmental effects. The missing heritability refers to the inability of large genome-wide association studies in species, including humans, to explain a large proportion of the genetic variation in a trait. One possible contributing factor to the missing heritability is that the expression of a phenotype may be due to rare alleles with large effects or indeed many common alleles with very small effects. Addressing the former may require deep sequencing of a large number of individuals for candidate genes, identified through systems biology.

Identifying common alleles with very small effects can be achieved through larger data sets in genome-wide association studies. Considerable data sets are required however to detect loci with small effects. A candidate gene approach may reduce the requirement for larger data sets. Genome-wide association studies, using currently available SNP array platforms, are unlikely to detect the causal mutation. However, by using bioinformatics, genes in the vicinity of the detected genetic markers or overrepresented biological pathways may be detected, which will aid in identifying putative candidate genes for further interrogation.

In terms of food processing, the accepted application of MG in dairy foods in the future will undoubtedly unveil a wealth of opportunities to increase their nutritional quality and safety, and as already mentioned may create a whole new role for dairy foods in areas such as medicine, making this a high-value sector. Moreover, as scientists unravel how nutrition influences metabolic pathways and homeostatic control of individuals through nutrigenomics, it is possible that MG may be used to produce dairy foods for personalized nutrition. Further progress supported by more cost-effective methodologies alongside systems biology approaches will undoubtedly lead to greater understanding of gene functionality and the effects of genetic manipulation whether in starter cultures or in transgenic livestock and should answer the many questions that still loom for both the public and regulatory authorities.

NUCLEOSIDES AND NUCLEOTIDES IN MILK

D Martin, E Schlimme, and D Tait, Max Rubner-Institute, Federal Research Institute of Nutrition and Food, Kiel, Germany

© 2011 Elsevier Ltd. All rights reserved.

Structural Aspects

Nucleosides are *N*-glycosides of pyrimidines and purines. The sugar moiety is either β-D-ribofuranose (ribonucleosides) or 2-deoxy-β-D-ribofuranose (2′-deoxyribonucleosides). The C1 carbon atom of the pentose is bound to N1 of a pyrimidine or N9 of a purine. The *N*-glycosidic linkage is in the β-configuration. Modified or rare nucleosides represent compounds with chemical modifications in the heterocyclic base and/or the sugar moieties. **Figure 1** shows the structures of nucleosides that occur in milk or that are otherwise of dietary interest. Only ribose forms are considered in this overview.

Nucleotides are *o*-phosphoric acid esters of nucleosides. The esterification may be present on position 2′, 3′, or 5′ in ribonucleosides and on 3′ or 5′ in 2′-deoxyribonucleotides. The most common site of esterification in naturally occurring nucleotides is the C5-hydroxyl group. Such compounds are called nucleoside-5′-phosphates (5′-nucleotides). This contribution discusses monophosphorylated 5′-nucleotides only. Nomenclature and usual abbreviations are as follows: adenosine (ado), 1-methyladenosine (m1ado), N6-methyladenosine (m6ado), N6-dimethyladenosine (m6,2ado), N6-(2-isopentenyl)-adenosine (ip6ado), N6-carbamoyl-L-threonyl-adenosine (t6ado), guanosine (guo), 1-methylguanosine (m1guo), 7-methylguanosine (m7guo), N2-methylguanosine (m2guo), N2-dimethylguanosine (m2,2guo), cytidine (cyd), inosine (ino), 1-methylinosine (m1ino), 7-methylinosine (m7ino), uridine (urd), pseudouridine (ψ), thymidine (thy), adenosine-5′-monophosphate (5′-AMP), cytidine-5′-monophosphate (5′-CMP), guanosine-5′-monophosphate (5′-GMP), inosine-5′-monophosphate (5′-IMP), uridine-5′-monophosphate (5′-UMP).

Compositional Aspects

Milk contains nucleotides and nucleosides as well as pyrimidines and purines as free bases in the micromolar concentration range. They are part of the nonprotein-nitrogen (NPN) fraction of milk. The concentrations of these compounds in the milk of several different mammalian species have been investigated. In bovine, ovine, and human milk, the concentrations of these compounds are highest directly after parturition, and most of the compounds generally tend to decrease as lactation or nursing proceeds. The composition and concentration patterns of the different compounds are specific for the milk of a given species. The fact that these species-specific patterns have not been eliminated by the evolutionary process implies that they are physiologically significant and important in the diet of the neonate. Owing to their potential as dietary modulators, there is currently great interest in the supplementation of infant formula with certain nucleotides. In view of these facts, it is surprising that nucleosides have become a topic of nutritional research only in the past 2–3 decades.

Nucleosides

Studies have been carried out on milk from cattle fed under controlled conditions. These studies show that the concentrations of the nucleosides in milk initially decrease during the colostral phase and remain constant at more mature stages of lactation. Thus, the concentrations of the common nucleosides (ado, cyd, guo, ino, and urd) are relatively constant after 3 weeks postpartum,

Each mean value is the arithmetic mean of determinations (three measurements each week in duplicate) in the first lactation week postpartum (bovine colostrum) as well as throughout the whole lactation period with the exception of the first 3 weeks postpartum (mature milk).

[b] Adapted from Martin D, Clawin-Rädecker I, Lorenzen PChr, Ziebarth M, and Barth K (2005) Ribonucleosid-Gehalte in Schaf- und Ziegenmilch. *Kieler Milchwirtschaftliche Forschungsberichte* 57(1): 21–32. Each mean value is the arithmetic mean of determinations (weekly in duplicate) throughout the whole lactation period with the exception of the colostrum.

All values rounded to one digit after the decimal point.

while the concentrations of the rare nucleosides m1ado and t6ado are constant after only 1 week postpartum. The distinct maxima observed in the graphic plots of concentration versus time postpartum for certain nucleotides are not observed for the corresponding nucleosides (**Table 1**). The sum of the concentrations of the pyrimidine nucleosides (17 μmol l^{-1}) is approximately fivefold greater than that of the purine nucleosides (about 3 μmol l^{-1}). The concentration of urd exceeds that of the other nucleosides by 1–2 orders of magnitude, probably reflecting the importance of uracil nucleotides (e.g., UDP-hexoses) for lactose biosynthesis in the mammary gland. The large, severalfold differences in the concentrations between colostrum and mature milk probably result from the greater metabolic activity in the mammary gland and the increased transfer rate of the nucleosides circulating in the blood through the blood–milk barrier in the first few days postpartum. In this period, colostrum contains relatively high concentrations of blood constituents. Therefore, postsecretory metabolic processes attributable to milk enzymes (e.g., alkaline phosphatase, adenosine deaminase), somatic cells, and microorganisms are stronger in this period.

The results in **Table 1** also support the reports of high contents (up to 300 μmol l^{-1}) of UDP-glucose and UDP-galactose during the colostral phase.

The raw milk of goats and sheep contains markedly greater concentrations of the unmodified nucleosides urd and ino than that of cows (**Table 1**). The species-specific patterns of nucleoside contents are particularly recognizable in the unmodified nucleoside contents and by calculation of nucleoside concentration ratios (unmodified and modified nucleosides). Thus, nucleoside determination is suitable for distinguishing raw milk from cow, sheep, and goat.

The nucleosides in human milk, however, differ both qualitatively and quantitatively from those in the milk of ruminants. **Table 2** shows the interindividual mean

values of common and some rare nucleosides quantified during mature stages of lactation. The concentration profiles of the nucleosides tend to decrease steadily in the course of lactation.

Nucleotides

Table 3 presents the concentrations of some common nucleoside-5′-monophosphates in samples of raw bovine milk taken at different stages of lactation. Shortly after parturition (0–1 day), lower concentrations of most nucleotides are observed followed by a maximum 1–2 days postpartum. The concentrations then gradually decrease as lactation continues. The initial concentrations of 5′-AMP and 5′-CMP are reduced by half, while the levels of 5′-UMP decrease by two orders of magnitude. A similar pattern is also seen in the total amount of nucleotides, that is, including nucleoside-5′-mono-, di-, and triphosphates (ΣA_t, ΣC_t, ΣG_t, ΣU_t) as well as UDP-galactose and UDP-glucose. Two days postpartum, the concentrations (μmol l^{-1}) were $\Sigma A_t = 67.8$, $\Sigma C_t = 60.5$, $\Sigma G_t = 36.5$, $\Sigma U_t = 1495.0$, UDP-galactose = 320.2, and UDP-glucose = 362.3. Not shown in **Table 3** is orotic acid, which is the main nucleotide-related compound in bovine milk. Its concentration increases in the course of lactation by about one order of magnitude to a maximum of about 400 μmol l^{-1} 6 months after parturition.

The concentrations of common nucleotides exceed those of the corresponding nucleosides by 1–2 orders of magnitude. 5′-AMP and 5′-CMP are present in all milk samples from colostral to mature stages of lactation, while 5′-UMP has not been detected later than 3 weeks postpartum. The 5′-GMP content of bovine milk has been reported to be less than the limit of detection.

The reported concentrations of nucleotides in human milk vary within the range 4–70 mg l^{-1}, corresponding to about 10–200 μmol l^{-1}. At least part of the variation results from the different analytical procedures used. Concentrations in human milk at different stages of lactation are shown in **Table 4**. Most of the data show that cytosine and uracil nucleotides make up the largest fractions of the total nucleotide content, agreeing well with the pattern found for nucleosides shown in **Table 2**. Generally, the total nucleotide content of the milk of humans exceeds that of ruminants. On the other hand, orotic acid, which is present at relatively high concentrations in the milk of ruminants, is absent in human milk.

Table 3 Nucleotides (μmol l^{-1}) in bovine milk at different days postpartum

Days	*5′-AMP*	*5′-CMP*	*5′-GMP*	*5′-UMP*
0–1	39.7	31.9	n.d.	186.3
1–2	61.8	52.5	n.d.	390.0
30	27.5	33.2	n.d.	n.d.
60	20.3	18.9	n.d.	n.d.

n.d., not detectable.

Values (μmol l^{-1}) rounded to the nearest whole number.
TPAN, total potentially available nucleosides.

Although refined techniques of nucleoside and nucleotide analysis have been well established for many years, only a few studies report quantitative data on all the sources of nucleosides and nucleotides in body fluids, for example, nucleoproteins, nucleic acids, various derivatives including coenzymes all of which may contribute to the observed contents. Total amounts of nucleic acids (RNA, DNA) have been estimated so far to range from 190 to 580 mg l^{-1} for bovine and from 118 to 720 mg l^{-1} for human milk. The analytically accessible nucleoside content has been termed 'total potentially available nucleosides' (TPAN). The TPAN values for human milk shown in **Table 4** include the contents of nucleosides, nucleotides, and oligo- and polymeric ribonucleic acids as potential sources available in milk for the generation of these compounds by digestion and metabolism. As **Table 4** shows, including such potential sources increases the total concentration and alters the concentration ratios of the four nucleosides. The relatively small value of the ratio of adenine nucleotides initially present to the TPAN content of this nucleoside reflects above all the relevance of adenine nucleotides in bioenergetics and biosynthesis. Ino was detected in a few samples of human milk at concentrations one order of magnitude smaller than the

TPAN values of the other four nucleosides in **Table 4**. In most of the milk samples, however, ino was not detectable.

In a further study on the TPAN value in human milk, 160 samples were collected from 135 healthy, lactating women from different Asian countries at four stages of lactation. The average TPAN concentrations were 171.9 μmol l^{-1} in colostrum, 208.1 μmol l^{-1} in transitional milk, 221.6 μmol l^{-1} in early mature milk, and 210.6 μmol l^{-1} in late mature milk, with no notable geographical differences. The major sources of ribonucleosides were RNA (43.3% of TPAN) and free ribonucleotides (39.9% of TPAN). The sources of ribonucleosides and percentages of nucleotide bases are similar for all stages of lactation. For all stages after colostrum, more than 91% of the TPAN is present in the noncellular component. In addition, the study shows that the average TPAN level in Asian women is similar to that in European and American women, and free ribonucleotides in human milk represent less than half of the TPAN.

Functional Aspects

Biofunctional Properties

Biofunctional properties of food constituents are related to their dietary value and possibly to regulatory processes beyond basic nutritive functions. Although nucleosides and nucleotides are only minor components of milk and of many other foods, they are essential for cellular function and metabolism, and energy conservation and transfer. Furthermore, they are the monomeric precursors of nucleic acids.

Mammals meet their needs for nucleosides and nucleotides by a combination of *de novo* syntheses, reutilization of these compounds by the salvage pathway, and by dietary supply. Dietary nucleosides and nucleotides are ingested mainly as nucleoproteins, which are converted in the intestine into monomeric compounds. Nucleosides and nucleobases are transported across the plasma membrane by specific facilitated-diffusion carriers and/or sodium-dependent transporters.

In some tissues, for example, the intestinal mucosa, the salvage pathway is dominant because of a limited capacity for *de novo* synthesis. Therefore, the exogenous supply of nucleic acid-derived components is important for optimal function of such tissues. For example, when rat weanlings were fed a diet supplemented with nucleosides, both the formation of mucosal protein and DNA in the proximal segment of the gut and the length of the villi in this segment were greater than in a control rat group. Thus, nucleotides and related compounds have been recognized to be semiessential for rapidly growing tissues.

The following findings concerning food-related effects are of particular interest because they indicate possible therapeutic uses of these compounds especially for neonates:

- Ingestion of ino increases uptake of iron from the intestine of rats. Human milk therefore has been suggested as a factor in facilitating iron absorption in breast-fed infants.
- Dietary nucleotides may stimulate α-lipoprotein synthesis and thus be involved in lipid metabolism.
- A diet supplemented with nucleotides improved development (indicated by weight, body length, and head circumference) in a group of infants born small for gestational age. The authors attributed the observations to beneficial trophic effects of nucleotides on the intestinal mucosa.
- Clinical studies compared the effects on adults of RNA-supplemented and RNA-free enteral food. From these studies, it has been concluded that optimal patient outcome during a period of stress may depend on provision of dietary nucleotides. These data support the claim that dietary nucleotides are conditionally essential nutrients.
- The presence of specific nucleosides and/or nucleotides in human milk may be a factor in the immune response of breast-fed infants. These compounds are also postulated as growth factors for the neonate. A study of 370 full-term healthy infants reported that infant immunity is enhanced by diets of human milk and of infant formula supplemented with ribonucleotides at the same concentrations as in human milk. The development of the infants' immune systems for the first year of life was monitored by measuring the antibody response to the immunization vaccination. The study also registered the incidence of diarrhea and noted that this was less frequent in infants fed with nucleotide-fortified formula or human milk.

The following biochemical effects of nucleosides and nucleotides on human cell culture systems imply that these compounds have regulatory potential beyond their nutritive functions:

- Recent reports show the influence of nucleosides and nucleotides on liver regeneration *in vitro* and *in vivo.* DNA and RNA syntheses in hepatocytes as monolayer cultures were studied after the addition of ino, cyd, urd, thy, and 5′-GMP. The results confirm the importance of nucleosides and nucleotides in enhancing nucleic acid metabolism.
- The sucrase activity in the intestinal mucosa of early-weaned rats was enhanced when they were fed a nucleotide-supplemented diet of composition similar to human milk. *In vitro* studies showed that

culture media fortified with nucleotides enhanced the proliferation and maltase activity of cultures of small intestine crypt cells (ICE-6). The data suggest that nucleotide supplementation may enhance enterocyte proliferation and maturation *in vitro* and *in vivo*.

- The effects of added nucleosides on the *in vitro* proliferation and apoptosis of models of human cell cultures, namely peripheral blood lymphocytes (PBLs), promyelocytic leukemia cells (HL-60), and colon adenocarcinoma cells (Caco-2), have been investigated. Of the 16 nucleosides tested, the modified adenine ribonucleosides ip6ado and m6,2ado showed the strongest effects. Micromolar concentrations of these compounds inhibited proliferation of all three cell types and induced apoptosis in the PBL and HL-60 cultures. Ado, m1ado, m6ado, and m2,2guo (**Figure 1**) also markedly inhibited the proliferation of PBL and HL-60 cells. The same nucleosides, with the exception of m1ado, induced apoptosis in HL-60 cultures. Interestingly, the antiproliferative effect in HL-60 cells – and to a lesser extent the enhancement of apoptosis – increases with the degree of chemical modification of the adenine molecule.

Furthermore, ribonucleosides, in particular modified nucleosides, serve as valuable pathobiochemical marker molecules for cancer. In addition, chemically modified nucleosides have already found interesting applications as pharmaceutically active compounds in the treatment of different illnesses.

Infant Formulae – New Developments

Owing to their biofunctional properties, nucleotide supplements have been used in infant and follow-on formulae for many years in Japan, in some member states of the European Union as well as in some developing countries. As no harmful effects are known, the European Commission (EC) Directive 2006/141/EC (2006) permits the supplementation of infant and follow-on formulae with nucleotides according to the concentrations specified in **Figure 2**.

Supplementation of infant and follow-on formulae with nucleotides and/or nucleosides should be allowed up to levels present in human milk. Findings concerning the TPAN including all mono-, oligo-, and polymeric sources available in milk are given in **Table 4**.

The current EC Directive 2006/141/EC takes into account the contribution to the TPAN of milk of only the common, unmodified nucleosides and neglects the modified nucleosides and nucleotides that may be released by RNA degradation. Such modified or rare compounds may show regulatory effects but this has so far not been studied adequately.

Technofunctional Properties

The relatively constant concentration pattern of these minor constituents throughout lactation changes markedly on processing. As the changes depend on the processing conditions, the compounds are useful as chemical indicators allowing quantification of adulteration of milk and milk products, identification of different thermal treatments, and the characterization of differently processed products, for example, butter types. Furthermore, high-pressure treatment influences the nucleoside contents and the activities of the milk enzymes alkaline phosphatase and adenosine deaminase, which are of relevance to nucleosides.

Heat-Induced Changes

Heating raw milk under the conditions termed ‘thermization’ (e.g., 65 °C by 15 s) or ‘holder pasteurization’ (e.g., 30 min at 62 °C) causes the concentrations of cyd, guo, and ino to increase severalfold – up to 10-fold in the case of ino – and the ado concentration to decrease by 30%. The changes in milk nucleoside contents occurring during common dairy processes such as pasteurization, ultra-high temperature (UHT) treatment, and sterilization are mainly attributable to the increased catalytic activity of the milk enzymes adenosine deaminase and alkaline phosphatase during the heating-up phase. Stronger heating conditions with a sterilization value, F_0, exceeding 30 min, however, can cause hydrolysis of the phosphate groups of nucleotides, leading to an increase in the corresponding nucleoside concentration.

Thus, cyd, guo, and particularly ino can be used as chemical parameters for detecting thermization and, in particular, holder pasteurization. Unmodified nucleosides of milk seem to be unsuitable for characterizing heat treatment in the region of short-time pasteurization, high-temperature pasteurization, and UHT heating and sterilization.

The concentrations of modified, rare nucleosides such as t6ado and m1ado also vary only slightly throughout lactation. Typical values for t6ado and m1ado in raw bulk milk are 0.7 and 0.4 μmol l^{-1}, respectively. A further modified nucleoside, m6ado (**Figure 1**), is normally not detectable in fresh raw milk but forms in measurable concentrations when the milk is heated under certain conditions. Thus, on UHT treatment or sterilization of milk, it forms as a function of the initial m1ado concentration and of the temperature and holding time of the heat treatment. However, it is not detectable after heating to thermization, holder pasteurization, and short- and

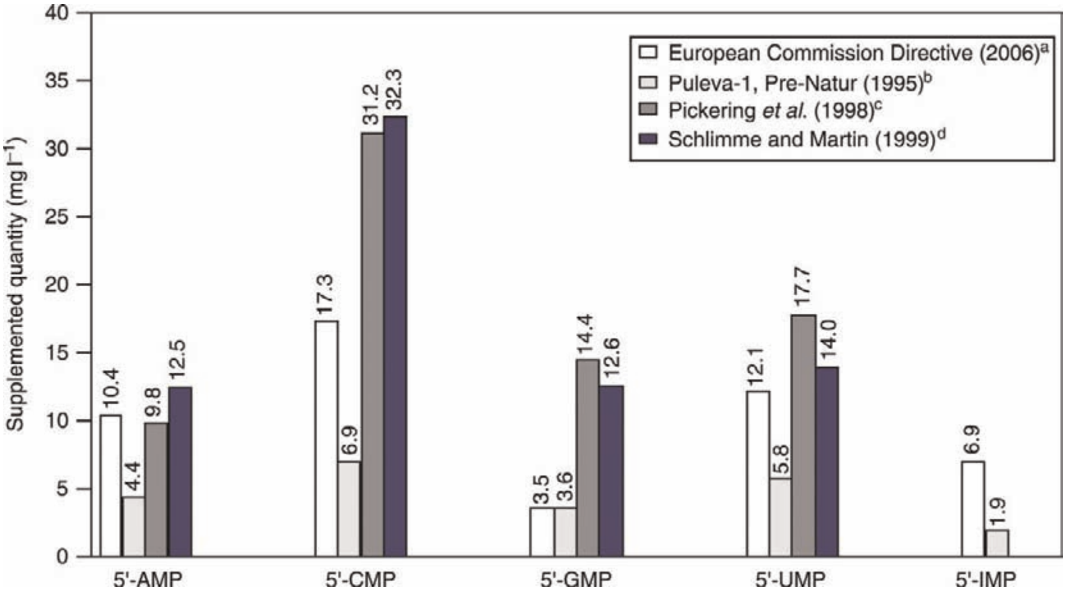

Figure 2 Comparison of the supplemented quantity of nucleotides (mg l^{-1}) in infant and follow-on formulae. The conversion to mg nucleotide per liter infant formula was calculated assuming that the infant formula is isocaloric with human milk (69 kcal 100 g^{-1} milk); nucleotide values are given as disodium salts. 5′-IMP, which was not used for nucleotide fortification of infant formula in the Pickering study (compare c), was also not recommended (compare d) because of its small contribution to the total potentially available nucleosides (compare d).

a. According to the European Commission Directive 2006/141/EC (22 December 2006), the following nucleotides (mg 100^{-1} kcal) may be added: 5′-AMP (1.5), 5′-CMP (2.5), 5′-GMP (0.5), 5′-IMP (1.0), and 5′-UMP (1.75); the total concentration of nucleotides must not exceed 5 mg 100^{-1} kcal.

b. Values adapted from Gil A and Uauy R (1995) Nucleotides and related compounds in human and bovine milk. In: Jensen RG (ed.) *Handbook of Milk Composition*, pp. 436–464. San Diego, CA: Academic Press; the conversion to mg l^{-1} was calculated assuming that the infant formula is isocaloric with human milk (69 kcal 100 g^{-1} milk).

c. Supplementation according to Pickering LK, Granoff DM, Erickson JR, *et al*. (1998) Modulation of the immune system by human milk and infant formula containing nucleotides. *Pediatrics* 101: 242–249.

d. The recommendation by Schlimme E and Martin D (1999) Nucleotid-Supplementierung von Säuglingsnahrung. *Kieler Milchwirtschaftliche Forschungsberichte* 51: 215–224 based on TPAN contents in human milk published by Leach JL, Baxter JH, Molitor BE, Ramstack MB, and Masor ML (1995) Total potentially available nucleosides of human milk by stage of lactation. *American Journal of Clinical Nutrition* 61: 1224–1230.

long-time pasteurization. The formation of m6ado is consistent with a Dimroth rearrangement from m1ado and follows first-order kinetics in the temperature range of 115–150 °C with holding times of 2–128 s. On stronger heating, however, the product decomposes so that depletion of m6ado competes with its formation, thus interfering with the study of its kinetics. However, the kinetics can still be readily analyzed under the conditions of temperature and holding times corresponding to milk sterilization values (F_0) ranging from 0.4 to 22 min. The kinetic parameters are well characterized in the temperature range of 110–150 °C (**Table 5**).

The z and Q_{10} values of 26.8 °C and 2.4, respectively, are similar to those determined for other thermally induced chemical reactions in milk. This confirms the suitability of the rearrangement of m1ado to m6ado as a chemical process parameter in the upper range of high-temperature pasteurization, the whole range of UHT heating, and in the range of sterilization normally applied in dairy technology.

Chemical Parameters for Identification of Butter Type

The German Butter Regulation in combination with the EU Regulation for Spread Standards defines three butter types: the two traditional products ‘cultured (ripened) cream’ butter and the ‘sweet cream’ butter and the novel ‘mildly soured’ butter. A declaration and quality control of the grading category of the butter types – defined for the first time in the German Butter Regulation of 16 December 1988 – is possible with a linear combination of at least three compositional parameters of the aqueous butter phase, namely, citric acid, lactic acid (sum of L- and D-isomers), and specific nucleosides (ado and urd). To aid the computer-assisted validation of analytical data,

Table 5 Thermal coefficients of the Dimroth rearrangement

Heating temperature *δ [°C]*	*D-values* *[s]*	*z-value* *[°C]*	*Q_{10}-value*
110	6069	26.8	2.4
114	3807		
115	3170		
119	2451		
135	608		
140	294		
140	318		
142	341		
150	247		

The *D*-value (decimal reduction value) is defined as the time necessary at a given temperature to reduce the reactant concentration to 90% of the initial value. The *D*-value is calculated according to $D = 2.303/k$ (s), where *k* is the reaction rate constant.
The *z*-value is defined as the increase in temperature in degree Celsius needed to increase the *D*-value 10-fold.
The Q_{10}-value is defined as the change in the reaction rate when the temperature is raised by 10 °C; Q_{10} is calculated according to $Q_{10} = 10^{10/z}$.
Adapted from Schlimme E, Ott FG, and Kiesner C (1994) Reaction kinetics of heat induced formation of N6-methyladenosine in milk. *International Dairy Journal* 4: 617–627; Martin D, Kiesner C, and Schlimme E (1997) Ribonucleoside: *Chemical parameters for controlling the heat treatment of milk.*

artificial neural networks have been successfully applied. The results of compositional analyses of butter samples were used as inputs for a three-layer, feed-forward, back-propagation network. A two data input network of the pH value and the citric acid content was satisfactory for the chemometric identification of most samples of the three butter types. However, a few butter samples were with respect to citric acid on the borderline between traditionally cultured and alternatively acidified (mildly soured) butter. The chemometric characterization of such samples requires an additional compositional parameter, for example, the urd content of the aqueous butter phase, thus creating a three parameter input network. This application of a neural network is the basis of the German standard DIN 10474 for the determination of butter types.

High-Pressure-Induced Changes

High-pressure treatment is an interesting technological process for preservation of food products. High-pressure treatment of raw milk induces the release of ribonucleosides, for example, for urd 11.50 ± 0.09 μmol l^{-1} at normal pressure and 50 °C and 15.12 ± 0.01 μmol l^{-1} at 500 MPa and 50 °C. In preheated milk, such as UHT milk, the changes are considerably smaller. The changes seem to be enzyme-controlled. High-pressure treatment (500 MPa at 50 °C) of raw milk causes a slight decrease in alkaline phosphatase activity, whereas adenosine deaminase is partially inactivated. The deaminase activity decreases from 673 ± 17 mU l^{-1} when heated to 50 °C at normal pressure to 318 ± 8 mU l^{-1} when pressure treated. High-pressure treatment of reduced-fat milk also induces a loss of enzyme activity. This activity reduction of approximately 53% is independent of the fat content. Due to the fact that adenosine deaminase converts ado to ino, the lower ino contents detected in samples treated by high pressure may be explained by a process-related reduction of adenosine deaminase activity.

Concluding Remarks

Nucleosides are *N*-glycosides of pyrimidines and purines; nucleotides are *o*-phosphoric esters thereof. Both groups of compounds belong to the bioactive substances in milk and colostrum. The concentration pattern is specific for the milk of a given species. The physiological capacity of these compounds in milk is given by the TPAN, that is, all potential sources available in milk for the generation of these compounds by digestion and metabolism. Especially in the early stages of life, the biofunctional properties of dietary nucleosides and nucleotides seem to be important in regulatory processes beyond basic nutritive functions. For example, they enhance antibody responses, contribute to iron absorption from the intestine, and are involved in lipid metabolism. Modified nucleosides, in particular, inhibit cell proliferation and activate apoptosis in human cell model systems. Owing to their biofunctional properties, nucleotides have been used as supplements in infant and follow-on formulae in Japan, in some member states of the EU as well as in some developing countries. As no harmful effects are known, the EC permits the supplementation of infant and follow-on formulae with nucleotides according to specified concentrations.

The relatively constant concentration pattern of nucleosides throughout lactation changes markedly on milk processing. Thus, these compounds, in particular the modified forms, are useful chemical indicators in dairy technology.

Introduction

Nutrients consumed by weaned dairy cattle are subject to fermentation by microbes in their rumen or, more properly, their reticulorumen. This pregastric fermentation also affects the dynamics of digestion and absorption in subsequent segments of their digestive tract and, ultimately, the amount and pattern of nutrients available for metabolism.

The rumen microbial ecosystem in cattle fed typical diets is both open and complex, composed mainly of strictly anaerobic bacteria, archaea (single-celled microorganisms that have an evolutionary history and biochemistry that differ from bacteria), protozoa, and fungi. Symbiotic and other interactions of these microbes with each other and with the host animal are also nutritionally relevant. Anaerobic fermentation partially metabolizes nutrients consumed by the host, providing energy and nutrients needed by the microbes. Some end products of microbial metabolism (e.g., volatile fatty acids (VFAs) or short-chain fatty acids, primarily acetate, propionate, and butyrate, but not CO_2 and CH_4) and the microorganisms themselves then provide nutrients for the host. This relationship allows the host to capitalize on the ability of some ruminal microbes to digest plant cell wall carbohydrates (cellulose, hemicellulose, and pectin) otherwise unavailable to mammals. Additional benefits of pregastric fermentation are that the host animal can digest microbial protein passing from the reticulorumen, obtain vitamins synthesized by the microbes, and reduce the effects of some antinutrients (e.g., phytate and gossypol). The interaction of rumination with fermentation is also nutritionally important: chewing during rumination accelerates microbial colonization and fermentation, and as a result digesta particles become more fragile and susceptible to comminution during rumination.

Direct microscopic counts of bacteria in the rumen are 3- to 10-fold those of viable (i.e., culturable) bacteria. Recent data based on studies of rRNA confirm that many more species of bacteria are present in the rumen than have been cultured or identified to date. Some uncultivated organisms are abundant; however, isolated bacteria and archaea are able to perform most of the major transformations known to occur in the reticulorumen and provide a model of the ecosystem. At 1–5 μm in size, and assuming an individual cell volume of 1 μm^3 (or 10^{-9} μl), ruminal bacteria account for about 1% of fluid volume when present at $10^{10}\,ml^{-1}$ or 10% of fluid volume if counts reach $10^{11}\,ml^{-1}$. The larger ruminal protozoa vary in size from 20 to 200 μm and are normally present at concentrations of 10^4–$10^5\,ml^{-1}$; therefore, they can account for approximately half of the total microbial cell contents in the rumen. Counts of protozoa and bacteria in the rumen tend to be inversely related because the former prey on the latter. Anaerobic fungi are also part of this microbial ecosystem. Although they are difficult to quantify because of their complex life cycle, they have been estimated to contribute about 6% of total biomass.

A lactating, mature, 680-kg Holstein cow consuming a sample diet will provide the framework for this discussion of fermentation in the reticulorumen. It is assumed that the cow produced 45 kg of milk per day with 3.5% fat and 3.0% true protein; lived in a thermoneutral environment; and ate (on a dry matter basis) 7.08 kg of steam-flaked maize, 6.16 kg of immature legume hay, 5.61 kg of maize silage, 2.53 kg of whole cottonseed (with lint), 2.26 kg of sorghum-sudan silage, 1.41 kg of solvent-extracted soybean meal (48% crude protein), 0.98 kg of midmaturity grass (C3) hay, 0.87 kg of coastal Bermudagrass hay, 0.51 kg of a vitamin and mineral premix, 0.23 kg of ring-dried blood meal, 0.12 kg of sodium chloride, 0.09 kg of calcium carbonate, and 0.04 kg of monosodium phosphate (monohydrate) per day – a total of 27.9 kg of feed dry matter, 4.1% of body mass. The ration, as consumed, also included 18.9 kg of water and the cow drank an additional 115.6 kg of water per day; therefore, total water intake was 134.5 kg per day and total nutrient consumption was 162.4 kg per day. Ignoring contributions by saliva and scurf (sloughed epithelial cells from the digestive tract), the profile of nutrients entering the reticulorumen was then estimated using tabulated feed composition data (**Figure 1**). Nonnutritive lignin was accounted for; it and similar but unquantified compounds (e.g., tannins and acid-insoluble ash) are discussed separately. Once swallowed and upon entering the reticulorumen, nutrients become potential substrates for microbes to utilize; their various fates are now considered in turn.

Water

Considerably more water than dry matter is consumed by the lactating cow, 4.8 times as much in our example. Even more would have been consumed during periods of high environmental temperature. Although often an overlooked nutrient, water is clearly an extremely important one and consumption of such large amounts also impacts fermentation in the reticulorumen. Water is required for fermentation itself because the enzymatically catalyzed chemical reactions by which complex molecules in carbohydrates, protein, and fat are converted into assimilable forms, that is, hydrolysis, involve water.

A portion of imbibed water, perhaps 5–18%, bypasses the reticulorumen; however, the rest equilibrates with the 60–80 l of fluid normally present. Water in the

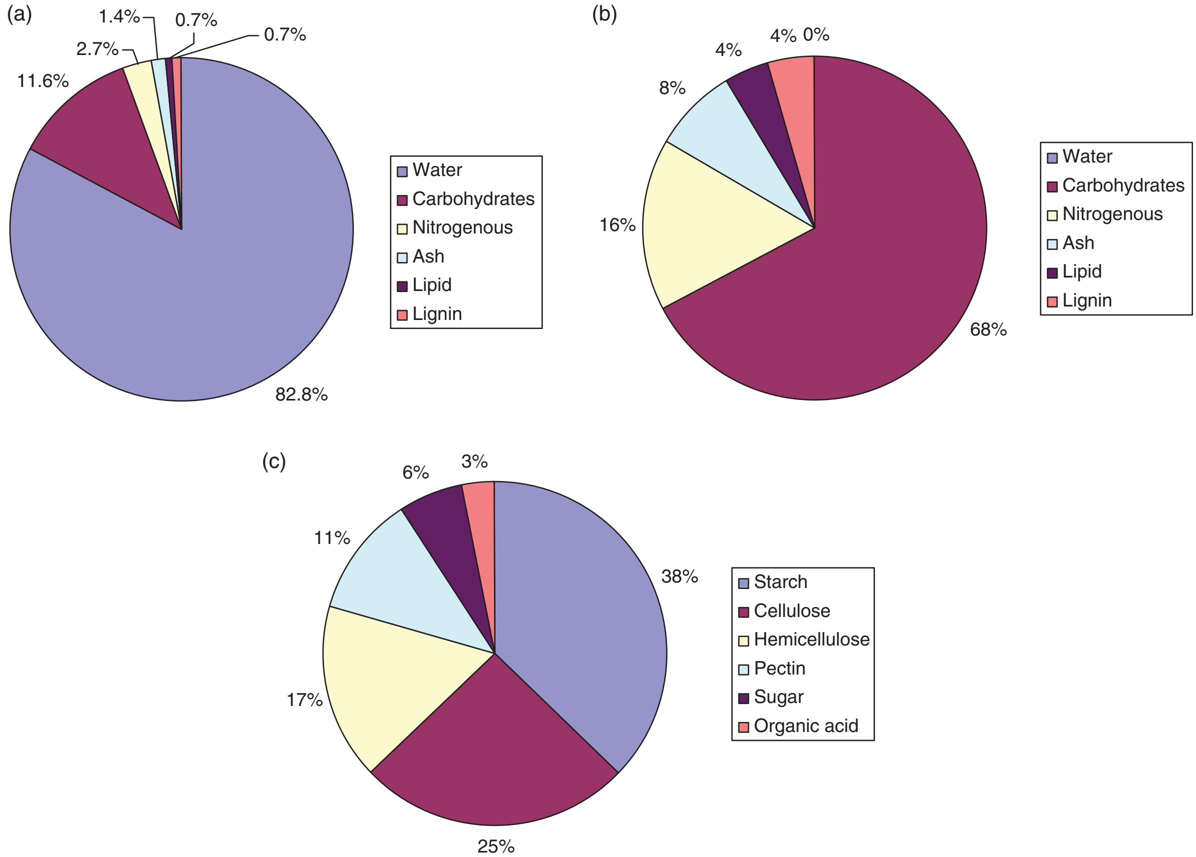

Figure 1 The profile of nutrients entering the reticulorumen: (a) nutrient consumption; (b) dry matter consumption; and (c) carbohydrate consumption.

reticulorumen (either drunk, from saliva, or in feed) also exchanges rapidly with body water; the half-life of water molecules in the reticulorumen is about 1 h. The fractional dilution rate in the reticulorumen is typically 10–17% h^{-1}; in our example, the value is likely toward the high end of this range. Unless a microbial species is continually reinoculated, it must multiply at least as quickly as the fractional dilution rate, attach to digesta particles having a slower fractional passage rate, or perhaps (if motile) sequester in a location having a slower turnover rate to avoid being removed from the reticulorumen. Microbes growing more quickly also grow more efficiently because a smaller proportion of their energy is utilized for maintenance.

Carbohydrates

The sample ration provided 18.8 kg day^{-1} of carbohydrates. The carbohydrate fraction of feeds is a complex mixture of monomers and polymers making up about 68% of dietary dry matter (**Figure 1**(**b**)). Carbohydrates can be fractionated, based on various analytic procedures related to chemical composition and rumen fermentability, into starches, cellulose, hemicellulose, pectins, sugars, and organic acids. Although various ruminal microbes are adapted to utilize all carbohydrate fractions, the dynamics of fermentation vary considerably. There are also known interactions between carbohydrate fractions; for example, too much or too rapid a fermentation of starch can cause ruminal acidosis that inhibits fiber (cellulose, hemicellulose, and pectin) digestion.

The overall scheme of carbohydrate fermentation by ruminal microbes is similar regardless of source (**Figure 2**). If not already in hexose form, carbohydrates are hydrolyzed and converted to hexose monomers. These are metabolized to pyruvate via Embden–Meyerhof glycolysis in bacteria and the Entner–Doudoroff pathway in archaea. Subsequent metabolism of pyruvate leads to the production of VFAs, CO_2, and CH_4. Methane is produced from CO_2 and hydrogen by the archaea (e.g., *Methanobrevibacter ruminantium*). Some methanogens are found attached to protozoa (exosymbionts) where they derive hydrogen directly from specialized protozoal organs (hydrogenosomes). The CH_4 cannot be utilized by the cow and represents a loss of 5–7% of the gross energy in her ration. That said, production of CH_4 does dispose of hydrogen and allow anaerobic fermentation to proceed. Although CH_4 production by a mature lactating cow consuming the sample ration would be nearly maximal in terms of liters per day, CH_4 production per kilogram of milk yield would be approaching its minimum; that is, the emission of 'anthropogenic' CH_4 per unit of human food produced is lower than it would be in cows producing less milk.

Starches

Fifty to ninety percent of the 7.0 kg day^{-1} of starch entering the rumen of the cow would be expected to be fermented in her reticulorumen, the large range indicating potential effects of many factors affecting starch degradation. The rate of starch fermentation varies with its source and processing. Starch in oats or wheat is degraded more quickly in the reticulorumen than starch in maize or sorghum; some of this difference is related to starch solubility and the ease with which proteins surrounding starch granules in the cereal's endosperm are fermented. Starch degradation rate is increased by cracking or grinding, and steam flaking. These processes increase relative surface area and disrupt starch granules. As with other nutrients, feed consumption affects the proportion of consumed starch fermented because it influences the fractional passage rate of digesta from the reticulorumen. This means that, for the cow fed the sample diet and eating 4% of her body mass in dry feed per day, starch digestion in the reticulorumen would likely be closer to 50% than 90% of that consumed.

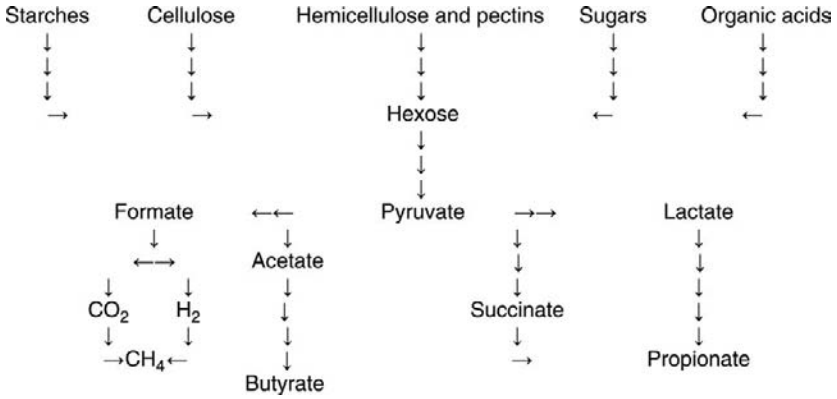

Figure 2 Overview of carbohydrate fermentation in the reticulorumen.

Predominant species of ruminal bacteria utilizing starch include *Butyrivibrio fibrisolvens*, *Ruminobacter amylophilus*, *Prevotella* sp., *Streptococcus bovis*, *Succinomonas amylolytica*, and some strains of *Selenomonas ruminantium.*

Cellulose

The sample ration provided 4.8 kg day^{-1} of cellulose to the reticulorumen and 30–60% of it would be hydrolyzed in the reticulorumen, albeit more slowly than starch. Among predominant ruminal bacteria able to use cellulose are *Fibrobacter succinogenes*, *Ruminococcus albus*, *R. flavefaciens*, and some strains of *B. fibrisolvens*.

Hemicellulose and Pectins

As with cellulose, 30–60% of the 3.2 kg day^{-1} of hemicellulose and 2.1 kg day^{-1} of pectins would be hydrolyzed in the reticulorumen. *Butyrivibrio fibrisolvens* and *Prevotella* sp. are predominant organisms using hemicellulose or pectins. *Lachnospira multiparus* is another predominant pectin fermenter.

Sugars

Fermentation of the 1.2 kg day^{-1} of sugars in the sample ration would be rapid; many ruminal microbes can utilize them. In cattle fed low-forage, high-grain diets, the half-lives of both sugars and starch in the reticulorumen are about 4 h. Predominant species of ruminal bacteria utilizing sugars include *B. fibrisolvens*, *S. ruminantium*, *S. bovis*, *Eubacterium ruminantium*, and *L. multiparus*.

Organic Acids

The 0.6 kg day^{-1} of organic acids provided by the sample ration, probably mostly citrate and malate, would be rapidly fermented in the reticulorumen. *Wolinella succinogenes* is a species that can use malate.

Nitrogenous Compounds

About 70% of the 4.5 kg day^{-1} of dietary protein and nonprotein N entering the reticulorumen of the cow fed the sample ration would be fermented there, leading to the production of microbial protein and ammonia. Considerable recycling of N can occur within the reticulorumen: between bacteria and protozoa, between one bacterium and another, and between the cow and the reticulorumen. Depending on the circumstances, these processes may be advantageous or disadvantageous to the nutrition of the cow. The advantages include microbial conversion of nonprotein N into protein that can then be digested to provide amino acids to the cow, conversion of poor-quality dietary proteins into higher-quality microbial protein, and utilization of salivary urea to provide protein to the cow when N intakes are low. The processes can be disadvantageous when degradation of dietary protein exceeds synthesis of microbial protein or when unprotected proteins of higher quality than microbial protein are fed. Defaunation (i.e., removal of protozoa from the reticulorumen) reduces N recycling; however, this has a potential downside. By ingesting starch granules, some protozoa (entodinomorphs) buffer its rate of fermentation and reduce the potential for lactic acidosis. A similar benefit can be provided by those protozoa (holotrichs) that compete directly with bacteria for soluble sugars.

Predominant rumen bacterial species utilizing protein, peptides, or amino acids are *Clostridium aminophilum*, *C. sticklandii*, *Megasphaera elsdenii*, *Peptostreptococcus anaerobius*, and *Prevotella* sp. *Clostridium aminophilum*, *C. sticklandii*, and *P. anaerobius* are all obligate amino acid fermenting bacteria; they cannot utilize carbohydrates for energy but deaminate amino acids much faster than other ruminal bacteria. Ammonia can be used by a majority of rumen bacteria for biosynthesis of amino acids and protein.

Minerals

The 2.2 kg day^{-1} of minerals in the sample ration can affect fermentation in the reticulorumen. Fermentation can also alter both the dynamics of mineral metabolism in the cow and the ultimate availability of some of these elements to the host.

Minerals soluble at the pH of the reticulorumen, normally 5.5–7.0, increase the osmolality of fluid in this compartment of the digestive tract and this can enhance the fractional dilution rate. Many of these elements (e.g., Cl, I, K, Mg, Na, S (in sulfide form), and Zn) can be absorbed from the reticulorumen. Carbonates also help buffer rumen pH and reduce the adverse effects of low pH (rapid fermentation) on fiber-degrading microbes. Provided that the ration contains adequate Co, fermentation in the reticulorumen supplies enough vitamin B_{12} (cobalamin) to meet requirements of the cow.

A three-way interaction of Cu, Mo, and S affects the availability of Cu in ruminants. Briefly, fermentation of Mo and S in the reticulorumen produces thiomolybdates. Copper reacts with thiomolybdates in the rumen to form highly insoluble complexes that are poorly absorbed. Thiomolybdates can also be absorbed by the cow, reducing the availability of systemic Cu.

Lipids

Most of the 1.2 kg day^{-1} of lipids ingested in the sample ration would undergo some form of transformation by fermentation in the reticulorumen. For example, dietary triacylglycerols (fats and oils, like those in cottonseed) would be normally hydrolyzed completely to free fatty acids and glycerol. The latter would be rapidly fermented to produce propionate, whereas 70–90% of the unsaturated fatty acids released in this process would be extensively biohydrogenated. A predominant bacterial species that hydrolyzes dietary triacylglycerols to free fatty acids and glycerol with little accumulation of mono- or diacylglycerols is *Anaerovibrio lipolytica.*

Fatty acids can interfere with fermentation in the reticulorumen both indirectly and directly. Their association with digesta particles may reduce microbial access to substrate. They can also directly inhibit microbial growth and metabolism.

Lignins

Although a portion of the 1.2 kg day^{-1} of lignin phenolics in the sample ration would be digested, absorbed, metabolized, and excreted in urine as aromatic acids, most would pass, unaltered, through the reticulorumen. Any delignification of plant cell walls would increase the availability of cellulose and hemicellulose in the reticulorumen.

Fiber Digestion in Pasture-Based Cows

J Gibbs, Lincoln University, Canterbury, New Zealand

J R Roche, Dairy NZ Ltd, Hamilton, New Zealand

© 2011 Published by Elsevier Ltd.

Introduction

When all ruminants are considered, pasture is the major feed consumed; however, for most dairy cows, grazed pasture is, in general, a less important feed than conserved forage and grain. Pasture-based dairying is becoming increasingly popular in industrialized nations because of the advantages it can offer in reduced input costs and perceived improvements in animal health and welfare.

There is, correspondingly, a large body of literature on the nutrition of pasture-fed cows. The traditional research emphasis, however, has been on remedying energy and protein deficiencies encountered relative to total mixed rations (TMRs).

In recent decades, there have been significant advances in both genetic improvement of pasture species and pasture management strategies, resulting in greater energy density and higher dry matter (DM) yield, particularly in temperate species such as perennial ryegrass (*Lolium perenne* L.). During the same period, there has been a steady increase in the knowledge of rumen function within TMR-feeding systems, and this has begun to reveal an important role for supplementary fiber; fiber supplementation has been demonstrated to improve rumen function and animal production when included in the ration above previously defined thresholds. These two distinct lines of pasture and rumen research have been drawn together in recent years, with attempts to extend to pasture systems the role demonstrated for fiber in TMR.

However, there are several reasons why the existing research on dietary fiber and rumen function in TMR systems should be extrapolated to grazing ruminants cautiously. A brief review of the history and development of our current understanding of fiber in ruminant diets assists in this explanation.

Fiber Assessment in Ruminant Nutrition

Fiber is considered to be that fraction of the diet contained in plant cell wall material and is not digested by endogenous mammalian enzymes; in general, it is generally accepted that this fraction is also either not digested or relatively slowly digested by the symbiotic microbial communities of the ruminant.

The original Weende assay technique used to assess the indigestible fraction of feeds, which was termed crude fiber (CF), was developed in the nineteenth century and remains a formally recognized method, although it is known to underestimate cell wall contents. To improve the determination of these cell wall contents, an alternative method was developed by Van Soest and colleagues in the United States Department of Agriculture. The method that they developed was known as the neutral detergent fiber (NDF), which includes all the plant material understood to compose 'fiber', broadly, lignin, cellulose, and hemicellulose. They then extended the classification to another fraction, acid detergent fiber (ADF), which represents the least digestible fiber content of lignin and cellulose only.

Role of Fiber in Rumen Function and 'Effective Fiber'

The role of fiber in the rumen environment has been intensively studied since the 1930s. Early research demonstrated that low levels of CF in the ration were associated with reduced rumen motility, including rumination, and lower milk fat content. This research led to further investigation of the mechanisms by which rumen motility and rumination were triggered, and it was demonstrated that reticulo-rumen epithelial contact, weight of rumen contents, rumen distension, and infusion of certain volatile fatty acids (VFAs) all altered rumen movement. In particular, it was demonstrated that firm particles of a critical size ('scabrous' material, or 'roughage') were effective in increasing rumination rates compared with 'softer' forage or concentrate diets.

With the increase in TMR feeding, the need to structure rations with appropriate 'roughage' suitable for producing satisfactory rumen environments directed research efforts toward alternative approaches to characterizing and measuring fiber content. The initial research was empirical, with fiber included from different sources and at different levels in the ration. The parameters measured were the time spent chewing, milk fat concentrations, and the ratio of acetate to propionate in rumen fluid. NDF began to be used as the standard classification of dietary fiber, rather than CF, because of the improved accuracy in determining total fiber content. From this research, the concept of 'effective' NDF (eNDF) or effective fiber was developed. This fraction is commonly defined as "NDF of a source and preparatory treatment that induces adequate chewing and therefore milk fat concentration", but it was limited in its usefulness because it was difficult to categorize feeds on their effect on animal production.

A method of classifying the particle size distribution of NDF in rations was developed to enhance the animal scientist's ability to define the appropriate effectiveness of ration fiber. This measure was termed 'physically effective' NDF (peNDF) and involved sieving feeds to determine particle size and comparing this against cow responses. This peNDF concept has been reported to satisfactorily predict cow responses to the feed.

Limitations of 'Effective Fiber' in Pasture

With the demonstration that the peNDF approach could satisfactorily assess the physically effective fiber content of TMR, there was considerable interest in application to pasture diets. However, several immediate difficulties arose. Determining the peNDF by the proportion of the diet that remains on a given sieve size is unsuitable for pregrazed pasture as it is generally presented to the ruminant intact, and is, therefore, of relatively large 'particle size'. For similar reasons, there is no reliable measure of the particle size distribution of pasture even immediately after mastication. Given that the physical separation of the ration was a key concept of peNDF quantification, to use the method for grazing cows it was necessary to ascribe to pastures an eNDF value by comparison with feeds for which peNDF could be measured. This could be done subjectively, on the basis of shared characteristics (e.g., suitably prepared silages) or on the basis of rumen pH and rumen passage rates of the feed. As an example of the latter approach, a meta-analysis study estimated the eNDF of a particular high-quality pasture to be in the range of 29–78%, with a mean of 43%.

This necessity for some extrapolative comparison with other feeds demonstrates that the critical difficulty for peNDF estimation of pasture is the unsuitability of particle size assessment in fresh uncut forages. A practical example of these difficulties is the poor prediction of ruminal pH of pasture-fed cows using models that more satisfactorily predict ruminal pH of cows fed a TMR, when energy density and other fermentation factors are broadly standardized. If the physical characteristics of pasture fiber cannot be determined accurately, it is evident that any further attempt to use them to guide ration development of pasture-fed cows needs to be approached cautiously.

In addition, it is important to note that the measurements used to determine the fiber content in pasture do not explain the corresponding rumen environment as satisfactorily as that of TMR-fed cows. This is because the current understanding of the actual mechanisms by which dietary fiber induces rumen motility and chewing remains incomplete. Physically effective fiber (peNDF) is considered to exert a positive effect in the rumen by altering chewing behavior (eating and rumination) and maintaining a physical separation between the rumen 'mat' and rumen fluid. However, both chewing times and the stratification of rumen contents in pasture-fed cows are very different to TMR-fed cows. In cows consuming a high proportion of pasture, rumen contents can be greater than 20% of live weight, and the rumen digesta effectively forms a single, relatively homogeneous mass with markedly reduced physical stratification or differentiation compared to that of cows fed TMRs, and greater rumen fill. In this environment, in contrast to rumens of TMR-fed cows, there is little effective separation of rumen contents.

The effect that differences in rumen content stratification have on rumination rates is not well understood; it is possible, however, that the reasons why high-peNDF feeds such as long chop straw are not as dominant an influence in inducing rumination in pasture-fed cows as in TMR-fed cows could be due to this basic difference in the rumen environment of grazing animals. Given the other rumen motility 'triggers' that have been identified (e.g., weight of rumen contents, rumen distension, VFA concentration), it may be that rumen epithelial contact with peNDF is not as critical a 'driver' of rumination in cows consuming a high proportion of pasture.

In addition, rumination may be a behavior as well as a physiological reflex, and little is understood about how rumination rates are affected by intake, or time available for grazing or loafing in pasture-fed cows. This is important because, in general, grazing animals have greater harvesting costs associated with a given energy intake; extended grazing periods may well reduce rumination time, not because of reduced rumen stimuli, but because free time that may have been spent resting and ruminating might be allocated to grazing. In contrast, if rumination is a behavior that is selected by the cow independent of direct rumen stimuli (e.g., in times of rest), there may be no advantage to increased rumination rates, above a physiologically necessary level, in improving the rumen environment or animal production. As the research to determine minimum chewing thresholds has been done with TMR-fed cows rather than pasture-fed cows, it is not possible to define what level of chewing activity is associated with adequate rumen function in pasture-based cows. Because of this, ascribing higher effective fiber content to certain pastures on the basis of higher rumination rates is, at present, outside the boundaries of the available research.

Research on the Effects of Supplementary Fiber in Pasture Grazing Cows

To date, the studies investigating the responses of pasture-based cows to supplementary fiber support the use of caution when directly extending the principles of effective fiber concepts developed under TMR feeding to pasture-based systems. The supplementation of cows grazing temperate pastures and legumes with additional fiber, in the form of cereal or grass straws, has not been demonstrated to alter the rumen environment in the manner an increase in peNDF has been demonstrated with TMR-fed cows.

A series of experiments in Australia, New Zealand, and Europe have examined the effect of supplementary straw fed to cows grazing ryegrass pastures with and without additional grain supplements. The Australian work used cows grazing good-quality ryegrass and legume pastures in different seasons and at different grain supplement levels to measure the changes in dry matter intake (DMI), pasture intake, milk yields, and various rumen function parameters, with the addition of supplementary straw up to 3 kg DM a day. No significant improvements in rumen pH, acetate-to-were propionate ratio, milk yield, or milk composition were demonstrated by the addition of supplementary straw. However, significant pasture substitution and reduced milk yields with increasing straw content were reported. Similarly, New Zealand work using a split herd trial design on ryegrass pastures reported that the provision of supplementary straw at 2 kg per cow daily was associated with a significant reduction in milk yield in that treatment group in spring.

Recent work at Lincoln University in New Zealand and by European researchers with real-time *in situ* assessment of rumen pH via indwelling sensors has noted that the addition of supplementary straw to high-production cows grazing ryegrass did not increase rumen pH across the diurnal cycle, did not significantly alter rumen VFA ratios, and did not increase rumination rates or milk yield and composition. This is despite the low rumen pH recorded in these grazing cows and, in the Lincoln University work, the relatively low NDF content of the pastures (320–380 $\mathrm{g\,kg^{-1}}$ DM). For example, in the Lincoln University work, the rumen pH recorded across approximately 500 days from cows grazing different pastures and during different seasons and has consistently presented with daily pH nadirs of between 5.0 and 5.5. Such pH nadirs appear to be common in these pasture grazing systems.

Overall, these studies have consistently reported no significant benefit in milk production or composition and no improvement in rumen pH or acetate-to-propionate ratios, while in some reports supplementary straw reduced pasture intake and milk production. Given the reports of measured rumen pH being commonly below 6.0 in pasture grazing cows of similar intakes, the consistent lack of a positive response to supplementary straw reported in these studies is revealing. It suggests that the rumen environment produced with high-quality pastures is less subject to influence by peNDF than the rumens of TMR-fed cows. It also suggests that the current understanding of the role of fiber in the nutrition of high-producing pasture-fed cows is incomplete; perhaps the central concepts of fiber nutrition in TMR-fed cows – the role in increasing chewing, particularly by rumination, through physical contact of the feed with the rumen – need to be reassessed in pasture-fed cows.

Conclusion

The role of fiber in the nutrition of pasture-fed cows is identifiably different from that of cows fed TMR, and attempts to directly extrapolate the existing research from the latter system to pasture-based cows have demonstrated the need for caution in doing so. The research undertaken to assess the response of pasture-based cows to supplementary straw has not demonstrated any significant advantage, and in some instances has reported notable disadvantages in milk production and intake. There is a need for further research specifically targeting the differences in the dominant mechanisms by which rumen motility and function are influenced in pasture grazing cows compared with TMR-fed cows.

Small Intestine of Lactating Ruminants

J D Sutton and C K Reynolds, The University of Reading, Earley Gate, Reading, UK

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The small intestine is the primary site of absorption of most major nutrients except the volatile fatty acids (VFAs) in ruminants. Long–chain fatty acids, amino acids, glucose, and most vitamins are absorbed only from the small intestine, while most minerals are absorbed there primarily. Because all these nutrients are vital for milk synthesis, with glucose and amino acids being potentially limiting nutrients, the small intestine plays a particularly important role for the lactating ruminant. Thus, quantification of the extent of digestion and amounts of nutrients absorbed from the small intestine is central to attempts to determine metabolic limits to milk production.

The principal functional difference between the small intestine of ruminants and that of nonruminants is that the substrates the former has to digest consist of those parts of the feed that have escaped digestion in the stomach together with the products of rumen microbial fermentation. Because lactating ruminants, particularly dairy cattle, have high rates of feed intake and thus passage of digesta, there is less time for digestion to occur in the stomach; therefore, more amounts of potentially fermentable feed enter the small intestine. Essentially all soluble carbohydrates and variable proportions of starch and fiber are removed by the time the digesta enter the duodenum. The amounts of protein and lipids entering the duodenum from the abomasum do not differ greatly from the amounts consumed, but they will have been extensively modified by microbial action.

Anatomy and Physiology

The small intestine constitutes about 80–85% of the total length of the intestines and is found to be 42–52 m long in lactating Friesian cows, while 26 m is quoted for sheep and goats. The small intestine of ruminants is anatomically and functionally very similar to that of nonruminant mammals. The duodenum is only about 1 m long in the cow and 60 cm in the sheep and goat. The duodenum is less convoluted than the jejunum (**Figures 1** and **2**(**a**)) and includes a proximal, ascending portion, which lies adjacent to the pancreas and liver, and a distal, descending portion, which leads to the duodenojejunal flexure (**Figures 2**(**a**) and **2**(**b**)). The jejunum and ileum constitute the remainder of the small intestine and cannot be easily distinguished from one another, although anatomically the ileum is the small intestine attached to the ileocecal fold (**Figure 2**(**a**)). The principal glands serving the small intestine are the pancreas and gallbladder, both of which secrete into the duodenum, and a series of glands in the gut wall. The principal enzymes secreted by the pancreas are amylase, trypsin, chymotrypsin, and lipase. Enzymes secreted by glands of the intestinal wall generally digest the incomplete breakdown products of pancreatic enzyme digestion into simpler monomers that can be absorbed.

Digesta enter the duodenum from the abomasum at an acidic pH of about 2.0–3.0, but this acidity is rapidly neutralized by the pancreatic and bile secretions. However, passage is also fast in the first part of the small intestine so that pH may not reach neutral values until the mid–jejunum. The digesta are very liquid, containing about 40 g DM kg^{-1}, though this varies from 20 to 60 g kg^{-1} between diets and between individual animals. Thus, the digesta flow through the proximal duodenum of a high–producing dairy cow may amount to 400 kg day^{-1}. During passage through the small intestine, a net uptake of fluids occurs so that at the terminal ileum the DM content will have risen to about 60–80 g kg^{-1}.

The flow of digesta into the duodenum varies over the day, though less so than in nonruminants due to the buffering effect of the rumen. In sheep it has been shown to increase shortly after a meal and then decline over a period of a few hours before gradually increasing, with the result that the flow to the duodenum in ruminants fed twice daily may be greatest overnight. There is very little information on digesta passage times through the small intestine of lactating ruminants. Passage is most rapid in the cranial part of the small intestine, and in sheep opaque markers have been shown to take only 20–40 min to pass from the duodenum to the proximal ileum but a further 2 h to reach the terminal ileum.

The intestines are supplied with blood via the celiac artery to the proximal duodenum and the cranial mesenteric artery to the rest of the small intestine and part of the colon. There is also a lymphatic system. In contrast to sheep and goats, the cranial mesenteric artery and vein of the small intestine of the cow include a collateral branch (**Figures 2**(**a**) and **2**(**b**)), which ensures adequate blood supply to the distal jejunum if contraction and convolution impede flow in the main branch. The portal–drained

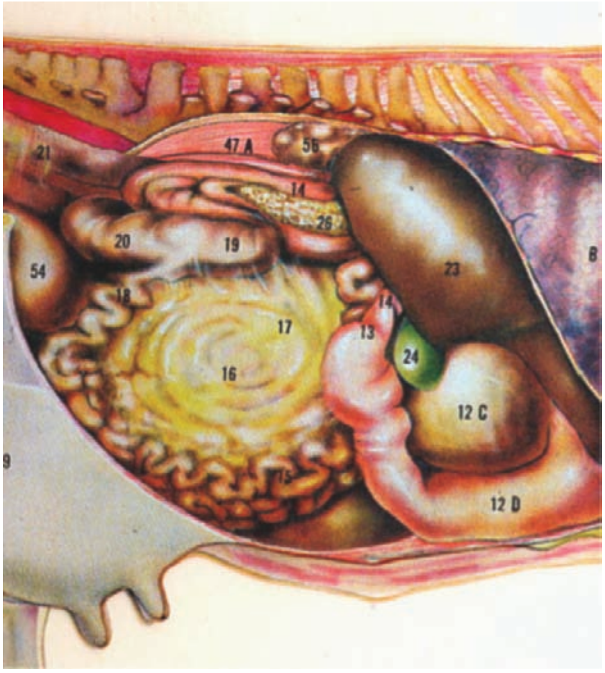

Figure 1 Position of the small intestine within the abdominal cavity of the dairy cow. Note the position of the abomasum (12D), pylorus (13), duodenum (14), jejunum (15), ileum (18), cecum (20), and colon (19). Also shown are the liver (23), gallbladder (24), and pancreas (26). viscera (PDV; entire gastrointestinal tract, pancreas, spleen, and mesenteric and omental fat) account for up to 25% of the total energy requirements of the lactating ruminant in part due to the high rate of protein turnover. Within the PDV, the tissues drained by the cranial mesenteric vein of cattle (largely the intestines and cecum) account for roughly half of the oxidative metabolism. Thus, the blood supply provides nutrients to maintain this activity as well as to remove nutrients absorbed from the digestive tract.

Various methods have been used in attempts to quantify digestion in the small intestine. Apparent digestion is the net difference between the amount of a nutrient entering the duodenum from the abomasum and the amount leaving the terminal ileum. In contrast, true digestion takes account of amounts secreted into the gut from glands, passing across the gut wall from the blood, or as cells being sloughed off the gut wall. Measurements of both true and apparent digestion depend on the use of cannulas inserted permanently into the proximal duodenum and terminal ileum.

Cannulation of the proximal duodenum has been a common research tool for studying digestion in all classes of ruminants and provides the basis for dividing the digestive tract into the stomach and intestines (usually, but inaccurately, referred to as the ruminal and postruminal tract). However, estimates of digestion in the small intestine additionally require cannulation of the terminal ileum to distinguish digestion in the small intestine from further fermentation in the cecum and large intestine. This presents greater surgical problems, and considerably fewer reports of the application of this technique in lactating ruminants have been published.

An alternative approach to quantifying digestion in the small intestine is to measure net uptake of glucose or amino acids into venous blood. Appreciable amounts of some amino acids and glucose are utilized by the PDV, so there is a significant difference between the amounts of these nutrients absorbed from the lumen of the gut and their net appearance in the portal vein. Glucose and

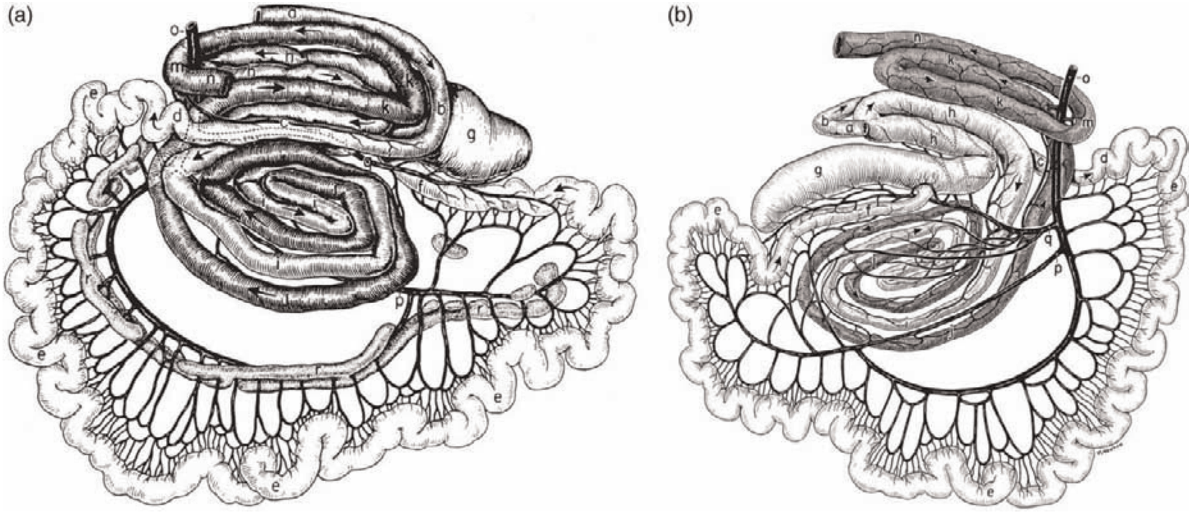

Figure 2 The intestine of the dairy cow: (a) left–side and (b) right–side view. Landmarks shown include the descending duodenum (a), duodenojejunal flexure (d), jejunum (e), ileum (f), cecum (g), cranial mesenteric artery (o) and collateral branch (p), and jejunal lymph nodes (r). amino acids are used by the PDV both during their initial absorption from the gut, before reaching the mesenteric veins, and during their absorption from the arterial blood. Thus, the measurement of true rates of absorption can be obtained only by using isotopic labeling techniques. Though surgically difficult, much progress has been made in this area over the past 25 years.

Carbohydrates

The principal carbohydrates entering the duodenum from the abomasum are cellulose, from fiber, and starch. Essentially all the soluble sugars, oligosaccharides, and pectin from the feed are fermented to VFAs in the rumen.

Fiber is variably digested in the rumen, depending on various factors including its source and how it is processed, so only about 50–70% of the amount consumed reaches the duodenum. None of this is digestible by mammalian enzymes, so it is reasonable to assume that none will be digested in the small intestine. Although some fermentation may occur in the distal ileum, which could, in theory, allow limited fiber digestion proximal to the ileo–cecal valve, the amount is likely to be negligible and, for all practical purposes, all measured postruminal digestion of fiber can be assumed to occur in the hindgut.

Starch is by far the most important carbohydrate digested in the small intestine, as it provides the only exogenous source of glucose for the ruminant. The starch entering the duodenum is primarily the fraction of feed starch that has escaped fermentation in the rumen either because it passes through the rumen more rapidly or because it is more slowly fermented. The amount varies widely, being affected primarily by the amount and the chemical and physical form of starch in the diet, but also by the level of total diet intake through its effect on retention time in the rumen. Typically, wheat, barley, and cassava are rapidly fermented, while maize and sorghum are more slowly fermented. Starch supplies to the duodenum of lactating cows can exceed 5 kg day^{-1} when diets based on more slowly fermented starch sources such as ground maize or sorghum are fed, but this can be halved if the grain is flaked (steam–rolled) to make it more digestible. Wheat or barley in the ground or cracked form is rapidly fermented allowing only about 1 kg starch day^{-1} to reach the duodenum, but if it is fed as whole grains as in the case of mature whole–crop wheat, starch supplies to the small intestine can be enhanced to over 2 kg day^{-1} in cows but not in sheep or goats, which are more efficient at chewing small grains. A small proportion of duodenal starch, perhaps 5–10% of the total depending on the microbial population in the rumen, may be of protozoal origin.

Many estimates of postruminal digestion of starch (duodenum to feces) in lactating dairy cows have been published. Values for total postruminal digestion of maize starch average about 82% with little evidence of any change with increasing starch flow into the duodenum (**Figure 3(a)**). Of the various sources of starch, only sorghum is clearly less digestible than the average. A much greater difficulty is quantifying the contribution of the small intestine to this postruminal digestion. This is a key question as digestion within the small intestine is primarily, though not exclusively, by mammalian enzymes yielding glucose, whereas digestion in the large intestine is by fermentation yielding VFAs. A recent review of the published papers where duodenal–ileal digestion has been measured in lactating dairy cows showed that the small intestine contributed 88% of the total postruminal starch digestion (**Figure 3(b)**). The digestibility of duodenal starch in the small intestine averaged 69%, but with a wide variation associated with differences in starch sources and especially in grain processing. A lower mean value of 53% has been calculated for beef cattle.

The maximum capacity of the small intestine to digest starch has not been defined reliably in either beef or dairy cattle though the highest reported digestion in lactating cows is 3.4 kg day^{-1}. Digestive capacity is determined by the activity not only of pancreatic amylase, which breaks down starch to disaccharides, but also of intestinal

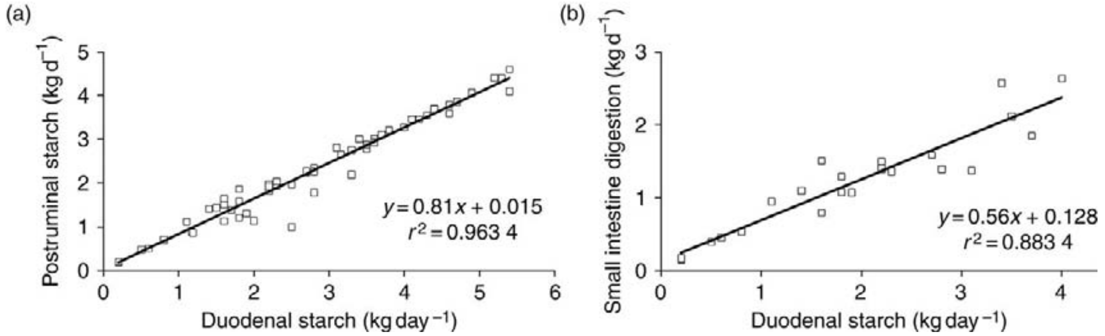

Figure 3 Relationship between duodenal starch flow and postruminal starch digestion (a) and small intestinal starch digestion (b) in lactating dairy cows.

disaccharidases (mainly maltase and isomaltase), which are needed to produce glucose. The buildup of oligosaccharides in the ileal digesta of steers suggests that both these enzyme groups may be limiting on occasion. Surprisingly, there is evidence from steers that amylase activity is greater on lucerne diets than on maize–based diets, which is contrary to the expectations that a mechanism might have evolved that would allow amylase secretion to increase in response to increased supplies of the substrate. However, recent studies suggest that protein and energy supplies have a more dominant role in determining pancreatic amylase secretion than starch supply *per se*.

A key question in relation to the lactating ruminant is how much of the apparently digested starch in the small intestine increases glucose supplies in the blood and so becomes available as a substrate for milk synthesis. In critical intraabomasal or intraduodenal infusion studies with steers, net recovery of apparently digested starch as glucose in the portal vein has been only about 35%, but this fails to account for incomplete digestion of starch. Higher recoveries of 38–57% have been found with glucose infusions, but even this still leaves large amounts of glucose unaccounted for. The problem arises from the fact that glucose is extensively metabolized by the PDV and the associated adipose tissues so that net absorption in lactating cows is often zero or even negative because metabolism by the PDV matches or exceeds the amount absorbed from the lumen of the gut.

Lipids

In ruminants the lipids entering the duodenum in the digesta have undergone fermentation in the rumen and hence have been extensively modified. The principal effect is to hydrolyze triglycerides to form free fatty acids (FAs) and then partially or completely hydrogenate the unsaturated FAs to form more saturated FAs via *trans*–conjugated dienes and monoenes (*see* **Nutrients, Digestion and Absorption**: Fermentation in the Rumen), some of which are associated with milk fat depression. In addition, some net microbial synthesis of lipid occurs but the extent is subject to debate. The total FAs entering the duodenum in the digesta may be higher or lower than the amounts consumed. In general, small increases of around 20% have been found with dairy cows given diets unsupplemented with dietary fat and containing around 20 g FA kg^{-1} DM intake compared with little change or small decreases of around 5–10% with diets supplemented with fat and containing about 60 g FA kg^{-1} DM.

There is no evidence of net FA absorption from the large intestine, so most of the net postruminal digestion of FAs as commonly measured between the proximal duodenum and the feces must be assumed to occur in the small intestine. Estimates of net absorption vary widely from 55 to 90% with most values ranging from 75 to 85% (**Table 1**). The reasons for the variability are uncertain, but clearly are not related to chain length or isomeric form. The efficiency of postruminal digestion has been found to decline with increasing dietary intake, with little effect noted in dairy cows with intakes of fat up to about 1000–1500 g day^{-1} but a declining efficiency observed above that threshold. Most studies of the mechanism of lipid digestion and absorption have been conducted in sheep and goats, but the main principles may be assumed to apply to dairy cows also. Small amounts of lipids enter the duodenum in the digesta as triglycerides, but most are in the form of FAs adsorbed onto particulate matter (feed particles and bacteria). These triglycerides are hydrolyzed by pancreatic lipases and phospholipases. Polyunsaturated FAs and lecithin from bile and pancreatic secretions are added to the lipid fraction of the digesta in the duodenum, the lecithin being hydrolyzed to lysolecithin by pancreatic enzymes in the jejunum. The FAs must be released from adsorption by the action of the bile salts and lysolecithin to form micelles, which is an essential prerequisite for absorption. The net effect is that the proportion of free FAs in the aqueous phase increases as

Table 1 Flow of fatty acids (FAs) through the digestive tract (g day^{-1}) and apparent postruminal digestibility (%) in dairy cows given high–and low–roughage diets

digesta pass through the jejunum to the ileum, and most of the absorption is thought to occur from the distal jejunum and ileum where the pH will have risen to about 7. Absorption is mainly into the lymph, but, with diets high in fat, some absorption of certain FAs into the portal vein may occur. FAs enter the lymph mainly in the form of very low–density lipoproteins in which form they are then transported via the thoracic lymph duct to the blood circulation and thence to the mammary gland and other tissues.

Differences between individual FAs in their absorptive efficiency are small though highly saturated FAs are less well absorbed. The data in **Table 1** show that the *trans*-18:1 FAs, which are produced during rumen fermentation of dietary unsaturated FAs, are absorbed as efficiently as *cis*–18:1 postruminally.

Energy

The current energy rationing systems, whether using net energy or metabolizable energy as the unit, are based on measurements of overall energy digestibility and metabolizability with no distinction between sites of digestion within the digestive tract. Thus, unlike protein rationing systems (see below), they do not depend on estimates or prediction of sites or products of energy digestion despite the importance of these factors in determining both the efficiency and the nature of energy utilization in lactating ruminants.

Most studies of sites of digestion in lactating ruminants have concentrated on quantifying the digestion of the major feed fractions and the products of that digestion, and few have measured these in energy units. Clearly, the contribution of the small intestine to the overall energy digestion will vary with a number of factors, in particular, the type of diet. A high–forage diet will result in a smaller proportion of the dietary energy being digested in the small intestine than, for instance, a diet containing a large amount of slowly fermentable starch or a high–fat diet. The published estimates, though small in number, suggest that, on average, the small intestine contributes about 30% of total apparent energy digestion with most diets in lactating dairy cows, but may reach 40% with diets high in maize grain.

Protein

Digestion of protein and absorption of amino acids in ruminants occur much the same way as in nonruminants, but, as for lipids, rumen fermentation markedly transforms the form and quality of the protein ingested before it reaches the duodenum. Fermentation has less of an effect on the quantity of protein passing through the stomach, but in general there is a slight gain in total N, which occurs as a consequence of endogenous N contributions. Depending on the nature of the protein and carbohydrate consumed and the rate of passage, digesta entering the small intestine include variable proportions of microbial, undigested feed and endogenous proteins, nucleic acids, peptides, and limited amounts of free amino acids. Most of the modern protein rationing schemes place much emphasis on the quantification of rumen N metabolism and prediction of the flow of microbial and undigested feed N in the digesta to the small intestine (*see* **Nutrients, Digestion and Absorption**: Fermentation in the Rumen). However, they usually rely on a single digestibility coefficient for predicting the uptake of amino acids from the small intestine despite the fact that this is such a vital step in the prediction of metabolizable protein supplies.

Protein digestion begins in the abomasum, where the acidic conditions solubilize proteins and activate pepsins that cleave specific peptide bonds. Peptide flow into the duodenum stimulates pancreatic enzyme secretion via the action of cholecystokinin. Pancreatic trypsin and chymotrypsin are active above pH 7; thus, as for lipids, further digestion is restricted until the pH of the chyme is effectively buffered by secretions of the pancreas and Brunner's glands within the duodenal mucosa, a process that may not occur until the chyme passes well into the jejunum. In the jejunum and ileum, peptides are reduced to smaller subunits and free amino acids by the action of carboxy–, di–, and aminopeptidases secreted by the mucosa. Free L–amino acids are absorbed into the epithelial cells by active transporters specific for groups of amino acids. These transporters also transport Na^+; thus, the maintenance of membrane potential requires a countertransport via Na–K–ATPase activity. Although amino acids compete for specific transporters, the absence of free amino acids in ileal digesta suggests that transporter activity is not limiting, even in lactating dairy cows. This is supported by the results of abomasal or duodenal infusion studies, which have rarely exceeded the digestive capacity of the entire postruminal digestive tract. Apparent amino acid digestibility in the small intestine ranges from 65 to 80% and appears to be unaffected by duodenal flow over a wide range (**Figures 4(a)** and (**b**)). Little difference has been observed between the digestibility of microbial protein and that of undigested feed proteins. More variability is observed in the digestibility of individual amino acids, tending to be as low as 50% for histidine and glycine and over 80% for arginine. Heat treatment of protein may reduce digestibility in the rumen, thus increasing rumen bypass, but also tends to reduce digestibility in the small intestine. Generally, the digestibility of specific proteins in the small intestine parallels their digestibility in the rumen.

Endogenous protein losses in the ileum must be accounted for when estimating true digestion of protein

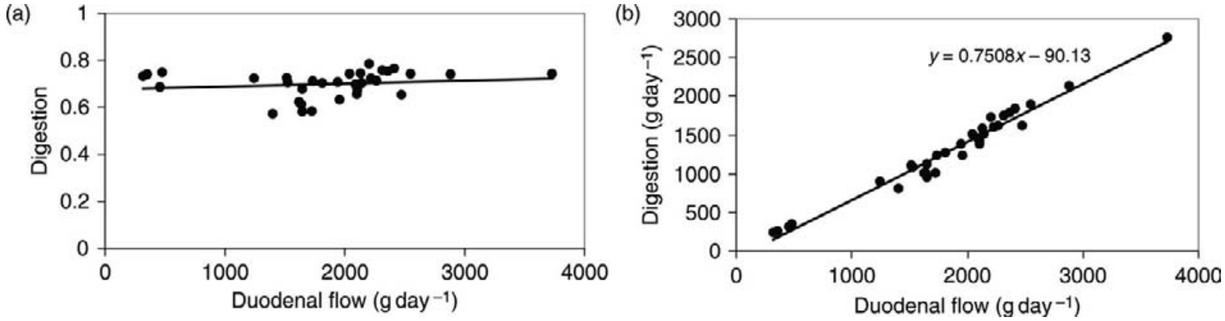

Figure 4 (a) Fractional digestion of total duodenal amino acids in the small intestine of lactating dairy cows. (b) Apparent digestion of total amino acids in the small intestine of lactating dairy cows. Data from Benchaar C, Vernay M, Bayourthe C, and Moncoulon R (1994) Effects of extrusion of whole horse beans on protein digestion and amino acid absorption in dairy cows. *Journal of Dairy Science* 77: 1360–1371; Reynolds CK, Harmon DL, and Cecava MJ (1994) Absorption and delivery of nutrients for milk protein synthesis by portal–drained viscera. *Journal of Dairy Science* 77: 2787–2808; Reynolds CK, unpublished.

and absorption of amino acids in the small intestine. In addition, endogenous protein losses are an important component of many systems for rationing protein to dairy cows. Measurements of isotopically labeled amino acid transfer from blood indicate that about 15% of protein flow in the ileum of dry and lactating cows is of endogenous origin. Like endogenous protein flow in the duodenum, this proportion does not vary with intake level such that total endogenous losses rise and fall with total protein flow and are not a fixed, basal amount as assumed in some systems used to calculate protein requirements.

In contrast to nonruminants, ruminants have an abundant secretion of ribonuclease from the Brunner's glands and are efficient at digesting purines, a source of both N and P, and purine digestibility in the small intestine averages about 80%. On average, nucleic acids account for about 20% of the nonammonia N flowing to the small intestine.

A considerable portion of amino acid absorption occurs via the transport of di–and tripeptides into intestinal epithelial cells. Historically, it has been presumed that these peptides were subsequently catabolized by membrane–bound peptidases or within the epithelium and absorbed into blood as free amino acids. Recent interest in the possibility that some peptides may be absorbed directly into the portal vein has not generated conclusive evidence that peptides represent a major route of absorption of digesta amino acids into the blood draining the small intestine.

As with the digestion of starch and the subsequent absorption of glucose, measurements of the net appearance of amino acids in the portal vein typically fail to totally account for amino acid disappearance from the lumen of the small intestine. This is often attributed to amino acid metabolism during absorption, as the intestinal mucosa has a high rate of protein turnover and preferentially uses some nonessential amino acids to meet energy requirements. However, this disparity between amino acid absorption from the small intestine and net appearance in the portal vein is also attributable to the use of amino acids from arterial blood to meet the amino acid requirements of other portal–drained tissues, such as the rumen and hindgut. In this regard, measurements of the net absorption of amino acids into the anterior mesenteric vein more closely equate with disappearance from the small intestine lumen, depending on the amino acid absorbed. In general, however, the PDV appears to meet its amino acid requirements largely from arterial blood, rather than exacting huge tolls during absorption across the small intestinal mucosa.

Minerals

Minerals are absorbed via passive diffusion or carrier–mediated transport mechanisms, which in many cases are highly regulated. while many minerals are absorbed by passive diffusion throughout the gastrointestinal tract, the small intestine is the predominant site of absorption for most of the macro–and microminerals. Exceptions include Mg, for which the primary site of absorption is the rumen and a considerable capacity for absorption is available in the colon. The rate of absorption of minerals entering the small intestine is affected by a variety of factors, including the molecular form of the mineral fed and interactions with other minerals within the digestive tract. For example, P in grain phytate is largely available to the cow through the actions of microbial phytase in the rumen, but any phytate bypassing the rumen as a consequence of the high rate of passage in lactating dairy cows would be as indigestible in the small intestine of the cow as in the pig or poultry. There are numerous interactions between minerals that affect their absorption, such as the inhibition of Mg absorption by K. Ca and P have antagonistic effects on each other's absorption when fed in excess, so diets are usually formulated to specific Ca:P ratios. Similarly, Ca can have antagonistic effects on the absorption of Zn and other divalent cations. Although many such interactions among minerals may occur, the true extent and importance of these in most production systems is not certain. However, most nutritionists would balance mineral concentrations in diets fed to avoid negative interactions.

Ca and P requirements for milk synthesis substantially increase their dietary requirements and alter the efficiency of their absorption from the small intestine. The absorption of Ca involves a Ca–binding protein in the enterocyte that is downregulated when Ca requirements are low, such as during the dry period. Losses of Ca in colostrum and the subsequent milk yield in early lactation dramatically deplete the blood Ca pool and plasma Ca levels, causing an increase in parathyroid hormone secretion. Parathyroid hormone has a variety of effects on Ca homeostasis that act to replete serum Ca levels, in particular the activation of vitamin D, which increases the absorptive capacity of the intestine for Ca. The absorption of other minerals such as P and Fe is also regulated, such that their net disappearance from the small intestine is reduced if their supply in the diet exceeds beyond requirements.

As for other nutrients, endogenous secretions of minerals occur throughout the digestive tract and influence the net absorption that occurs in the small intestine. In addition to minerals contained in sloughed cells and mucosal secretions, saliva, bile, and gastric and pancreatic juices all contain minerals; thus, there is a substantial endogenous secretion of many minerals into the duodenum. These endogenous minerals may be absorbed and thus recycled, as is the case for P, which is secreted in saliva at levels up to 5 times the amount consumed in feed. However, endogenous losses in feces also represent a substantial component of the maintenance requirement of the lactating dairy cow for many minerals.

Absorption of Minerals and Vitamins

N Suttle, Moredun Foundation, Penicuik, UK

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Minerals and vitamins differ from macronutrients in two important respects. First, absorptive processes vary enormously among micronutrients for a variety of reasons: contrasting properties of the micronutrient (vitamin solubility in water or fat; mineral ions that are positive or negatively charged); the capacity of the animal to up- or downregulate absorptive mechanisms depending on the balance between supply and demand; the need to provide protection from sporadic excesses of potentially toxic, essential ions and physicochemically similar nonessential ions. Second, the micronutrients themselves do not need to be broken down to simpler forms (i.e., digested) to be assimilated. However, the amounts of micronutrients presented for absorption and absorbed can be profoundly affected by digestive and physiological processes. Some micronutrients are present in feeds in complexes, which must be broken down before absorption can take place (e.g., P in the phytate molecule), while others interact with products of digestion to become more or less absorbable (Cu with sulfide). Fermentation in the fore stomachs greatly augments the supply of water-soluble vitamins (WSVs). The profuse flow of saliva induced by the ingestion of dry roughages can recycle minerals (e.g., P and Na), shifting the route of excretion from urine to feces and influencing the absorption of others (Mg). The stimulation of biliary secretion can have similar effects on Cu and Mn absorption. Simplistic techniques such as balance trials and repletion-slope ratio are widely used to measure absorption but may not fully characterize either the capacity of a feed to provide absorbable micronutrient or the capacity of the animal to absorb that which is absorbable. The individuality of micronutrient absorption may mean that average results from small experiments are not representative of wider populations. Our knowledge of mineral absorption is woefully inadequate for many micronutrients yet manipulation of micronutrient absorption by the animal or producer can determine the success and sustainability of milk production. The provision of organic mineral supplements has had a checkered history in that regard.

Major Minerals

Major minerals are distinguished from microminerals in being required in gram rather than milligram per kg dry matter (DM) concentrations while presenting relatively low risk of toxicity. The major challenge is to meet peak demands of late pregnancy and/or early lactation by complementing the obligatory mobilization of skeletal mineral reserves with a minimal supply of absorbed mineral and to provide an excess of mineral during late lactation and/or the dry period to replete the skeletal reserve. Optimization of absorption is preferable to permanent luxus supply because large additions of strongly ionized minerals can affect acid:base balance, prejudice the absorption of other minerals, and pollute the environment.

Calcium

Calcium is chiefly absorbed by facilitated diffusion across the small intestinal mucosa, the facilitator being a Ca-binding protein (CaBP), calbindin. CaBP is inducible by vitamin D_3, once the vitamin has been converted by twofold hydroxylation – first in the liver, then in the kidney – to a physiologically active form and bound to basally located mucosal receptors (vitamin D receptors (VDRs)) (see section 'Vitamin D'). However, studies with VDR-knockout mice show that Ca absorption (A_{Ca}) can continue by other pathways such as transcellular absorption and lysosomal transport. VDRs are induced by parathyroid hormone (PTH), which itself is induced by subnormal plasma Ca levels (hypocalcemia). Thus, Ca is absorbed according to the need, and absorptive efficiency will be low if the studied animals have low needs (i.e., are slow growing or nonlactating) or the feed is rich in Ca (alfalfa). CaBP is surprisingly nonspecific and its induction can increase the absorption of potentially toxic elements (PTEs) such as Pb and Al. The high-yielding dairy cow is unique in having a greatly increased Ca need once lactation commences. In the dairy sheep and goats, particularly those carrying more than one fetus, the need for Ca in late pregnancy is as great as that in early lactation. However, reported efficiencies of A_{Ca} in late pregnancy and early lactation are unexpectedly low. The most likely explanation is that obligatory mobilization of bone matrix to furnish the protein needs of offspring releases Ca into the bloodstream, lessening the perceived need. Adding more Ca to the diet either side of parturition will reduce the efficiency of A_{Ca} and can be counterproductive, turning off hormonal control mechanisms, which include the mobilization of Ca from bone by PTHs. The common disorder of dairy cows, milk fever, is a postparturient problem of inadequate bone Ca resorption rather than insufficient A_{Ca}. The incidence of milk fever is reduced by low ($<5\,g\,kg^{-1}$ DM) and raised by high dietary Ca ($>20\,g\,kg^{-1}$ DM), but treatment with massive oral doses of Ca can be successful because sufficient Ca is passively absorbed to alleviate hypocalcemia. Feeding low-Ca diets prior to late lactation to prime the hormonal mechanisms and enhance A_{Ca} is a high-risk preventive strategy and totally unsuited to species other than the dairy cow. Feeding 'acidified' or 'low-cation' diets around calving can reduce the incidence of milk fever in housed, high-yielding herds, but do so by improving bone Ca resorption rather than A_{Ca}.

There is no convincing evidence that Ca sources vary widely in availability for absorption and a high proportion (around two-thirds) is absorbable from most feeds. Reports of low A_{Ca} in feeds usually reflect low needs for one reason or another. It has been claimed that forages rich in oxalates provide poorly absorbable Ca, largely on the evidence of Ca oxalate crystals once detected in feces. However, rumen microbes adapt to oxalate-rich feeds by increasingly metabolizing oxalate and the animal should adapt to losses of unabsorbable Ca crystals by increasing the use made of absorbable Ca. Addition of fats to mineral-rich, concentrate diets may decrease A_{Ca} through the formation of insoluble soaps, but lipids naturally present in forages have yet to be shown to obstruct absorption. Phytate that escapes rumen degradation may form unabsorbable complexes with Ca.

Phosphorus

Although nutritionists have traditionally regarded Ca and P as inextricably linked, the link is established postabsorptively in bone and their absorption could hardly be more different. Phosphorus is primarily absorbed passively by diffusion down electrochemical gradients in the small intestine and the animal exerts little hormonal control over matters. The P absorption of ruminants is unique in two respects: first, copious secretion of P-rich saliva ensures that the diet is the minor source of P entering the rumen; second, most salivary and dietary P is sequestered in rumen microbial protein and microbial P is marginally less absorbable than inorganic phosphate (PO_4). Repeated cycling of P via saliva contributes to high efficiencies of absorption (A_P; 60–90%). Nevertheless, incomplete absorption of salivary P enables the feces to be the major route of excretion and therefore A_P cannot be measured in balance trials without correcting for endogenous loss. Grains contain most of their P in the form of mineral–phytate complexes but exposure to microbial phytases in the rumen during digestion can liberate nearly all of it as hydrolyzable phosphate (PO_4), 63% of the P in phytate-rich bran being absorbed by sheep. Lush herbage contains no phytate P and A_P can reach 90% in grazing beef cows. Phytate can increase microbial phytase activity by substrate induction but not if there is an abundant supply of PO_4. Surveys of fecal P in dairy farms in the United States found that 18% was present as phytate, about half the percentage present in the rations, suggesting that one-fifth of dietary phytate escaped degradation on average: degradation decreased as the levels of dietary PO_4 and Ca supplementation increased. Excessive dietary Ca (>5 g Ca per kg DM) can lower soluble P in the rumen at low dietary P levels and reduce A_P by about one-fifth in sheep on diets with dietary Ca:P ratios of >3.6. Direct measurement of duodenal flows of phytate P in cows given whole crop (wheat) silage showed that 75% phytate P escaped degradation and this was attributed to the passage of whole grains through the rumen. Thus, A_P will probably decline as the state of maturity of the ensiled crop advances, unless the grains are mechanically damaged. The only other important constraint on A_P might occur in the grazing animal exposed to infective nematode larvae on pasture either for the first time ('naive' offspring) or as immunosuppressed, periparturient dams. No studies have been made in cattle but infections of the small intestinal mucosa with *Trichostrongylus vitrinus* can almost halve A_P in sheep. The excretion of excess P in feces or urine is a major cause of pollution of surface waters, and the best way of reducing pollution is to stop overfeeding dairy herds with P and Ca and avoid feeding whole grains.

Magnesium

In ruminants, Mg is unusual among elements in being principally absorbed from the rumen by two mechanisms: one is active and the dominant force at lower Mg intakes, moving Mg against an electrochemical gradient across the mucosa; the other is passive and increases in importance as Mg intake increases. The active process is Na-dependent and inhibitable by K. Since the fecal endogenous loss of Mg is relatively small and constant, the apparent absorption of Mg (AA_{Mg}) recorded in balance trials is highly correlated with true absorption (A_{Mg}). Green forages contain sufficient K to reduce the overall efficiency of A_{Mg} substantially, the extent varying between diets and species to such an extent that the use of sheep to provide a model for A_{Mg} in cattle on unsupplemented natural diets is invalid. In sheep given fresh grass, AA_{Mg} falls from around 45 to 20% as the K level increases from 20 to $40\,g\,kg^{-1}$ DM; with mixed dry diets, A_{Mg} is only one-third as sensitive to K. In cattle, AA_{Mg} from grass is lower than in sheep at the same low K level (20% at 20 g K per kg DM), the difference narrowing as K increases. This may be due to a greater inhibitory effect of K in the bovine rumen and lower compensatory increases in A_{Mg} from the small and large intestines. In both sheep and cattle, AA_{Mg} is exceedingly poor from K-rich, dried grass (<15%). If the diet is deficient in Na, the compensatory increases in salivary and rumen K are sufficient to lower A_{Mg}. In sheep, Mg absorption from the rumen is also lowered by increases in pH and in rumen ammonia concentrations but the latter effect may be short-lived due to adaptation of the microflora. It is possible that sensitivity to both pH and ammonia may be less in pastured cattle. In general, health hazards related to inadequate A_{Mg} are largely confined to the period of transition from winter diets to spring grass, when all the factors mentioned above are at their most antagonistic, A_{Mg} is minimal, and hypomagnesemic tetany is caused. Provision of salt and sparing use of K fertilizers aid A_{Mg}. On mixed dry diets, A_{Mg} is usually >40% because all antagonisms are lessened and supplementation becomes unnecessary.

Sodium and Potassium

Na is actively absorbed through the activity of Na pumps in the intestinal mucosa. By contrast, K is absorbed passively from the rumen and is less regulated. The high solubility of Na and K inherent in and added to feeds ensures that efficiencies of absorption (A_{Na} and A_K) are close to 100% in healthy animals. When livestock become Na depleted, secretion of aldosterone causes a decrease in salivary Na and an increase in K. The resultant replacement of Na by K in the rumen delays the reduction in daily Na absorption and provides short-term protection from depletion. The principle threat to A_{Na} comes from damage to the absorptive mucosa by gut nematodes. Combined parasitism of the abomasum and small intestine is particularly harmful because the former increases the flux of Na into the gut lumen and the latter restricts reabsorption as well as absorption of dietary Na. The problem may be most critical in early lactation when immune resistance to parasitism is reduced and demand for Na is maximal due to high outputs in milk. High absorptive loads of K in forage-fed stock may weaken the homeostatic defenses against Na deprivation.

Sulfur

The absorption of S by ruminants is unusual in that the simpler of the three main forms in which it is absorbed, sulfide (S^{2-}) and sulfate (SO_4^{2-}), are virtually useless to the animal and only that reaching the small intestine as undegraded dietary protein, elaborated or incorporated into rumen microbial protein from degradable dietary S, is of nutritive value. The article dealing with amino acid absorption should be consulted (*see also* **Feed Ingredients**: Feed Supplements: Ruminally Protected Amino Acids). The focus here is on the factors that influence S^{2-} and $SO_4{}^{2-}$ absorption and what must be done to minimize absorption by these routes to optimize microbial – and hence milk – protein yield. Most of the S consumed, whatever the initial form, is rapidly degraded to S^{2-} during rumen fermentation and would pass by diffusion across the rumen wall if it were not partially captured by the microbes. Microbes require synchronous supplies of fermentable carbohydrate, ammonia, and soluble P to incorporate S into the S-amino acids of their cellular proteins. The aim must be to reduce the area under the postprandial rumen S^{2-} curve: this can be achieved by slowing the rate of food consumption and improving the degradabilities of dietary fibre and nitrogen. Provided these steps are taken, the provision of S as methionine analogs that are protected from rumen degradation is unlikely to improve S-amino acid absorption sufficiently to improve milk yield. Defaunation (i.e., suppression of protozoal populations) of the rumen improves the capture of dietary S in microbial protein, lowering rumen sulfide concentrations and raising the absorption of Cu, Mo, and Pb. Some S leaves the rumen in digesta as sulfate and is absorbed as such by an active transport mechanism in the ileum: together with material produced endogenously from the oxidation of S^{2-}, some SO_4 re-enters the rumen via saliva to begin the cycle again. Recycling is particularly important during the dry period and is quantitatively more important in species that do not continuously 'lose' S-amino acids to wool production (i.e., cattle > sheep). The S needs of dairy sheep and goats in terms of absorbed S-amino acids require investigation.

Trace Minerals

The prime determinants of the absorption of trace minerals are as diverse as their chemistries: for some (Cu), dietary composition and rumen fermentation dominate; for others, including Ca and Fe, the animal dominates by absorbing according to its need; and for those presented as anions (P, I, Se), absorption can be extensive and poorly regulated, although with P and Se the process is influenced by the intervention of rumen microbes. Because free cations are generally toxic, absorption has to involve complexation and carrier proteins to protect the absorptive mucosae. Most elements are absorbed by two processes: one is active, specific, and upregulated during deficiencies of the element; the other is nonspecific and downregulated when mineral intakes exceed the need. The latter involves divalent metal transporter-1 (DMT-1) and is responsible for a host of adverse interactions affecting mineral absorption. The form in which minerals occur in feeds is generally of little importance because rumen microbial activity is a great 'leveler': the notable exception is selenium, as described later. The forms of minerals in supplements appear to be relatively unimportant, beyond their purity. Superficially, it might appear that chelated or complexed trace element supplements would be immune to powerful antagonists in the gut, and early focus was placed on amino acid chelates because trace elements were thought to be absorbed principally as peptide complexes. However, the synthetic complex must have a higher affinity constant for the bound metal than any natural antagonist, remain stable in acid regions of the gut, and then release the mineral for normal absorption or metabolism. No organic mineral complex has yet been shown to possess such properties. Isolated production responses to organic minerals do not necessarily arise from superior availability: they may arise by chance (the number of trials conducted far outweigh the number whose results are published), through diminished rates of feed deterioration during storage, or through replacement of a subclinically toxic inorganic mineral being supplied in excess of need.

Chromium

The essentiality of Cr as an insulin potentiating factor is now generally accepted but the scope and need for manipulating A_{Cr} in dairy animals remain unclear. Supplements of organic Cr given at times of environmental or physiological stress (after transportation and prior to parturition) can have sustained effects on food intake and blood biochemistry without consistently improving health or productivity and may constitute pharmacological responses. Little is known about the forms in which Cr occurs in feeds or their fate in the rumen but inorganic Cr can be incorporated into glucose tolerance factor *in vivo.* The chelated form, Cr picolinate, is not degraded by rumen microbial activity – a rare quality among trace element chelates – and is probably absorbed intact but may not be readily utilized.

Copper

While the young are totally reliant on milk or milk substitutes, they absorb Cu with consistently high efficiency ($A_{Cu} > 80\%$), compensating for the low Cu concentration in milk; there is probably some decline with age as processes unique to the neonate (e.g., absorption of cuproproteins such as ceruloplasmin intact by endocytosis) wane. Weaning brings about a further abrupt decline because the intervention of anaerobic fermentation and S degradation creates a S^{2-}-rich environment in which any soluble Cu is rapidly converted to insoluble CuS, which passes unscathed through the acid abomasum and is excreted. Factors that promote S capture by microbes (e.g., defaunation) enhance A_{Cu} but ruminants rarely absorb >10% of the Cu they ingest. On S-rich green forages, A_{Cu} drops to below 3% and can reach <1% if pastures are underlain by alkaline, molybdeniferous soils that raise herbage Mo levels (>2 mg kg^{-1} DM). Molybdenum (Mo) enhances the antagonicity of S by allowing the formation of thiomolybdates ($MoO_{4-x}S_x$) in the rumen, which bind Cu irreversibly to the solid phase of the rumen contents when substitution of S for O is maximal (i.e., as tetrathiomolybdate (MoS_4)). High Fe intakes (from soil or supplements) can also reduce A_{Cu} substantially by an antagonism that is also partially S-dependent. Thus, it is dietary S, Mo, and Fe concentrations rather than Cu intake that determine the amount of Cu absorbed by ruminants. Furthermore, the risk of Cu deprivation is relatively high in all grazing livestock and low in housed stock because exposure to the antagonists is greater in the grazing situation. Use of defaunating agents increases A_{Cu} by reducing antagonism from sulfide. At low to moderate Cu intakes, absorbable Cu is taken up primarily by binding to a specific mucosal binding protein (Crt1) and at higher intakes by the nonspecific DMT-1. Attempts to bypass the rumen-based antagonisms by providing supplementary Cu in a 'protected' form, 'chelated' to specific or mixed peptides, have been unsuccessful. A Cu-glycinate has recently been shown to improve A_{Cu} on a diet high in Mo and S but the magnitude of the response suggests that A_{Cu} remained well below 10%. Threefold differences in A_{Cu} between 'meat' (Texel, high) and 'hill' (Scottish Blackface, low) breeds of sheep determine vulnerability to Cu toxicity and deficiency but corresponding data for dairy sheep and goats are limited: one comparison showed the East Friesland to retain Cu less efficiently than the Texel. Indirect evidence for differences between cattle breeds is emerging, although the differences are much smaller; comparisons of blood and liver Cu status in separate studies indicate that rankings in terms of AA_{Cu} may be Galician Blond < Holstein Friesian (HF), Jersey < HF, and Simmental < Aberdeen Angus.

Iron, Manganese, and Zinc

Iron, manganese, and zinc share the property of being absorbed according to the need, through the induction of receptor proteins in brush border and basement membranes in the intestinal mucosa. While some receptors are specific (e.g., hephaestin and ferriportin for Fe), DMT-1 can bind several essential and nonessential elements. Thus, excess Mn can reduce the efficiencies of Fe and Cu absorption (A_{Fe} and A_{Cu}) by downregulating DMT-1, which can facilitate the absorption of all three elements. By contrast, Fe deficiency can increase Pb uptake by upregulating DMT-1. Foraging livestock ingest large amounts of Fe and Mn as soil in both arid and cool temperate climates; although only a small fraction is absorbable, it may be sufficient in the case of Fe to cause subclinical hepatotoxicity and sufficient in the case of Mn to lower A_{Cu}. In the suckling or milk-fed young, A_{Fe} and A_{Mn} are high because demands are high and milk is low in Fe and Mn, but A_{Zn} may be relatively low because milk is rich in Zn (*c.* 35 and 48 mg Zn kg^{-1} DM in sheep and cattle, respectively). The normal abundance of Fe and Mn in the diet of the weaned animal ensures that only small proportions of ingested Fe and Mn (<10%) are generally absorbed but A_{Zn} can reach 70% from natural roughages; this is much higher than the level attainable in grain-fed monogastrics, because the major potential antagonist of absorption, phytate, is usually destroyed in the rumen. There may be partial escape of phytate when whole or finely milled grain is consumed by cattle, lowering A_{Zn}. There are no reported differences in A_{Zn} in feeds for ruminants in contrast to pigs and poultry, and the same probably applies to Fe and Mn. Chelated forms of Fe, Mn, and Zn are widely held to be substantially more 'bioavailable' than inorganic sources but production responses have generally been small and inconsistent. In the particular case of Zn, the provision of chelated Zn was claimed to stimulate replenishment of keratin in the teat canal in a way that inorganic Zn could not, but a recent study has failed to support the claim.

Iodine

Iodine, like se, is well absorbed but the two elements are absorbed by quite different mechanisms and at different sites. The abomasum provides the major site of absorption of I, possibly because the acid environment releases I, which is then passively absorbed. Iodine is retained rather than absorbed according to the need, and dietary excesses are removed in urine and milk. The fate of antagonists of I (goitrogens) in the rumen and their subsequent absorption and transfer to milk are arguably more important as causes of I deprivation but coverage is beyond the scope of this article.

Selenium

Most of the Se in feeds is present as selenomethionine (SeMet), which is absorbed by the pathway for methionine and enters the methionine pool: thereafter, some Se may continue to 'tag' the methionine, entering muscle or milk protein, for example. Rumen microorganisms are able to incorporate inorganic Se into SeMet. Selenite or selenate that escapes capture in the rumen is well absorbed in the small intestine and rapidly incorporated into the physiological transport forms as Se-cysteine. With grain, pasture, or inorganic Se providing moderate Se intakes (<0.3 mg kg^{-1} DM), AA_{Se} is around 65%. At higher Se intakes, that figure increases with SeMet as the source but decreases with inorganic sources, probably because more 'excess' SeMet escapes biliary secretion. Commercial pressures have spawned an illusion that provision of 'organic' rather than inorganic Se can benefit the cow and/or her calf but there is no evidence that it does. Selenium given as SeMet in Se-yeasts is less available for synthesis of selenoenzymes such as the important family of glutathione peroxidases (GPX). Supplementation of diets with SeMet certainly raises blood and tissue Se in cow and calf more than inorganic Se and also raises milk Se but these are all poor guides to functional availability to the animal and consumer of dairy products. Indeed, it is arguable that absorption of dietary SeMet is part of the problem rather than a panacea when it comes to Se-responsive diseases such as paralytic myoglobinuria and retained placenta. When increased muscular activity suddenly increases the need for antioxidants, of which GPX is one, Se that has 'tagged' or is tagging methionine may be 'unavailable for work'.

Cobalt

Co is an unusual micronutrient in three respects: first, rumen microbes incorporate Co into two physiologically active forms of vitamin B_{12}, methylcobalamin and adenosylcobalamin, that are essential to the host; second, these have to be complexed to intrinsic factor (IF), secreted in the abomasum, and facilitate absorption in the ileum, leaving vast quantities of B_{12} analogs, also produced in the rumen, to be harmlessly excreted in feces; third, rumen microbes have the same B_{12}-dependent biochemical pathways as the host, the one dependent on adenosylcobalamin working in reverse to promote the production of propionate from succinate. Rumen fermentation can therefore be affected by low-Co diets, succinate being produced at the expense of propionate. Host demand for adenosylcobalamin to process propionate may thus be reduced. For the first few weeks of life, IF is not produced and the young rely on the absorption of B_{12} bound to specific proteins in milk; this may be a device for denying potentially harmful gut pathogens a supply of the micronutrient that they also need. Once IF is induced, it acts as a carrier for vitamin released from binding to salivary R proteins by pancreatic proteases; this preliminary binding may stabilize B_{12} at the acid pH of the abomasum. The B_{12}–IF complex is absorbed by endocytosis and the B_{12} is transferred to a nonspecific carrier protein, cubulin, in the intestinal mucosa. The overall efficiency of conversion of ingested Co to absorbed vitamin B_{12} after weaning is poor (<15%), limited partly by the synthetic capacity of rumen microbes. Parasitism of the gastric or intestinal mucosa might be expected to limit vitamin B_{12} absorption but neither abomasal (*T. circumcincta)* or intestinal (*T. vitrinus*) parasitism in lambs accelerated the decline in plasma B_{12}, which commonly follows weaning, in one study.

Water-Soluble Vitamins

There is copious synthesis of essential WSVs during the course of rumen fermentation and they become available for absorption during the digestion of rumen microbial protein in the small intestine. The presence of complexed forms in feeds (e.g., of biotin, folacin, niacin, and riboflavin) should present no problems, since these are degraded in the rumen, unless there is heavy reliance on whole grain feeding in larger species. However, the potential methyl donors – dietary choline and its oxidation product, betaine – are degraded in the rumen. Possible benefits in milk production from the provision of rumen-protected choline and betaine to enhance methylation have been explored with inconsistent results, which may reflect the capacity of the animal to generate choline endogenously from methionine. Similarly, claims that supranutritional supplements of vitamin B_{12} and folate may increase milk yield, despite adequate dietary supplies of Co, by increasing methylation (folate facilitates the transfer of the methyl group from methylcobalamin) may only be justified if methionine is limiting. Vitamin C is converted to its reduced form in the rumen. Studies with monogastric animals indicate that some WSVs, such as riboflavin and niacin, can be absorbed by active, saturable, carrier-mediated processes, but in ruminants with a luxus endogenous supply, they are mostly absorbed well (>70%) by passive diffusion. Inefficiency of passive absorption may explain the low efficiencies of post-rumenal absorption of riboflavin and biotin (35 and 28%). Since WSVs pass readily into milk, the suckling is also presented with plentiful supplies of these nutrients in readily utilizable forms. Folate is strongly bound to proteins in milk, and in the neonate, these complexes may be directly absorbed, bypassing the normal receptor-mediated processes. Antinutritional factors that impair vitamin synthesis can occasionally cause problems. Rumenal outflow of thiamine can be reduced by 25% if sulfur intake is high. Provision of carbohydrate-rich rations encourages thiaminase production in the rumen, while the ingestion of certain weeds (e.g., bracken fern and horsetail) can introduce thiaminase. Thiaminases split the thiamine molecule, and the consequent absorption of the analogs produced and enhanced tissue needs for the vitamin conspire to produce a thiamine-responsive polioencephalomalacia. The disease, also known as cerebrocortical necrosis (CCN), can be a problem on molasses-based regimens. Relationships between vitamin intake and excretion in urine or secretion in milk could be used to measure the efficiency of absorption, which has received little study.

Fat-Soluble Vitamins

Little information has been published on fat-soluble vitamin (FSV) absorption (A_{FSV}) in ruminants, but in nonruminants, it was assumed to be influenced primarily by the quality and quantity of fat in the diet, absorption being better when the fat was unsaturated than saturated and poorer when fat was lacking. In ruminants, saturation of fat during rumen fermentation lessens the significance of fat quality, and any problems related to fat quantity are probably related to excess rather than deficiency. Thus A_{FSV} may fall with decreases in fat digestibility when tallow or Ca soaps are added to diets as energy supplements. However, A_{FSV} is far more complex. Absorption of carrier sterols is modulated by ATP-binding cassette (ABC) transporters, nuclear receptors, and intracellular trafficking proteins. Interactions between vitamin A, D, and E can arise because the modulators are themselves influenced by retinoic acid X-receptors, synthesized in the liver. Plant sterols have inhibitory effects on β-carotene and α-tocopherol absorption, which vary in magnitude, depending on whether they are esterified or not. In nonruminants, fat digestibility is impaired by pancreatic insufficiency, but parallels in ruminant nutrition have not been studied. In particular, Zn is required for the activity of phospholipase A2, needed for the reduction of fat globules to an absorbable size (chylomicrons). Severe Zn deprivation can thus reduce A_{FSV}. Reduced bile salt secretion from livers damaged by plant hepatotoxins or fluke (*Fasciola hepatica*), reduced acid secretion during abomasal parasitism, and damage to the intestinal mucosa by intestinal parasites may each impair absorption of all FSVs. In other respects, the individual vitamins are affected very differently by the processes of digestion and absorption.

Vitamin A

The major sources of vitamin A are provitamin A carotenoids that are partially released from feeds by proteolytic enzymes, lipases, and esterases in the stomach and small intestine. Carotenoids aggregate in lipid droplets and are absorbed inefficiently by passive diffusion and then partially cleaved by dioxygenases to retinaldehyde in the mucosal cells. Studies with monogastrics indicate that only 15% of ingested carotenoids end up in liver stores: although ruminants may be no better, the abundant supply of carotene in forages usually compensates for inefficient capture. Carotenoids differ in their potency, and shifts in isomer distribution may explain why carotene in alfalfa is more available than that in grass hay and why ensilage lowers availability. Any vitamin A added as a dietary supplement (i.e., retinol) is absorbed by facilitated diffusion, probably with high (*c.* 75%) efficiency, but it may lower the absorption of α-tocopherol.

Vitamin D

The natural source of vitamin D in plants is a provitamin, ergosterol, which is poorly absorbed and little is converted to ergocalciferol (D_2) in the tissues. Ruminants rely on UV irradiation to convert D_2 to cholecalciferol (D_3) in the skin while outdoors, but when housed for long periods they must receive supplements of $D_{3.}$ Vitamin D_3, like vitamins A and E, can be absorbed with high efficiency in fat micelles from the upper small intestine. Regulation of A_{Ca} (see section 'Calcium') depends partly on receptors for dihydroxy D_3 (VDR) in the gut but their number may decrease with age, making older females vulnerable to hypocalcemia when lactation commences.

Administration of analogs of vitamin D_3 by injection can override the mechanisms that regulate A_{Ca} but exposure to excess soluble Al may inhibit the response to D_3 by binding to calbindin (see section 'Calcium') if studies with broiler chicks are anything to go by.

Vitamin E

Unlike vitamins A and D, vitamin E occurs widely in feeds as a variety of tocopherols and tocotrienols, of which the D-α-tocopherol is the most prevalent and potent. Green and oily feeds are rich in tocopherol, and vitamin E status rises steadily while livestock graze lush pasture. The occurrence of vitamin E-responsive myopathies at turnout in spring is due to multifactorial increases in oxidative stress, which accelerate vitamin turnover, rather than poor absorption of the vitamin. Slow adaptation of rumen microbes to greatly increased supplies of polyunsaturated fatty acids (PUFAs) contributes to that stress. Vitamin E is more stable than vitamins A and D in the rumen, its kinetics after bolus administration being those of a soluble marker, and absorption occurs principally in the jejunum. Supplements of vitamin E are usually given as esters because they are relatively stable, but incomplete hydrolysis restricts their absorption, compared with tocopherol. The most widely used form, tocopherol acetate, is given a potency one-third less than that of α-tocopherol, while water-soluble esters such as the succinate are even less absorbable. Plasma α-tocopherol concentrations are commonly used to assess status but they can be poor indicators of vitamin E absorption when oxidative stress is high (e.g., when PUFA intakes are high) because turnover of the vitamin is greatly increased. Supplementation with vitamin E can enhance the absorption of vitamin A.

Vitamin K

Little is known about ruminant digestion and absorption of either the naturally occurring forms of vitamin K in plants, the phylloquinones (K_1), or synthetic forms such as menadione (K_3), rarely used as supplements. Of the FSVs, K alone is synthesized *de novo* by gut microbes and it is not included routinely in vitamin supplements.

Introduction

As early as 4000 BC, milk and dairy foods were valued by various societies as an important dietary staple because of their high nutritional quality. In the early twentieth century, as essential nutrients necessary for humans were being identified, scientists ascertained the nutrient content of milk and dairy foods. Detailed analyses revealed that milk and dairy products made from it are nutrient-rich foods that contain the essential nutrients and have these nutrients in appropriate concentrations. Thus, milk was recognized as an effective source of essential nutrients as part of a balanced diet. More recently, scientists have recognized that there are unique and complex structures that have emerged in milk through its evolution that provide a variety of health-promoting functions in humans beyond simple nutrition. This article provides an overview of the specific nutrients and bioactive compounds in milk and dairy foods, their nutritional contributions to Western diets, and their impact on human health. In addition, this article highlights emerging scientific discoveries and techniques that will allow scientists to delineate how milk and dairy foods affect human health.

Contribution of Milk and Dairy Foods to Nutrient Intake

During the first half of the twentieth century, scientists established the identities of all the essential nutrients. Chemists determined the precise molecular structures of all the essential nutrients, vitamins, minerals, amino acids and fatty acids; biochemists described their functions in cells; and nutritionists determined the amounts necessary in diets to prevent nutrient deficiency diseases. Foods were then analyzed for their nutrient content. As a direct result of the unique evolutionary role of milk in the complete nutritional support of mammalian infants, milk and dairy foods contain a uniquely complete package of essential nutrients. Including dairy products in human diets has been demonstrated to ensure adequate nutrient intakes across the life span. Together, milk, cheese, and yogurt are major contributors of calcium, potassium, phosphorus, protein, vitamin A, vitamin B_{12}, riboflavin, and niacin (as niacin equivalents). In addition, vitamin D-fortified milk and dairy foods are important dietary sources of vitamin D. Moreover, data from the Continuing Survey of Food Intakes by Individuals in the United States show that total milk and dairy intakes are associated with higher nutrient intakes in Americans. Because milk and dairy products supply substantial amounts of macro- and micronutrients in the diets of Americans, the 2010 *Dietary Guidelines Advisory Committee* reinforced the 2005 *Dietary Guidelines for Americans* recommendation to consume three servings of low-fat or fat-free milk or equivalent milk products daily (for individuals 9 years and older) as part of a healthy diet and lifestyle. In addition, official dietary recommendations in other countries recognize the importance of milk and other dairy foods in the diet to improve diet quality.

Macronutrients

Protein

Cow's milk is about 3.5% protein by weight, and milk and milk products contribute significantly to the protein available in the US food supply. Specifically, in 2005, milk and dairy foods (excluding butter) contributed approximately 18% of the protein available in the United States. Milk protein is a heterogeneous mixture of proteins and an excellent source of high-quality protein, containing all of the nine essential amino acids in varying amounts that humans require and in proportions resembling the distinct pattern of the various amino acids required in the diet. Of the total protein in milk, approximately 80% is casein and 20% is whey protein. As scientific research has begun to realize that dietary proteins exhibit biological activities beyond the simple provision of amino acids, milk proteins have been shown to be highly bioactive. Studies have shown that individual milk proteins exhibit a range of beneficial functions, such as stimulating muscle recovery after exercise, reducing the risk of dental caries, and inhibiting vasoconstriction.

Carbohydrates

Lactose is the principal carbohydrate in milk, accounting for about 4.8% of bovine milk by weight. In addition, milk contains minor quantities of glucose, galactose, and oligosaccharides. Milk and milk products contribute minimally to overall carbohydrate intake in the United States, accounting for only about 4.3% of the carbohydrates available in the US food supply.

The digestion of lactose in mammalian intestine requires the enzyme lactase. This enzyme is no longer produced in sufficient amounts after weaning in most mammals. Some individuals consuming large quantities of lactose experience symptoms resulting from the failure to digest lactose and this condition is called 'lactose intolerance'. In practice, this is defined as the inability to digest the amount of lactose in one quart (0.95 l) of milk without any unpleasant gastrointestinal symptoms. Remarkably, in human history, when milk was available in the diet due to the domestication of cows, individuals who contained distinct genetic mutations in their genomes that enabled them to continue to produce lactase throughout their lives were more likely to survive. As a result, about 25% of the world's population today is genetically able to digest lactose as adults. Additionally, research has demonstrated that individuals with lactose maldigestion can drink up to two cups of milk per day if milk is consumed with meals. Moreover, if an individual with lactose maldigestion continues to consume dairy foods on a regular basis, the body seems to adapt, resulting in fewer gastrointestinal symptoms. These results indicate that individuals without an active lactase enzyme are able to digest lactose due to the presence of specific bacteria within their intestines. In addition, other dairy foods, such as aged cheese and yogurts, with live and active cultures, are well tolerated by most individuals with lactose maldigestion. Therefore, by following simple dietary strategies, individuals consuming milk and other dairy foods regularly consume the nutrients without deleterious consequences due to lactose.

Advances in analytical chemistry and microbiology have allowed milk constituents with physiological benefits beyond simple nutrition to be identified. Oligosaccharides are a class of bioactive molecules that are composed of 3–10 monosaccharides covalently linked through glycosidic bonds. Interest in milk oligosaccharides began with the observation that human milk oligosaccharides stimulate the preferential growth of beneficial bacteria in the gastrointestinal tract. The benefits of these bacteria include a reduction in the incidence of pathogenic diseases by inhibiting the binding of pathogens to epithelial cells. Recently, approximately 40 free oligosaccharides were identified in cows' milk, with the majority of oligosaccharides containing a sialic acid. Research has suggested that sialic acids inhibit pathogen binding and enhance cognitive development. Similar results were obtained in a study that characterized free oligosaccharides in whey permeate. Interestingly, half of the oligosaccharides in whey permeate were identical to those found in human milk. Although this area of research is still emerging, preliminary data suggest that cows' milk could be a premier source of bioactive oligosaccharides with important biological functions.

Fat

The nutrition, appearance, texture, flavor, and satiability of milk and dairy foods are partly related to milk fat. The requirement for polyunsaturated fatty acids as essential fatty acids is quantitatively small in humans. The fatty acid composition of all mammalian milks is influenced by the mother's diet, tissue stores, and biosynthetic capacity of the mammary gland. Bovine milk is low in all unsaturated fats because of biohydrogenation of dietary fats within the rumen. Although milk is not typically rich in polyunsaturated fatty acids, it does contain adequate levels. The majority of lipids in milk are triglycerides, with lesser quantities of phospholipids, cholesterol, cholesterol esters, diacylglycerols, monoacylglycerols, and free fatty acids.

Observational data and human and animal studies have suggested that the consumption of diets high in saturated fatty acids elevates serum cholesterol. This relationship has been extended to examining populations consuming diets high in saturated fat, finding that saturated fat in the diet is positively associated with hypercholesterolemia (i.e., increased low-density lipoprotein (LDL)) in many cases, which is a risk factor for cardiovascular disease. However, large, retrospective epidemiological studies relating cardiovascular disease to milk consumption do not typically find evidence of a positive association between increased milk consumption and increased risk of heart disease. Ongoing research is attempting to find out the reason for this. In 2005, milk and dairy foods contributed approximately 8 and 16% of the total fat and saturated fat in the US diet, respectively. Although studies have shown that saturated fatty acids can raise blood total lipoprotein and LDL levels, individual fatty acids differ in their ability to raise blood cholesterol levels. For instance, milk fat contains a relatively high proportion of short- and medium-chain saturated fatty acids, which have been shown to have a neutral or even beneficial effect on blood LDL levels. Similarly, although the intake of industrially produced *trans* fatty acids is associated with increased cardiovascular disease risk, there is no scientific evidence that naturally occurring *trans* fatty acids in milk fat are atherogenic.

Emerging scientific evidence indicates that milk fat contains several unique fat-soluble components that may be beneficial to human health. For instance, milk fat is the richest natural dietary source of conjugated linoleic acid, which may reduce the risk of several types of cancer and cardiovascular disease and enhance immune competence. Additionally, dairy products are a good source of both sphingolipids (approximately 0.2–1.0% of the total lipids of milk) and the four-carbon short-chain fatty acid butyric acid, which have been shown in animal studies to protect against certain cancers.

Micronutrients

Vitamins

Milk and dairy foods are rich in several vitamins. Vitamin A is required for normal vision, reproduction, embryonic development, cell and tissue differentiation, and immune function. Both vitamin A and its precursors – carotenoids – are present in milk fat. One 8-oz (237 ml) serving of whole milk supplies about 258 international units (IU) of vitamin A. Because vitamin A is fat soluble, it is removed from milk and milk products when fat-free, low-fat, and reduced-fat milk or milk products are produced. Consequently, vitamin A must be added to the level in whole milk or fortified to 300 IU per 8-oz serving. However, most dairy processors in the United States fortify milk to a level of 500 IU of vitamin A per 8-oz serving. Overall, milk and milk products are an important dietary source of vitamin A, contributing approximately 11% of vitamin A in the US diet.

Vitamin D plays important roles in maintaining calcium homeostasis, insulin secretion, muscle function, immunity, and cellular differentiation. Vitamin D is present in unfortified milk, albeit at low levels (47–105 IU l^{-1}). In the United States, nearly all fluid milk is fortified with vitamin D, providing 100 IU per 8-oz serving. Therefore, vitamin D-fortified milk and milk products are a major dietary source of vitamin D in the United States. Although vitamins E and K are found in a wide variety of nutrient-rich foods, milk also contains low amounts of these fat-soluble vitamins. Vitamin E is a lipid-soluble antioxidant that helps maintain cell membrane integrity; vitamin K is required for blood clotting. One 8-oz serving of milk contains 0.06 mg per 100 g of vitamin E and 0.2 μg per 100 g of vitamin K.

In addition to the essential fat-soluble vitamins, milk and milk products are a significant source of B vitamins. Milk and milk products contain significant amounts of thiamine, a coenzyme required for numerous reactions of carbohydrate metabolism, contributing over 4% of the thiamine in the US diet. Consumption of three 8-oz servings of milk provides approximately 29 and 27% of the thiamine recommended for adult males and females in the United States, respectively. Milk and milk products are also excellent sources of riboflavin, which functions as a precursor for different coenzymes involved in the oxidation of glucose, fatty acids, and amino acids. Milk and milk products contribute 25% of the riboflavin to the US diet and three 8-oz servings of milk provide enough riboflavin to meet the US requirements for both adult males and females. Vitamin B_{12} is required for the maintenance of nerve tissue and red blood cell formation. Milk and milk products provide 0.44 μg of vitamin B_{12} per 100 g; therefore, three 8-oz servings will provide the recommended amount of B_{12} for most adults in the United States. Milk also contains variable amounts of niacin, vitamin B_6, folate, and ascorbic acid, contributing approximately 1.1, 6.8, 3.3, and 2.5% of each nutrient in the US diet, respectively.

Minerals

Milk and milk products are important dietary sources of essential minerals, especially calcium, magnesium, phosphorus, potassium, and zinc. Because the mineral content of milk is influenced by environmental factors and genetics and stage of lactation of the animal, the mineral content in milk may vary.

Milk and milk products are an excellent source of bioavailable calcium, providing nearly 300 mg per 8-oz serving. In fact, milk and milk products contribute more than 70% of the calcium in the US diet. Calcium is recognized as a key mineral in promoting and maintaining skeletal health. In addition, calcium is required for other important physiological functions, such as muscle contractions, blood coagulation, and myocardial function. Recently, Gao and coworkers modeled diets to determine the practical feasibility of meeting the recommended intake of calcium without the consumption of milk or milk products. The authors concluded that, although it was feasible to meet calcium recommendations by consuming calcium-fortified foods, adequate calcium intake cannot be met with a dairy-free diet while still meeting the recommendations for other macro- and micronutrients within a typical US dietary pattern.

Milk is also a good source of phosphorus, which plays a central role in metabolism and is a structural component of lipids, proteins, and carbohydrates. Milk and milk products contribute about 30% of the phosphorus in the US diet, with three 8-oz servings of milk supplying about 95% of the amount of phosphorus recommended in the United States. Magnesium is a cofactor for over 300 enzymes. Despite magnesium being found in a variety of nutrient-rich foods, especially those of vegetable origin, milk and milk products contribute nearly 14% of the magnesium in the US diet. Potassium is required for the transmission of nerve impulses and is involved in muscle contraction. Milk and milk products contribute about 16% of the potassium in the US diet, with three 8-oz servings of milk supplying about 55% of the 4700 mg of potassium per day recommended for persons aged 14 years and older. Moreover, according to the US Department of Agriculture national food intake surveys, milk is the top dietary source of potassium among US adults. To help meet potassium requirements, the 2005 Dietary Guideline Advisory Committee increased the amount of milk and milk products recommended to three cups of milk or milk equivalents per day for all persons aged 9 years and older.

Milk and milk products are rich in zinc, a trace mineral that is a constituent of about 100 enzymes. Milk and milk products supply 15% of the zinc available in the US diet. Furthermore, three 8-oz servings of milk provide about 27 and 37% of the recommended amount of zinc per day for adult males and females, respectively. Selenium is an integral component of the enzyme glutathione peroxidase, which is involved in the removal of reactive oxygen species. Although the selenium content of milk varies widely because of the selenium content of a cow's diet, three 8-oz servings of milk provide nearly 50% of the recommended amount of selenium per day for adults in the United States. In addition, milk and milk products contain insignificant amounts of other trace minerals, such as iron and iodine.

Beyond Nutrient Content: Milk as a Delivery System

From the first scientific breakthroughs discovering the principle of nutrient essentiality and the various molecules that are essential in the diets of humans, milk has been highly instructive. For example, the quantitative requirement for various nutrients ranges widely from submilligrams of particular vitamins to gram quantities of others. Assembling these various nutrients into a complete ensemble, each at their appropriate quantities, is vividly accomplished by milk. Furthermore, as scientists examined the essential nutrients, they recognized that most of the essential nutrients are poorly absorbable and readily form insoluble salts, crystals, or conjugates. Milk is conspicuous for its ability to contain all of the nutrients, each in complex forms that are able to ensure their absorption from the intestine. Calcium is largely present in milk complexed to phosphate within casein protein structures, making both of these nutrients bioavailable. Many essential nutrients are chemically reactive, and milk reveals mechanisms that simultaneously minimize reactivity and yet maintain bioavailability. Iron is highly reactive to a wide range of susceptible biomolecules. In milk, iron is complexed to proteins such as lactoferrin in which it is unreactive and yet bioavailable. Lipid-soluble vitamins are dissolved in milk lipids, enhancing their bioavailability. The difficulty in making all nutrients absorbable simultaneously is another challenge solved by milk in ways that scientists are still discovering. When saturated fatty acids are present in the intestine, they tend to bind calcium and reduce the bioavailability of both. In milk, the saturated fatty acids are generally present in the *sn*-2 position of the triglyceride. Because the digestive lipases do not release the *sn*-2 position fatty acid, it remains as a monoglyceride and is absorbed intact. Free fatty acids are not released, and calcium is highly absorbable due to this structural specificity.

Milk as an Intestinal Regulator

The basic view of nutrition is that nutrient availability is critical to the value of food as a carrier of essential nutrients. However, little research has examined whether nutrients should be absorbed rapidly and studies on milk are beginning to reveal principles that the most rapid absorption may not be the most nourishing. The net absorption of amino acids is slowed by the ability of caseins to form aggregates (gels) within the stomach. This has the net effect of slowing the absorption of amino acids, maintaining their concentrations in the bloodstream for a longer period.

Dietary constituents are not all digestible and absorbable. Their consumption has an interesting effect on human intestine, however, as they are available to large numbers of bacteria within the human intestine. Scientists are only beginning to address the complexity of these bacteria, their functions, and the consequences of their presence and activity. Germ-free animals provide some clues. Their intestines are poorly differentiated, their immune systems are naive, and their metabolic activities are inefficient. However, the simple absence of bacteria does not provide information as to how to alter bacteria in human intestines for benefit. Milk contains significant quantities of oligosaccharides that are neither digestible nor absorbable by humans. Nonetheless, their complex structures are digestible by a rare group of bacteria that predominate in the intestine of breast-fed infants. These data reveal a new function of diet – the guidance of a net beneficial microflora.

Nutritional and Health-Promoting Properties of Dairy Products: Bone Health

A Zittermann, University of Bochum, Bad Oeynhausen, Germany

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The most common bone disease worldwide is osteoporosis, affecting several million people. Osteoporosis results in a reduced bone mass leading to enhanced bone fragility. Postmenopausal women and elderly male subjects are the most affected. The prevalence is higher in the white race than in blacks and Asians. The incidence of osteoporosis is still expanding owing to demographic changes that lead to an increase in the number of elderly people in the developed and also in the developing countries. Osteoporosis can be prevented by achieving maximal bone mass in young subjects compatible with their individual genetic background and by reducing the rate of bone loss in elderly subjects.

Bone Mass Changes during Lifetime

Bone mass increases until the third decade of life, and then gradually decreases (**Figure 1**). Bone health involves a complex interplay of genetics, mechanical forces, and hormonal and nutritional factors. According to the Utah paradigm of skeletal biology, muscle mass/strength is the most important force for bone health. Thus, the lower muscle mass of women as compared to men can also explain the lower bone mass observed in the female population.

In women, estrogens enhance bone density. Consequently, bone mineral density decreases in postmenopausal women. In the first 5 years after menopause 15% of the peak bone mass will be lost, and up to 30–50% will be lost before the age of 70, when menopause-related bone loss is completed. The bone loss rate associated with the process of aging is approximately 1% per year in both men and women. Therefore, having larger bones and spending it more parsimoniously, that is, reducing bone loss, delays reaching the bone density level at which fracture risk is high. Fracture incidence in individuals whose bone density is more than 1 SD above the mean is 50% lower at the age of 80 years.

Calcium and Bone Health

Calcium is considered to be an important nutrient for bone health. As more than 99% of the body's calcium stores are located in hard tissues like teeth and bones, a positive calcium balance is necessary to increase bone mineral density and, thus, bone strength. In contrast, a negative calcium balance always results in a loss of bone mineral density.

Very low calcium intake in children induces rickets, osteomalacia, and growth retardation. Infants who intake below 200 mg day^{-1} are susceptible to radiographic appearance of rickets. Clinical intervention trials provide evidence that increasing the dietary intake of calcium in pubertal girls above their habitual calcium intake of about 900 mg day^{-1} to the recommended intake of 1200–1300 mg day^{-1} is associated with positive effects on bone mineral accretion. However, mounting evidence from randomized clinical trials also suggests that the bone mass gained during childhood and adolescence through calcium supplementation is not retained postintervention. Thus, data indicate that an adequate calcium intake is necessary lifelong to preserve the positive effects of calcium on bone. The adequate daily calcium intake for middle-aged people is 1000 mg, and it is 1200 mg for people 51 years and older. The tolerable upper level of calcium intake is set at 2500 mg day^{-1}. Intakes above that level increase the risk of hypercalcemia and deposition of calcium in soft tissues. Randomized, prospective studies have demonstrated a 12% reduction in fracture risk by calcium supplements. The effects were more pronounced in subjects whose daily calcium intake was less than 700 mg. Moreover, the treatment effects were the best, when calcium doses of 1200 mg or more were used. However, controlled clinical trials in older men and women have also shown that daily calcium intakes close to and above the tolerable upper limit of intake increase the risk of cardiovascular events, indicating that the adequate daily intake level of calcium should not be exceeded by too high a margin. (*see* **Milk Salts**: Macroelements, Nutritional Significance).

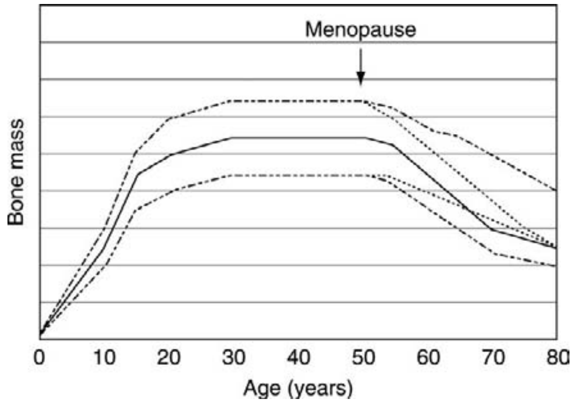

Figure 1 Changes in bone mass during lifetime. The solid line indicates the mean age-related change in bone mass. The dotted lines indicate the deviation in bone mass accretion during growth and early adulthood and the deviation of bone mass loss in elderly subjects.

Consumption of Dairy Foods in the Evolutionary Context

Dairy foods represent a distinct group in human nutrition and have a relatively high calcium content. Calcium in nondairy sources is less concentrated, making it difficult to meet the recommended dietary allowance of 1000–1300 mg day^{-1} for adolescent/adult subjects without concomitant consumption of dairy foods or supplements (**Table 1**). Cereal products and meat products are low in calcium content, but relatively high in energy content. Hence, without the consumption of dairy products, even an adequate energy intake can be associated with an insufficient calcium ingestion.

Dairy foods have not been part of the diets of adults for the most part of human evolution. In prehistoric times, a high daily calcium intake of approximately 1600–1800 mg was achieved primarily through ingestion of calcium-rich wild fruits and wild vegetables. Cereal grains were seldom consumed by hunters and gatherers, but these foods became a major part of the diet after the adoption of agriculture. In parallel to this adoption and to the domestication of dairy animals, selected populations began to use dairy products regularly well past the age of weaning. As a consequence, intestinal β-galactosidase activity remained high in the majority of these populations, for example, in white adults living in Central and Northern Europe. Hence, these people were able to consume milk without the occurrence of any gastrointestinal side effects like cramps, flatulence, and diarrhea.

Vitamin D promotes intestinal calcium absorption. In Europe there is a lack of ultraviolet rays in the sunlight during wintertime, resulting in an insufficient skin synthesis of vitamin D. The low vitamin D status during wintertime results in a concomitant low rate of calcium absorption. Nevertheless, lactose tolerance enabled the

European populations to increase the amount of absorbed calcium by simply increasing their oral calcium intake. Lactose tolerance could, thus, decrease the risk of rickets and female pelvis deformations in former times, which might have been important for the survival of the European population groups.

Calcium Content of Dairy Products

The calcium content of dairy products is listed in **Table 2**. Of all dairy products, cheeses, especially hard cheeses, have the highest calcium content, because of their low water content. One portion (30 g) of Emmental cheese, for example, delivers approximately 300 mg calcium, whereas the calcium content of one portion of fresh cheese (30 g) is only 24 mg. In the western diet, dairy products are the most important sources of calcium. Representative nutrition surveys have shown that approximately 60–70% of the daily calcium intake comes from these foods. The calcium/energy ratio of most dairy products is high and the relative calcium density is clearly above the recommended level of 1. Exceptions are fresh cheese and the nondairy product milk chocolate.

Milk and some foods with a high milk content are rich in lactose (**Table 3**). However, most cheeses

[a] rND = relative nutrient density; ratio of the Ca density of a food (mg Ca MJ^{-1}) to the recommended Ca density (mg MJ^{-1}) of a distinct population group (here: postmenopausal women, aged 51–65 years, 135 mg MJ^{-1})
Adapted from Souci SW, Fachmann W, and Kraut H (1994) *Food Composition and Nutrition Tables*. 5th revised and completed edn. Stuttgart: Medpharm GmbH Scientific Publishers.

are lactose-free owing to the bacterial degradation of sugars during cheese ripening. Cheese is therefore well-tolerated even by people with lactose intolerance. Moreover, nonheated yogurt is an alternative source of calcium for people with lactose malabsorption, even though yogurt contains significant amounts of lactose. But yogurt also contains relatively high amounts of bacterial β-galactosidase and this enzyme can be reactivated in the human gastrointestinal tract to metabolize the lactose from yogurt.

Calcium Bioavailability from Dairy Products

Besides its high calcium content, milk has a good calcium bioavailability (~30%). A few nondairy foods, like spinach, sesame, kale, and certain mineral waters, also are rich in calcium content. However, though the calcium absorption from kale and from calcium-rich mineral water is comparable to that from milk, calcium bioavailability from sesame (783 mg Ca per 100 g) and from spinach (126 mg Ca per 100 g) is much lower than that from milk and clearly below 10%.

Contrary to earlier suggestions, lactose content of milk has no beneficial effect on intestinal calcium absorption. In lactose-tolerant subjects, lactose is rapidly digested in the upper small intestine indicating that no lactose-specific mechanism exists to enhance intestinal calcium uptake. Moreover, postprandial parathyroid hormone response, an indirect indicator of the amount of calcium absorbed, does not differ after ingestion of similar amounts of calcium from milk and from (lactose-free) ripened cheese.

The native vitamin D content of milk is low. However, in some regions of the world, for example, North America, fortification of milk with vitamin D is obligatory (10 μg per US quart (= ~0.95 l)). In other regions, for example, in Europe, such a measure is unusual or even prohibited. A better vitamin D nutrition may improve vitamin D status and may, thus, contribute to an improved intrinsic ability to absorb calcium. In particular, home-bound elderly people or elderly persons living in nursing homes often have an insufficient vitamin D status and a very low calcium intake (often below 500 mg day^{-1}). They might improve their calcium balance through a higher intake of (vitamin D-fortified) milk.

Calcium/Sodium Ratio of Different Dairy Products

The sodium content of dairy products can vary widely (**Table 4**). The differences are mostly due to the addition of sodium chloride during the technological process of cheese production. Sodium chloride has a calciuretic effect because of sodium–calcium exchange in the proximal renal tubule. An additional sodium intake of 1 g (43 mmol) has been associated with a renal calcium loss of 20–40 mg (0.5–1.0 mmol). If unremedied, the extra sodium would result in a skeletal loss of approximately 1% per year.

The calcium/sodium ratio of dairy foods varies from approximately 2.7 for milk to 0.21 for fresh cheese. Even in different cheeses, the calcium/sodium ratio can vary by a factor of 10. Young adults are able to adapt to a high sodium chloride intake owing to an increase in gastrointestinal calcium absorption and/or a decrease in

Table 4 Protein and mineral content of dairy foods

Food	*Sodium (mg/100 g)*	*Calcium/sodium ratio (mg mg^{-1})*	*Potassium (mg/100 g)*	*Protein (g/100g)*	*Calcium/protein ratio (mg:g)*
Milk					
Cow milk (3.5% fat)	45	2.67	141	3.34	35.9
Skimmed milk	53	2.32	150	3.50	35.1
Goat milk	42	3.02	181	3.69	34.4
Dairy products (except cheese)					
Buttermilk	57	1.91	147	3.50	31.1
Yogurt (3.5% fat)	48	2.50	157	3.88	30.9
Cream (10% fat)	40	2.52	132	3.10	32.6
Cheese					
Fresh (min. 60% fat in dry matter)	375	0.21	95	11.30	7.0
Brie (50% fat in dry matter)	1170	0.34	152	22.60	17.7
Limburger (40% fat in dry matter)	1300	0.41	128	22.40	23.8
Camembert (45% fat in dry matter)	975	0.59	110	21.00	27.1
Edam (45% fat in dry matter)	654	1.04	67	24.80	27.3
Emmental (45% fat in dry matter)	450	2.27	107	28.70	35.5

endogenous fecal calcium loss. However, such a mechanism probably no longer exists in postmenopausal women and elderly people. Consequently, in postmenopausal women sodium chloride can induce a rise in bone resorption processes.

Calcium/Protein Ratio of Different Dairy Products

Protein intake is related to renal calcium excretion. To offset protein's calciuretic effect, calcium allowances have been recommended at a calcium/protein ratio (in mg:g) of 20:1. In milk this ratio is 36:1 and, thus, more favorable than the recommended value. In other dairy products, however, the calcium/protein ratio varies between 35:1 (Emmental cheese) and 7:1 (fresh cheese). Although a low calcium/protein ratio may increase the risk of a negative calcium balance, there is evidence that, at least in young subjects, the higher renal calcium loss during high protein intake can be compensated by an increase in intestinal calcium absorption rate.

Dairy protein consumption may also be beneficial to bone health. The protein value of dairy foods is high, and an adequate protein intake is important for maintaining muscle mass. Especially, elderly subjects are at an increased risk of inadequate protein intake. The Framingham Osteoporosis Study has demonstrated that elderly persons in the lowest quartile of protein intake, which is below the recommended daily protein intake, have the highest bone loss. Similar to the overall protein effect, a lower percentage of animal protein is related to bone loss at specific skeletal sites of increased osteoporotic fracture risk (spine and femoral sites).

Potassium Content of Dairy Products

Potassium appears to play an important role in protecting against calcium loss from the renal acid load of protein. The mammary gland is able to concentrate the potassium content against a high serum gradient. Frequent intake of certain dairy products like milk and yogurt can significantly contribute to the total daily potassium intake of 2–3 g. Epidemiologic data indicate a protective effect of potassium intake on bone density. Administration of potassium to postmenopausal women at significantly higher levels than the recommended protein intake has been found to decrease urinary excretion of the bone resorption marker hydroxyproline and increase serum osteocalcin, a marker of bone formation.

Is the Consumption of Dairy Products a Risk Factor for Osteoporosis?

Some cross-cultural comparisons have reported positive correlations between calcium intake and fracture risk. Moreover, some epidemiologic studies indicate a positive association between the intake of animal protein and the incidence of osteoporosis. In western diets, both calcium intake and protein intake are closely linked to the intake of dairy products. In some nonscientific publications, the relatively high consumption of dairy products in western societies has been made responsible for the high risk of osteoporosis. However, the cross-sectional nature of the above-mentioned data and the absence of controls for confounding factors such as genetic and lifestyle differences point toward a fluke association.

To obtain valid scientific data about the association between dairy consumption and bone health it is absolutely necessary to perform controlled clinical trials.

Lactose Intolerance and Bone Health

The impact of consumption of dairy products on bone health can be elucidated by examining the risk of osteoporosis in lactose absorbers and lactose malabsorbers of a population group. The prevalence of β-galactosidase deficiency in Central and Northern Europeans and their descendants ranges from 3 to 30% and rises up to approximately 50% in the subgroup of elderly subjects. As milk consumption can cause gastrointestinal symptoms in lactose malabsorbers, a marked reduction in milk consumption (and often also in the consumption of other dairy products) can be the consequence. White females with β-galactosidase deficiency have a mean lactose intake of 6–7 g day^{-1}, which is only one-third to one-half of the regular lactose intake of their lactose-tolerant counterparts. In parallel, dietary calcium intake also can get reduced by 50%. In clinical studies, a higher prevalence of lactose malabsorption has been found in osteoporotic than in non-osteoporotic women: prevalence of lactose malabsorption ranged from 26 to 65% in osteoporotic women and from 0 to 20% in nonosteoporotic women. However, lactose malabsorption is not the only reason for a spontaneous avoidance of milk and milk products. The true culprit for motivating the avoidance of lactose-related foods in the diet is not malabsorption as such, but gastrointestinal intolerance due to malabsorption of this carbohydrate. Lactose malabsorption, in fact, does not always lead to intolerance. Reasons for the variability of gastrointestinal symptoms among individual malabsorbers are the ability of the colon to absorb short-chain fatty acids derived from the bacterial fermentation of malabsorbed lactose; hydrogen consumption by colonic methanogenic bacteria and/or reduced colonic pH, which could lead to a significant decrease in the volume of colonic gas; and the possible induction of colonic bacterial lactase by lactose malabsorption. When lactose malabsorption is accompanied by symptoms of intolerance it represents a particular risk factor for osteoporosis.

Although yogurt and cheese are normally well-tolerated by subjects with lactose intolerance (see above), those who are not aware of this connection avoid these dairy products and are, thus, at an increased risk of inadequate dietary calcium intake. Approximately 50% of the subjects diagnosed with lactose malabsorption tolerate one single portion of 10 g lactose (equivalent to 250 ml milk) without sustaining gastrointestinal symptoms.

In the past, the association between β-galactosidase deficiency and osteoporosis has been questioned because African-Americans, among whom β-galactosidase deficiency occurs in approximately 90% of the adult population, have a lower incidence of osteoporosis than do whites. However, this discrepancy can be explained by the different genetic background, resulting in a higher initial bone mass, a resistance of bone to calciotropic hormones, and an altered bone remodeling, of African-Americans when compared to whites. These associations, however, are not an argument against the prevention of osteoporosis by a higher intake of dairy products in the white population.

Controlled Trials on the Effect of Dairy Products on Bone Health

Only randomized controlled trials can confirm or reject the hypothesis that adequate milk and dairy product consumption supports good bone health. Such a study design is mandatory, as epidemiological studies are not able to accurately assess dietary intake. Even a large sample size does not overcome that weakness of epidemiological studies. During the last decade, some interventional studies have been performed on pubertal/adolescent girls. These investigations have demonstrated a beneficial effect of dairy foods on bone health. No unfavorable results for this category have been published. Postintervention observations indicate that it is mandatory to continue with a lifelong high-dairy product diet to preserve the positive effects on bone health. The limited number of studies done so far do not allow the determination of the effect of dairy foods consumption on bone density. However, with an additional intake of 300 ml of milk per day it seems possible to increase the increment in bone mineral density during puberty by more than 10%. The beneficial effect may occur at least due to the higher dietary intakes of calcium, vitamin D, and protein.

In postmenopausal white women, diet supplementation by milk powder can result in cessation of bone loss at the hip. There is also evidence from controlled trials that school milk intervention and milk supplements, respectively, can increase bone mineral density in Chinese girls and young Japanese women, and in postmenopausal Chinese women. But increasing the consumption of dairy products alone seems to be less beneficial to postmenopausal bone mineral content than combining it with an additional restriction of dietary sodium chloride intake. It should be noted that no unfavorable results of interventional trials of dairy consumption on postmenopausal bone health have been reported.

Conclusions

There is evidence that adequate dairy foods consumption supports good bone health in adolescent girls and probably in postmenopausal women. Dairy products can contribute to adequate calcium and protein intake and, thus, to the maintenance of muscle and bone mass. However, some dairy products, particularly some processed cheese products, have a high sodium chloride and protein content relative to their calcium content. In postmenopausal women in particular, these nutrients can possibly adversely affect calcium metabolism. Accordingly, not all dairy products are equally good vehicles of calcium, and they may, hence, differ in their effect on bone mineralization.

There have been too few studies on white males and other ethnic groups, except Chinese females, for conclusions to be drawn about the effect of any dairy food on bone health among those groups.

Introduction

Worldwide, colorectal cancer ranks fourth in frequency of all cancers among men and third in women, with an estimated 1 million new cases being diagnosed annually around the globe. Though incidence rates are highest in the developed world – it is the second most common malignancy affecting humans in westernized cultures – they are increasing elsewhere, especially in Asia. Given that most instances of colorectal cancer arise from a benign polyp, screening and surveillance programs to detect polyps at a premalignant stage have been initiated in several countries and promise to reduce colorectal cancer incidence and mortality significantly. Parallel research into the genetics and molecular biology of this cancer has not only significantly enhanced our understanding of its pathogenesis, but also has provided some optimism for the future development of simpler, less-invasive diagnostic methods. Most colorectal cancers are sporadic, with only a small number (2–3%) arising in the context of genetic syndromes such as familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC, also known as the Lynch syndrome) or of preexisting diseases such as inflammatory bowel disease. A family history of one or more affected first-degree relatives has been obtained in 20% of cases. The sporadic form of the disease is now thought to represent the end result of a multistep genetic process (the adenoma–carcinoma sequence) involving mutations in a number of key genes that normally regulate cell growth and differentiation. A better understanding of the pathogenesis of the disease, including genotypic changes and phenotypic expression at different stages, provides the opportunity both for elucidating its mechanisms and for identifying the points at which reversal of the disease process might be possible with appropriate interventional, including dietary, strategies (**Figure 1**). Though our understanding of initiatory factors is poor, it is nevertheless clear that, along with aging (over 50% of cases occur among those over 50 years of age), diet can have a significant promotional or inhibitory effect on the disease. In some societies such as African nationals eating traditional diets the disease is virtually unheard of, whereas in some other societies it occurs with a prevalence of 30–50 cases per 100 000 population. Within some high-incidence societies a threefold difference in expression has been identified between urban and rural communities and between differing geographical climes with varying food–lifestyle preferences, for example, northern versus southern populations of India, Italy, and Sweden. The relevance of diet can also be readily deduced from the impact on colorectal cancer incidence of changes in dietary habits and, specifically, the effects of a move to a 'westernized' diet, whether occurring within a country (such as has happened in Japan) or to groups of individuals on migrating to the West.

With regard to diet and lifestyle, a number of factors such as the consumption of meat, animal fat, tobacco, and alcohol have been shown to increase risk, whereas high dietary intakes of fiber, fruit, and vegetables have appeared to be protective. Other features such as ethnic origin, physical inactivity, excess body weight, and central adiposity may also confer increased risk. It must be stressed, however, that the interpretation of studies on the relationships between diets or dietary components and colorectal cancer is fraught with difficulties. Confounding factors abound; those who eat more vegetables, for example, typically consume less meat, take more exercise, and are less likely to be obese; dissecting out the relative contributions of each of these factors in epidemiological studies and from dietary surveys is almost impossible. The issue of confounding factors must similarly be borne in mind when assessing the literature on the impact of dairy food consumption. A further complication in this instance is the theoretical possibility of different components of dairy products conferring diametrically opposite effects on cancer risk: calcium, for example, potentially reduces risk, while the high fat content of dairy foods may increase risk. Furthermore, colorectal cancer, though often treated in epidemiological studies as a single homogeneous entity, in reality comprises at least three distinct types: right-sided, left-sided, and rectal cancer, which not only demonstrate different clinical behaviors, but may have quite distinct molecular paths. It should come as no surprise, therefore, that though the study of dietary eating patterns and their influence on

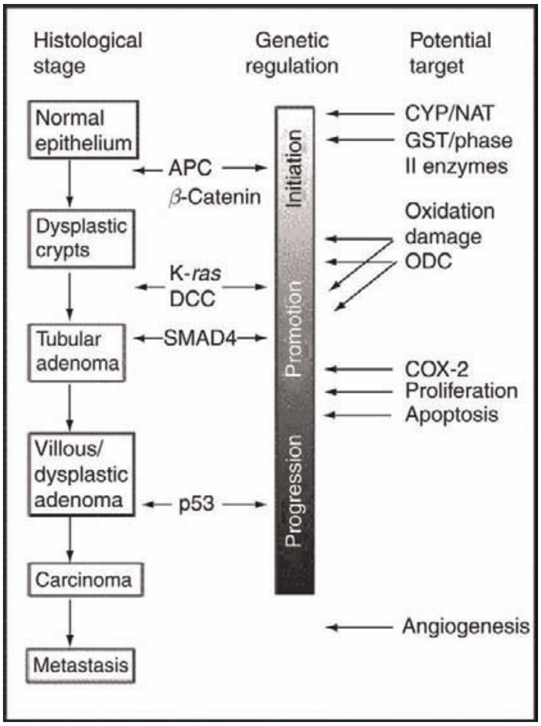

Figure 1 Multistep model of carcinogenesis with targets for chemoprevention. colon cancer risk has produced some detailed and comprehensive analyses of populations at risk, it has also led to some inconsistent results. For example, the 1997 report of epidemiological evidence by the World Cancer Research Fund and American Institute for Cancer Research came to the conclusion that "the evidence on the relationship between colon cancer and dairy products is inconsistent; no judgement is possible", adding the ambivalent statement "any increased risk may be due to fat, whereas decreased risk may be the consequence of vitamin D and calcium". The latter statement acknowledged the potential for protection, and that there was substantial support for several possible agents being effective in this respect. In examining the issue of dairy products, one must also be fully aware of dramatic variations in the consumption of milk and dairy products, as well as of the diversity of such products among countries and among regions within countries.

Some of the earliest case–control and epidemiological studies pointed to dairy foods such as milk, cheese, and/or other fermented dairy foods as being protective. The suggestion that dairy fat has a negative influence owing to its calories promoting cancer may be too simplistic, as there are a number of components in dairy fat (e.g., sphingolipid, vitamin D, conjugated linoleic acid (CLA), butyrate) that distinguish it from animal carcass fat and might be instrumental in protecting against cancer. There is significant evidence supporting the view that dairy products do not increase, but rather decrease risk. The presence of significant amounts of dairy food in the diet may also allow interactions or synergies with other major components of the diet, such as cereal grain foods. Commercial food processing is now an inevitable part of food preparation in western food cultures, and some significant changes may result, such as loss of nutritional value and production of reaction products (Maillard reaction products) that might bring about their own influences, such as antioxidant effects and/or altered digestibility. This may then influence the impact of such food preparations on large bowel health and colon cancer risk.

Studies of individual components of dairy foods and their influence on *in vitro* cancer cells and animal models of cancer have provided useful insights into possible mechanisms whereby they might reduce risk in humans; such studies have demonstrated anticancer effects of a variety of components in dairy products, including calcium, CLA, whey proteins, lactoferrin, α-lactalbumin, lactose, sphingolipids, and probiotics (in fermented milk products). However, translation of such experimental data to clinical impact has been more problematic and, in most instances, their relevance to man remains to be confirmed in carefully controlled dietary intervention studies. In examining the relationship between dairy foods and colon cancer, epidemiological and intervention studies will be discussed, along with what is known regarding the mechanisms of the effects of dairy foods and components on colon cancer expression.

Epidemiology

Studies spanning several decades have presented evidence that dairy foods, including fermented products, are associated with longevity and reduced risk of several cancers, including colon cancer. As long ago as 1933, a case–control study involving 462 cancer cases and matched controls in London, England, noted that cancer patients were more prone to have constipation, drank less milk, and ate less wholemeal bread and vegetables than controls. Milk and vegetable consumption was singled out as being worthy of further study. Since then, there have been case–control and/or cohort studies in India, Sweden, Finland, Russia, France, Italy, The Netherlands, Australia, and the United States, which have largely confirmed a protective effect for dairy foods against adenomas and/or colon cancer.

Three recent reviews have critically evaluated these data. Cho and colleagues pooled data from 10 cohort studies including a total of 534 536 individuals, among whom 4992 cases of colorectal cancer occurred over a 6- to 16-year follow-up period. Comparing the highest level of milk intake ($\geq 250\,\mathrm{g\,day^{-1}}$) with the lowest ($<70\,\mathrm{g\,day^{-1}}$) revealed a 15% reduction in distal colon and rectal cancers but not in proximal colon cancers. They went on to estimate that each $500\,\mathrm{g\,day^{-1}}$ increase in milk intake was associated with a 12% reduction in colorectal cancer incidence. Nonsignificant trends were observed for cheese and yogurt intake. Calcium was also protective, the highest level of intake being associated with a 14–22% reduction in colorectal cancer. In contrast, the protective effect for vitamin D was seen only when associated with the highest levels of calcium intake. Pufulete, reviewing the literature, also concluded that milk consumption is protective, but noted that this effect seemed greater for skim milk than for full-fat milk. She also contended that evidence for a protective effect of cheese, though suggestive, was inconclusive and that there was no apparent effect of fermented milk products. Huncharek and colleagues performed a meta-analysis of 26 335 cases from 60 observational studies and confirmed a significantly reduced relative risk (0.78) of colon cancer for high intakes of milk and dairy products. No protection was evident for rectal cancers. High calcium intake, in contrast, appeared protective for both distal colon and rectal cancer, and evidence for an independent effect of vitamin D was unimpressive. It should be noted, with regard to the latter, that dairy foods offer only modest amounts of dietary vitamin D (milk $30–40\,\mathrm{IU\,l^{-1}}$) unless fortified, as practiced in the United States. One recent study from Sweden deserves special attention; here, Larsson and colleagues prospectively examined relationships between high-fat dairy food consumption and CLA intake and colorectal cancer incidence among 60 708 women in the Swedish mammography cohort during an average of 14.8 years of follow-up. Comparing the highest intake of high-fat dairy foods ($\geq$4 servings per day) with the lowest intake (<1 serving per day) revealed a relative risk of 0.59 for colorectal cancer; this effect was greater for distal colon cancer (0.28) than for proximal colon (0.84) and rectal (0.62) cancers. These effects were independent of calcium intake. Protective effects of cheese, full-fat cultured milk, and butter, but not of whole milk, were also noted. The highest quartile of CLA intake was associated with a relative risk of 0.71 when compared with the lowest quartile of CLA intake. This study must be interpreted in the context of a population whose milk, cheese, and other milk product intake is considerably higher than average.

Intervention Studies

Given the long lead time associated with the development of colorectal cancer, intervention studies have used a number of surrogate measures to identify reduced cancer risk, with colonocyte proliferation and polyp recurrence being two of the most commonly used measures. Even though most cancers originate from adenomatous polyps, only 1–10% of polyps will progress to cancer. Other studies have examined fecal water cytotoxicity and/or genotoxicity, as well as other metabolic markers such as pH and the concentrations of secondary bile acids and butyrate, as possible biomarkers of risk. People at risk of developing sporadic polyp and colon cancer have regularly been enlisted for such intervention studies – that is, men and women aged 50 years and over, when incidence begins to increase dramatically.

One study examined the influence of removing dairy foods from the diet on risk markers in a group of healthy young male and female volunteers (**Table 1**). There was a 13% decrease of energy intake following the removal of dairy foods, mainly as a result of lower fat and protein ingestion, though carbohydrate and fiber remained constant. Calcium was lowered from 1488 to $372\,\mathrm{mg\,day^{-1}}$, which indicated that the dairy portion accounted for 75% of daily calcium intake.

Phosphate and vitamin D were lowered similarly. Fecal water was extracted from stools and cytotoxicity and genotoxicity measured using *in vitro* HT29 colon cancer cells and the comet assay. Cytotoxicity increased significantly in fecal water in the absence of dairy foods (seen as lower HT29 cell survival), whereas genotoxicity was not affected. This result pointed to dairy foods

Table 1 Human fecal water parameters in dairy-rich and dairy-free diet period

	Dairy product-rich	*Dairy product-free*	*Significance*
Wet weight of feces	130 ± 63	115 ± 50	ns
pH of fecal water	7.0 ± 0.5	6.7 ± 0.3	0.012
%HT29 cell survival	34 ± 28	20 ± 22	0.025
Caco-2 genotoxicity	6.1 ± 5.7	6.5 ± 5.9	ns

Eighteen healthy male and female volunteers were enrolled in a crossover design. Mean±SD $n = 18$.

Table 2 Influence of calcium supplements on colorectal adenoma recurrence over a 4-year period of intervention in postpolypectomy subjects

Calcium supplemented daily for 4 years (1200 mg) placebo with 409 423 subjects with a recent history of adenomas – repeated colonoscopies

Adjusted risk ratio: adenoma recurrence was 0.81 (CI = 0.67–0.99, $p = 0.04$)

Adjusted ratio: average number of adenomas was 0.76 (CI = 0.6–0.96, $p = 0.02$)

Calcium supplementation is associated with a significant though moderate reduction in the risk of recurrence, independent of initial dietary fat or calcium intake

Reproduced with permission from Baron JA, Beach M, Madel JS, *et al.* (1999) Calcium supplements for the prevention of colorectal adenomas. *New England Journal of Medicine* 340: 101–107.

providing significant protection, a result that was attributed to the presence of increased calcium and phosphate concentrations in the colon.

Calcium has been shown to reduce significantly the proliferation of colonocytes in the upper region of colonic crypts; this is another indicator of risk. A calcium polyp prevention study involving a randomized double-blind trial showed a 20–25% reduction in polyp recurrence over 4 years, associated with a daily supplement of calcium (1200 mg) as calcium carbonate. This result was independent of fat or calcium intake in the background diet (**Table 2**).

A large European randomized double-blind intervention trial study showed a slight but significant reduction in polyp recurrence with a daily ingestion of 2 g calcium as calcium gluconolactate and carbonate. This reduction was not seen in the other arm of the study, which examined the effect of a soluble psyllium fiber supplement of 3.5 g day^{-1}.

A recent Cochrane review, assessing these two studies, concluded that though calcium supplementation might contribute to a moderate degree to the prevention of colorectal cancer, there was no sufficient evidence to justify recommending calcium supplementation to prevent colorectal cancer. Intervention studies with vitamin D have been disappointing.

Mechanisms

Calcium and Vitamin D

The influence of calcium in the diet on colon function and cancer prevention has been investigated with animal modeling of a westernized diet, characterized by low calcium and vitamin D, high phosphate, high fat, and low fiber. The western diet is associated with an elevated epithelial cell proliferation and an increased tendency to develop aberrant crypts and tumors induced in rodents by 1,2-dimethylhydrazine or azoxymethane. Though the responsible mechanisms may be only partially understood, there is now good experimental evidence for significantly increased fecal water cytotoxicity associated with the diet, probably as a result of free fatty acids, secondary bile acids from microbiological activity, but possibly also resulting from genotoxic products of microbiological origin. The influence of these products is effectively diminished or eliminated in the presence of adequate calcium by neutralization and/or precipitation as innocuous soaps. A lowered pH may influence this process, through the fermentative production of short-chain fatty acids (**Figure 2**). Vitamin D assists with calcium uptake and utilization from the diet, and this has also been shown to affect cell function and diminish proliferation at the level of colonocytes in the large bowel (*see* **Milk Lipids:** Nutritional Significance; **Milk Salts**: Macroelements, Nutritional Significance; **Vitamins**: Vitamin D).

Probiotics

Probiotic bacteria have been shown to reduce the expression of tumorigenesis in animal models of colon cancer. Epidemiological evidence has been inconsistent in showing protection, even though there are some studies that showed clear benefits of fermented dairy foods, as mentioned previously. The main probiotic bacteria used in dairy foods have been strains of *Lactobacillus acidophilus* and bifidobacteria species, which are regularly added to fermented dairy foods like yogurt because of their perceived functional benefits to gastrointestinal health. Although a number of possible benefits in antimutagenic and anticarcinogenic terms have been reported, which have been demonstrated by *in vitro* and animal studies,

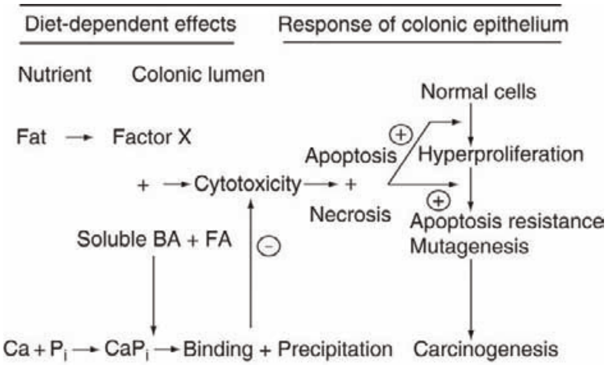

Figure 2 Proposed mechanism of the effects of dietary fat, calcium, and phosphate on colon carcinogenesis. BA, secondary bile acids; FA, fatty acids; CaP$_i$, insoluble amorphous calcium phosphate. convincing evidence from human studies is lacking. On the other hand, benefits in the control of diarrhea, improved immune responsiveness, alleviation of constipation, and treatment of food allergies have been reported and appear to be promising potential applications (*see* **Bacteria, Beneficial**: Probiotics, Applications in Dairy Products).

Dairy Proteins

Some epidemiological and experimental studies provide evidence supporting a protective role of dairy proteins relative to red meat, eggs, and some other alternative protein sources. Experimental investigation has been made possible by the availability of concentrated purified protein products (isolates and concentrates). Whey proteins, in particular, appear to offer significant protection in the rodent model of chemically induced colon cancer. Though the mechanisms of protection are still not well understood, the contribution of sulfur amino acids seems to be important. Lactoferrin and α-lactalbumin are some of the richest sources of cystine (disulfide bridge compounds) and in prior studies were associated with significantly increased hepatic glutathione, an important antioxidant and xenobiotic deactivating agent (**Figures 3** and **4**). It has a major role in protecting the host against toxic/mutagenic factors.

Fat levels in feces also appear to be significantly influenced by the protein source, and this effect may have reflected associations, such as saturated fat with red meat and soluble fiber components with soy protein in soybean meal. Dairy proteins have been identified in *in vitro* assay systems as being significantly antimutagenic and/or anticarcinogenic. Whether they can play a significant role in protection against colon cancer as part of a normal human diet is not yet established, but there is some evidence that they probably do (*see* **Milk Proteins**: Nutritional Quality of Milk Proteins).

Lactose and Lactulose

The possibility that lactose and/or lactulose might have a significant influence on colon cancer risk has been proposed and is an interesting possibility deserving further investigation. Lactose intolerance is not an uncommon condition in adult populations (prevalence in Australian adults may be somewhere in the range 4–20%) and could be having a significant influence on large-bowel health. It is capable of causing significant bloating and colic, and softening of the stool, owing to active fermentation in the hindgut. Lactulose can form during the heat processing of milk (e.g., ultra-heat-treated (UHT) milk 10–50 mg 100 ml^{-1}), and is commercially produced by enzymatic processing of lactose. Daily supplements of lactulose (e.g., 8–60 g day^{-1}) have been shown to reduce stool pH, transit time, and bile acid pool size (35%) and concentration (including deoxycholic acid, a cocarcinogenic secondary bile acid), and to increase stool size and frequency. Japanese studies have shown a major shift toward bifidobacteria in the stools of people ingesting 8 g lactulose day^{-1}. In many respects, lactose (in lactose maldigesters) and its derivatives, lactulose and lactitol, behave similarly to dietary fiber, providing an enzyme-resistant carbohydrate, which is fermented in the hindgut, possibly also altering the balance of bacterial flora in the process. Products of that fermentation could include short-chain fatty acids (including butyrate); other possible effects are reduced pH and bulking and other stool changes, which might act to reduce colon cancer risk. Feeding studies in rats colonized with human gut flora showed significantly reduced DNA damage (genotoxicity) by 1,2-dimethylhydrazine in their colonocytes as a

result of feeding 3% lactulose in place of sucrose in the diet. Increased lactobacilli were evident in the cecal flora of these rats, which may have provided some protection.

Sphingomyelin

The phospholipids and sphingolipids present in the fat component of milk act as a significant source of biologically active molecules, which may play an important role in signal transduction and cell regulation. Hydrolysis of sphingomyelin in the gut leads to the generation of phosphocholine and ceramide, a potent inducer of cell differentiation and programmed cell death (apoptosis). Sphingosine, a deacylated product of ceramide, is a potent inhibitor of protein kinase C, which otherwise induces significant cell proliferation and increases the risk of tumorigenesis. It competes with the inducers of this enzyme. These sphingolipids are released throughout the gastrointestinal tract during digestion and, given their antiproliferative effects, they have been referred to as tumor suppressor lipids. Along with significant amounts present in dairy fats/buttermilk, they are also found closely associated with whey protein isolates and concentrates. In chemically induced rodent colon cancer studies, sphingolipids have been shown to inhibit tumorigenesis, when present in concentrations of 0.025–0.1% sphingomyelin in a purified rodent diet.

Butyrate

The presence of significant amounts of the short-chain fatty acid butyrate in dairy fat derives from fermentation of carbohydrates in the cow's rumen and raises the possibility that it might provide some of its known antineoplastic and/or differentiating effects. There would appear to be rapid utilization of butyrate from the fat throughout the gastrointestinal tract epithelium, and hence it seems unlikely that it will reach the large intestine at least from this source. When provided in a stable form (e.g., tributyrin, a triglyceride with three butyrate molecules attached), significant systemic blood levels of butyrate were achieved, which have been associated with reduced cancer expression in a chemically induced model of breast cancer in rats. Butyrate, when present in the rat colon (direct infusions into the rat colon have been undertaken in amounts of about 400 mmol day^{-1} or by fermentative generation), leads to reduction of azoxymethane-induced aberrant crypt foci (early preneoplastic markers of cancer risk) adenomas and/or adenocarcinomas. However, when butyrate (as sodium butyrate) was included in the diet so as to deliver similar amounts, no effect was observed. At this stage, therefore, it remains speculative whether butyrate ingested through dairy products has any significant influence on colon health.

Conclusion

Some epidemiological studies have identified fermented and nonfermented dairy foods as providing significant protection against colon cancer. Though the interpretation of such data is complicated by the presence of many confounding factors, the effect of milk intake on distal colon cancer has been consistent. Though calcium, which in most diets is largely derived from milk and which is present in milk in a highly bioavailable form, has usually been considered the milk constituent most likely to confer this benefit, recent data point to the effect of milk and milk products independent of calcium.

Even though no data for intervention studies are available for milk and milk products *per se*, two intervention studies in adenoma-prone populations in Europe and the United States showed that calcium supplements in excess of 1 g day^{-1} produced a significant, though modest, reduction in adenomatous polyp recurrence rates.

Other components of dairy foods that have been shown to reduce mutagenicity or genotoxicity or diminish colon tumor formation in animal models of the disease include whey proteins, vitamin D, CLA, sphingolipids, lactulose, and butyrate. It is not possible currently to prioritize these components in terms of their potential contribution, to evaluate adequately their effects in combination, or to confirm their relevance in humans, but the fact that they occur together in dairy foods is supportive of their potential value as part of a cancer-preventing diet.

A number of possible mechanisms could be operating in cancer prevention, and this is a very productive area for ongoing research. It should in time help to confirm desirable dietary strategies, as well as to predict any modifications to dairy foods that are likely to be of additional benefit in this respect.

Nutritional and Health-Promoting Properties of Dairy Products: Fatty Acids of Milk and Cardiovascular Disease

P W Parodi, Dairy Australia, Melbourne, VIC, Australia

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Milk from domesticated animals has been used as a food item for more than 8000 years. Early in the twentieth century, public health bodies realized the nutritional benefits of milk and its products and recommended their consumption, especially for children and the elderly. However, during the past four decades, the nutritional image of milk and its products has suffered a decline because its content of saturated fatty acids (SFAs) is believed to increase serum cholesterol levels, which is considered a risk factor for coronary heart disease (CHD) and cardiovascular disease (CVD). Despite half-a-century of intensive research into prevention of CHD, multiple public health messages that largely advise reduction in SFA intake and lowering of serum cholesterol levels, and the production of 'heart-healthy' products by the food and pharmaceutical industries, CHD is still the leading cause of death in developed countries. This article examines, in a historical context, the strength of the evidence that associates SFA intake with the risk of CHD.

Early History

The introduction of penicillin in 1941, with other antibiotics following rapidly, resulted in infectious diseases, formally the leading cause of morbidity and mortality, being brought under control and as a result life expectancy increased. However, an alarming rise in the incidence of CHD was observed. At this time, the cause or causes of CHD were largely unknown. In 1948, the then National Heart Institute instituted the first longitudinal study to determine the risk factors for CHD among residents, aged 35–59 years, from the town of Framingham in Massachusetts. The first report from the Framingham study appeared in 1961 and noted three risk factors: elevated serum cholesterol levels, high blood pressure (BP), and an electrocardiography pattern of left ventricular hypertrophy.

Many later studies, including several large well-known prospective epidemiological studies conducted in different countries, also found a positive association between serum cholesterol levels and the risk of CHD. Subsequently, other important risk factors were established, such as cigarette smoking, obesity, lack of physical activity, diabetes, psychosocial issues, and elevated serum homocysteine levels. It is interesting to note that in the often-cited Seven Countries Study, 25-year follow-up data showed that serum cholesterol levels were linearly related to CHD mortality in all participating countries. However, the absolute levels of CHD mortality were strikingly different. At a serum cholesterol level of $5.2\,\mathrm{mmol\,l^{-1}}$, there was a fivefold greater mortality rate in Northern Europe than in Japan. These differences in mortality risk applied after adjusting for age, smoking, and systolic Blood Pressure (BP). This study suggests that there are other powerful, yet to be determined, risk factors for CHD in industrialized communities.

In 1954, before the first report from Framingham, Ahrens and colleagues from the Rockefeller Institute in New York reported the results of a carefully conducted metabolic ward study, which showed that when plant fats were substituted isocalorically for animal fats in men, there was a significant reduction in serum cholesterol level. This group later showed that the lowest serum cholesterol levels were seen when corn oil, safflower seed oil, or cottonseed oil constituted the sole dietary fat. Increased cholesterol levels were found with all other sole dietary fats with coconut oil and butterfat providing the highest levels. As a result of a number of studies with different types of oils and fats, Ancel Keys and colleagues produced a regression equation in 1957 that showed

$$\Delta\mathrm{Chol} = 2.74\Delta\mathrm{S} - 1.31\Delta\mathrm{P}$$

The equation showed that SFAs (S) had about twice the effect in raising serum cholesterol levels (ΔChol) as polyunsaturated fatty acids (PUFAs) (P) had in depressing it. Later, with more studies and improved data, other regression equations appeared. However, prediction equations are applicable to only large groups and not to individuals.

Not all SFAs raise serum cholesterol levels to the same degree. The short- and medium-chain length fatty acids C4:0, C6:0, C8:0, and C10:0 and some C12:0 that are present in milk fat are absorbed from the intestine, enter the portal circulation, and pass rapidly to the liver where they are oxidized. They are not incorporated into chylomicrons and have no serum cholesterol-elevating effect. The remainder of C12:0 together with C14:0 and C16:0 are hypercholesterolemic. C12:0 is possibly more potent than C14:0, which in turn is more potent than C16:0 in elevating total cholesterol levels. C18:0, like monounsaturated fatty acids (MUFAs), does not appear to influence serum cholesterol levels.

Associations between Saturated Fatty Acid Intake and the Risk of Coronary Heart Disease: The Epidemiological Evidence

Multiple studies have investigated the association between intake of SFAs and the risk of CHD.

Ecological Studies

Early epidemiological studies employed the international comparison or ecological format, where the apparent per capita intake of SFAs (or other items) is correlated with the death rates for a number of countries or regions. Most of these studies found that the intake of SFAs, dairy fat, animal fat, and total fat was strongly correlated with CHD death rates. However, other food items, such as protein, eggs, and sugar, and total energy often provided equally strong correlations as did other factors such as the number of TV and radio licenses, the number of registered motor vehicles, and national per capita income, factors that represent affluency. Ecological studies tell nothing about the diets of individuals who develop CHD and those who do not. Many other factors that may have a relationship to CHD can also differ between countries, which make the ecological format unsuitable for the determination of causality.

Case–Control Studies

Conducting within-country epidemiological studies can eliminate many of the disadvantages associated with the ecological format because the habits of the participants are more homogeneous. The simplest form is the case–control study where the diet and characteristics of patients with CHD are compared with that of control subjects free of the disease. Seven case–control studies were found. Four early studies analyzed the difference in mean daily intake of SFAs (in terms of $\mathrm{g\,day^{-1}}$ and as a percentage of daily caloric intake) between patients who had suffered a CHD incidence and representative control subjects who were free of the disease. The results are shown in **Table 1**. There were no statistically significant differences in the intake of SFAs between cases and control subjects. Three later studies used multiple logistic regression analyses to measure relative risk (RR) after adjustment for various confounders. Only one study, study 7 in **Table 2**, found a statistically significant association between SFA intake and the risk of CHD. None of the studies in **Tables 1** and **2** found a role for total fat, MUFAs, and PUFAs in the risk of CHD. Even so, the outcome of case–control studies can be influenced by bias because of failure to select appropriate control subjects, survivors of a heart attack failing to provide accurate data because of perceived gilt, and failure to include in the study individuals who died as a result of a heart attack.

Prospective (Cohort) Studies

Prospective or cohort studies are the preferred format for determining associations between dietary components and risk of CHD. Participants report their diet before the diagnosis of the disease and at a time closer to its initiation. Cases and control subjects are from the same community. Twenty-four publications on cohort studies that determined the associations between SFA intake and risk of CHD were found. Five of these publications were extended follow-ups of cohorts previously reported. Some studies presented results by age group, sex, area, and different CHD end points, which overall provided 33 data sets. **Table 3** lists 15 early studies that used a format where daily intake of energy, total fat, SFAs, and PUFAs in individuals with CHD was compared with the intake in those free of the disease. **Table 4** shows data from nine later studies that used multiple regression models to determine relative risk (RR) RRs of CHD with 95% confidence intervals (CIs) for the highest compared to the lowest intakes of total, saturated, monounsaturated, and polyunsaturated fats.

Only 5 of the 33 data sets show a statistically significant association between SFA intake and the risk of CHD. Studies 4 and 8 in **Table 3**, which are 6- and 10-year follow-up, respectively, from the Honolulu Heart Program found a positive association between percentage energy intakes of SFAs and risk of CHD, but not from absolute intake. In this cohort, there was also a positive association between PUFA intake and risk of CHD. There was also a positive association between percentage energy intakes, but not absolute intakes of SFAs and risk of CHD in the Ireland–Boston Diet Heart Study (study 10). A small Canadian study (study 17) found that increasing energy intake from saturated fat was significantly related to CHD mortality among 30–59 year olds (RR 1.11, 95% CI 1.04–1.18), but not among 60–79 year olds (RR 0.96, 0.88–1.03). Another small study from Britain found 100 g per week increase in saturated fat intake corresponded to an RR of 1.40 (1.09–1.79) in women. There was no increased risk for men (RR 1.00, 0.86–1.18). It is noteworthy that the largest three cohort studies, the Nurses' Health Study (study 22), the Health Professionals Follow-up Study (study 16), and the Alpha Tocopherol, Beta Carotene Cancer Prevention Study (study 19), did not find a positive association between saturated fat intake and CHD risk in fully adjusted models.

On the other hand, two cohort studies found a statistically significant negative association between SFA intake and the risk of CHD. Data from two Italian cohorts of the Seven Countries Study (study 12) showed that both the absolute and percentage energy intakes of SFAs were

statistically higher in control subjects than in cases. In the Alpha Tocopherol, Beta Carotene Cancer Prevention Study (study 19), the RR of major CHD events and CHD death for the highest quintile of SFA intake compared to the lowest was 0.87 (0.73–1.03) and 0.73 (0.56–0.95), respectively. In this study, the so-called hypercholesterolemic fatty acids C12:0 to C16:0, which represented 62% of total SFA intake, were investigated separately. The RRs were 0.88 (0.74–1.04) and 0.74 (0.57–0.96) for total CHD events and CHD deaths, respectively. Data from the Nurses' Health Study were also used to determine associations between groups of SFAs and CHD risk, but no significant associations were found. For the highest versus lowest quintiles of C4:0 to C10:0, the RR was 1.00 (0.82–1.21); for C12:0 to C14:0, the RR was 1.05 (0.83–1.32); for C16:0, the RR was 1.03 (0.71–1.50); for C18:0, the RR was 1.16 (0.81–1.66); and for the sum of C12:0 to C18:0, the RR was 1.04 (0.72–1.48).

In only one cohort, the Nurses' Health Study, a statistically significant association between the intake of PUFAs and the risk of CHD was found. At 14-year (study 18) and 20-year (study 22) follow-up, the RRs for the highest versus lowest intake were 0.68 (0.53–0.88) and 0.75 (0.60–0.92), respectively. On the other hand, a statistically significant positive association between percentage energy intakes of PUFAs and risk of CHD was found in the Honolulu Heart Study at 6- and 10-year follow-up (studies 4 and 8) and in the Puerto Rico Heart Health Program for urban but not rural participants (study 5). Null associations were found in all the other studies.

It is interesting to note in **Table 3** that in all 12 cohorts the subjects free of CHD had a higher intake of energy than those who succumbed to the disease. This may be due to their higher rate of physical activity, which is considered a protective factor for CHD.

Autopsy Studies

Two studies were found that related the extent of atherosclerosis in the coronary arteries and aortas measured at autopsy with previous diet. Neither study found an association between SFA intake and degree of atherosclerosis.

Comment

The epidemiological studies provide no compelling evidence that SFA intake is associated with the risk of CHD, nor is there persuasive evidence that consumption of PUFAs will prevent the disease. However, epidemiological associations cannot be used to ascribe causality; for this, well-conducted randomized placebo-controlled clinical trials are required.

Randomized Controlled Trials

A randomized controlled trial (RCT) to determine if dietary SFAs are causally related to CHD would require isocaloric substitution of SFAs with unsaturated fatty acids without changes in total fat content, other dietary components, and lifestyle factors that could influence the risk of CHD. The study should be large enough to produce significant results, be blinded, and conducted for many years. These conditions are very difficult to obtain in practice, but a few studies have been conducted where SFA reduction was obtained by reduction in total fat intake, while others substituted animal fat in the diet by vegetable oils without undue difference in other factors. Six RCTs of diets with lowered SFA levels for CHD prevention are listed in **Table 5**. Because the various studies used different classifications for nonfatal CHD events, total and CHD mortality are used as end points. The Finnish Mental Hospitals Study is often cited as support for SFA and butter consumption as risk factors for CHD. This study is not included in **Table 5** because the design was unsound. The hospitals were randomized and not the inmates and therefore it was a cluster randomized trial with only two clusters. The inmates in the hospitals changed during the trial and there were differences for a number of CHD risk factors between hospitals. The hospital that fed the low-SFA, cholesterol-lowering diet also had a lower intake of trans fatty acids, now known to be more atherogenic than SFAs.

None of the estimates of risk for total and CHD mortality in **Table 5** attained statistical significance.

[a] S, secondary prevention trial; P, primary prevention trial.
[b] Difference in mean serum cholesterol between diet and control groups at the end of the trial.
CHD, coronary heart disease; CI, confidence interval.

One study was a primary prevention study, but lasted just over 1 year; in another study, participants were both free from and recovering from CHD at entry; the remaining studies were secondary prevention studies. Overall, it can be justifiably claimed that the patients were not representative of the general population, the numbers were too small, the duration of the trials was too short, and arteriosclerosis was too far advanced to benefit from dietary treatment. However, it is these studies, together with epidemiological studies and the serum total cholesterol-raising effect, that formed the basis for the demonization of saturated fat.

Multifactor Intervention Studies

Many multifactor intervention studies designed to reduce serum cholesterol levels were conducted. They variously reduced SFA intake in conjunction with reduced consumption of total fat and increased consumption of PUFAs and other beneficial dietary items, together with changes in lifestyle factors such as cessation of smoking and weight reduction. Some studies used medication to reduce BP and serum cholesterol levels. In general, apart from a benefit for a small proportion of patients at very high risk of death from CHD, cholesterol-lowering interventions failed to produce statistically significant reductions in CHD and total mortality until the advent of the statin drugs.

Serum Lipoproteins and Their Properties

Cholesterol is sparingly soluble in aqueous solution and is transported in blood attached to proteins, which are called apoproteins. Together with triglycerides and phospholipids, they form a lipoprotein complex. The lipoproteins are an extremely heterogeneous mixture with different chemical compositions, physical properties, and metabolic functions. Lipoproteins are crudely classified according to increasing density and decreasing size. There are five main classes: chylomicrons, very low-density lipoproteins (VLDLs), intermediate-density lipoproteins (IDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs). As the density increases, the protein content increases whereas the triglyceride content decreases. Cholesterol content increases from about 8% in chylomicrons to about 48% in LDL, with about 20% in HDL. Each lipoprotein class has a distinctive apoprotein profile. Like serum total cholesterol, high levels of VLDL and LDL cholesterol are positively associated with the risk of CHD. On the other hand, high HDL cholesterol levels are negatively associated with the risk of CHD. The ratio of total to HDL cholesterol is considered a more powerful predictor of CHD than either value alone.

Apoproteins or apolipoproteins (apo) are designated by the letters A–E, with Roman numerals used for subspecies. Apoproteins have characteristic chain lengths and amino acid sequences and possess different physiological and biochemical properties. It is the composition of the apoproteins that determines the atherogenic properties, not the cholesterol. For example, positively charged regions of apoB of LDL interact with matrix proteins, including negatively charged proteoglycans (complex glycoproteins containing highly negatively charged carbohydrate chains) within the artery wall, an initiating event in atherosclerosis. Chylomicrons, VLDL, IDL, and LDL contain one molecule of apoB on their surfaces, but their cholesterol content varies and it is the apoB that reflects the number of atherogenic particles, although all particles may not be equally atherogenic. Serum apoB levels are considered superior to LDL cholesterol levels as a risk marker for CHD. ApoA is present on all HDL particles and is inversely related to the risk of CHD. The ratio apoB:apoA is the most important indicator of risk of CHD.

The major lipoprotein classes are themselves heterogeneous in size, density, composition, and properties. LDL size varies greatly among individuals and is genetically influenced. Small dense LDL particles are believed to be more atherogenic than larger more buoyant LDL particles. They are more easily taken up by the arterial wall, bind more tightly to arterial wall proteoglycans, and have greater oxidative susceptibility and reduced LDL receptor affinity. HDL is also a heterogeneous lipoprotein, which is metabolically dynamic with a number of subspecies that differ in apoprotein and lipid composition, size, and density and possess different physiological properties.

The Action of Saturated Fatty Acids on Lipoproteins

Early studies that provided a link between SFA intake and CHD, the so-called diet–heart or lipid hypothesis, depended on the measurement of serum total cholesterol levels, which is a crude measure of atherogenic potential. Although C12:0, C14:0, and C16:0 acids increase serum total and LDL cholesterol levels when substituted for carbohydrate or oleic acid, they concomitantly increase the level of antiatherogenic HDL cholesterol. The acids that increase LDL cholesterol the most likewise produce the greatest increase in HDL cholesterol. Regression models from a meta-analysis of 60 controlled dietary trials showed that C12:0 greatly increased total cholesterol, but most of its effect was on HDL cholesterol such that there was a decrease in the total:HDL cholesterol ratio. C14:0

and C16:0 acids had little effect on the ratio and C18:0 reduced the ratio slightly.

Lipoprotein(a) is an LDL-like particle where apolipoprotein(a) is linked to the C-terminal region of apoB of LDL. Its serum level is largely influenced by genetic factors and it may be more atherogenic than LDL. Normal lipid-lowering protocols do not reduce lipoprotein(a) levels and low-fat, high-carbohydrate diets increase its levels. However, SFAs, especially those present in milk fat, are known to reduce levels. Overall, when the effect of SFAs on all lipoproteins is considered, rather than just total and LDL cholesterol, they may well be atherogenically neutral.

Nondietary Causes of Hypercholesterolemia

There are many causes of hypercholesterolemia other than diet and SFA intake. Serum cholesterol levels increase with age, obesity, and in postmenopausal women due to cessation of estradiol production. Mental stress is an underemphasized cause of hypercholesterolemia and it is well documented that in students at exam time and accountants at peak work periods, serum cholesterol levels can rise substantially. A decline in cholesterol levels often occurs in metabolic ward patients, even those consuming a cholesterol-raising diet, as a result of reduced day-to-day stresses.

About 50% of the variation in serum cholesterol levels in the population can be explained by genetic polymorphisms in lipoproteins and related regulation factors. Examples are severe elevation in LDL cholesterol level that occurs when there is a mutation in the gene encoding the LDL receptor, which is responsible for the clearance of LDL cholesterol from the circulation. A defect in apoB, the ligand for binding LDL to its receptor, can also impair LDL clearance. There are many other points in the synthesis, secretion, and metabolism of lipoproteins where mutations in key elements can contribute to hypercholesterolemia

Even so, it is commonly cited that most people who succumb to CHD have normal or near-normal serum cholesterol levels. There is extensive overlap in distribution curves for total and LDL cholesterol levels in men with and without CHD. However, CHD patients with total cholesterol levels in the normal range mostly have other significant dyslipidemia. A study from Tufts University of men under 60 years of age with angiographically confirmed CHD found that more than half had a familial lipoprotein disorder. Only 12% had primary hypercholesterolemia, whereas the prevalence of HDL cholesterol and triglyceride abnormalities accounted for more than 50% of the lipoprotein abnormalities. For many years, public health bodies, nutritionists, and dietitians have recommended a high-carbohydrate, low-fat diet as a preventative measure for CHD. Whereas these diets may reduce serum LDL cholesterol levels, they may also decrease HDL cholesterol and increase serum triglyceride levels.

The Statin Drugs, Serum Cholesterol, and Coronary Heart Disease

The statin drugs are powerful hypolipidemic drugs. Depending on the class of statin and an individual's variability in response, they lower serum total cholesterol by 22–42%, LDL cholesterol by 27–55%, and triglycerides by 10–35% and increase HDL cholesterol by 4–8%. Statins act by competitively inhibiting 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) reductase, the enzyme that catalyzes the conversion of HMG-CoA to mevalonate, the rate-limiting step in cholesterol biosynthesis. Reduction in hepatic cholesterol levels results in an increased expression of LDL receptors to increase the uptake of serum LDL to maintain cholesterol homeostasis, which in turn lowers serum LDL cholesterol levels. Many studies have been conducted on primary and secondary prevention of CHD in clinical practice using statins and it is enthusiastically claimed that they reduce the risk of major coronary events by about 30%. These large reductions in serum total and LDL cholesterol levels with attendant CHD risk benefits are claimed to have justified the diet–heart hypothesis.

The Cholesterol Treatment Trialist's Collaborators recently conducted a meta-analysis of data from 90 056 participants in 14 randomized trials of statins. The mean duration of follow-up among survivors was 4.7 years. At 1 year, the weighed average difference in LDL cholesterol between controls and those on statin therapy was $1.09\,\mathrm{mmol\,l^{-1}}$. The RR for a $1.0\,\mathrm{mmol\,l^{-1}}$ LDL cholesterol reduction on nonfatal CHD, CHD death, and total mortality was 0.74 (0.70–0.79), 0.81 (0.75–0.87), and 0.88 (0.84–0.91), respectively. During the trial period, 6.2% of the control group suffered nonfatal CHD against 4.4% in the statin group. This translated to a 29% proportional reduction per $\mathrm{mmol\,l^{-1}}$ LDL cholesterol reduction. For CHD deaths and all-cause mortality, the corresponding figures are 4.4, 3.4, and 23% and 9.7, 8.5, and 12.4%. However, it is important to realize that the absolute risk reduction was small and on the order of 2% or less.

It is often suggested that reduction in LDL cholesterol by statins is the major, if not the only, mechanism for their beneficial effect in preventing CHD. However, there are a number of lines of evidence to suggest that this may not be the case and statins may possess cholesterol-independent properties (pleiotropic effects). Statins also reduce serum triglyceride levels and increase the levels of HDL cholesterol. To some extent they reduce homocysteine levels, and depending on the class they may also increase LDL particle size. There is also evidence that statins may reduce BP, lower the risk of developing diabetes, and improve left ventricular function. It is now generally accepted that inflammation plays an important role at all stages in the development and progression of atherosclerosis. Many lines of evidence from clinical and animal studies show that statins can modulate aspects of the inflammatory component of atherosclerosis. C-reactive protein (CRP) is a highly sensitive marker of systemic inflammation and is considered a stronger independent predictor of CHD than the LDL cholesterol level. A systematic review of 13 studies showed that statins reduced the concentration of CRP by 13–50% compared with placebo. This reduction was independent of their effect on serum lipid levels.

Vascular endothelial dysfunction is a strong and independent predictor of CVD. Vascular endothelial dysfunction was improved in patients taking a statin drug, but not in patients taking the cholesterol absorption inhibitor ezetimibe, even though both drugs lowered serum cholesterol levels to the same level. In addition to its role in the pathway to cholesterol synthesis, mevalonate can form activated isoprenes that condense to form geranylgeranyl and farnesyl pyrophosphates. These isoprenes bind (prenylate) a range of G proteins that transduce signals involved in inflammation. Squalestatin is an experimental statin that inhibits squalene synthase, thus preventing the synthesis of squalene downstream from mevalonate and the penultimate step in cholesterol synthesis. An animal study demonstrated that common statin drugs that inhibited mevalonate synthesis, but not squalestatin that inhibited squalene synthesis, produced antiinflammatory effects.

Given the small absolute reduction in CHD events after long-term treatment with statin drugs and their recorded pleiotropic effects on markers of CVD, their cholesterol-lowering effect cannot be used as evidence to support the diet–heart hypothesis. After all, the large reduction in LDL cholesterol levels may be considered as a surrogate measure of the efficiency of HMG-CoA reductase inhibition and its metabolic sequel.

Conclusion

The evidence presented in this article does not support a meaningful relationship between SFA intake and the risk of CVD. Even so, SFAs are not consumed as a single dietary entity, and in the case of milk and its products they are consumed along with considerable MUFAs and some PUFAs. The high calcium content of milk and dairy products can help lower BP, a major risk factor for CVD. BP levels may also be ameliorated by small digestion-resistant peptides encrypted in milk proteins. A recent meta-analysis of 15 prospective studies on milk and dairy consumption and the risk of CHD and stroke found that the RR for the highest level of consumption compared to low consumption levels was 0.84 (0.76–0.93) for CHD and 0.79 (0.75–0.82) for stroke.

At the time of the follow-up period for these studies, the milk consumed was almost entirely whole milk.

Meta-analyses of a smaller number of prospective studies found that the RRs for high versus low intakes of milk and dairy products and the incidence of type 2 diabetes and the metabolic syndrome, both important risk factors for CVD, were 0.92 (0.86–0.97) and 0.74 (0.64–0.84), respectively. By reducing the intake of milk fat for fear of CVD, individuals are deprived of a range of bioactive components, such as butyric acid, sphingolipids, and rumenic acid, certain branched-chain fatty acids, and fat-soluble vitamins with anticancer potential.

Nutritional and Oral Health-Promoting Properties of Dairy Products: Caries Prevention and Oral Health

H Whelton, University College, Cork, Cork, Ireland

This article is a revision of the previous edition article by E. C. Reynolds, Volume 3, pp 1306–1313, © 2002, Elsevier Ltd.

Introduction

Treatment of oral disease is extremely costly, and it is the fourth most expensive disease to treat in most industrialized countries. Oral diseases and disorders, although largely preventable, are ubiquitous and affect the vast majority of the world's population with varying degrees of severity. The available mechanisms of oral disease prevention are effective at the individual level and have also had success at the population level. However, although the severity of oral diseases has been reduced, they are still highly prevalent and there is scope for development of new approaches to prevention that are less reliant on behavioral change at the individual level.

Dairy products currently do not play a major role in dealing with oral diseases but progress is being made in the identification of dairy constituents and use of dairy products to promote oral health. A general overview of the prevalence of oral diseases precedes a summary of the pathogenesis of dental caries and periodontal disease. This is followed by consideration of research developments in the use of dairy constituents for the prevention of both diseases; other oral conditions are then considered.

Overview

Dental caries is the most common chronic disease of childhood and affects an estimated 95% of the world's population. Periodontal disease, a condition affecting the supporting structures of the tooth, affects an estimated 15% of the population and is most common in older age groups. The third condition, progressive tooth surface loss, although not a disease, is increasingly recognized as a potential challenge to the maintenance of a functioning dentition for life. The prevalence of this condition internationally is not well defined, but in two national surveys tooth wear into dentine was found to affect over one-third of 16- to 24-year-olds and approximately 90% of dentate 65+ year-olds in Ireland and the United Kingdom. Other oral conditions vary in frequency internationally. These include oral mucosal lesions including oral cancer, orodental trauma, denture stomatitis, candidiasis, noma (orofacial gangrene found in Africa and Asia), oral manifestations of systemic disease (e.g., HIV/AIDS), and congenital defects including orofacial clefts. These disorders add to the economic burden of oral disease with varying effect.

Microbes are a contributory factor in the development of the two most common of these conditions, caries and periodontal disease.

Dental Caries

Pathogenesis

Dental caries is a process that involves demineralization of apatite crystals in the tooth and the release of calcium, phosphate, and hydroxyl ions. It is a multifactorial disease and its development is determined by the interaction of three main factors over time (**Figure 1**), namely, host and teeth factors, microorganisms in dental plaque biofilm principally mutans streptococci and lactobacilli, and substrate, predominantly sucrose. Time is also an important factor because, even in the presence of the other three factors, the development of dental caries is a relatively slow process and clinically visible destruction of the enamel (cavitation) may take years to develop depending on age and surface type. The influence of the host is mediated by the saliva; saliva has powerful protective properties providing cleansing, lubrication, pellicle formation (provides a diffusion barrier), antimicrobial action to regulate oral bacteria, an ion reservoir for remineralization of enamel, and buffers to counteract acids in the mouth from bacteria and diet. Within the host, different teeth and tooth surfaces vary in their susceptibility to dental caries, with the majority of caries occurring on the biting and pit and fissure surfaces of the posterior teeth. The approximal surfaces of the posterior teeth are the next most commonly affected. Microorganisms are the second of the three factors necessary for caries to develop. Although many oral bacteria are acidogenic, the Gram-positive facultative anaerobe *Streptococcus mutans* is most frequently associated with the initiation of caries. It is well adapted as an early colonizer of enamel because of its ability to produce

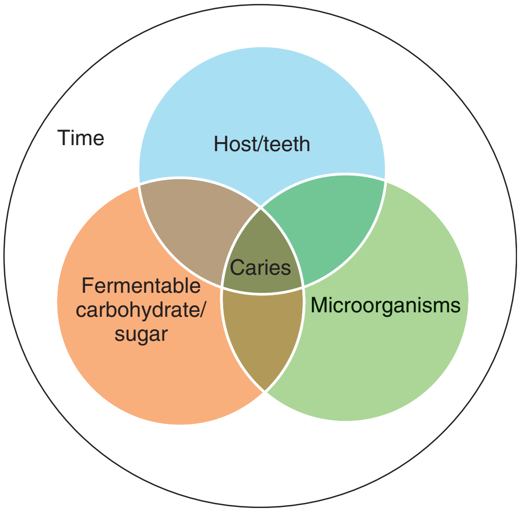

Figure 1 Occurrence of dental caries over time given the interaction of three essential factors.

extracellular dextran-based polysaccharides, which allows it to adhere to the smooth enamel surface. Thus the plaque biofilm starts to form and becomes colonized by other species. Once plaque is present, there is the capacity for dental caries to develop. The plaque biofilm produces acids as the bacteria metabolize fermentable carbohydrates. These acids can dissolve or demineralize the calcium phosphate mineral of the tooth enamel or dentin. Early enamel demineralization is not obvious to the naked eye. As it progresses, the demineralized surface looks white and chalky. If this process is not halted or reversed via remineralization, that is, redeposition of mineral via saliva, it eventually becomes an open cavity and the damage is irreversible.

The third factor is dietary sugars. Following ingestion of fermentable carbohydrate, cariogenic bacteria metabolize disaccharides such as sucrose to monosaccharides which they further metabolise producing lactic acid as a by-product. As a result, plaque pH falls below the critical pH, around pH 5.5, below which enamel demineralization occurs. Plaque pH falls almost immediately after sucrose ingestion and takes up to 40 min to recover; once it recovers, the enamel remineralizes again. Dilution and buffering by saliva play an important role in neutralizing plaque pH. The enamel remains intact so long as remineralization and demineralization are balanced.

Although dental caries is an almost ubiquitous disease, it has declined in severity since the 1960s, largely due to the widespread use of fluorides. The effect of fluoride is largely topical; teeth remineralize faster in the presence of fluoride, and fluoride also interferes with bacterial metabolism. Water fluoridation is the most effective and cost-effective public health measure for the control of dental caries. Currently, approximately 400 million people globally reside in communities served with water supplies containing added fluoride. The effectiveness of fluoride toothpastes is also now well established and it is estimated that over a billion people worldwide use them regularly. Other means of controlling dental caries include reduction in the frequency of consumption of foods and drinks sweetened with sugar and placement of resin sealants on the vulnerable pit and fissure surfaces.

Role of Dairy Products

The cariostatic effects of milk and cheese have been illustrated by animal studies, laboratory studies, and human observational and interventional studies since the 1950s. Some of the anticariogenic properties of milk may be attributable to its calcium, phosphate, casein, and lipid content. Postulated mechanisms involve buffering, salivary stimulation, reduction of bacterial adhesion, reduction of enamel demineralization, and/or promotion of remineralization by casein and ionizable Ca and P. The cariostatic properties of dairy products may result from a combination of the effects described in addition to the action of minor milk proteins and biologically active peptides in the protein fraction and/or that of naturally occurring probiotics.

Whole products

Traditionally milk and cheese are associated with healthy teeth and in the past have been marketed as being good for teeth. Milk, although it contains the natural sugar lactose, is not considered a cause of dental caries; lactose is known as one of the less cariogenic sugars. Early animal studies indicated that supplements of dairy products given with a cariogenic diet lowered the incidence of dental caries in rats. Epidemiological studies in recent years reported that children and adolescents with low incidence of dental caries drank more milk than those with high caries incidence. Frequency of cheese consumption has also been negatively associated with caries experience in 4-year-old children. A lower incidence of root surface caries development has been found in elderly people who eat cheese several times per week. The quantity of milk and milk products consumed has also been negatively associated with the number of root caries events during a 6-year study of 70-year-olds. Milk has even been recommended as a saliva substitute in patients with hyposalivation. The role of milk and dairy products in dental caries prevention has been the subject of a number of reviews. Following its expert consultation on Diet, Nutrition and the Prevention of Chronic Diseases (2003) the WHO/FAO report concluded that there was probable evidence that consumption of hard cheese decreased the risk of developing dental caries and possible evidence that consumption of milk reduced the risk of caries and dental erosion.

Although there have been numerous studies that have suggested a role for whole dairy products in the management of dental caries, an application to the European Food Safety Authority Panel on Dietetic Products, Nutrition and Allergies to deliver an opinion on the scientific substantiation of a health claim related to dairy foods (milk and cheese) and dental health in children received a negative judgment. The panel found that "on the basis of the data presented, a cause and effect relationship has not been established between the consumption of milk or cheese and dental health (prevention of dental caries) in children". The panel considered all studies presented for consideration to have too many weaknesses to allow definitive conclusions in 2008. Although one human interventional study was available for cheese, there was none for milk.

It appears that although dairy products have been identified as having cariostatic factors, the large volume required for a therapeutic effect limits their effectiveness in their natural state. Thus, identification and exploration of dairy derivatives with caries-protective or therapeutic properties for use as food additives or in oral health products has become a focus for researchers.

Derivatives

Dairy peptides

Much of the current research is based on the oral health-promoting potential of peptides and probiotics as they represent areas of interest in the rapidly growing functional food industry. Identification and isolation of the components of dairy products that are protective against dental caries could lead to an enhancement of the oral health benefits and functionality of dairy products or other products to which these components are added.

Cow's milk has two major groups of proteins – caseins (insoluble at pH 4.6), which represent ~80% of the total protein, and whey proteins (soluble in their native forms independent of pH), representing ~20% of total protein. Whey proteins include many minor dairy proteins such as enzymes, enzyme inhibitors, metal-binding proteins, vitamin-binding proteins, and growth factors. The bioactive properties of some of these minor proteins have been identified and they are used in nutraceutical products.

Extensive scientific evidence has illustrated the potential health benefits of biologically active peptides from dairy products. Some of the health-promoting effects are attributed to physiologically active peptides encrypted in, for example, milk and cheese protein molecules. These peptides are inactive within the sequence of the parent protein and can be released during gastrointestinal digestion or food processing. Bioactive peptides can also be produced from milk proteins through fermentation of milk, by starters employed in the manufacture of fermented milks or cheese. In fact, cheese in its natural form contains a huge reservoir of peptides; the technology for isolating these cheese peptides has been developed and future research will determine their bioactivity in the mouth.

One area that is the subject of ongoing research is the caries-preventive capacity of casein phosphopeptides and their use in oral health products and chewing gum. Casein phosphopeptide–amorphous calcium phosphate (CPP–ACP) nanocomplexes, derived from bovine milk protein, casein, calcium, and phosphate, have been proposed as nontoxic, anticariogenic agents that could supplement the effects of fluoride. The suggested anticariogenic mechanism for CPP–ACP is the stabilization of calcium and phosphate as bioavailable ions and localization of calcium and phosphate ions into plaque producing a favorable concentration gradient, thus depressing enamel demineralization and enhancing remineralization. An alkaline, stable, and highly soluble CPP–ACP has been trademarked as Recaldent™ and has been commercialized in sugar-free gum and mints and in dental professional products (Tooth Mousse™).

A 2-year randomized clinical trial of the anticariogenic effect of sugar-free gum containing CPP–ACP nanocomplexes on approximal caries (caries on adjacent contacting tooth surfaces, between the teeth) among a fluoridated low caries risk population has been reported. The double-blind trial was carried out on Australian schoolchildren aged 11–13 years who were asked to chew their assigned sugar-free gum with (test gum ($n = 892$)) and without (control gum ($n = 857$)) 54 mg CPP–ACP per serving for 10 min, 3 times per day. Caries progression on approximal surfaces was estimated on digital radiographs taken at baseline and 24 months using an 8-point ordinal scale. Caries progressed on 5.4% of approximal surfaces in the CPP–ACP gum group compared with 6.5% of surfaces among the control group and there was a significant difference in the frequency distribution of caries transition scores along the 8-point ordinal scale (odds ratio (OR) = 0.82, $p = 0.03$). However, data on the effect of the product on caries on all surfaces among the two groups were not presented, but would be required to determine the overall efficacy of the product and the clinical relevance of the results.

Much of the earlier research on the anticariogenic effect of CPP–ACP was carried out using animal or laboratory-based studies or *in situ* studies using human volunteers who were asked to wear removable appliances containing blocks of artificially demineralized enamel. CPP–ACP has been reported to increase the level of calcium phosphate in plaque, to inhibit *in situ* demineralization of enamel, and to enhance *in situ* remineralization. Although most of the human studies had a small sample size (none exceeding 30) and were conducted under controlled conditions, the results of the Australian studies consistently show that products containing CPP–ACP produce greater subsurface remineralization compared to products with no CPP–ACP and that there is a dose–response effect, with higher doses producing greater remineralization. An independent study compared three calcium-containing chewing gums – two chewing gums (one with zinc citrate and one without) contained dicalcium phosphate, calcium gluconate, and calcium lactate, and one chewing gum contained CPP–ACP nanocomplexes – with a chewing gum lacking calcium. Conversely, this study found no significant difference in average remineralization or lesion depth between various calcium-containing compounds and controls; the authors concluded that the use of chewing gum offers no additional remineralizing benefit to buccal (cheek facing) tooth surfaces, even if the chewing gum contains calcium compounds. However, another study found that CPP–ACP was similar to dicalcium phosphate dehydrate in reducing lesion depth or lesion mineral content and that both products were significantly different from the control.

While the current evidence on the effectiveness of foods containing casein derivatives in remineralizing enamel under real life conditions is encouraging, the evidence is not universally accepted and further human trials are needed.

Fortified products

Milk is supplemented with many nutrients in several countries, i.e. Ca, Vitamin and D, I. Milk fluoridation programs are currently operating in six countries of the world (England, Bulgaria, Macedonia, Russia, Chile, Thailand). Studies on the clinical effectiveness of fluoridated milk in caries prevention have been carried out in several countries using different research methods. A Cochrane review concluded that there are insufficient studies with good quality evidence examining the effects of fluoridated milk in preventing dental caries. Of the two randomized controlled trials (RCTs) that satisfied the review's inclusion criteria, one used 7 ppm fluoride in 200 ml milk and the other used 2.5 ppm fluoride in 180–200 ml milk. These studies also varied in the delivery of fluoridated milk; one used a drinking cup and the other a straw. The results of the RCTs suggested that fluoridated milk was beneficial to schoolchildren, especially to their permanent dentition; however, more well-conducted research is necessary. Another review in 2007 suggested that fluoridation of milk can be recommended as a caries-preventive measure where the fluoride concentration in drinking water is suboptimal, caries experience in children is high, and there is an existing school milk program. It was recommended that the program should aim to provide fluoridated milk for at least 200 days per year and should commence before the children are 4 years of age.

Probiotics are added to food to promote alimentary health. The term probiotic is a relatively new word meaning 'for life' and it is currently used to name bacteria associated with beneficial effects for humans and animals. Probiotics have been isolated from dairy products and they have also been identified from other areas and delivered in dairy products. Both sources are considered here under the umbrella of probiotics and dairy products.

The Food and Agriculture Organization of the United Nations (FAO) and World Health Organization (WHO) have adopted a definition of probiotics as "live microorganisms, which, when administered in adequate amounts, confer a health benefit on the host". Probiotics differ greatly; their mechanism of action is not clearly understood; they are likely to exert their effects through a variety of mechanisms including

1. competitive exclusion; prevention of colonization, cellular adhesion, and invasion by pathogenic organisms;
2. competition for essential nutrients;
3. direct antimicrobial activity, for example, production of bacteriocins; and
4. stimulation of the local and systemic host immune response.

The FAO and WHO suggest that the health benefits for which probiotics can be applied include conditions such as gastrointestinal infections, certain bowel disorders, allergy, and urogenital infections; they also point to emerging evidence to indicate that probiotics can be taken by otherwise healthy people as a means to prevent certain diseases and modulate host immunity.

The most commonly used probiotic agents are bacteria from the genera *Lactobacillus* and *Bifidobacterium*, which form part of the normal healthy intestinal microbiota.

Although the greatest body of probiotic research has focused on the colon, some progress has been made on the application of probiotics to promote oral health. One of the earliest papers on the use of probiotics for oral health was published in Russian in 1996. Since then, numerous probiotic strains have been investigated for their oral benefits. These include *Lactobacillus rhamnosus* GG (LGG), *Lactobacillus rhamnosus* LC705, *Lactobacillus rhamnosus* LB21, *Lactobacillus casei*, and *Lactobacillus reuteri.*

LGG is one of the probiotics investigated for the prevention of dental caries. LGG is a strain of *L. rhamnosus* isolated from the intestinal tract of a healthy human being – GG represents the last names of two of the researchers who identified the probiotic bacterium, Sherwood Gorbach and Barry Goldin. It is particularly effective for the treatment of rotaviral diarrhea and it has also been shown to inhibit cariogenic mutans streptococci. It has also been studied for its effect on dental caries. Milk containing the probiotic LGG may have beneficial effects on children's dental health; LGG is unable to ferment sucrose or lactose, and this property increases its safety for oral use. A randomized double-blind placebo-controlled study ($n = 594$) to measure the effect of consumption of LGG in milk for a period of 7 months on dental caries and caries risk in 1- to 6-year-old Finnish children showed less dental caries in the LGG group and lower mutans streptococcus counts at the end of the study, especially in 3- to 4-year-old children. LGG reduced the risk of caries significantly ($\mathrm{OR} = 0.51$, $p = 0.004$), when controlled for age and gender.

LGG was combined with *L. rhamnosus* LC705 in cheese in another human intervention study in Finland. The study investigated the effect of daily consumption of 5×15 g of the probiotic cheese for 3 weeks on caries-associated salivary microbial counts in young adults. Altogether, 74 participants, who were 18- to 35-year-old subjects, completed this double-blind, randomized, placebo-controlled study. Stimulated salivary secretion rates, buffer capacity, and counts of salivary *S. mutans*, yeast, and lactobacilli were evaluated before and after the intervention and after a 3-week posttreatment period. Although there was no statistically significant difference between the groups in *S. mutans* counts after the intervention, at the 3-week posttreatment examination, these counts were significantly lower in the intervention group compared to the control group ($p = 0.05$). However, *S. mutans* counts decreased in 20% ($p = 0.01$) and yeast counts in 27% ($p = 0.005$) of all the subjects, regardless of the intervention group.

Combining probiotics with fluoride in daily milk drinks has provided encouraging results. Milk fortified with both *L. rhamnosus* LB21 (10^7 cfu ml^{-1}) and 2.5 mg fluoride per liter were found to have significant effects on caries development (prevented fraction 75%) and general health in Swedish 1- to 5-year-old children ($n = 248$) in a cluster-randomized, double-blind trial over 21 months. Children in the intervention group were served 150 ml of supplemented milk for lunch, while the control group received standard milk. Data were collected through clinical examinations and questionnaires. The mean baseline caries experience was 0.5 decayed, missing, or filled primary tooth surfaces (dmfs) in the intervention units and 0.6 in the control units and after 21 months 0.9 and 2.2 ($p < 0.05$). Children of the intervention units displayed 60% fewer days with antibiotic therapy (mean 1.9 vs. 4.7 days) and 50% less days with otitis media (0.5 vs. 1.0) ($p > 0.05$). No serious side effects were reported.

It may be beneficial to add bovine-specific antibodies against mutans streptococci to probiotic LGG-containing milk products. High titers of IgG antibodies against human cariogenic bacteria *S. mutans* and *S. sobrinus* were produced in bovine colostrum through immunization of pregnant cows with a multivalent vaccine. The purified immune product (IP) of this preparation had a number of anticariogenic properties, such as inhibition of streptococcal adherence to saliva-coated hydroxyapatite and inhibition of glucosyltransferase enzymes. IP added to LGG-fermented milk maintained its antibody activity against cariogenic streptococci during the expected shelf life of the product.

Lactobacillus casei has been evaluated for its caries-protective effects. A study in the early 1980s showed that rats monoinfected with *S. mutans* developed higher levels of caries than rats with greater than 1% *L. casei* in their plaque. *Lactobacillus casei* in a bioyogurt has been shown to inhibit oral streptococci. *Lactobacillus bulgaricus* in yogurt has also been shown to inhibit *S. mutans* when consumed twice daily for 8 weeks.

Lactobacillus reuteri has shown activity against *S. mutans*, when given in yogurt, water, or lozenge form, illustrating the potential for further development of foods containing this probiotic for the control of dental caries.

Current research on probiotics includes characterization of human oral lactobacilli and the selection of potential probiotic strains for oral health. Further strains have been identified that have antimicrobial properties against *Aggregatibacter actinomycetemcomitans*, *Porphyromonas gingivalis*, *Prevotella intermedia*, and *S. mutans*. Thus, research continues to progress in this area, which in the future may have a major impact on the prevention and treatment of oral disease.

Other antimicrobial bacterial products have also been identified and purified from dairy products. An example with potential anticaries activity is lacticin 3147, which is a broad-spectrum lantibiotic produced by the food-grade strain *Lactococcus lactis* DPC3147. A powdered fermentate containing lacticin is effective in inhibiting a range of natural cariogenic *S. mutans* strains, and is effective in reducing this pathogen in human saliva. Further research on its effect on dental plaque biofilm is required to determine the potential of this powder as a nutritional additive for dairy products with the added benefits of preventing dental caries.

A small number of probiotics with potential for reducing caries risk by decreasing the level of *S. mutans* in the mouth have been identified and it is likely that this number will increase in the future as our knowledge and understanding of the area continues to improve. Use of probiotics in combination with other preventive agents has shown promise and is likely to be another avenue for future research. Probiotics may not replace conventional preventive approaches but the incorporation of strains with even slight oral health benefits in commonly consumed foods such as dairy products may provide a useful improvement in oral health at the population level.

Periodontal Diseases

Gingivitis that is initiated by microbial plaque is another very common oral disease affecting the vast majority of the population from time to time. Unlike dental caries, it is usually painless; the disease is characterized by inflamed gingivae, which may bleed on brushing or probing. Removal of plaque and maintenance of good oral hygiene results in resolution of the condition. The disease is modified by several factors, including smoking and hormonal changes such as those seen in puberty or pregnancy. Periodontitis is also initiated by microbial plaque and follows on from gingivitis, but occurs in a lesser proportion of the population than gingivitis. According to the WHO, 10–15% of the adult population worldwide suffer from advanced disease with deep periodontal pockets ($\geq$6 mm). Bacteria associated with periodontal diseases include Gram-negative anaerobic bacteria: among these, *Porphyromonas gingivalis*, *P. intermedia*, *Tannerella forsythensis* (formerly *Bacteroides forsythus*), and *Treponema denticola* are strictly anaerobic and *Aggregatibacter* (formerly *Actinobacillus*) *actinomycetemcomitans* and *Campylobacter rectus* are facultative/microaerobic organisms. Periodontal disease risk is influenced by genetic predisposition, the individual's immune and inflammatory response, and demographic and behavioral characteristics, such as gender, age, race, and smoking, as well as socioeconomic status. Local infection and inflammation of the periodontal ligament, the supporting structure that maintains the tooth in its bony socket, result in progressive destruction of both the ligament and the supporting alveolar bone, leading to various degrees of periodontal attachment loss in affected teeth. These changes are irreversible, but progress can be arrested by effective treatment. Prevention of the disease is centered on plaque control, which is also an important aspect of its treatment. Improving oral hygiene to ensure effective plaque control at a level consistent with disease prevention or treatment usually requires a behavioral change on the part of the affected person. Traditional educational interventions have been shown to be of little value in achieving long-term behavioral change, although there is tentative evidence from low-quality studies that psychological approaches to behavior management can improve oral hygiene-related behaviors. The development or identification of foods or products to help reduce either the quantity or virulence of plaque in the mouth could represent important progress in the management of periodontal diseases.

Role of Dairy Products

Whole products

The importance of minerals (and vitamins) in the prevention of periodontal disease has been investigated both directly and indirectly. The direct approach has involved the study of dietary intakes among populations with and without periodontal disease. While cross-sectional dietary analyses are not ideal in the study of this sporadic and chronic, usually slowly progressing disease, they can indicate where there are dietary components worthy of further research and can be useful for hypothesis formulation. One example is that of the third US National Health and Nutrition Examination Survey (NHANES III), a cross-sectional survey of 12 764 adults, which revealed that increased intake of dairy products was associated with a lower prevalence of periodontal disease. Individuals in the highest quintile of intake of dairy products were 20% less likely to have periodontitis than those in the lowest quintile. The inverse association between consumption of dairy products and periodontal disease was also reported in a cross-sectional study carried out in Japan. A study involving 942 adults showed that those eating $\geq$55 g lactic acid-containing foods per day had a significantly lower prevalence of deep probing depths (PDs) and severe clinical attachment loss (CAL) compared to those not eating these foods, after adjusting for confounding variables; the ORs for generalized deep PD and severe CAL were 0.40 (95% confidence interval (CI): 0.23–0.70) and 0.50 (95% CI: 0.29–0.87), respectively. These studies suggest a protective benefit of dairy products against periodontal disease, but further research is required to clarify this relationship and identify the specific protective factors.

The indirect approach looks at the relationship between bone mineral density (BMD) elsewhere in the body and periodontal disease. Besides exercise, a diet rich in calcium, phosphate, and vitamin D helps to protect against loss of BMD with advancing age. If periodontal disease is related to loss of BMD, then such foods could be considered to protect against osteoporosis as well as periodontal disease. Evidence for an association between BMD and alveolar bone loss has been reported, although some studies failed to find an association.

While there may be scope to fortify foods with vitamins and minerals to promote periodontal health, there is as yet insufficient evidence to support this development. However, recommending foods effective in improving general bone health and preventing osteopenia may be considered useful to promote alveolar bone health.

Derivatives

Compared to research on foods with caries-protective properties, there has been little progress in the development of foods with specific periodontal benefits. Development of probiotics in this area has focused on application of these products as therapeutic agents rather than as dairy food ingredients.

Other Conditions

Tooth surface loss describes the noncarious loss of tooth tissue, one of the causes of which is the consumption of acidic diets including acidic soft drinks. Milk does not have this problematic side effect.

There is some preliminary evidence that probiotic microorganisms can prevent or delay the onset of certain cancers outside the mouth (WHO/FAO, 2001). However, it is too early to make definitive clinical conclusions regarding the efficacy of probiotics in cancer prevention, and further research is required.

The use of probiotics for the control of *Candida albicans* has also been studied. *Candida* is the most frequently isolated yeast genus in the mouth, of which *C. albicans* is the most common species. An estimated 18% of the healthy and 40% of hospitalized people carry *C. albicans*; however, only a proportion of the population colonized by *C. albicans* develop candidiasis. A mixture of probiotics (LGG, *L. rhamnosus* LC705, *Propionibacterium freudenreichii* subsp. *shermanii* JS) delivered in 50 g cheese divided in two portions per day reduced the prevalence of oral *Candida* spp. and diminished the risk of hyposalivation and the feeling of dry mouth in an elderly population over a 16-week period. Over 16 weeks, probiotic intervention reduced the risk of high yeast counts by 75% and decreased the risk of hyposalivation by 56%; this outcome warrants further investigation.

Conclusion

Given the high prevalence of caries, gingivitis, and periodontal disease, the potential impact of new effective approaches to their prevention or treatment is considerable. Dairy products have been investigated for use in this respect for over 50 years. Further well-conducted RCTs are needed to determine the impact of whole unfortified dairy products such as milk and cheese on oral health. The enhancement of dairy products with single agents or combinations of agents can function to prevent or protect against a variety of oral conditions including dental caries, periodontal disease, tooth surface loss, and oral mucosal diseases including candidiasis. Derivatives of dairy products have demonstrated oral health-promoting activity and the potential exists to develop them as oral health-promoting additives for other foods or as therapeutic agents in oral health products.

Given the high prevalence of oral diseases and the cost of treating them, the development of even small preventive or therapeutic effects for commonly consumed dairy products has the potential to have an important impact on the burden of oral diseases at the population level.

Milk Allergy

E I El-Agamy, Qassim University, Qassim, Saudi Arabia

© 2011 Elsevier Ltd. All rights reserved.

Background

It is well known that human milk is the most appropriate food for infants, but when breast-feeding is not possible, milk from other species or infant formula milk is usually used as a substitute for human milk. This substitution can lead to some nutritional and immunological problems. One of these is milk protein allergy. In this context, the term milk allergy (MA) is focused on allergy caused by cow milk proteins because cow MA is one of the most common food allergies in children. Although most children outgrow MA by the age of 4 years, some retain the allergy for life. MA may occur in adults usually involving immediate allergic reactions or eczema. Several population-based studies in different countries have reported that the incidence of MA varies widely from 0.3 to 7.5%. MA occurs in some infants after ingestion of an amount of cow milk. In some cases, allergy to goat and sheep milk or to cheeses made from them has also been recognized.

Definition of Allergy

The word allergy means an altered or abnormal reaction. Such a reaction may occur when there is contact between a foreign protein, 'an allergen', and body tissues that are sensitive to it. The allergen may reach the tissues by direct contact with the skin or mucous membranes or through the bloodstream after absorption.

Types of Allergic Reactions

Allergic reactions have been classified into two types:

- The immediate reaction type in which the allergic manifestations occur within hours of the patient coming in contact with the allergen and often within seconds or minutes; in this form of allergy, skin tests are nearly always positive.
- The delayed reaction type in which manifestations may not appear for many hours or even for 2 or 3 days; in this type, skin tests are usually negative.

Milk Protein Allergy and Intolerance

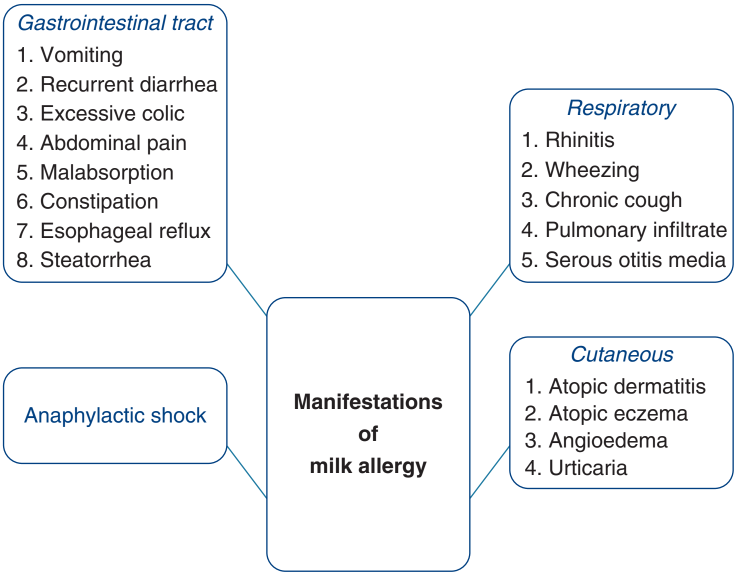
MA is clinically an abnormal immunological reaction to milk proteins, which may be due to the interaction between one or more milk proteins and one or more immune mechanisms, and resulting in immediate immunoglobulin (Ig)E-mediated reactions. On the other side, reactions not involving the immune system are defined as milk protein intolerance (MPI). MPI produces a non-IgE antibody and is not detected by allergy blood tests. Meanwhile, it produces a range of symptoms very similar to MA symptoms, but can also include blood or mucus in the stool.

Clinical Manifestations of Milk Allergy

Symptoms of MA can appear immediately or start several hours or even days after the intake of moderate to large amounts of cow milk or its infant formula. A wide spectrum of clinical manifestations has been recorded with MA (**Figure 1**). Clinical symptoms involve immediate or delayed reactions operating separately or together. Immediate reactions are mainly IgE dependent, leading to cutaneous, intestinal, or respiratory symptoms and in some cases to anaphylactic reaction. Delayed reactions involve T-cell-dependent mechanisms and can be operative at both the skin and the intestinal level. The most frequent symptoms among the common manifestations of MA are gastrointestinal, which have been encountered in 50–75% of patients with MA. Respiratory and skin symptoms are also commonly involved in MA. These symptoms were recorded in 10–30 and 50% of patients with MA, respectively. Rhinitis is the most common respiratory manifestation of MA in some infants. Anaphylactic shock is a particularly serious symptom of MA. In some cases, death can result. Anaphylaxis was noted in 12% of patients with MA, but it was less commonly observed than most other symptoms.

Diagnosis of Milk Allergy

The clinical diagnosis of MA differs widely due to the multiplicity of symptoms. Diagnosis can be achieved by skin or blood tests. The positive blood or skin test is accomplished only with the immediate reactions



Gastrointestinal tract
1. Vomiting
2. Recurrent diarrhea
3. Excessive colic
4. Abdominal pain
5. Malabsorption
6. Constipation
7. Esophageal reflux
8. Steatorrhea
Respiratory
1. Rhinitis
2. Wheezing
3. Chronic cough
4. Pulmonary infiltrate
5. Serous otitis media
Anaphylactic shock
Manifestations of milk allergy
Cutaneous
1. Atopic dermatitis
2. Atopic eczema
3. Angioedema
4. Urticaria

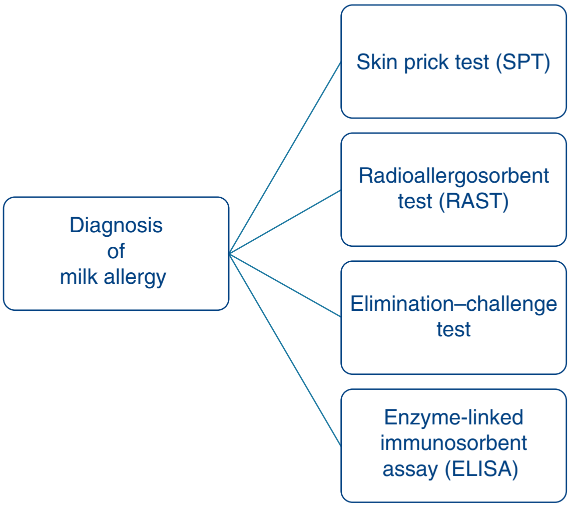
that develop after a few minutes because these tests detect IgE antibodies that are involved in the immediate type reaction. In the young child, about 60% of MA reactions are not of the immediate type but the delayed type (intolerant), and consequently are unlikely to give positive results with blood and skin tests. Different reliable diagnostic tests are shown in **Figure 2**.

Skin prick test (SPT) is especially accurate in the young child. The test is based on IgE being produced in patients when they are exposed to cow milk proteins. Once formed, IgE antibodies reside on the surface of mast cells present in the skin. Therefore, small drops of the suspected milk are placed on the forearm of patients to expose the mast cells present in the skin to the specific allergens (milk proteins). After 15 min, a wheal and flare reaction may appear, revealing that the patient is allergic to milk. Generally, the use of SPT for the diagnosis of MA cannot be considered reliable unless a strong reaction is noted. If it is desired to know to which particular protein the allergic individual is sensitive, then purified proteins must be used. Meanwhile, a 'patch' test may be more sensitive than SPT. There is no minimum age for SPT, which can be performed in babies and older children with useful results.



Diagnosis of milk allergy
Skin prick test (SPT)
Radioallergosorbent test (RAST)
Elimination–challenge test
Enzyme-linked immunosorbent assay (ELISA)

Figure 2 Methods for the diagnosis of milk allergy.

Radioallergosorbent test (RAST) and enzyme-linked immunosorbent assay (ELISA) are being used frequently to give more reliable results. Both measure the levels of IgE in the blood serum of the patient. In elimination–challenge test, allergy is confirmed if elimination of cow milk and products containing cow milk from the diet results in symptomatic improvement and if reintroduction of cow milk causes recurrence of symptoms.

Recently, a combination of assays was used for MA diagnosis, such as proliferation assay of peripheral blood mononuclear cells to cow milk, the quantitation of tumor necrosis factor-α (TNF-α; one of the mediators involved in adverse reactions to cow milk proteins), and serum-specific IgE determination. These assays are useful to identify MA among patients with immediate and nonimmediate adverse reactions, and they reduce the need for allergen challenges in young children.

Types of Milk Protein Allergens

Cow milk contains more than 20 protein allergens that can cause allergic reactions. The main proteins are caseins and whey proteins. Casein fractions (α_{s1}-casein, α_{s2}-casein, and

β-casein) and β-lactoglobulin (β-Lg) are the main allergens in cow milk. Allergic reactions to bovine serum albumin (BSA), IgG heavy chain, and α-lactalbumin (α-La) were also noted. Genetic polymorphisms of milk proteins play an important role in MA development. Goat milk with the α_{s2}-casein genotype caused less intestinal and systemic sensitization than goat milk with the α_{s1}-casein genotype in guinea pigs. This is very interesting and may have great potentials in selecting goat breeds for different casein genotypes, especially for α_{s2}-casein, which is not found in cow milk, and against α_{s1}-casein, which is dominant in cow milk. Allergic responses to lactoferrin and some cow milk enzymes have been detected in some patients with MA but none to mammalian lysozyme. The balance between casein and whey proteins in cow milk may determine its allergenicity. Allergenicity to goat and sheep milk caseins and cheese has been reported from some patients.

Infant Formula

Infant milk formula is an alternative cow milk substitute in which the protein is a hydrolyzed cow milk protein or goat milk protein. Casein, whey, or soy protein is hydrolyzed by proteolytic enzymes to develop a number of casein, whey, or soy protein hydrolysates. The products have been classified according to the degree of protein hydrolysis as extensively or partially hydrolyzed protein products. Casein hydrolysates have been used for almost 50 years, whereas whey hydrolysates are a more recent alternative. Both casein and whey hydrolysates appear to have a similar clinical tolerance. Generally, infant formulae can be classified into three categories:

Extensively hydrolyzed formula (EHF): This is a cow milk-based formula that has been treated with proteolytic enzymes. This formula often has a poor flavor and the taste may be bitter; however, it is recommended as a first alternative in children with MA before using other formulae. EHF is different from the partially hydrolyzed formula, since the latter is not indicated as a supplement for cow milk allergic children. In Italy, formulae made from goat milk are used and recommended by some physicians for feeding babies with MA.

Amino acid-based formula: This is another cow milk-based formula. It is necessary in around 10% of MA children who are allergic to EHF.

Soy formula: Soy formulae offer equivalent nutritional benefits to EHF but are more palatable. Soy formulae are not recommended for all cases of MA infants, since 17–47% of milk allergic infants can have adverse reactions to soy. However, around 53–83% of MA children can tolerate soy-based formula.

Alteration of MA

Different attempts have been made to reduce the allergenicity of cow milk proteins, and various technological processes have been applied in order to have better use of cow milk in infant formulae.

Heat treatment: Applications of prolonged heat have been made to modify the protein components of cow milk in an effort to reduce their allergenic potential. It was found that heating milk at 120 °C for 15 min did not affect the antigenicity of caseins from cow, buffalo, or goat milk. Heating bovine whey protein at 100 or 115 °C for 30 min resulted in no sensitization of guinea pigs or anaphylaxis. Heating of goat milk at 100 °C for 30 min resulted in alteration of BSA and IgG, whereas the antigenicity of α-La and β-Lg was not affected by heat treatment. Allergenicity of bovine β-Lg is affected by heat treatment, since rats immunized with native β-Lg had higher levels of total serum IgE than those immunized with heat-denatured β-Lg.

Enzymatic treatment: Another attempt to reduce allergenicity of milk proteins was by enzymatic treatment with a variety of enzymes. However, it was found that products resulting from enzymatic treatment have not had acceptable taste due to the development of bitterness and off-flavors, which are attributed to the liberation of peptides and amino acids from proteolysis. Meanwhile, the proteolytic digestion might itself generate new antigenic substances. It was reported that partial digestion of bovine milk with pepsin, or pepsin and trypsin resulted in peptides that belonged to β-Lg and which bound IgE from patient's sera with MA. The antigenicity of bovine β-Lg and α-La decreased by treatment with soybean trypsin inhibitor for 1 h, while BSA and Igs were more stable.

It was found that the effect of peptic or tryptic treatment on the allergenicity of goat milk proteins was different. Goat casein lost its own antigenicity by pepsin or trypsin treatment for 3 h, whereas goat α-La lost its whole antigenicity by pepsin but not by trypsin treatment. On the other hand, goat β-Lg antigenicity was not altered by either pepsin or trypsin treatment for 3 h.

Human Milk Proteins and Their Alternatives

Human milk proteins are different in their composition and structure from those of the milk of other species. It is known that the major whey proteins of bovine milk are β-Lg with 55% of total whey proteins, α-La with 20%, and BSA with 7%. These proteins differ in their types and ratios between goat, sheep, cow, camel, human, and buffalo milk. Human milk is free of β-Lg, one of the major allergens in cow milk, similar to camel milk, which also has no β-Lg. On the contrary, β-Lg is a major whey protein in cow, buffalo, sheep, and goat milk. Caseins in the milk of these species differ in fraction number and their charges, amino acid composition, and their peptide mappings. β-Casein is the major (70%) casein fraction in goat milk, while α_s is the minor one (30%), which is more like that of human casein and different from cow casein. β-Casein was more sensitive in goat and human casein to the action of pepsin than α_s-casein. The peptide mappings of goat and camel milk α-La and β-Lg are completely different from those of cow milk.

Several studies have evaluated the clinical use of milk from different animals such as cow, goat, camel, sheep, mare, donkey, and buffalo as alternatives to human milk. Some studies revealed that goat, donkey, and camel milk can be considered as proper alternatives to human milk due to hypoallergenic properties of their proteins. On the other hand, other studies have shown that the milk of goat, sheep, and buffalo cannot be useful in all cases as alternatives to human milk, because they can be as allergic as cow milk.

Milk Protein Cross-Reactivity

Cross-reactivity between milk allergens from different mammalian species and humans occurs when they share part of their amino acid sequence or when they have a similar capacity to bind specific antibodies due to their molecular structures. The cross-reactivity between milk proteins from different animal species has been studied. It was found that IgEs from sera of children allergic to cow milk are capable of recognizing most parts of milk proteins from sheep, goat, and buffalo. Weak cross-reactivity was observed with milk proteins from mares and donkeys, but none with camel milk. IgEs from a child allergic to sheep milk did not recognize any proteins of camel milk. Cross-reactivity between α_s-caseins from goat, sheep, and cow milk and their allergic potential were studied. In the three types of milk, α_s-casein was sharing more than 85% identical amino acids. When sera of allergic children to cow milk proteins were tested, significantly higher levels of IgE and IgG binding to goat and sheep α_s-casein were recorded, supporting a conclusion that goat and sheep α_s-caseins have an allergic potential and are not always suitable for the nutrition of cow milk allergic patients. Another study showed cross-reactivity between goat and human caseins, when anti-goat casein was used in immunoblotting technique. No cross-reaction between human α-La and antibodies against bovine α-La was detected. However, it was noted that human α-La is highly homologous to bovine α-La with 66% identity. Cross-reactivity between β-Lg and casein from cow and goat milk was detected by immunoblotting technique. It was reported that guinea pigs fed cow milk proteins and goat milk proteins with high α_{s1}-casein content developed high titers of anti-β-Lg, IgG1, with an important cross-reactivity between goat and cow β-Lg. A recent study showed that when specific antisera to camel milk proteins were applied in immunoblotting analysis, no immunological cross-reactivity between camel and cow milk proteins was found. Similar results were obtained when sera from some children allergic to cow milk were tested for the specificity of their IgE to camel milk casein or whey proteins (**Figure 3**). The study concluded that the absence of immunological similarity between camel and cow milk proteins can be considered an important criterion from the nutritional and clinical points of view, since camel milk may be suggested as a new protein source for the nutrition of children allergic to cow milk and can be used as such or in a modified form.

Introduction

Type 1 diabetes (formerly called insulin-dependent diabetes mellitus (IDDM)) is an autoimmune disease that presents as a loss of insulin production, often in younger members of the population. It is also known as juvenile-onset diabetes. Type 1 diabetes affects less than 1% of the population, although the incidence of the disease varies considerably between countries and ethnic groupings. The exact cause of type 1 diabetes is currently unknown; however, the disease is genetically linked: those individuals with alleles that predispose them to diabetes may get the disease, while those individuals without such alleles will not get it. It is believed that for individuals to develop diabetes they must be genetically predisposed to the disease and also be subjected to one or more environmental triggers. A number of triggers have been proposed, including viral and bacterial infections, exposure to chemicals, and the consumption of certain food types. Of the food types, special attention has been given to cows' milk because of its relatively early introduction into the diet and its role in infant formulae as a replacement for breast milk. There are studies that show an effect of cows' milk on the incidence of human diabetes, but a similar number of studies show that milk has no effect on the development of diabetes. The main evidence in support of an effect of the consumption of cows' milk on type 1 diabetes is epidemiological. Many of the major proteins in milk have been implicated as possible triggers of type 1 diabetes.

Type 2 diabetes (formerly called non-insulin-dependent diabetes mellitus (NIDDM)) is found at a much higher frequency than type 1 diabetes and affects over 5% of the population, although, as with type 1 diabetes, the incidence varies between countries and ethnic groupings. Unlike type 1 diabetes, which results from a problem with insulin production, type 2 diabetes is characterized by insulin resistance, or a problem with the way cells respond to insulin. In its early stages, type 2 diabetes can be managed through modifications of diet and exercise. Type 2 diabetes, like type 1 diabetes, is genetically correlated, but in contrast to type 1 diabetes the environmental factors that trigger type 2 diabetes are well known, with poor diet, a lack of exercise, and obesity promoting an alarming increase in the frequency of the disease. Approximately 90% of all cases of diabetes are type 2, with the frequency increasing in parallel with the increase in metabolic syndrome – a cluster of health risk markers including obesity, atherogenic lipoprotein profile, insulin resistance, and hypertension. Milk and dairy product consumption is inversely associated with insulin resistance and type 2 diabetes, although the underlying mechanism is yet to be established.

Type 1 Diabetes

Type 1 diabetes results from the progressive destruction of insulin-producing pancreatic β cells, which leads to the development of hypoinsulinemia and hyperglycemia. Although type 1 diabetes is genetically linked, identical twins are only ~40% concordant for the disease, suggesting that environmental factors are very important in triggering the disease. As cows' milk is a major component of infants' diets and is used almost universally as a replacement for breast milk in infant formulae, it has been scrutinized as a possible trigger of type 1 diabetes. An international meeting devoted to the subject of cows' milk and type 1 diabetes concluded in 1999 that there was nothing unique about cows' milk and that a number of different food types may be diabetogenic. Thus, the consumption of cows' milk may influence the development of type 1 diabetes in genetically susceptible humans, but many other foods could be expected to act in a similar manner. Despite the widespread acknowledgment that the induction of type 1 diabetes is multifactorial, the intense interest in cows' milk (the so-called 'cows' milk hypothesis') has overshadowed the other factors. It is possible that this intense attention paid to the effect of cows' milk on diabetes has led to a type 1 statistical error, leading to an overestimation of the effect.

Epidemiological Evidence for the Cows' Milk Hypothesis of Type 1 Diabetes

Between-country comparisons of the per caput consumption of milk and dairy products (inferred from national consumption data) and the incidence of type 1 diabetes have been proposed as evidence that milk is involved in some way in triggering this disease. Other evidence used to support the cows' milk hypothesis is based on comparisons of the incidence of type 1 diabetes in children who were breastfed for a prolonged period with that of children where infant formula was introduced into the diet before 3–6 months of age. In addition, some studies have reported higher levels of blood serum antibodies to certain milk proteins in children with type 1 diabetes than found in normal, age-matched children. The conclusions drawn from comparisons of breast-feeding with infant formula feeding have been challenged: a number of studies have been unable to find an effect of the early introduction of cows' milk on the induction of type 1 diabetes. Similarly, there is evidence that there are no specific differences between antibody levels to certain milk proteins in diabetics versus healthy controls. It should be noted that studies investigating antibodies to cows' milk need to take into account the possibility of diabetics being more immunosensitive than the control group. Meta-analyses of all the evidence for an effect of early introduction of cows' milk into the infant diet on type 1 diabetes found the effect to be statistically significant. However, and most importantly, epidemiological studies do not provide evidence for cause and effect and more specific mechanistic evidence is needed to establish whether cows' milk consumption is a factor in the induction of type 1 diabetes, or is merely correlated with some other as yet unidentified factor.

Animal Feeding Experiments and Type 1 Diabetes

Some animal model feeding studies have shown a significant effect of milk protein on the incidence of diabetes, whereas other studies have found that milk proteins have no influence on the occurrence of diabetes. If animal models of type 1 diabetes do represent good models of the human disease, then the timing of the introduction of milk protein into the diet and its interaction with other dietary components might be important in determining if it can influence the development of diabetes. The non-obese diabetic mouse (NOD mouse) and the biobreeding rat (BB rat) are the two animal models of choice for studying type 1 diabetes.

Some researchers have reported a high incidence of diabetes in NOD mice when they were fed a diet containing β-casein A1 but not when fed a diet containing β-casein A2. However, multinational interlaboratory studies using BB rats and NOD mice found that there was a significantly higher incidence of diabetes in rodents fed a cereal-based diet containing no milk components than in rodents fed diets containing milk components. With the exception of the cereal diet, individual laboratories did not produce consistent results. Results from animal feeding experiments indicate that even if milk proteins do contribute to the triggering of diabetes, it is likely that there would be little effect on the level of diabetes in the population if milk were to be removed from the diet, due to the consumption of other foods, particularly some cereals, that are equally likely to be triggers for diabetes.

Work with BB rats has shown that the stimulation of diabetes by diet is not a trigger-like process, but is cumulative and dose dependent. This finding is consistent with epidemiological studies on humans showing increased type 1 diabetes with increased per capita consumption of milk or per capita consumption of β-casein A1.

Evidence for the Involvement of Milk Proteins in Type 1 Diabetes

Of the proteins in milk suspected to be involved in the triggering of type 1 diabetes, bovine serum albumin (BSA), β-casein, and bovine insulin have received most attention.

Bovine serum albumin

The proposed link between BSA and type 1 diabetes is based on observations of elevated levels of anti-BSA antibodies in the blood of subjects with type 1 diabetes when compared with controls. It is proposed that, upon digestion, a peptide called ABBOS, which corresponds to BSA residues 126–144, is released and that the ABBOS peptide enters the bloodstream and causes the production of an immunoglobulin G (IgG) antibody that is specific for this peptide, but which also cross-reacts with a protein on the surface of the insulin-producing islet cells in the pancreas, targeting these cells for destruction. Through a process of molecular mimicry and autoimmunity, the insulin-producing capacity of the body is destroyed. However, the proposed relationship between BSA and type 1 diabetes has not been supported by the results from recent studies.

β-Casein

A specific T lymphocyte-mediated immune response to β-casein has been shown in diabetics, but not in normal humans. As with BSA, it has been proposed that exposure to cows' milk triggers anti-β-casein antibodies, which may cross-react with proteins on the surface of islet cells in the pancreas, leading to their destruction. However, other research showing that an elevated cellular immune response to β-casein was not specific to diabetics does not support this hypothesis.

There is epidemiological evidence that the consumption of β-casein variants with a histidine at position 67 (the A1-type genetic variants, which include A1 and B; also the minor variants C, F, and G) is highly correlated with type 1 diabetes. The consumption of other common variants of β-casein (A2 and A3) was not significantly correlated with type 1 diabetes. It is important to note that only 10 countries were included in the study and a number of unsubstantiated assumptions were made. The sample of cows phenotyped or genotyped for β-casein variants in each country was assumed to be representative of that country's milk supply, and the per capita consumption of milk protein (inferred from disappearance data) may not be representative of the consumption of milk protein by children within the countries examined. Many other countries were excluded from the study because of significant milk imports (which will distort derived consumption data), inadequate data on β-casein variants in the national dairy herd, or inadequate reliable data on diabetes incidence. Other evidence for an effect of the β-casein A1 variant comes from the animal feeding experiments described above.

Bovine insulin

Human insulin autoantibodies are generally observed to be present during the progression of an individual from a normal state to type 1 diabetes. Elevated levels of antibodies to bovine insulin have been observed in newly diagnosed patients suffering from type 1 diabetes. It is proposed that the presence of bovine insulin in infant formula and milk will stimulate the production of anti-bovine insulin IgG, which will then lead to immunization against human insulin. Evidence for such a mechanism is currently very limited and further research in this area is needed before this hypothesis can be critically assessed.

Possible Mechanisms Triggering Type 1 Diabetes

Molecular mimicry

Molecular mimicry has been proposed as a possible mechanism by which proteins present in milk induce the immune system to produce antibodies that are cross-reactive with either surface proteins on the insulin-producing cells or with human insulin produced by these cells.

Oral tolerance

Another mechanism may involve a breakdown in the oral tolerance mechanism. Oral tolerance usually results in the development of immune tolerance to antigens of dietary origin. It has been proposed that a breakdown in oral tolerance can be induced by the constituents of milk and other foods, or bacterial/viral infections. The proinflammatory immune response associated with the breakdown in oral tolerance could then make the digestive tract more permeable to food and other antigens. These antigens could in turn cause a breakdown in the self-recognition immune process, possibly through molecular mimicry.

Bioactive peptides

Milk proteins can release a number of bioactive peptides upon digestion. There is *in vitro* evidence that β-caseins A1 and B release a 7 amino acid bioactive peptide β-casomorphin-7 (BCM-7) in the presence of digestive enzymes, whereas β-casein variants A2 and A3 do not release this peptide. BCM-7 has been shown by various groups to have marked bioactivity, including immune modulation and opiate activity.

Selective release of BCM-7 from β-casein A1-type variants is believed to be due to a single amino acid change at position 67 in the 209 amino acid sequence of this protein. β-Casein A1-type variants have a histidine at this position and β-casein A2-type variants have a proline at this position. The presence of the proline causes a structure that cannot be hydrolyzed by digestive enzymes at the 66–67 peptide bond. Human β-casein has a proline at the equivalent position in the sequence, suggesting that BCM-7 is not released during the digestion of human milk.

BCM-7 has been observed to have a marked inhibitory effect on immune cell activity in NOD mice and extracted immune cells from NOD mice and prediabetic humans. In contrast, BCM-7 appeared to activate immune cell function in normal mice and normal humans. The administration of naloxone (a μ-receptor blocker) eliminated the effect of feeding β-casein A1 milk on the induction of diabetes in NOD mice. It is proposed that this is due to the blocking of the binding of BCM-7 to the μ-receptor on cells.

The role of β-casein and BCM-7 in the promotion of type 1 diabetes and other diseases is controversial. However, based on the current balance of scientific evidence, it is unlikely that β-casein or BCM-7 promotes the development of type 1 diabetes. It is also important to note that any cereal that contains gluten (including rye, wheat, and barley) is also capable of releasing exorphin peptides upon digestion, and that more NOD mice and BB rats developed diabetes when fed diets containing these cereals than when fed diets containing milk protein.

Camels' Milk and Type 1 Diabetes

There is some evidence to suggest that camels' milk may have a protective effect for type 1 diabetes. A small population study of an area in India where camels' milk is commonly consumed showed zero incidence of diabetes in camels' milk-consuming members ($n = 501$), while the incidence of diabetes in a control group consuming no milk was 5.5% ($n = 529$). Other studies have shown that consumption of camels' milk by type 1 diabetic subjects results in a decreased requirement for insulin. The mechanism of this effect is not known, but it has been proposed that the effect may be due to high levels of insulin in camels' milk and because camels' milk does not coagulate in the stomach and transits rapidly to the intestine, making intact insulin potentially available.

Absence of Breast Milk and Type 1 Diabetes

A mechanism based on the absence of breast milk rather than the presence of cows' milk has been proposed as a possible cause of type 1 diabetes. In such a mechanism, various factors, such as growth hormones and cytokines in human milk, would normally be required for the development of the systemic and/or gut immune system. When these factors are not present, the immune system does not develop as required, rendering genetically predisposed individuals susceptible to the development of IDDM. Currently, there is little evidence to support such a mechanism.

It is possible that elements of any or all of the proposed mechanisms could play a role in the induction of IDDM. It is also possible that there is nothing unique about cows' milk and that a number of different food types may be just as diabetogenic. Correlations with cows' milk may simply exist, as this is often the first food encountered after or in replacement of breast milk. They may also be found just because researchers are continually looking for them. Replacement of cows' milk with milk substitutes may thus have little influence on the development of IDDM in susceptible individuals.

Type 2 Diabetes

Metabolic syndrome is a serious international health problem and appears to be increasing in frequency. Metabolic syndrome is predictive of type 2 diabetes, as well as coronary heart disease. It is estimated that by 2025 there will be over 300 million people with type 2 diabetes, a doubling of the current level. Another disturbing trend is the increase in type 2 diabetes frequency in children, believed to result from poor diet and a lack of adequate exercise.

Diet and Type 2 Diabetes

Maintenance of a healthy weight through proper nutrition, exercise, and consequential energy balance is generally accepted as the best way to avoid type 2 diabetes. There is mounting evidence that the consumption of dairy products can help to prevent metabolic syndrome, insulin resistance, and type 2 diabetes. Combined data from four cross-sectional studies showed an inverse relationship between dairy intake and prevalence of type 2 diabetes when dairy foods were consumed at levels of between 3 and 4 serves per day (odds ratio 0.71; 95% confidence interval 0.57–0.89). A modest effect was observed in the meta-analysis of prospective studies. Recent observational studies have shown a variety of effects of dairy and milk consumption on type 2 diabetes, from a strong inverse relationship to no effect on incidence.

The mechanism by which milk and dairy products can provide a level of protection against type 2 diabetes is yet to be established. The calcium and vitamin D contents of milk and dairy products have been proposed as one of the mechanisms for the observed protective effects of milk and dairy products. Investigators have examined the effect of calcium and vitamin D on type 2 diabetes in studies focusing on supplement use, biochemical measures of calcium status, and dairy food intake (measured by serves eaten). Vitamin D is reported to have a supportive role in pancreatic β-cell function and extracellular calcium regulation. Calcium levels have been shown to have effects on insulin secretion and insulin action. The vitamin D and calcium contents of milk are the most discussed, but may not be the only mechanisms by which cows' milk and dairy products affect type 2 diabetes, and it is important not to focus only on the calcium and vitamin D contents of milk without consideration of a possible role of other components found in dairy products.

Other hypothesized mechanisms for the effect of dairy consumption on type 2 diabetes include

- magnesium as a cofactor for enzymes involved in glucose metabolism;
- the digestion of milk proteins, releasing insulinotropic peptides, amino acids, and incretin hormones;
- dairy fat contains medium-chain fatty acids which have a positive effect on insulin sensitivity;
- dairy foods have a relatively low glycemic load; and
- dairy proteins may enhance satiety, helping to maintain energy balance.

One study also found that the omega-3 fatty acids from milk were associated with a lower incidence of type 2 diabetes.

Galactosemia

A Flynn, University College, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Galactose is an energy-providing nutrient and also a necessary basic substrate for the biosynthesis of many macromolecules in the body. Galactose is an important constituent of the complex polysaccharides, which are part of cell glycoconjugates, key elements of immunological determinants, hormones, cell membrane structures, endogenous lectins, and numerous other glycoproteins. In addition, galactose is incorporated into galactolipids, which are important structural elements of the central nervous system.

Metabolic pathways for galactose are important not only for the provision of these macromolecules but also to prevent the accumulation of galactose and galactose metabolites. Problems with galactose metabolism that result in galactosemia can cause a variety of clinical manifestations in humans.

Dietary Sources of Galactose

The principal dietary sources of galactose are milk and milk products, in which it occurs mainly as a component of lactose. Galactose can also be derived from lactose used as an extender in drugs.

Small amounts of galactose are present in cereals, fruits, legumes, nuts, organ meats, seeds, and vegetables in either the free form or bound in various glycosidic linkages and as a component of lipids. Considerable amounts of free galactose occur in some legumes (dried beans and peas), and bound galactose, in various glycosidic linkages, such as α-1,6, β-1,3, and β-1,4, and as a component of lipids, is ubiquitous in animals and plants. The bioavailability of these bound forms of galactose is unknown. Foods fermented by microorganisms for preparation or preservation purposes may contain free galactose.

Galactose Metabolism in Humans

Galactose is released (together with glucose) from lactose in the small intestine by the action of β-galactosidase (lactase) and both monosaccharides are absorbed by an active transport mechanism across the gut wall into the blood. The brush border of the human small intestine contains a sodium-dependent carrier, which is shared by glucose and galactose, and interaction between the carrier and a localized sodium pump allows the monosaccharides to be actively concentrated within the cell.

Hydrolysis of lactose by lactase is believed not to limit the rate of galactose absorption in lactose-tolerant humans. However, the absorption of both galactose and glucose is slower when ingested as lactose than when ingested as a mixture of monosaccharides. It is not clear why this should be so. In lactose-intolerant subjects, the absorption of galactose and glucose is much slower when ingested as lactose than when ingested as hydrolyzed lactose because lactose hydrolysis by intestinal lactase is rate-limiting.

The main route of metabolism of absorbed galactose is the Leloir pathway (**Figure 1**), which involves four enzymes and results in the overall conversion of galactose to glucose-1-phosphate. This metabolic pathway is critical for cellular energy production, modification of cellular macromolecules, for example, glycoproteins and glycolipids, and normal human development. UDP galactose is an important donor of galactose via galactosyl transferase reactions to form glycoproteins and glycolipids.

The liver is the primary site of the Leloir pathway but this pathway is also present in other tissues, including the kidney and erythrocytes. The congenital absence or inactivity of any of the first three enzymes of this pathway results in the clinical condition galactosemia.

There are three minor pathways for galactose metabolism in humans. The Isselbacher pathway involves conversion of galactose-1-P to UDP-galactose by the enzyme UDP-galactose pyrophosphorylase.

Reduction of galactose to the sugar alcohol galactitol is catalyzed by aldose reductase; this reaction is important in the development of cataracts in people suffering from galactosemia. Human tissues have only a limited capacity for further metabolism of galactitol.

Dehydrogenation of galactose produces galactonic acid, which can be detected in the urine of both galactosemic and nongalactosemic subjects after a galactose load.

Molecular cloning and characterization of all three human galactose metabolic genes have led to the identification of a number of mutations that result in three forms of galactosemia, which are caused by deficiency of the kinase (galactokinase (GALK)), the transferase (galactose-1-P:uridyl transferase (GALT)), or the epimerase (UDP-galactose-4 epimerase (GALE)). Of these, GALT deficiency, referred to as 'classical galactosemia', is the most widely studied. All forms occur as inborn

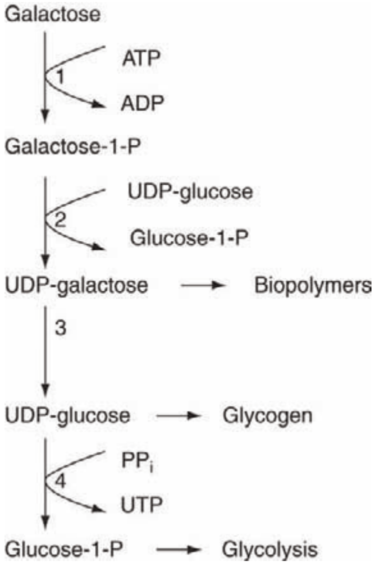

Figure 1 The Leloir pathway for galactose metabolism. 1, Galactokinase; 2, galactose-1-P:uridyl transferase; 3, UDP-galactose-4 epimerase; 4, UDP-glucose-pyrophosphorylase.

errors of galactose metabolism. Tolerance of galactose is reduced and the ingestion of galactose results in a chronically elevated blood galactose concentration with the subsequent accumulation and/or excretion of galactose and galactose metabolites. All conditions can be treated by means of a galactose-free diet.

Classical Galactosemia

Classical galactosemia is an autosomal recessive disorder due to a deficiency of GALT; ingested galactose can be phosphorylated to galactose-1-P but not metabolized further, and this results in the accumulation of galactose and galactose-1-P in tissues. GALT is immunologically intact although enzymatically defective; thus, a structural gene mutation is involved. At the cellular level, galactose-1-P interferes with the metabolism of glucose and the synthesis of glycoproteins and glycolipids and reduces the level of ATP in the cell.

Occurrence

The worldwide incidence of classical galactosemia is estimated at about 1:70 000. However, the incidence varies between countries – Norway, 1:96 000; Sweden, 1:81 000; Switzerland, 1:58 000; Germany, 1:40 000; United States, 1:62 000 – varying from 1:30 000 to 1:191 000 in different populations. In Japan and China, only a few cases have been detected, and in Japan, classical galactosemia is thought to be only one-twentieth as frequent as it is in Caucasian populations of the United States. A high incidence of 1 in 480 has been reported in the Traveller group (an endogamous group of commercial industrial nomads within the Irish population) in Ireland, compared to 1 in 30 000 among non-Traveller communities in Ireland.

Symptoms

Galactose-1-P accumulates in the newborn in various tissues when lactose or galactose is ingested. Galactosemic infants appear normal at birth but subsequent to milk ingestion they develop symptoms, including liver malfunction (hepatomegaly, jaundice), cataract, cerebral edema, mental retardation, renal damage, failure to thrive, and susceptibility to sepsis. Failure to thrive is the most common initial clinical symptom of galactosemia. Vomiting or diarrhea usually begins within a few days of milk ingestion. Jaundice of intrinsic liver disease may be accentuated by the severe hemolysis occurring in some patients. Cataracts have been observed within a few days of birth. There appears to be a high frequency of neonatal death due to *Escherichia coli* sepsis, with a fulminant course. Except for cataract (see later), the underlying pathophysiology of these effects is poorly understood.

Treatment

Early introduction of a galactose-free diet restores normal growth and can prevent permanent liver damage and halt (or sometimes reverse) cataract development. However, mental retardation is irreversible if a galactose-free diet is not introduced within 2–3 months.

While a galactose-restricted diet free of lactose is lifesaving in patients with GALT deficiency, it is now recognized that this does not prevent long-term complications such as developmental delay, mental disability and neurological syndromes, speech defects, poor growth, and, in females, ovarian failure. Most subjects have cognitive impairment.

The cause of the unsatisfactory outcome of seemingly good control of galactose intake and the disturbances in long-term development despite treatment is unclear. Possibilities include chronic intoxication by galactose metabolites, deficiency of galactose-containing glycoproteins and/or glycolipids as a result of an overrestrictive galactose-free diet, or alteration in the glycosylation process of glycoproteins and glycolipids.

Well-treated galactosemics retain a low level of red cell galactose-1-P, which is nevertheless much higher than the almost undetectable levels in normal subjects, and which increases if the patient departs from the prescribed diet. It is unknown how the galactosemic individual maintains this base level of galactose-1-P, whether from hidden galactose in the diet or through galactose biosynthesis from glucose, or both.

Lactose, found in dairy products and as an extender in drugs, has been considered to be the primary source of galactose in the diet. However, small amounts of galactose are present in organ meats and many plant foods, including cereals, fruits, legumes, nuts, and seeds. The role of free and bound galactose in these foods in the poor outcome seen in some patients with GALT deficiency is unknown. However, since galactose is widespread in foods, it is unlikely that the lactose restriction for patients with GALT deficiency ensures a galactose-free diet.

It is also possible that endogenous production of galactose may contribute to the base level of galactose-1-P. There is evidence that galactosemic patients, as well as normal subjects, synthesize gram quantities of galactose per day and it has been suggested that this may be an important factor in the pathogenesis of the complications of the brain and ovary in treated galactosemics.

Ovarian Failure

It has been found that the mammalian ovary is particularly susceptible to damage from the accumulation of galactose and galactose metabolites. Gonadal dysfunction, specifically hypergonadotropic hypogonadism with ovarian atrophy, in female galactosemics is an almost universal symptom and because of this, pregnancy is rare in women with classical galactosemia. The consequences range from failure of pubertal development, through primary amenorrhea or premature menopause. In contrast, male galactosemics have a relatively low risk of gonadal dysfunction.

Several candidate toxic states may be involved, including the galactose metabolites galactose-1-P and galactitol, and proposed mechanisms include interference with ovarian apoptosis and gonadotropin signaling. It has also been suggested that this complication may be at least partly prenatal in origin and studies in animal models suggest that ovarian dysfunction may have been caused *in utero*. Current dietary restrictions of galactose are inadequate to prevent ovarian failure.

Cataract

The mechanism by which cataract develops in subjects with galactosemia has been elucidated by studies in experimental rats. The primary cause of cataract is the chronic elevation of plasma galactose concentration resulting in a high concentration of galactose in the lens of the eye. Galactitol, formed in the lens from galactose by the action of aldose reductase, accumulates to high concentrations and this exerts a strong osmotic effect. Sugar alcohols do not diffuse readily through biological membranes, so the retention of galactitol within the lens leads to the imbibition of water to maintain osmotic equilibrium, which leads to lens fiber swelling, vacuole formation, and subsequent opacification. The process of sugar cataract formation in animals can be prevented by inhibiting aldose reductase. The development of galactose-induced cataract in galactosemic humans is thought to occur by the same mechanism as described for the rat.

Effects of Galactosemia *in utero*

There is direct evidence that in galactosemia due to GALT deficiency, galactose, galactose-1-P, and galactitol accumulate in the fetus by week 20 of gestation. However, the metabolic abnormality may develop earlier than this, since the key enzymes in galactose metabolism have been shown to be present in normal fetal liver from week 10 of gestation. There has been a report of increased galactitol in amniotic fluid obtained at week 10 of gestation, the outcome being that the baby is affected.

Cataract formation in the fetus is rare and is the only direct evidence that galactosemia may have harmful effects *in utero*. However, it has been concluded that the liver pathology seen in some infants who died in the neonatal period originated prenatally, and some studies have found that galactosemia is associated with reduced birth weight. Other observations, particularly those made from animal models, would suggest that ovarian dysfunction may have been caused *in utero*.

With regard to maternal galactose restriction, available biochemical evidence is insufficient to suggest any advantage to the fetus and galactitol accumulates *in utero* despite maternal galactose restriction.

Screening of Newborns

Methods for mass screening of newborns for galactosemia have been available since 1964. These are based mainly on measurements in blood of galactose, with or without galactose-1-P, and sometimes also including assay of GALT activity. Although galactosemia is rare, a number of countries (e.g., Germany, Switzerland, Canada, Norway, and some states in the United States) have included screening for galactosemia in their national screening programs, but many have not. Prenatal diagnosis for this disorder may be carried out by GALT assay in cultured amniotic fluid cells or in chorionic villus biopsies and by galactitol estimation in amniotic fluid supernatant.

One of the outcomes of screening programs has been the discovery of subjects with partial GALT deficiency who have mildly elevated blood galactose. These occur with a frequency about 10 times that of classical galactosemia (homozygotes with essentially total GALT deficiency) and are considered to be heterozygotes for classical galactosemia. Although there is no evidence of adverse effects of galactose consumption in these subjects, elimination of dietary galactose for at least the early months of life has been recommended as a prudent measure.

Genetics

After the cloning and sequencing of the GALT gene, more than 160 mutations have been described that have been associated with GALT deficiency. Q188R is the most common mutation in north European populations and those predominantly of European descent. K285N is much rarer but in some countries of eastcentral Europe it is the second most common mutation. In some populations of northern Europe and the white population in North America, these two mutations account for 70–80% of mutant chromosomes. Both mutations appear to be associated with a complete loss of enzyme activity and thus, a more severe biochemical phenotype. S135L is found almost exclusively in galactosemic individuals of African origin. In North America, this accounts for 62% of the alleles causing galactosemia in the black population and is associated with good outcomes.

The Duarte galactosemia variant is caused by a single amino acid substitution, N314D, which is found on both Duarte 1 and Duarte 2 alleles. Additional base changes that are different on each distinguish D1 from D2 alleles. Homozygosity for N314D reduces GALT activity to 50%. When either E203K or L218L (a neutral polymorphism arising from the 1721C → T transition (Los Angeles variant)) is present in *cis* with N314D, GALT activity reverts to normal.

Galactokinase-Deficient Galactosemia

GALK-deficient galactosemia, which occurs with a frequency of about 1 in 40 000, is characterized by cataracts that occur in the first or second decade of life but the subject is otherwise normal. In such patients, ingested galactose remains unphosphorylated and may be converted into galactitol, which causes damage to the lens fibers of the eye. The marked differences between GALK-deficient galactosemia and classical galactosemia in the severity and diversity of the symptoms and in the timescales within which they occur demonstrate that galactose-1-P is much more toxic than galactitol.

GALK deficiency is readily treated with a galactose-free diet and if this is started early in life, the only complication, cataracts, is avoided.

Epimerase-Deficient Galactosemia

Impairment of GALE results in epimerase-deficient galactosemia, an inborn error of metabolism with variable biochemical presentation and clinical outcomes reported to range from benign to severe. Molecular studies of the GALE loci from patients with GALE deficiency reveal significant allelic heterogeneity, raising the possibility that variable genotypes may constitute at least one factor contributing to the biochemical and clinical heterogeneity observed.

Inherited deficiencies of GALE have been associated with two distinct phenotypes. The vast majority of North American patients are clinically asymptomatic, are identified through newborn screening programs for classical galactosemia, and are of African-American descent. However, a severe, generalized form of GALE-deficient galactosemia has been described in a small number of subjects. The initial presentation is similar to classical galactosemia, including cataract, sepsis, and liver, kidney, and brain abnormalities. Despite treatment with a galactose-restricted diet, all have shown poor growth and moderate learning difficulties.

A single substitution mutation, V94M, is present in the homozygous state in all patients genotyped with the severe, generalized form of GALE-deficient galactosemia. Studies on the enzyme in a yeast model system support the hypothesis that elevated levels of galactose-1-P may underlie the observed toxicity.

Conclusion

Significant advances have been made in recent years in understanding the genetics of galactosemia. However, clinical galactosemia is a complex trait and the phenotypic expression is often not predictable. Except for cataract, the pathophysiology of galactosemia is poorly understood. Despite the concept that there may be continuous endogenous production of galactose in affected individuals, the treatment remains a diet as devoid of galactose as possible, within the confines of adequate nutrition for normal growth and development. However, it is now recognized that this does not prevent long-term complications and there is a need for new approaches to treatment, in combination with diet therapy, that could improve the outcome of patients with galactosemia.

Nutrigenomics and Nutrigenetics

Introduction

In order to address the increasing incidence of many diet-related diseases, the role of diet and nutrition has been, and continues to be, studied extensively. To prevent the development of disease, nutrition research is investigating how nutrients and bioactive compounds can optimize and maintain physiological processes at the cellular, tissue, organ, and whole-body level. This involves a multitude of nutrient-related interactions at the gene, protein, and metabolic levels, and thus requires an understanding of how nutrients/bioactive food components act at the molecular level. The recognition that nutrients have the ability to interact and modulate molecular mechanisms underlying an organism's physiological functions has prompted a revolution in the field of nutrition with the emergence of the fields of nutrigenomics and nutrigenetics. These two fields, although with distinct approaches to elucidate the interaction between diet and genes, have a common ultimate goal, that is, to optimize health through the personalization of diet and to provide powerful approaches to unravel the complex relationship between nutrients/bioactive food components, genetic variation, and the biological system as a whole. This article will briefly overview the potential of these two fields for nutritional sciences.

Effect of Nutrition on Gene Expression

In the classic paradigm, genetic information encoded in the deoxyribonucleic acid (DNA) sequence of a given gene is first transcribed by ribonucleic acid (RNA) polymerases into messenger RNA (mRNA) and subsequently translated into proteins (**Figure 1**).

The transcription of a gene begins at the promoter region when double-stranded DNA is copied into mRNA. Transcription of a gene is not continuous or uninterrupted. Each gene contains DNA sequences that code for the amino acid sequence of the protein, which are called exons. The exons are interrupted by noncoding DNA sequences called introns, which are eventually spliced out during post-transcriptional processing. It is estimated that 80% of the influence of nutrients on the process of gene expression is at the level of transcription. Two types of factors regulate gene expression: *cis*-acting elements and *trans*-acting factors. *Cis*-acting elements do not encode proteins, but influence gene transcription by acting as binding sites for proteins that regulate gene transcription. These DNA sequences are usually organized in clusters located in the promoter region of the gene (i.e., TATA and CAAT boxes). *Trans*-factors, also known as DNA binding proteins, are proteins produced by other genes and include, for example, steroid hormone–receptor complexes, vitamin receptor proteins, and mineral–protein complexes. These *trans*-acting factors bind to specific DNA sequences in the promoter region of the target gene to promote gene transcription. Although the precise mechanisms by which *trans*-acting factors regulate gene expression have not been defined fully, it is thought that unfolding or folding of DNA may hide or expose regions of DNA.

A good example of how a nutrient impacts this step of the gene expression process is where vitamin D, in its active form, that is, 1,25-dihydroxyvitamin D, which interacts with the vitamin D receptor (VDR), stimulates the transcription of the gene encoding calbindin D9k – a cytosolic calcium-binding protein – in intestinal mucosal cells. Calbindin D9k facilitates the transepithelial transport of Ca^{2+}, thus enhancing efficiency of intestinal calcium absorption.

Once transcription has occurred, the resulting mRNAs are exported from the nucleus and form complexes with ribosomes, leading to the synthesis of polypeptides that form the given protein – this is translation. Three nucleotide bases within the mRNA molecule code for one amino acid and are referred to as codons. In some cases, multiple codons may code for and be translated into the same amino acid (e.g., the codons UGU and UGC both code for cysteine). The triplet AUG, known as the start codon (read as methionine), signals for commencement of translation from gene to protein. The subsequent codons are translated into amino acids, one at a time, to form polypeptides, which fold into complex and unique protein structures that are critical for normal body function. Nutrition can impact this step of the process by supplying amino acids and energy for the translational process. In some cases, the proteins require some post-translational modifications (chemical modifications) to become fully active. This post-translational modification of amino acids extends the range of functions of the protein by attaching to it other biochemical functional groups such as acetate, phosphate, and various lipids and carbohydrates, by changing the chemical nature of an amino

acid (e.g., citrullination), or by making structural changes, such as by forming disulfide bridges. Again, nutrients may impact this step of the process. An example of where nutrition impacts this step of the gene expression process is how vitamin K plays an important role in the post-translational activation of several biologically active proteins involved in clotting and bone metabolism. Vitamin K is a cofactor for γ-carboxylase, which adds a carboxyl group to glutamate residues of certain proteins and by so doing increases their functionality.

The impact of nutrition on the various steps involved in the gene expression process has been researched for many years with traditional molecular biology approaches such as Northern blotting, polymerase chain reaction, and Western blotting. Use of the new 'omic' technologies in the nutrition field may provide even greater insights into the role of nutrition in human health.

Defining Nutrigenomics

This relatively new area of molecular nutrition within the wider nutrition field has brought with it an array of new terms. Nutritional genomics (which has led to the coined term nutrigenomics) can be defined as the study of the genome-wide influences of nutrition (or dietary components) on the transcriptome, proteome, and metabolome (defined below) of cells, tissues, or organisms at a given time.

- *Transcriptome*: The complete collection of gene transcripts (mRNAs) in a cell or a tissue at a given time (transcriptomics – the study of the complete collection of transcripts).
- *Proteome*: The complete collection of proteins detected in a cell or a tissue at a given time (proteomics – the study of the complete set of proteins).
- *Metabolome*: The full set of metabolites (which are intermediates and products of metabolism including hormones, signaling molecules, and primary and secondary metabolic intermediates) found within a biological tissue or fluid at a given time (metabolomics – the study of the complete collection of metabolites).

Thus, nutrigenomics aims to understand how nutrients and other bioactive food components affect gene expression and, in turn, how these changes influence protein expression, metabolism, and, ultimately, health outcomes.

These omic approaches produce vast amounts of data and there is a need to convert the data into some biological meaning. The field of bioinformatics has an instrumental role in this regard. By definition, bioinformatics is the application of information technology and computer science to the field of molecular biology. It entails the creation and advancement of databases, algorithms, computational and statistical techniques, and theory to solve formal and practical problems arising from the management and analysis of biological data. The primary goal of bioinformatics is to increase our understanding of biological processes.

Systems biology as a field tries to explore the complex interactions among biological systems. While currently there is no unifying consensus on how nutritional systems biology should be defined, some experts have described it as "covering all approaches targeted towards understanding the key processes that define nutrition in the context of regulation of transcription, protein synthesis and turnover, metabolism and genome stability in health and disease states at all levels of its complexity, to simulate these processes and to predict the outcome of any alteration (whether genetic or nutritional) of the system. Nutritional systems biology starts at the molecular and cellular levels and takes the regulatory processes onto the level of the different organs and the inter-organ flow of information, nutrients and metabolites to describe most comprehensively the organism response and the processes quantitatively in mathematical terms". More simply, nutritional systems biology tries to integrate information obtained from the different omic approaches to allow us to see or predict the impact of a nutrient/food component on physiology.

How Has Transcriptomics Advanced Nutrition Research

Transcriptomic methods such as microarray analysis (a technology that utilizes a microchip-based approach to analyze the expression of thousands of genes simultaneously) of samples from nutritionally relevant cell culture and animal models have led to the identification of many genes that are regulated at the mRNA level by exposure to different dietary components. The application of transcriptomics technology in human nutrition intervention studies, while being used only to a limited extent to date, has the potential to allow for genome-wide screening of the effects of diets or nutrients on physiological events and may possibly result in biomarker profiles indicative of positive or adverse changes. For example, in a human intervention study investigating the effects of a high-carbohydrate or a high-protein breakfast on satiety, van Erk and coworkers attempted to evaluate the potential of gene expression profiling in blood cells. The analysis showed that consumption of breakfast resulted in differentially expressed genes in blood leukocytes from healthy men: 317 genes for the high-carbohydrate breakfast and 919 genes for the high-protein breakfast. Bioinformatic analysis of the gene expression data showed that consumption of the high-carbohydrate breakfast resulted in significant changes in the expression of genes involved in glycogen metabolism, while consumption of the high-protein breakfast resulted in differential expression of genes involved in protein biosynthesis. Another recent study reported the post-prandial effects of intake of different fatty acids on gene expression profiles of peripheral blood mononuclear cells of healthy men participating in a dietary intervention study. Whole-genome gene expression profiles in the blood cells were examined before and 6 h after the intake of drinks containing polyunsaturated fatty acids (PUFAs) and saturated fatty acids (SFAs). The expression of genes involved in 'liver X receptor' signaling, which plays a major role in cholesterol transport, increased in response to dietary SFA and decreased in response to PUFA intake in the healthy men, suggesting that SFA intake may increase cholesterol efflux from cells, while conversely, PUFA intake may inhibit this efflux. These and other studies clearly show the value and potential of transcriptomic analysis of human tissue samples in human nutritional intervention studies.

How Have Proteomics and Metabolomics Advanced Nutrition Research

The proteome, unlike the genome, is dynamic and varies according to the cell type and functional state of the cell. Proteomic technologies, namely two-dimensional (2D) gel electrophoresis followed by liquid chromatography mass spectrometry (MS)/MS, can be used to identify changes in protein expression following an alteration in nutrient supply or environment. While proteomic analysis has been applied to nutrition research in relevant cell culture and animal models and has provided valuable new data, its application in human studies may be as, if not more, important to human nutrition research. Analysis of the serum or plasma proteome may provide further insights into the effects of nutrition on human health. Recently, this type of analysis was applied to plasma samples collected from adults in a human intervention trial. Folic acid supplementation for 12 weeks increased the expression of more than 60 proteins involved in metabolic pathways related to complement fixation, coagulation, and mineral transport, thus opening new avenues of investigation.

Metabolomics is one of the newer 'omics' to be applied to nutrition research, which aims to quantify (using MS and/or nuclear magnetic resonance spectroscopy) the temporary changes in cellular small-molecular-weight compounds (i.e., hormones, signaling molecules, and metabolic intermediates) in human biotissues (i.e., urine and plasma) in response to nutrients and/or bioactive food compounds. A recent study investigated the role of dietary phytochemicals in shaping human urinary metabolomic profiles. First-void urine samples were collected from healthy adults following a normal diet, a 2-day low-phytochemical diet, or a 2-day standard phytochemical diet. Metabolomic analysis showed acute changes in urinary metabolomic profiles after the consumption of dietary phytochemicals, illustrating the potential of detecting diet-induced changes. A second example is a recent intervention study that aimed to elucidate the metabolic changes in blood plasma following weight loss and fish oil supplementation. Two groups of women followed a 12-week weight loss program, followed by a 12-week weight maintenance period, and were randomized to fish or placebo oil capsules; a control group did not follow the weight loss program and were given placebo oil capsules. Lipid profiles changed dramatically upon fish oil intake and subtly across the two weight loss groups. While the fish oil supplementation increased the proportion of various phospholipid species, previously reported reductions in total triacylglycerides (TAGs) upon fish oil intake were shown to be driven by a reduction in a specific subset of the measured TAGs. This metabolomic study showed that the observed remodeling of TAGs may represent further beneficial effects of fish oil supplementation. The potential of metabolomic analysis may lie in better quantification of nutrient and nonnutrient intake as well as in the identification of biomarkers (distinct metabolite fingerprints) of relevance to nutrition-related disease.

Limitations of These ‘Omics’ Technologies

While novel omics technologies and bioinformatics tools continue to offer enormous potential to investigate the complex relationship between nutrition and the transcriptome/proteome/metabolome, it is also important to recognize their limitations. For example, a number of limitations are associated with microarray analysis. When human blood samples are used, the inter-individual human variation in gene expression profiles makes it difficult to identify gene expression signatures in response to nutrient intervention. This is why many of the studies use cross-over designs that use subjects as their own controls and thus minimize variability in gene expression profiles and optimize the chance of detecting changes in these profiles arising from dietary modulation. However, not all human intervention studies can be cross-over type in design. Furthermore, because nutrient interventions generally result in relatively small gene expression changes, it can be difficult to accurately facilitate data analysis and interpretation of the experimental results. Costs associated with microarray analysis are very high, and are often compounded by the need for several repeat analyses to obtain statistically accurate results. In terms of proteomic analysis, there are a number of limitations in 2D gel electrophoretic analysis, such as poor resolution for low abundant proteins as well as the inability to detect proteins with extreme properties (i.e., very acidic, very basic, very large, very small). Furthermore, 2D gel electrophoretic analysis has proven to be a costly and time-consuming method. Limitations in metabolomic research arise from the highly dynamic nature of the human metabolome, which makes it difficult to link metabolites back to specific genes and proteins; furthermore, it is difficult to isolate metabolic effects of food supplements, drugs, physical activity, and stress, among several other physical factors.

Defining Nutrigenetics

Nutritional genetics (which led to the coined term nutrigenetics) can be defined as the study of how genetic variation (different genotypes) among individuals may modify their physiological response to diet and how this ultimately influences parameters of health or disease.

Nutrigenetics is closely associated with ‘personalized nutrition’, an emerging concept that an individual’s diet can be tailored to their genetic makeup to optimize health status and prevent the onset of disease. This field has received significant impetus since the publication of the human genome in 2003. The human genome comprises more than 3 billion base pairs, encoding for approximately 30 000 genes and 100 000 functionally distinct proteins. Although human individuals are 99.9% genetically identical, most genes have a number of small sequence differences known as polymorphisms that occur (on average) approximately every 1500 base pairs. Single nucleotide polymorphisms (SNPs; the switching of one nucleotide to another) in genes can affect protein translation by changing the reading frame of that gene such that mRNA codes for a different amino acid. For example, if the codon for cysteine (UGU) has an SNP located at the third nucleotide to form UGC (a codon that also translates to cysteine), then the mutation is known as ‘silent’ and does not affect the resulting protein or its function. However, if the SNP occurs at the first nucleotide to form CGU, then the codon is translated to an alternative amino acid, arginine, that may or may not alter protein functionality. SNPs located on the first or second nucleotide in a codon commonly alter translation of amino acids, possibly impacting protein functionality.

Most nutrition-related diseases such as cardiovascular disease, metabolic syndrome, cancer, and osteoporosis, among others, are complex multigene disorders that are associated with the effects of multiple genes in combination with lifestyle and environmental factors. Several candidate genes have been investigated in terms of their involvement in these diseases (see **Table 1** for a list of possible candidate genes that have been suggested to have

Table 1 Candidate genes for osteoporosis

Candidate gene	*Physiological function*
Vitamin D receptor (VDR)	Calcium absorption; osteoblast/osteoclast activity
Estrogen receptor α	Osteoblast/osteoclast activity
Estrogen receptor β	Osteoblast/osteoclast activity
Collagen I A I	Matrix component
Transforming growth factor β-1	Osteoblast/osteoclast activity
Androgen receptor	Osteoblast function
Interleukin 6	Osteoblast activity
Apolipoprotein E	Vitamin K transport
Parathyroid hormone receptor	Calcium homeostasis; osteoblast/osteoclast activity
Calcitonin receptor	Osteoclast function
Peroxisome proliferator-activated receptor γ	Adiposite differentiation
Osteocalcin	Matrix component
Calcium sensing receptor	Regulation of calcium homeostasis
Methylenetetrahydrofolate reductase	Homocysteine metabolism
Metalloproteinase-1 gene	Matrix component

some role in the risk of osteoporosis). A candidate gene is a gene located in a chromosomal region suspected of being involved in the expression of a disease trait, with the protein product indicating the gene in question. A candidate gene can also be identified by association with the phenotype and by linkage analysis to a region of the genome. There have been many associational studies in molecular medicine and associated fields that link the presence of one or more SNPs within a candidate gene with the increased risk of a certain disease. Clearly, this has enormous potential in the area of molecular diagnosis.

In many ways, nutrigenetics tries to explore and exploit the interaction between genetic variation (SNPs) and nutrition. In recent times, several human dietary intervention studies have included a genotype dimension to their design. This allows them to additionally explore whether the response of a physiological/disease outcome to the dietary intervention is modulated by SNPs in candidate genes such that individuals with different genotypes respond differently. As an example in the area of diet and bone health, SNPs in the VDR gene were among the first to be studied widely as genetic risk factors for osteoporosis. However, an example of moving beyond molecular diagnosis and more toward using genotype information to inform treatment or nutrition intervention/advice, was demonstrated by Graafmans and coworkers, who reported an interaction between one such VDR polymorphism (defined by the *Bsm* I restriction endonuclease enzyme) and response of bone mineral density to vitamin D supplementation. The mean increase in bone mineral density in the vitamin D-supplemented group was higher in subjects with the '*BB*' and '*Bb*' VDR genotype compared with those with the '*bb*' VDR genotype. Another example is in the area of nutrition and cardiovascular health. A study reported a significant interaction between a polymorphism in the estrogen receptor-β (ERβ) gene (defined by the *Alu*I restriction endonuclease enzyme) and dietary isoflavone (IF) supplementation in terms of the response of C-reactive protein (CRP), a biomarker of cardiovascular disease risk, in postmenopausal women. *Alu*I ERβ genotype significantly modulated the response of CRP to dietary IF supplementation, such that women with the *AA* (ERβ) genotype responded to treatment with significantly lower CRP concentrations compared with women having the same genotype but in the placebo group, who experienced significantly elevated CRP concentrations following the 8-week intervention. Dietary IF supplementation had no significant effect on CRP levels in the *GG* or *GA* ERβ genotype groups, suggesting a beneficial cardio effect of dietary IF for postmenopausal women with the *AA* ERβ genotype.

In terms of the application and realization of a 'tailored/personalized nutrition' approach, that is, an individual's diet can be tailored to their genetic makeup to optimize health status and prevent the onset of disease, the associations in studies such as those mentioned above would need to be consistently shown to be the case, providing a solid evidence base. Often, unfortunately, this is not the case and may well be due to an overly simplistic view that one nutrient will interact with one gene in isolation to influence a biological process, whereas in reality there may be interactions of the gene in question with other genes in addition to its interaction with a nutritional and/or other environmental factor(s).

Conclusion

It is hoped that by building up the knowledge base, nutrigenomics and nutrigenetics will promote an increased understanding of how diet and nutrition influence metabolic pathways and physiological events, which will then be used to prevent the development of chronic diet-related diseases. Ultimately, the application of these fields in nutrition research could lead to the development of functional foods that will keep people healthy according to their individual needs. However, both fields are still at a relatively early stage and many of the associated technologies and study design parameters are still in the process of further development and/or refinement. Thus, while expectations are high, we need to monitor their success over the next decade to truly know their impact.

Introduction

Milk contains many components with physiological functions, such as proteins and peptides, fats, oligosaccharides, vitamins, and minerals. These different milk components could be used as nutraceuticals to promote good health and prevent disease. Milk fat is contained within the fat globule and surrounded by a membrane: the milk fat globule membrane (MFGM) (*see* **Milk Lipids**: Milk Fat Globule Membrane). This particular structure is composed of a core of triglycerides and a membrane consisting of phospholipids, cholesterol, proteins, and glycoproteins. Both the membrane and the core components possess antimicrobial functions. Major sphingolipids in milk (glycosphingolipids) may play a role in the numerous antiproliferative pathways associated with the suppression of carcinogenesis. Other lipid compounds, such as conjugated linoleic acid (CLA), have several biological activities, such as inhibiting cancer and atherosclerosis (*see* **Milk Lipids**: Conjugated Linoleic Acid). Lactose derivatives such as lactulose, lactitol, and oligosaccharides stimulate the growth of bifidobacteria (*see* **Lactose and Oligosaccharides**: Lactose: Galacto-oligosaccharides). Milk is a source of exogenous regulatory substances, including bioactive proteins and peptides with various biological properties. These biologically active milk proteins include lysozyme and lactoperoxidase (enzymes), immunoglobulins, transferrin, and lactoferrin, as well as various growth factors. Bioactive peptides, which can be released during gastrointestinal digestion, have also been identified in the casein and whey protein sequences and represent a new criterion when assessing the nutritional value of protein. A variety of activities are associated with milk-derived peptides (*see* **Milk Protein Products**: Bioactive Peptides): (1) in 1979, opioid agonistic peptides derived from milk protein were identified for the first time and, in 1986, peptides with antagonistic opioid activity were characterized; (2) in 1982, peptides with angiotensin-converting enzyme (ACE) inhibitory activity were discovered and these ACE inhibiting peptides were shown to have an antihypertensive effect; (3) peptides with fibrinogen-like sequences and thus having antithrombotic activity have been described; (4) numerous immunomodulating peptides are capable of increasing phagocytic activity and lymphocyte proliferation; (5) some peptides, including phosphopeptides, facilitate the absorption of minerals, especially calcium, magnesium, and iron; and (6) some peptides exhibit antimicrobial activities. It should be noted that many milk peptides possess multiple functional activities.

Gastrointestinal Digestion of Milk Protein-Derived Peptides

Milk proteins are subjected to digestion and absorption processes in the gastrointestinal tract. They can act within the intestinal tract or may exert their activities in various peripheral organs following absorption. In order to become active, bioactive peptides must be released either during gastrointestinal digestion or after their absorption. Gastrointestinal processes control the release of amino acids and nitrogen into the body and hence their metabolic utilization. The principal milk proteins are caseins and whey proteins. Bovine casein has four components: α_{S1}- and α_{S2}-casein, β-casein, and κ-casein. The main components of whey proteins are β-lactoglobulin and α-lactalbumin. The first step in protein digestion consists of acid secretion and pepsin hydrolysis in the stomach. Whey proteins are soluble and are emptied quickly into the duodenum, mainly in an intact form. In contrast, caseins are precipitated in the stomach and then slowly released into the duodenum in the form of degraded products. In the duodenum, these products are subjected to pancreatic enzymes. In the intestinal lumen, α-lactalbumin, β-lactoglobulin, and lactoferrin have been found in an intact form, unlike the caseins. The intestinal brush border contains several peptidases, and the major peptides are degraded into dipeptides and tripeptides. Some peptides are relatively resistant to these enzymes and may reach their body target intact. Proline-containing peptides are generally resistant to degradation by digestive enzymes.

Bioactive peptides may act directly on targets present in the gastrointestinal tract. Dipeptides and tripeptides can also cross the intestine and reach peripheral target sites. Other specific transport systems have been described, such as transcytosis, implicated in α-lactalbumin, β-lactoglobulin, and lactoferrin transport. These proteins have been found in an intact form in the blood. Peptides may also be released by enzymatic proteolysis in the body. Whereas these peptides are inactive in the native protein, the bioactive sequence is released in the body. It should be noted that these peptides can be produced by proteolytic bacterial species.

Control of Gastrointestinal Processes

The gastrointestinal processes involved in milk digestion control the release and absorption of milk peptide-associated minerals, which include calcium, magnesium, and iron. Some milk protein-derived peptides may have a specific regulating effect on gastrointestinal physiology and metabolism.

Absorption of Minerals

Casein occurs in milk in the form of micelles, which are carriers of phosphates and calcium, magnesium, and iron ions. Milk is an important source of calcium and it also contains lactose, which increases intestinal permeability of calcium. Some peptides have been isolated from different phosphorylated regions of α_{S1}-, α_{S2}-, and β-caseins, and are called caseinophosphopeptides (CPPs). They are capable of binding minerals, particularly calcium. Phosphopeptides may enhance calcium absorption by preventing the precipitation of insoluble calcium phosphate. These peptides are released during the gastrointestinal digestion of casein. They are particularly resistant to gastrointestinal and plasma proteolysis, and some of them have been found in feces. A few experiments have been carried out in pigs and rats; however, useful results were obtained only under certain experimental conditions, and mainly during investigations on the short-term calcium balance in growing animals. Phosphopeptides have exhibited positive effects on mineral solubility and absorbability and bone mineralization. This could be considered as beneficial to bone health in certain groups of population.

Regulation of Intestinal Motility and Metabolic Processes

The caseinomacropeptide (CMP), which represents the 64-amino acid (106–169) C-terminal fragment of bovine κ-casein, has been demonstrated to have a variety of biological activities, including the modulation of gastrointestinal motility and regulation of the release of gastrointestinal hormones, such as cholecystokinin (CCK). It has been shown to stimulate secretions by the pancreas. Opioid peptides have been identified in milk; they have morphine-like activity through their interaction with opioid receptors (μ-, δ-, and κ-type). Various biological effects have been investigated with respect to opioid receptors in the body. They are located in the nervous, endocrine, and immune systems and are also found in the gastrointestinal tract. Opioid peptides isolated from bovine β-casein (fragments 60–70) have been named β-casomorphins. They have been characterized as μ-type ligands. β-Casomorphins have also been found in human β-casein. Their role in the organism is related to their bioavailability. β-Casomorphins are relatively resistant to the action of gastric and pancreatic enzymes, but are hydrolyzed by intestinal brush border peptidases. β-Casomorphins are released after the ingestion of milk and exert their effects mainly in the gastrointestinal tract. If they are to interact with opioid receptors located on the intestinal surface, opioid peptides must be applied directly. They can also exert an antidiarrheal effect by stimulating electrolyte absorption and inhibiting intestinal motility. β-Casomorphins have also been reported to increase the release of somatostatin and a pancreatic polypeptide, and stimulate the release and formation of insulin, which is dependent on the blood glucose level. Other opioid peptides have been isolated from bovine α_{S1}-casein (residues 90–96); these are δ-selective receptor ligands. Some peptides have been found in whey proteins: α-lactorphin, β-lactorphin, and serorphin have been isolated from bovine and human α-lactalbumin (residues 50–53), β-lactoglobulin (residues 102–105), and serum albumin (residues 399–404), respectively. Opioid antagonists have been isolated from bovine and human κ-casein and named casoxins. Lactoferoxin has been identified in human lactoferrin, and some fragments of α_{S1}-casein possess similar activity. These fragments bind to the opioid receptors and exhibit an antagonistic action, which may be observed following the administration of naloxone.

Enhancing Body Defenses

Bovine milk and colostrum have various antimicrobial activities. The colostrum contains several immunoglobulins, which confer passive protection on neonates against a wide range of microbes. Milk contains immunological components, such as enzymes (lactoperoxidase), immunoglobulins, and growth factors, as well as certain antimicrobial peptides, which can modulate the immune system. These anti-infective components can be considered as functional foods because they enhance nonspecific body defenses.

Antimicrobial Activities

CMP has been found to prevent the adhesion of oral actinomyces and streptococci to erythrocytes. It can also inhibit the binding of cholera toxin to its receptor. CMP may contain 0, 1, or 2 mol mol^{-1} sialic acid. Because sialic acid residues are present on the surface of the target cells required for influenza virus infection, CMP has been found to inhibit the hemagglutination of influenza virus. In addition, human CMP has also been found to enhance the growth of the beneficial bacterium *Bifidobacterium infantis*.

Lactoferrin is an iron-binding glycoprotein in milk and is involved in host defenses against infection. Iron is essential to microbial growth. The antimicrobial activity of lactoferrin is due not only to iron chelation. It is able to induce the release of lipopolysaccharides from the bacterial membrane. By altering membrane permeability, bacterial susceptibility to lysozyme is increased. Lactoferrin has antimicrobial effects against bacteria such as *Escherichia coli*, *Staphylococcus albus*, *Staphylococcus aureus*, *Streptococcus mutans*, and *Vibrio cholerae*, and certain yeasts, particularly *Candida albicans*. Lactoferricin, a fragment of 25 amino acid residues isolated by gastric pepsin cleavage of lactoferrin, is a more potent bactericidal substance than undigested lactoferrin. It contains several basic amino acid residues, and their asymmetric clustering generates an affinity for biological membranes. Lactoferricin may exert an antibacterial effect by increasing cell membrane permeability. It is highly effective against several pathogenic bacteria, including strains of *Escherichia*, *Listeria*, *Pseudomonas*, *Salmonella*, and *Campylobacter*, but not against beneficial bacteria such as *B. infantis*. This peptide is also effective against pathogenic yeasts such as *C. albicans*. A peptide of 47 amino acid residues, possessing similar activities, has been liberated from human lactoferrin.

Casocidin, which contains a high proportion of basic amino acids, has been isolated from α_{S2}-casein (residues 165–203). It inhibits bacteria such as *E. coli* and *Staphylococcus carnosus*.

Immunomodulating Effects

Some milk peptides have been found to act like immunopotentiating compounds. Peptides isolated during the tryptic and chymotryptic hydrolysis of α_{S1}- and β-caseins and α-lactalbumin enhance phagocytosis and modulate proliferation and differentiation of human peripheral blood lymphocytes. For example, an opioid peptide isolated from β-casein (residues 63–68) has been shown to stimulate the immune system and particularly phagocytosis. This example demonstrates that one peptide may have several biological activities. The mechanism by which peptides exert their immunomodulatory effect has not yet been defined, but it may be related to the opiate receptor. Two peptides isolated from human β-casein, a hexapeptide (Val-Gly-Pro-Ile-Pro-Tyr) and a tripeptide (Gly-Leu-Phe), were found to stimulate *in vitro* the phagocytic activity of sheep red blood cells by murine peritoneal macrophages and *in vivo* to prevent infection in mice after an intravenous injection of bacteria (*Klebsiella pneumoniae*).

Bovine and human lactoferrin inhibit lectin-stimulated lymphocyte blastogenesis. Human lactoferrin is able to differentiate CD4-/CD8-lymphocytes into CD4-helper T lymphocytes. It also has an effect on the release of cytokines in response to stimulation of monocytes by the lactoperoxidase system (LPS).

Isracidin is a fragment of α_{S1}-casein (residues 1–23). It inhibits the proliferation of *St. aureus* and *in vivo* protects mice from infection with *C. albicans* by stimulating phacocytosis and lymphocyte proliferation.

Following exposure to antigen, CMP decreases the immune response and especially the production of IgG-class antibodies by enhancing suppressor T lymphocytes.

In many cases, the immunomodulatory function of these milk peptides has been studied either *in vitro* or *in vivo*, and the studies have focused on specific components. In this field, it is important to investigate complex milk-derived products as well as individual milk proteins or peptides. Immunomodulating milk products are promising examples of health-promoting functional foods.

Putative Protective Effects on Chronic Diseases

Antihypertensive Effect

The angiotensin I-converting enzyme (ACEI) plays a key role in regulating the peripheral blood pressure. In the renin–angiotensin system, this enzyme converts angiotensin I into angiotensin II, which raises the blood pressure. Some milk peptides have been shown to inhibit this enzyme and lower the blood pressure. Such peptides have been identified mainly in α_{S1}-, β-, and κ-caseins. Some opioid peptides, such as α-lactorphin, have also been shown to possess an ACEI lowering activity. The antihypertensive effects of orally administered doses of Calpis sour milk or peptides (Val-Pro-Pro, Ile-Pro-Pro) were tested in spontaneously hypertensive rats (SHRs) and also in hypertensive patients. The systolic blood pressure had fallen significantly at 4 and 8 weeks after the beginning of ingestion. These effects on hypertension were mild in human volunteers. Most milk protein-derived peptides do not have an ACE inhibitory potential approaching that of captopril, one of the preparations commonly used to control blood pressure. However, as they are natural substances, they are not anticipated to produce the adverse effects associated with a synthetic preparation. Further clinical studies are necessary to demonstrate the efficacy and safety of these peptides as potential nutraceuticals (*see* **Fermented Milks**: Health Effects of Fermented Milks).

Antithrombotic Effect

A homology between the clotting of blood and milk has been described. Fibrinogen is essential for platelet aggregation. Some peptides from bovine κ-casein can act on platelet aggregation because of their structural similarity to the human fibrinogen γ-chain, particularly the (106–116) residue peptide. The latter inhibits the binding of fibrinogen and the aggregation of platelets treated with adenosine diphosphate (ADP). Shorter peptides also have antithrombotic activities. A peptide with a similar activity has been isolated from human lactoferrin (residues 39–42). These activities have been tested with *in vitro* models by evaluating ADP-induced platelet aggregation. After the ingestion of milk or yogurt, CMP, which contains an antithrombotic sequence, was detected in human plasma. After milk or milk product consumption, antithrombotic peptides may be found in the systemic circulation. The physiological consequences of their presence need to be demonstrated in humans.

Putative Anticarcinogenic Activity

Milk or its by-products may have beneficial activity with regard to the prevention of cancer. Recent epidemiological studies have suggested a relationship between the intake of milk components and a chemopreventive role in certain forms of cancer. However, research on the anticarcinogenic effects of milk components is difficult because of the different etiologies of cancer.

Many components have been studied in the context of cancer prevention, such as lactoferrin, dihydroxycholecalciferol (1,25$(OH)_2D_3$), calcium, phosphorus, lactic bacteria, butyrate, and CLA. Whey proteins also represent a source of anticarcinogenic components. Their putative anticancer activity has been studied extensively in animal models of tumorigenesis or during *in vitro* studies using tumor cell lines. In contrast to the lack of controlled clinical studies, the role of whey proteins in preventing cancer has been studied widely in rats. Their anticancer activity may be related to their high cysteine and glutamic acid contents, which serve as precursors of glutathione (GSH), a potent antioxidant whose release is enhanced during stress. Whey proteins may cause a depletion of GSH in cancer cells, thus slowing their replication, but not affecting normal tissues. A study performed on mice demonstrated that the incidence of colon cancer induced by dimethylhydrazine (DMH) was reduced in animals following the administration of whey proteins, because of enhanced tissue GSH concentrations. There is also some evidence from controlled clinical studies of the effectiveness of whey protein concentrate in limiting metastasis during anticancer therapy. Indeed, the beneficial effects of certain milk-derived components, such as lactoferrin or CLA, have been demonstrated in animals, although further studies under controlled clinical conditions are necessary. Other minor constituents, especially low-molecular-weight proteins and peptides, may also have anticancer properties, which need to be identified. Numerous clinical studies will be required to establish a clear relationship between consumption of dairy products and cancer prevention (*see* **Health Aspects of Dairy Products**: Nutritional and Health-Promoting Properties of Dairy Products: Colon Cancer Prevention).

Bone Resorption

Milk proteins have been shown to increase mineral absorption, and they can also act on bone resorption. Recent studies have shown that whey proteins contain active components that affect osteoclast-mediated bone resorption. Bone resorption and osteoclastic cell formation have been studied using an unfractionated bone-cell culturing system. The active components were isolated and their gut permeability was studied, and it was shown that they could be absorbed or transported via the intestine. Whey proteins could act on bone metabolism by suppressing osteoclast-mediated bone resorption and osteoclastic cell formation. Further investigations are necessary *in vivo* (*see* **Health Aspects of Dairy Products**: Nutritional and Health-Promoting Properties of Dairy Products: Bone Health).

Conclusion

Milk represents a source not only of essential amino acids and organic nitrogen but also of peptides with biological activities. Amino acid sequences with biological activities are well characterized in caseins and whey proteins. These peptides can be released by enzymatic degradation in the body and may be considered to act like exogenous metabolic modulators. The physiological importance of these peptides is the subject of extensive studies. They play a significant role in regulating gastrointestinal processes, such as intestinal motility, hormone release, and nutrient absorption. They can also act on the body defenses. They may be used for their health benefits in preventing chronic conditions, such as cardiovascular disease or cancer. On account of their different biological activities, these peptides represent some new and beneficial aspects in nutrition. However, further research is required, particularly in humans, to fully substantiate the role of these bioactive substances.

Effects of Processing on Protein Quality of Milk and Milk Products

Overall Effects of Processing and Storage on Milk Proteins and Their Nutritional Significance

Besides being a source of dietary amino acids, milk proteins have many unique features. From a technological point of view, proteins affect the properties of dairy products more than any other constituent. Many specific proteins appear to be biologically active and to act as enzymes, antimicrobial or antioxidant agents, metal or vitamin binders, or growth factors. More recently, the physiological impact of some peptides encrypted in milk proteins has been demonstrated as well. For all the above reasons, milk proteins have been studied so extensively in terms of structure, function, and stability that, at present, these probably represent the best-characterized food protein system.

Processes adopted in food manufacturing have the primary purpose of obtaining safe, nutritious, stable, and tasty products. Heat treatment is involved in the processing of almost all milk products, and heating conditions may vary from mild thermization (about 65 °C for 15 s) to severe sterilization (e.g., 120 °C for 10–20 min). To some extent, storage of the finished product may be regarded as an additional heat treatment. In fact, some dairy products, like processed cheese or sterilized milk, are kept at room temperature on the shelves for months.

During heating and storage, milk proteins are subjected to a number of modifications involving the molecule itself or resulting from interactions with other milk constituents or non-dairy ingredients. Both the nature and extent of these modifications are temperature- and time-dependent, although other factors, like amino acid sequence and protein conformation, pH, and water activity (a_w), may play a relevant role. The most important non-enzymatic mechanisms involved are related to (1) denaturation, with conformational changes of the protein molecule and irreversible modification of the three-dimensional structure, and (2) covalent modifications, in which the side-chains of amino acids participate. Most of the time, these two types of mechanism occur in combination, as covalent changes may imply a change in protein conformation and vice versa, and both affect stability and technological properties of the protein fraction in heated milk products (**Table 1**). At the same time, these modifications could decrease the digestibility and nutritional value of milk proteins (*see* **Milk Proteins**: Nutritional Quality of Milk Proteins).

Protein Denaturation

Because caseins lack typical stable secondary and tertiary structures, they are very heat-stable molecules. Milk at its natural pH may withstand heating at 100 °C for hours without apparent changes in casein solubility (*see* **Heat Treatment of Milk**: Heat Stability of Milk). In contrast, whey proteins are typical globular proteins and, when exposed to high temperatures, undergo unfolding, with exposure of the reactive free thiol groups, and subsequent irreversible denaturation and aggregation reactions. Upon heating, whey proteins can either self-aggregate or form stable aggregates with casein, mainly involving disulfide bonds. Both κ-casein and α_{s2}-casein have cysteinyl residues and therefore both could form covalent aggregates with denatured whey proteins. However, unlike κ-casein, α_{s2}-casein is located mainly in the interior of the micelle and, therefore, is poorly reactive. Under the usual conditions of heat processing of milk, whey protein denaturation begins at about 65 °C, while soluble whey proteins are no longer detected in in-bottle sterilized milk. From the technological point of view, whey protein aggregation with casein in milk intended for cheesemaking progressively results in an increased rennet coagulation time and a weaker gel. On the contrary, in yogurt manufacturing, denatured whey protein molecules help in determining the target firmness of the gel and improving its water-holding capacity. Although heat treatments are generally assumed to impair protein quality, contradictory results are reported concerning digestibility of milk proteins in milk heated under different conditions. In addition, the different criteria and conditions used to determine protein digestibility make it difficult to compare data from different studies. The actual nutritional consequences of milk heat treatment have rarely been evaluated *in vivo* in humans. However, quite a good agreement exists on the finding that protein digestion is more rapid after UHT milk ingestion than it is with pasteurized milk, leading to an increased transfer of dietary nitrogen into plasma protein and urea. This effect could be explained by a softer coagulation occurring in UHT milk, likely due to the presence of denatured

Table 1 Main effects of various heat-induced non-enzymatic modifications on some milk protein characteristics

Modification	*Conformation*	*Chemical composition*
Amino acid racemization	Yes	No
Amino acid isomerization	Yes	Yes
Deamidation	Yes/no	Yes
Dephosphorylation	Yes	Yes

Glycation	Yes/no	Yes
Cross-linking	Yes	Yes/no
Oxidation	Yes	Yes

whey proteins at the surface of casein micelles, and hence a higher susceptibility to enzymatic hydrolysis.

Maillard Reaction

Apart from the disruption and formation of disulfide bonds, leading to whey protein denaturation and casein–whey protein bonding, protein glycation via the Maillard reaction (MR), also known as non-enzymatic browning, is mainly involved in heat-induced covalent interactions in heated milk and milk products (*see* **Lactose and Oligosaccharides**: Maillard Reactions). The MR is usually described as divided into three stages: early, advanced, and final. The early stage involves the condensation reaction of the reducing moiety of lactose with an amine, mainly the ε-amino group of lysyl residues of casein and whey proteins. As a result, a Schiff's base forms and then rearranges to produce the more stable Amadori product lactulosyl lysine (LL). Other primary or secondary amines can react as well. The conjugation of lactose to milk proteins is greatly accelerated by heat, and it renders lysine biologically unavailable. Under severe heat treatments, LL further undergoes a complex series of condensation, rearrangement, and fragmentation reactions, forming a vast array of degradation products, predominantly poorly characterized and collectively named as advanced glycation end products (AGEs). Among these, N^{ε}-(carboxymethyl)lysine (CML) has been recognized as a biomarker of glycoxidative, lipoxidative, and oxidative stress in biological systems, as it may originate by different pathways, including oxidation of LL. As a result, the formation of CML in some dairy products, especially those dried, is not always closely related to the heat load applied in processing.

Many AGEs are unstable and may give rise to covalent intra- and inter-molecular cross-links involving other essential amino acids, thus affecting nutritional properties other than lysine bioavailability. During the final stage of the MR, which usually is not reached in dairy products, progressive polymerization into brown, water-insoluble melanoidins takes place. Their precursors, referred to as pre-melanoidins, can react with and destroy some vitamins and influence trace element metabolism. Direct nutritional effects of the MR on milk proteins are therefore mainly related to impairment of their bioavailability by derivatization of essential amino acids, such as lysine, arginine, histidine, and tryptophan, and, to a lesser extent, by cross-linking phenomenoa. In addition, it is possible that LL residues hinder the release of adjacent amino acids on digestion and therefore impair their utilization. Some of the molecules responsible for these phenomena will be considered later in this section. As a general remark, the biological role of exogenous food-derived AGEs is receiving much attention, given that the amount of MR products ingested daily with commonly consumed foods, such as heated milk, bakery products, and coffee, has been estimated to be 500–1200 mg of Amadori products and 25–75 mg of AGEs, which is much higher than the total amount of AGEs in plasma and tissues. Since a high proportion of the exogenous AGEs is absorbed and excreted via the kidneys, the contribution of AGEs and Amadori products in milk (based) products to plasma AGEs content could be greater in subjects with impaired renal function.

Other Modifications

A number of other non-enzymatic covalent cross-links of milk protein chains are formed starting from the heat-induced β-elimination reaction at cyst(e)ine or phosphoserine residues, which break down to form a dehydroalanyl (DHA) side chain. This reaction is enhanced when the pH of the protein microenvironment is increased. The subsequent reaction of DHA with adjacent nucleophilic lysyl, cysteinyl, or histidinyl side chains originates the xenobiotic cross-links lysinoalanine (LAL), lanthionine, or histidinoalanine, respectively (**Figure 1**).

Some essential amino acids are thus rendered non-bioavailable through this mechanism. It is generally accepted that *in vitro* digestibility of milk protein is adversely affected by heat and alkali treatment. This is primarily due to the formation of inter- and intra-molecular cross-links, which hinder access of proteolytic

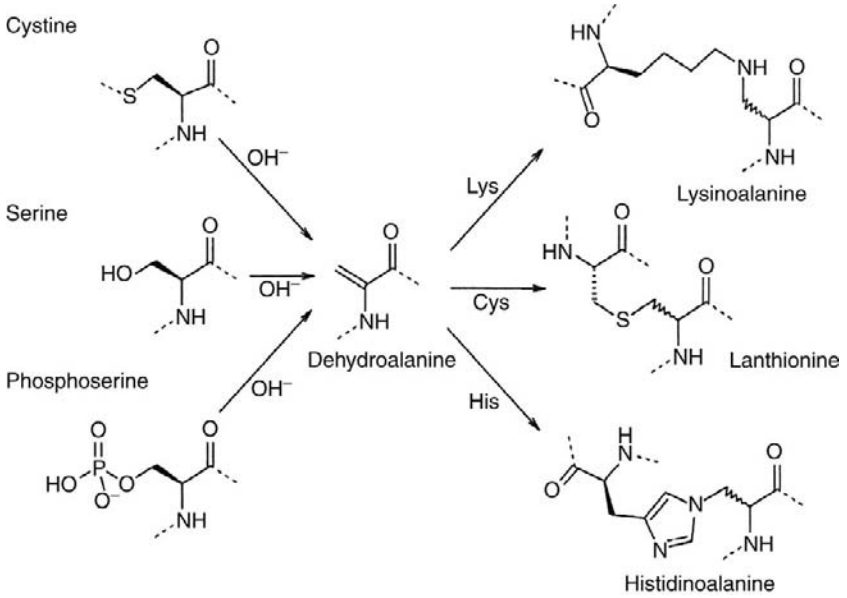

Figure 1 Formation of protein cross-links via β-elimination reactions.

enzymes. In addition, both lysyl and arginyl residues involved in cross-links are no longer recognized by specific proteases. It is still unclear to what extent dietary LAL ingested in heat-treated proteins is utilized by the human body. Urinary and fecal excretions in humans account for only about 60% of the intake, while lower recoveries were obtained with rats. The fact that rats exhibit renal lesions (cytomegaly) after consuming LAL-rich diets for several weeks has focused some toxicological interest on LAL; however, no similar effects have been observed in primates.

Furthermore, thermal dephosphorylation of phosphoserine residues of casein impairs the micelle's capacity to bind calcium and to produce bioactive caseinophosphopeptides, which, during the last decades, have been associated with some biological properties of caseins (*see* **Milk Protein Products**: Bioactive Peptides).

Formation of LAL is concurrent with racemization of amino acid residues in proteins; therefore, nutritional value and related changes resulting from the consumption of heat- and/or alkali-treated proteins arise as a consequence of both the chemical reactions. In addition, because D-isomers of some amino acids (alanine, valine, serine, leucine, isoleucine) are produced by various microorganisms used in the fermentation process, these are present in cultured milks or long-ripened cheeses independent of the heating conditions adopted in the manufacturing process. Owing to the wide species dependence of the nutritional utilization of various D-amino acids, a need exists to develop a better understanding of their specific role in human nutrition.

Amino acid deamidation refers to the hydrolysis of the side chain amides in asparagine and glutamine residues to form aspartic and glutamic acid, respectively. This phenomenon is responsible for the release of ammonia; nevertheless, only severe heat treatment in a restricted water environment can induce cleavage of the peptide chains yielding soluble peptides and increasing the non-protein nitrogen content of milk.

Evaluation of Chemical Markers as Indicators of Heat Damage of Processed Milk Products

The above-described chemical pathways have been studied extensively using simple model systems, comprising amines and reducing sugars, which allowed several newly formed molecules to be recognized and isolated. Nonetheless, the results obtained were not always directly transferable to more complex matrices such as milk and milk products. In recent years, the availability of advanced analytical techniques has allowed scientists to elucidate the heat-induced chemical pathways relevant to real milk products. On this basis, the quantification of some non-enzymatic, irreversible protein modifications has become a key criterion to assess the heat load applied during processing and, hence, to characterize the quality and nutritional value of the finished food. In this respect, the best applications concern the covalent interactions mediated by the MR. During the last few decades, in fact a variety of molecules have been studied, the formation of which is directly or indirectly consequent to the development of the MR in heated milk products. The best-known example is represented by LL, the formation of which is conveniently monitored by measuring the concentration

Table 2 Concentrations (mean ± standard deviation) of furosine, lysinoalanine, and blocked lysine in some dairy products

Type of product		*n*	*Furosine*	*Lysinoalanine*	*Blocked lysine*
			(mg 100 g^{-1} protein)		*(%)*
Liquid milk					
Raw		15	5.2 ± 0.5	<0.1	0.2 ± 0.02

UHT, ultra-high temperature sterilized.

of furosine (FUR), a derived molecule formed during acid hydrolysis. Due to the availability of a reliable, well-defined analytical method (i.e., International Standard ISO 18329:2004), the determination of FUR level has found wide application in the characterization of thermal treatments applied in the manufacture of different milk products, especially drinking milk (**Table 2**). Moreover, the concentration of this chemical marker for the lysine–lactose reaction may be used to calculate the percentage of blocked lysine in milk products.

A trace amount of FUR is found in raw milk, as non-enzymatic glycation of proteins also occurs *in vivo*. Mild heat treatments induce a limited increase in the extent of glycation, while the increase is sharp in sterilized milks, either UHT or in-can processed. Indirect heating via countercurrent flow heat exchangers results in a higher degree of protein modification than that occurring in direct heating via steam injection. However, indirect heating is, for economic reasons, the predominant process for UHT treatment. The innovative technology of high pasteurization by direct steam infusion could be very promising for the prolongation of shelf life of liquid milk products. However, a longer shelf life of liquid milk, as achieved by UHT treatment, is advisable in countries with predominantly high ambient temperatures and with a market structure that does not allow for constant refrigeration of the product. The level of FUR can be used for the classification of liquid milk and the evaluation of different heating processes and types of plant. At present, no upper limits are established to the severity of heat treatment, in terms of time/temperature conditions, for the different types of liquid milk. Consequently, unjustified abuse of heat could, in some cases, be used in milk processing, leading to enhanced levels of protein damage. This may be prevented by setting suitable upper limits for FUR in each class.

LAL is another very sensitive marker of heat treatment in milk proteins and also indicates the influence of alkaline pH during processing. As it is formed in the β-elimination reaction, it is particularly suitable for the evaluation of the heat load in milk products with a low lactose content. Under similar conditions of temperature, pH, and moisture, the formation of LAL is partly suppressed by lysine lactosylation in most of the dairy products, lactose being always present, although at different concentrations. In fact, while the lactose molecules are free to move and find lysine residues to react with, the DHA residues can react only with adjacent lysine residues. This partly explains why the ratio between the levels of FUR and LAL may vary widely but is always >1 (**Table 2**). The highest LAL concentrations are found in caseinates. In the industrial manufacturing process of these products, casein is acid-precipitated from milk, then solubilized with alkali, and dried. In caseinates, therefore, LAL level can reach tens of milligrams per 100 g of protein, while glycation is relatively low. In contrast, this molecule is not detectable in pasteurized milk and is present only at trace levels (<0.1 mg (100 g)$^{-1}$ protein) in genuine fresh cheeses, even in Mozzarella cheese which undergoes stretching in hot water.

The production of dried milk products represents the most convenient way of storing and shipping milk, as they are much more stable and reduced in weight and bulk with respect to the starting raw material. In milk powder production, the process includes a preheat treatment of liquid milk with the purpose of obtaining powders with different levels of denatured whey protein, the crucial parameter affecting the properties of the finished product. The subsequent evaporation and spray-drying steps do not denature whey protein significantly, the former being normally carried out at temperatures below 60 °C and the latter very rapid (*see* **Dehydrated Dairy Products**: Milk Powder: Types and Manufacture). In contrast, these two steps promote extensive glycation of the protein component as is globally indicated by the high levels of FUR and conveniently evidenced by the separations obtained using HPLC and CZE techniques for whey protein and casein, respectively (**Figure 2**). The modern membrane filtration processes, for example, ultrafiltration and microfiltration, allow large-scale industrial production of a variety of dried milk protein products (casein and caseinates, milk protein concentrates, milk protein isolates, whey protein concentrates, etc.) having a protein content roughly ranging from 35 to 90% (*see* **Milk Protein Products**: Milk Protein Concentrate; Whey Protein Products). As a result, both technological and nutritional characteristics of these dairy powders may vary tremendously, and this aspect is of crucial relevance because they are treated mainly as food ingredients. As has already been mentioned, both type and extent of protein modifications occurring in these products (**Table 2**) depend on the lactose content and the pH conditions during processing at least as much as on thermal treatment. In addition, the stability of protein powders during storage is critically affected by the moisture content, more precisely by the a_w, and the storage temperature, the effects of these two

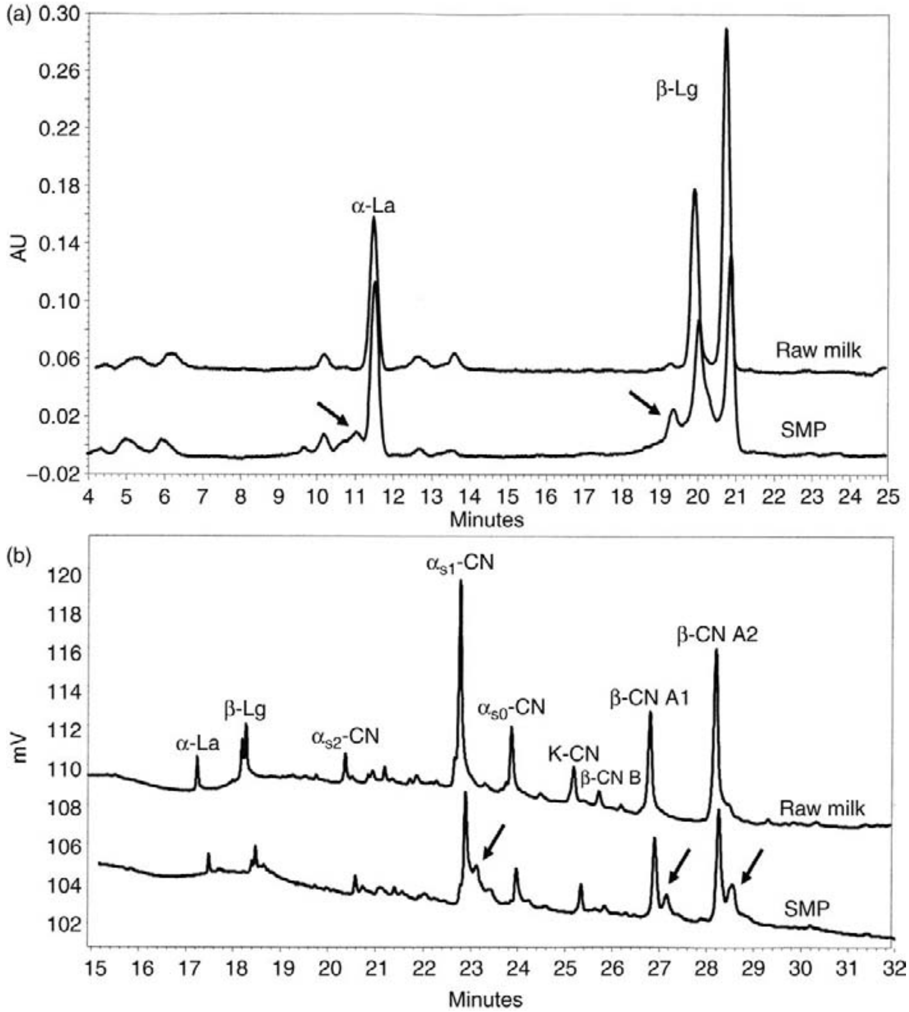

Figure 2 Separation of (a) soluble whey proteins by HPLC and (b) milk proteins by capillary electrophoresis of raw milk and reconstituted skim milk powder (SMP). Arrows: glycated forms.

factors being strictly dependent on each other. For example, for optimal preservation at 25 °C the a_w should be close to 0.2. Therefore, it is very important for the users of these ingredients in industrial food manufacturing to adopt methods for evaluating their keeping quality. This is particularly the case of food intended for infants and children, who have a high essential amino acid requirement. In fact, in infant formula manufacturing, besides the heat treatment applied, the use of processed ingredients (whey powder, caseinates, whey protein concentrates) in formulation may play a major role in promoting deep protein modifications in the finished product. As shown in **Table 2**, the highest values of FUR, and therefore the highest percentage of blocked lysine, can be reached in powdered infant formulae, whereas liquid UHT-treated formulae show levels of LAL comparable to those of in-bottle sterilized milk. In addition, storage under the conditions usually indicated by manufacturers (at room temperature for up to 12 and 24 months, for UHT and powdered products, respectively) promotes further protein modifications, as highlighted by the progressive accumulation of FUR and LAL shown in **Figure 3**. The evaluation of protein quality in infant formulae is of paramount importance since they may constitute the sole source of nutrition for newborns. In this regard, the substantial levels of both blocked lysine and molecular cross-link undoubtedly impair the nutritional quality of protein. Nevertheless, the LAL levels detected in infant formulae, even at the end of the shelf life, are far from those considered to be a health threat in rats (*see* **Dehydrated Dairy Products**: Infant Formulae).

Some milk-derived products may find application as ingredients in several food preparations and, therefore, undergo further processing during domestic cooking. This may have a great influence on quality-determining parameters like nutritional value and digestibility of protein components. In fact, FUR and LAL originate from the same complex series of reactions that produce the desirable flavor and color of baked and roasted foods. Therefore, to achieve an overall evaluation of the nutritional quality of protein in this kind of products, the effect of heat treatment applied during domestic cooking should be evaluated as well. Data reported in **Table 3** show the case of different types of cheese used as pizza toppings.

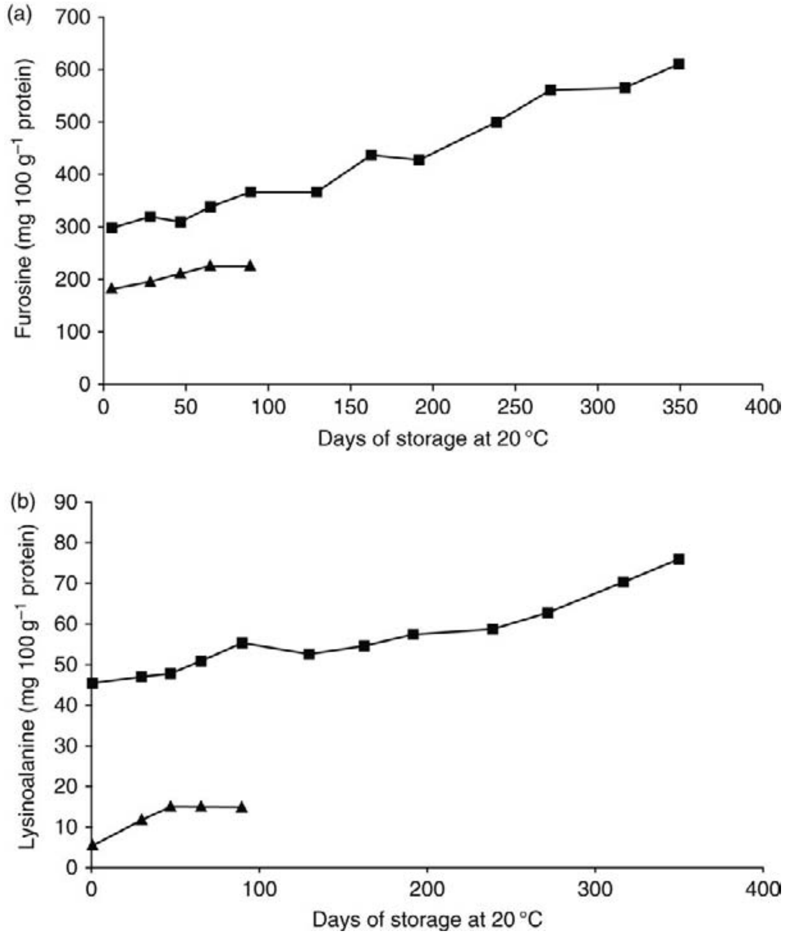

Figure 3 Accumulation of (a) furosine and (b) lysinoalanine in indirect UHT milk (▲) and in UHT liquid infant formula (■) during storage.

Table 3 Effect of domestic cooking in an electric oven on furosine and lysinoalanine levels in different types of cheese topped on pizza

	Furosine		*Lysinoalanine*	
	(mg 100 g^{-1} protein)			
Type of cheese	*Before cooking*	*After cooking*	*Before cooking*	*After cooking*
Mozzarella	7.4	50	0.1	0.5
Imitation Mozzarella	32	221	4.2	6.8
Processed	24	212	1.4	28

Following pizza baking at 200 °C for 20 min, the FUR content increased by a factor of 7–8 in all the topped cheeses, and in imitation Mozzarella and processed cheese it reached values characteristic of sterilized milk. The level of LAL showed a sharp increase in processed cheese only, probably because of its higher pH value. Both imitation Mozzarella and processed cheese, which are usually manufactured using dried dairy ingredients, like caseinates, milk protein concentrate (MPC), and whey powder, are often used in pizzas as a cheaper alternative to natural Mozzarella.

From the results presented above, it can be concluded that, for most milk and dairy products, a reliable assessment of type and extent of heat-induced covalent modifications of the protein components is feasible via the determination of FUR and LAL content. Nevertheless, when extremely severe thermal processes are adopted, the degradation of LL begins, with the consequent formation of either 1- or 3-deoxyosone (DG), depending on the reaction conditions, mainly the pH value of the environment. The unstable deoxyosones react readily with the side chain amino groups of the protein chain generating AGEs (**Table 4**) some of which have been identified in high-temperature-treated dairy products and proposed as additional indicators of the intensity of heat treatment and the type of the applied process.

The 3-DG-derived AGEs contain only the glucose moiety of the reacted lactose, as the β-1,4-glycosidic bond in lactose is broken during LL degradation. However, these compounds are generally present only in small amounts in heated milk and milk products, as this degradation pathway is not preferential for LL. As an example, protein-bound lysylpyrrolaldehyde (LPA) can form in the presence of lysine residues and it can be found in proteins of dairy products. Following alkaline or enzymatic hydrolysis, LPA can be quantified at microgram per 100 g protein amounts in sterilized milk and concentrated milks. Other 3-DG-derived AGEs are capable of cross-linking milk proteins; pentosidine (PTD), for example, is a product of cross-linking between residues of lysine and arginine. This molecule, although produced in significant amounts in model systems, was found only at low concentrations in UHT milk (0–7 μg (100 g^{-1}) protein), in-bottle sterilized milk (13–350 μg (100 g^{-1}) protein), and whey powder (0–8 μg (100 g^{-1}) protein). When LL degrades via the 1-DG pathway, the 1-4 glycosidic bond of lactose remains intact and, therefore, the whole carbon backbone of the disaccharide is still present in the derived AGEs. In this case, the rearrangement of 1-DG creates free molecules containing hetero rings (furans and pyrans). Galactosyl-β-pyranone (GAP) forms at heating conditions characteristic of milk sterilization. The level of GAP is well-correlated with the whole heat load of the process and therefore may allow direct UHT milk (0.1–1.5 mg l^{-1}) to be distinguished from indirect UHT milk (1.5–3 mg l^{-1}), and the latter from in-can sterilized milk (>6 mg l^{-1}). The level of GAP in UHT milk increases sharply when the proportion of milk recirculated in the plant is high or when milk is subjected to a second treatment. Upon prolonged heating or storage, GAP can dehydrate to form galactosyl-isomaltol (GAI), which has been detected in milk powders submitted to severe heating. Both GAP and GAI are soluble molecules and, therefore, their levels are not directly related to protein nutritional value. Nonetheless, they can further react with side chain amino groups, producing protein-bound xenobiotic molecules such as galactosyl-acetylpyrrole (GALP), pyridinium betaines, and furanones. Formation of GALP in casein–lactose model systems is promoted by heating conditions similar to those applied in industrial processes used for manufacturing processed cheese and infant formulae.

Table 4 Main AGEs deriving from lactulosyllysine degradation via deoxyosones

Via 3-deoxyosone	*Via 1-deoxyosone*
Lysylpyrrolaldehyde	Galactosyl-β-pyranone
Pentosidine	Galactosyl isomaltol
	Galactosyl-acetylpyrrole
	Pyridinium betaines
	Furanone

In conclusion, technological processes adopted in manufacturing liquid milk and other dairy products, mainly those involving high temperatures and extreme pH conditions, may affect the nutritional properties of protein components. Possible causes of protein damage include destruction of some essential amino acids, reduced digestibility owing to the formation of cross-linked amino acids, loss of phosphorus from casein, and adverse effects on mineral nutrition owing to chelation of trace elements. Although heat treatment is a necessary step in most cases, to meet the safety and shelf life requirements of the finished products, nutritional aspects could be disregarded by manufacturers, as they are not regulated. On this basis, operating conditions strictly following the GMP principles represent the only guarantee of avoiding abuse of heat load in milk processing. From this point of view, specific quality criteria based on chemical markers of heat load not only represent a tool for evaluating the overall quality of milk products but, with an adequate price structure, may also improve competitiveness among the producers. In the food industry, an increasing emphasis is today given to food products having higher nutritional value and, meanwhile, consumers are becoming more aware of the effects of diet on health. Both trends would be promoted by a better understanding of the effects of food manufacturing processes, mainly those requiring high temperatures, on the nutritional quality of proteins, a major component in many food products.

Cover Design: The Editors would like to acknowledge Ms Anne Cahalane, Senior Executive Assistant, School of Food and Nutritional Sciences, University College, Cork, Ireland, who designed the cover for the first edition of *Encyclopedia of Dairy Sciences*.

EDITORS' BIOGRAPHIES

John W. Fuquay, Professor Emeritus of Dairy Science at Mississippi State University, served on the faculty there from 1969 to 1999. His areas of emphasis in teaching and research were environmental physiology and reproductive physiology. He received his BS and MS degrees from North Carolina State University and his PhD degree from Pennsylvania State University, all in the area of dairy science. After completing the PhD degree in 1969, he accepted a teaching and research position at Mississippi State University, where he progressed through the ranks from assistant professor to professor before retiring in 1999. Professor Fuquay served as Coordinator for the Graduate Program in Animal Physiology from 1986 to 1999. He was a Visiting Professor in the Animal Sciences Department, University of California-Davis in 1979 and in 1985–86.

Professor Fuquay was active in his professional society, The American Dairy Science Association. He was a member of the editorial board of *Journal of Dairy Science* for seven years, an editor for four years, and served as the first Editor-in-Chief for six years (1997–2002). For his professional contributions and service to the Association, Professor Fuquay was recognized as a Fellow in the American Dairy Science Association in 2001 and received the Association's Award of Honor in 2002. Other recognitions include the World Association of Animal Production Jean Boyazoglu Award in 2003, the Distinguished Dairy Science Alumnus Award from Pennsylvania State University in 2003, and several teaching and research awards from his university.

Professor Fuquay has participated in a variety of international activities. He has presented short courses and lectures as well as provided consultations in a number of countries, primarily in Asia and Latin America. In addition to his research publications, he is the coauthor of a textbook, *Applied Animal Reproduction* (Prentice Hall), that has been widely used by universities in the United States and internationally. The first edition was published in 1980 and the last (sixth) edition in 2004. In 2010, he published a memoir, *Musings of a Depression-Era Southern Farm Boy* (Vantage Press), which reflects on how the experience of growing up on a farm in the southern United States during the great depression instills one with an understanding of the importance of strong family bonds and a sound work ethic in meeting the challenges of the adult world.

Patrick F. Fox was Professor and Head of the Department of Food Chemistry at University College, Cork (UCC), Ireland, from 1969 to 1997; he retired in December 1997 and is now Emeritus Professor of Food Chemistry at UCC. Prof. Fox received his BSc degree in Dairy Science from UCC in 1959 and PhD degree in Food Chemistry from Cornell University in 1964. After postdoctoral periods in Biochemistry at Michigan State University and in Food Biochemistry at the University of California, Davis, he returned to Ireland in 1967 to take up a research position at the Dairy Products Research Centre at Moorepark before moving to UCC in 1969.

Prof. Fox's research has focused on the biochemistry of cheese, the heat stability of milk, physicochemical properties of milk proteins, and food enzymology. He has authored or coauthored about 520 research and review papers, and authored or edited 25 text books on Dairy Chemistry. He was one of the founding editors of the *International Dairy Journal.*

In recognition of his work, Prof. Fox has received the Research & Innovation Award of the (Irish) National Board for Science and Technology (1983), the Miles-Marschall Award of the American Dairy Science Association (1987), Medal of Honour, University of Helsinki (1991), the DSc degree of the National University of Ireland (1993), the Senior Medal for Agricultural & Food Chemistry of the Royal Society for Chemistry (2000), the ISI Highly Cited Award in Agricultural Science (2002), the International Dairy Federation Award (2002), Gold Medal of the UK Society of Dairy Technology (2007), and an autobiography published in Annual Review of Food Science & Technology (2011).

Prof. Fox has been invited to lecture in various countries around the world. He has served in various capacities with the International Dairy Federation, including President of Commission F (Science, Nutrition and Education) from 1980 to 1983.

Paul McSweeney is Professor of Food Chemistry in the School of Food and Nutritional Sciences, University College, Cork, Ireland (UCC). He graduated with a BSc degree in Food Science and Technology in 1990 and a PhD degree in Food Chemistry from UCC in 1993 and also has an MA in Ancient Classics. He worked for a year in the University of Wisconsin (1991–92) as part of his PhD and as a postdoctoral research scientist in UCC (1993–94). He was appointed to the academic staff of UCC in 1995. The overall theme of his research is dairy biochemistry with particular reference to factors affecting cheese flavor and proteolysis during cheese maturation including the role of non-starter lactic acid bacteria and smear microorganisms, the ripening of hybrid and non-Cheddar varieties, the specificity of proteinases on the caseins, proteolysis and lipolysis in cheese during ripening, and characterization of enzymes important to cheese ripening (proteinases, peptidases, amino acid catabolic enzymes). He is the coauthor or coeditor of eight books, including the third edition of *Cheese: Chemistry, Physics and Microbiology* (Amsterdam, 2004) and the *Advanced Dairy Chemistry Series* (New York, 2003, 2006, 2009), and has published numerous research papers and reviews. Prof. McSweeney is an experienced lecturer and researcher and has successfully managed research projects funded through the Food Industry Research Measure and its predecessors administered by the Irish Department of Agriculture and Food, the EU Framework Programmes, the US–Ireland Co-operative Programme in Agriculture/Food Science and Technology, and Bioresearch Ireland and Industry. He was awarded the Marschall Danisco International Dairy Science Award of the American Dairy Science Association in 2004 and in 2009 a higher doctorate (DSc) on published work by the National University of Ireland.

GUIDE TO USE OF THE ENCYCLOPEDIA

STRUCTURE OF THE ENCYCLOPEDIA

The material in the Encyclopedia is arranged as a series of entries in alphabetical order. Some entries comprise a single article, whilst entries on more diverse subjects consist of several articles that deal with various aspects of the topic. In the latter case the articles are arranged in a logical sequence within an entry.

To help you realize the full potential of the material in the Encyclopedia we have provided three features to help you find the topic of your choice.

1. CONTENTS LISTS

Your first point of reference will probably be the contents list. The complete contents list appearing in each volume will provide you with both the volume number and the page number of the entry. On the opening page of an entry a contents list is provided so that the full details of the articles within the entry are immediately available.

Alternatively you may choose to browse through a volume using the alphabetical order of the entries as your guide. To assist you in identifying your location within the Encyclopedia a running headline indicates the current entry and the current article within that entry.

2. CROSS REFERENCES

All of the articles in the Encyclopedia have been extensively cross referenced. The cross references, which appear at the end of an article, have been provided at three levels:

i. To indicate if a topic is discussed in greater detail elsewhere.
ii. To draw the reader's attention to parallel discussions in other articles.
iii. To indicate material that broadens the discussion.

Example

The following list of cross references appear at the end of the entry entitled **Bacteria, Beneficial** | Lactic Acid Bacteria: An Overview

See also: **Bacteria, Beneficial**: *Bifidobacterium* spp.: Applications in Fermented Milks; *Bifidobacterium* spp.: Morphology and Physiology. **Lactic Acid Bacteria**: Citrate Fermentation by Lactic Acid Bacteria; Lactic Acid Bacteria in Flavor Development; *Lactobacillus* spp.: General Characteristics; *Lactobacillus* spp.: *Lactobacillus acidophilus*; *Lactobacillus* spp.: *Lactobacillus casei* Group; *Lactobacillus* spp.: *Lactobacillus delbrueckii* Group; *Lactobacillus* spp.: *Lactobacillus helveticus*; *Lactobacillus* spp.: *Lactobacillus plantarum*; *Lactobacillus* spp.: Other Species; *Lactococcus lactis*; *Leuconostoc* spp.; *Pediococcus* spp.; Physiology and Stress Resistance; Proteolytic Systems; *Streptococcus thermophilus*; Taxonomy and Biodiversity. **Pathogens in Milk**: Enterobacteriaceae.

3. INDEX

The index will provide you with the volume number and page number of where the material is to be located, and the index entries differentiate between material that is a whole article, is part of an article, or is data presented in a table or figure. Detailed notes are provided on the opening page of the index.

4. COLOR PLATES

The color figures for each volume have been grouped together in a plate section. The location of this section is cited in the contents list. Color versions of black and white figures are cited in figure captions within individual articles.

5. CONTRIBUTORS

A full list of contributors appears at the beginning of each volume.

6. GLOSSARY

A glossary of terms used within the work is provided in Volume Four before the Index.

PREFACE

We are pleased to present the second edition of the *Encyclopedia of Dairy Sciences*. The first edition was published in 2003 by the Major Reference Works Division of Academic Press, now part of Elsevier Sciences, and it comprised 427 articles. The objective was to satisfy the need for an authoritative source of information for people involved in the integrated system of production, manufacture, and distribution of dairy foods. It was realized from the beginning that a program of revision would be needed to keep the Encyclopedia up to date. This goal has been met in the second edition through 503 articles, of which 121 are new articles and 382 are revised articles. We express appreciation to the Editorial Advisory Board for its role in evaluating articles for needed revision, reviewing new and revised articles, and for help in identifying new topics to be included along with appropriate authors. Likewise, we are grateful for the contributions of the many authors who have either revised their articles or prepared new articles.

The main topics related to milk production and dairy technology are addressed in addition to providing information on nutrition, public health, and dairy industry economics including aspects of trade in milk and dairy products. All species that produce milk for human consumption have been included in this work. Some of these species are of regional significance only, but they have been included because of the essential role that their milk plays in the nutrition of people inhabiting various regions of the world. A significant addition to the second edition is four introductory articles addressing the history of Dairy Science and Technology. A synopsis has been prepared for each article in the second edition and will appear with the online listing of the articles in this publication.

The primary aim of the Encyclopedia is to provide a complete resource for researchers, students, and practitioners involved in all aspects of the dairy sciences as well as those involved with economic and nutritional policy and members of the media. We have tried to do this with a writing style that is easily comprehended by persons who are not highly trained in the technical aspects of the Dairy Sciences. Users should be able to access information on topics that are peripheral to their areas of expertise.

We express appreciation to the staff of the Major Reference Works Division, responsible for this Encyclopedia, for their timely responsiveness to the needs of the editors and their essential administrative role in keeping this major reference work on-track toward a satisfactory completion within the desired time schedule. We remember Nancy Maragioglio, Senior Life Sciences Editor, who initiated the work and was ever responsive to queries by the editors, as well as Sera Relton, Esmond Collins, Milo Perkins, and Claire Byrne, Development Editors, and Charlotte (Charlie) Kent, Publishing Administrator, who kept things moving through their communication with editors, authors, and reviewers and who exhibited almost flawless administrative skills. Sera Relton was particularly helpful as she assisted us in moving through the final submission and review stages. Laura Jackson is recognized for her contributions as Production Manager of the Encyclopedia.

Special recognition is due to Ms Anne Cahalane, Senior Executive Assistant, School of Food & Nutritional Sciences, University College, Cork, whose stylized representation of a cow, a milk can, and a wedge of cheese adorns the cover of the first and second editions of the Encyclopedia of Dairy Sciences.

John W. Fuquay
Patrick F. Fox and
Paul L. H. McSweeney

FOREWORD

The cow is the foster mother of the human race. From the days of the ancient Hindoo to this time have the thoughts of men turned to this kindly and beneficent creature as one of the chief sustaining forces of human life.

William Dempster Hoard (1836-1918)
Former governor, state of Wisconsin, USA (1889-1891)
Founder of **Hoard's Dairyman** (1885)

We must never forget that milk and milk products are and will always be important sources of basic food nutrients for humans both young and old. The more scientific facts we can discover, understand, and apply related to producing, processing, and marketing milk and milk products, the better we will serve the nutritional needs of humanity throughout the world.

More than 2000 years ago Aristotle noted, *Everyone honors the wise and excellent.* We are indebted to those *wise* enough to conceptualize and envision the favorable global impact that is certain to follow by bringing together this exhaustive, rich collection of 503 pertinent articles written and reviewed by more than 700 world-renowned disciplinary experts representing 50 countries – persons each of whom bears the mark of *excellence.* Happily these timely topics are now recorded in four informative, important, engaging volumes. We thank, commend, and salute the prodigious efforts of the *wise* and *excellent* authors who generated, compiled, and put the spotlight on the useful information and data, and who now share them through their well-written articles.

One noteworthy value and enduring virtue of these articles is bringing into clear perspective the context of both the state-of-the-art and the future of dairy sciences. When the history and contributions of scholarly publications related to the all-important global dairy industry are recorded, the second edition of the *Encyclopedia of Dairy Sciences* will be cited often and with great respect and appreciation.

Fundamental to continued progress and success in the dairy industry have been the signal service, cooperation, and collective contributions of dedicated scientists, teachers, agricultural advisors/extension workers, and representatives of governments and industries. Additional exciting breakthroughs in applying new findings and developments in research and technology to the production and processing of milk are sure to follow as we move surefootedly through the twenty-first century. This continued growth and success will be aided immensely by the vast and extraordinarily useful knowledge base made available by the idea-rich, insightful authors, editorial advisory board members, editors, and publisher of the second edition of the *Encyclopedia of Dairy Sciences.*

Indeed, by perusing the comprehensive and authoritative articles of this greatly needed and monumental encyclopedia, readers will be made even more aware of the tremendous progress that has occurred in the basic and applied sciences underpinning the global dairy industry.

Ours is an internationally competitive and incredibly technological world. And unless talented, creative scientists continue to work together in researching and applying the most effective and economical ways and means of providing

an abundant, safe supply of milk and milk products for an ever-increasing world population, we will never reach our noble goal of adequately feeding all the earth's people.

May we utilize the comprehensive scientific knowledge base made available through this second edition of the *Encyclopedia of Dairy Sciences* as we pledge to realize advances in the health and well-being of the undernourished millions – including many who need and deserve to be rescued from the ugly grip of hunger – by increasing the availability of nature's most nearly perfect food – milk!

Pure milk from healthy animals is a luxury of the rich, whereas it ought to be the common food of the poor.

Mohandas Gandhi (1869-1948)
Indian nationalist leader

OFFICE OF INTERNATIONAL EPIZOOTIES

Mission, Organization and Animal Health Code

B Vallat and B Carnat, World Organisation for Animal Health (OIE), Paris, France

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The need for a global approach in the fight against animal diseases is now very clear. The World Organisation for Animal Health (which is also known by its historical acronym OIE (Office International des Epizooties)) is leading this fight worldwide. The OIE is the international standard-setting organization for animal disease control, the safety of international trade of animals and animal products, animal disease prevention, surveillance, control, and information, animal welfare, animal production, and food safety.

The purpose of this article is to describe the OIE and its efforts and importance in improving animal health in the world, thereby improving human health. In order to better understand the organization, its history, structure, mandate and activities, and its major publications such as the Animal Health Codes for Terrestrial and Aquatic Animals will be examined.

A Brief History of the OIE

In 1920, rinderpest, a devastating plague of cattle, was introduced to Belgium, through the port of Antwerp by zebu cattle that were en route by boat to Brazil from India. This was the impetus for an international conference to examine the animal health situation in the world, to discuss the exchange of animal health information, and to consider export health measures and disease control methods. This so-called ‘Paris Conference’ expressed the wish that an ‘international office of epizootics for the control of infectious animal diseases’ be set up in Paris. Thus, in 1924, more than 20 years before the creation of the United Nations, an agreement was signed by the veterinary authorities of 28 countries from Europe, North and South America, Africa, and Asia to establish the OIE in Paris – where it remains to this day.

In 1995, the World Trade Organisation (WTO) recognized the OIE as the international standard-setting organization for trade in animals and animal products under the agreement on the application of sanitary and phytosanitary (SPS) measures. The WTO’s SPS agreement states that “to harmonize sanitary and phytosanitary measures on as wide a basis as possible, Members shall base their sanitary or phytosanitary measures on international standards, guidelines or recommendations”. The agreement names the OIE as the relevant international standard-setting organization for animal health, including diseases transmissible to humans.

In May 2003, the representatives of all OIE members agreed to change the name of the organization from ‘Office International des Epizooties’ to ‘World Organisation for Animal Health’ but decided to keep its historical acronym ‘OIE’. As of 2009, the organization has 175 member countries and territories and more than 200 reference laboratories and collaborating centers. It has formal agreements with 35 international and regional organizations such as FAO, WHO, the World Bank, Codex Alimentarius, and non-governmental organizations representing producers and animal welfare groups.

The OIE’s financial resources are derived principally from regular annual contributions, backed up by voluntary contributions from members. The amount of the annual budget of the organization makes the OIE one of the most cost-efficient international organizations.

In 2004, the OIE established the World Animal Health and Welfare Fund, for the purpose of projects of international public utility relating to the control of animal diseases, including those transmissible to humans, and the promotion of animal welfare and animal production food safety. This effort was funded initially by international donors, including the World Bank, the United States Department of Agriculture, Switzerland, Japan, France, Canada, and Australia.

Structure of the OIE

The World Assembly of Delegates

The General Assembly of Delegates is the highest authority and the governing body of the OIE. It is comprised of one delegate per country, who is usually the chief veterinary officer (CVO), and is officially nominated by the Government of the member country. It meets every year at the annual general session in May in Paris.

The main functions of the General Assembly of Delegates are to adopt international standards in the field of animal health and the control of animal diseases; to elect the members of the governing bodies (President and Vice President of the general assembly, members of the council, members of the regional and specialist commissions); to appoint the Director General (by secret ballot); and to examine and approve the annual report of activities, the financial report of the Director General, the annual budget, and the strategic plans of the OIE.

Voting by delegates within the World Assembly of Delegates respects the democratic principle of ‘one country, one vote’. All resolutions voted by the World Assembly must be implemented by the Director General.

Council

The Council represents the World Assembly of Delegates during the interval between the assemblies. It meets at least twice a year to examine technical and administrative matters and, in particular, the working program and the proposed budget to be presented to the members. There are six elected members in addition to the President, Vice President, and past president of the World Assembly. The members are elected to reflect the regional balance.

Headquarters

The OIE headquarters is based in Paris, France. Under the authority of the Director General, the headquarters implements and coordinates disease information, and the scientific and administrative activities that the members have decided upon, as well as the World Fund for Animal Health and Welfare.

Furthermore, it provides the secretariat for the annual World Assembly of Delegates and for the meetings of the specialized commissions and other technical meetings. Assistance is also given by the headquarters to the secretariat of the OIE regional and technical conferences.

Regional Commissions

There are five regional commissions, for Africa; the Americas; Asia, the Far East, and Oceania; Europe; and the Middle East, whose objective is to promote cooperation and organize regional activities in the field of prevention and control of animal diseases and animal welfare promotion.

The President and three other members of each regional commission are elected by countries of each region for a 3-year term. A regional commission conference is organized once every 2 years in one of the countries of the region. These conferences are devoted mainly to technical items and to regional cooperation in the control of animal diseases.

Regional Representations

The OIE maintains representations in Africa, the Americas, Asia and the Pacific, eastern Europe, and the Middle East, and maintains close links with the relevant regional commissions.

The goal of these representations is mainly to provide regionally adapted capacity building programs to relevant policy makers of OIE members.

There are also currently sub-regional representations for the Southern African Development Community (SADC) in Botswana, in Tunis for northern Africa, in Brussels for western Europe, in Panama for Central America, and in Thailand for southeast Asia.

Specialized Commissions and Companion Groups and Supports

There are four specialized commissions. Their role is to use current scientific information to study the problems of epidemiology and the prevention and control of animal diseases, to develop and revise OIE’s international standards, and to address scientific and technical issues raised by member countries. The members of these commissions are elected at the World Assembly for a 3-year term.

Terrestrial Animal Health Standards Commission and Aquatic Animal Health Standards Commission (Code Commission)

Founded in 1960, these commissions are responsible for the preparation of standards adopted by members contained in the Terrestrial Animal Health Code and the Aquatic Animal Health Code (Terrestrial and Aquatic

Code) to ensure that they reflect current scientific information on the protection of international trade and surveillance methods for terrestrial and aquatic animal diseases. They work with internationally renowned specialists in *ad hoc* and permanent working groups to prepare proposed standards in light of advances in veterinary science. The Aquatic Animal Health Standards Commission is also responsible for the Manual of Diagnostic Tests and Vaccines for Aquatic Animals.

The Scientific Commission for Animal Diseases

The Scientific Commission for Animal Diseases, founded in 1946, assists in identifying strategies and measures for animal disease control. It also examines member country submissions for requests to be certified free of the four diseases for which the OIE can officially certify country freedom: foot-and-mouth disease, bovine spongiform encephalopathy, rinderpest, and contagious bovine pleuropneumonia.

The Biological Standards Commission

The Biological Standards Commission, founded in 1949, also referred to as the Laboratories Commission, is responsible for the preparation of the Manual of Diagnostic Tests and Vaccines for Terrestrial Animals. It establishes standards for methods of diagnosing diseases of animals and for testing biological products, such as vaccines.

Permanent and ad hoc *working groups*

Comprising leading specialists from all OIE members, these expert groups are brought together to support specialist commissions for the preparation of draft standards and guidelines.

There are currently three permanent working groups: on wildlife disease, on animal production food safety, and on animal welfare.

Ad hoc groups are not permanent. Recently, they have been convened on a wide range of topics including biotechnology, brucellosis, communication, diseases of camels, epidemiology, and the evaluation of veterinary services (VSs).

OIE reference laboratories and collaborating centers

OIE reference laboratories are centers of expertise designated to pursue all the scientific and technical problems relating to a disease on the OIE list. The reference (leading) expert, responsible to the OIE and its member countries with regard to these issues, is an active researcher helping the reference laboratory to provide scientific and technical assistance and expert advice to the OIE and its member countries on diagnostics and topics linked to surveillance and control of the disease for which the reference laboratory is responsible. The laboratories also provide and coordinate scientific and technical studies in collaboration with other laboratories or relevant stakeholders.

By the end of 2009, the OIE had a global network of 187 reference laboratories with 161 experts covering 100 diseases/topics in 36 countries. The network brings together experts from many fields. This is an incalculable resource for the OIE headquarters and developed and developing countries, promoting research and encouraging development of laboratory standards. The laboratories provide members with confirmation of diagnostics, current methods for diagnosis, vaccine production, disease surveillance for animal diseases and zoonoses, and safe trade in animals and animal products.

OIE collaborating centers are centers of expertise in a specific designated sphere of competence relating to the management of general questions on animal health issues such as epidemiology, risk analysis, veterinary training, or validation of diagnostic tests. Twenty-nine collaborating centers are currently involved in the network covering 27 topics in 18 countries. In its designated field of competence, an OIE collaborating center provides its expertise internationally, and operates as a center of research, standardization, capacity building, and dissemination of techniques.

Laboratory twinning

Since a large majority of OIE member countries are developing countries and have variable scientific capacity or access to scientific expertise within their national veterinary laboratories, a project of laboratory twinning was developed, the main objective of which is to assist laboratories in developing or in-transition countries to build their capacity and scientific expertise with the eventual aim that some of them could become OIE reference laboratories in their own right. To apply this concept, a direct link between an existing OIE reference laboratory or collaborating center and another laboratory or institution in a developing or in-transition country is established on a strictly voluntary basis for exchange of scientific expertise and capacity building.

OIE Mandate

The core mandate of the OIE is to improve animal health in the world. Under this overarching mandate, the OIE is dedicated

- to guarantee the transparency of animal disease status worldwide,
- to collect, analyze, and disseminate veterinary scientific information,
- to provide expertise and promote international solidarity for the control of animal diseases,

- to guarantee the sanitary safety of world trade by developing sanitary rules for international trade in animals and animal products,
- to improve food safety from the farm to the abattoir,
- to develop standards for animal welfare, and
- to improve the legal framework and resources of national VSs.

Disease Information

Obligations of member countries

Information on the presence of disease is essential for controlling it. With the goal of minimizing the spread of disease comes the obligation to share information about disease outbreaks. Member countries of the OIE are therefore obligated to report disease outbreaks of the OIE-listed diseases, as well as any new relevant epidemiological event.

The OIE list of diseases: There are almost 100 OIE-listed diseases included in the first chapter of the Terrestrial Animal Health Code. The criteria used to determine whether a disease appears on the list are as follows:

- Is there international spread of disease, that is, has it spread internationally in the past, or is it currently affecting three or more countries?
- Does it have zoonotic potential, that is, can this animal disease affect people?
- If not, is it spreading in the native population with important morbidity (infecting a high percentage of animals) or mortality (killing an important percentage of the animals that are infected)?
- Is it an emerging disease with rapid spread or zoonotic potential?

A positive answer to any of these – international spread, zoonosis or high morbidity or mortality or an emerging disease – means that the disease is included on the OIE list.

Member countries are committed to report as follows. Immediate notification is required for the first occurrence of a listed disease or infection, the reoccurrence following a report, the first occurrence of a new strain of a pathogen, a sudden and unexpected increase in the morbidity, mortality, or distribution of a disease, or a change in the epidemiology of a disease. The immediate notification is to be by e-mail, fax, telephone, or telegraph. These are to be followed by weekly updates.

Members are further committed to semi-annual reports describing the situation regarding OIE-listed diseases in each country and annual reports, which also include information on diseases that are not on the OIE list and diseases of wildlife, the impact of zoonoses on the human population, animal population statistics, the structure of the VSs, national reference laboratories and the diagnostic tests they can perform, and, where appropriate, vaccine manufacturers and the vaccines they produce.

Tools for transparency

WAHIS is the World Animal Health Information System. It is the web interface that is available to member countries for disease notification, allowing countries to notify electronically in a rapid and simple manner. However, when the capacity for electronic reporting is not available, submission of paper reports is acceptable. Many countries have nominated a focal point for specific diseases, or species, whose responsibility is to report disease information to the OIE. This focal point receives specific training from the OIE.

WAHID – World Animal Health Information Database – is openly available on the OIE website. With the capacity to search by country or by disease, it provides a rapid, clear, and evident overview of the disease status of a country, the presence or absence of a disease, disease outbreaks or timelines, and the populations of animals in a country, even allowing a comparison of the animal health status of two countries.

The OIE publishes 'World Animal Health' every year, which is a compilation of all the information listed above. This publication is unique worldwide.

Disease tracking

OIE is also engaged in active search and verification of disease outbreaks. Seeking unofficial information from the reference laboratories, the regional representations, collaborating centers, internet resources, or the press, the OIE gathers information, analyzes it, and asks the member for verification where relevant. This is an extremely effective tool.

The OIE does not work alone. The Global Early Warning System for Animal Disease including Zoonoses (GLEWS) is a joint OIE/FAO/WHO initiative that synergistically builds on combining and coordinating the disease tracking and alert and response mechanisms of the three organizations. Through sharing of information on animal disease outbreaks and epidemiological analysis, the GLEWS initiative aims at improving global early warning as well as transparency among countries for controlling animal disease as well as zoonoses including food-borne diseases.

Veterinary Scientific Information

Reference laboratories, collaborating centers, and the four specialist commissions develop and gather scientific information on animal disease prevention and control methods, including zoonoses and food-borne diseases, and on animal welfare.

The OIE provides this information through various channels including

- global and regional scientific conferences,
- web site,
- The Bulletin,
- the yearly publication of the World Animal Health Situation,
- The Scientific and Technical Review, and
- other publications (handbooks).

The Bulletin is published 4 times yearly. Each issue is focused on a specific topic (e.g., animal welfare, wildlife diseases, or food safety). It also provides member countries with an update on current issues, on activities of headquarters and regional offices, and upcoming events and notifications of self-declarations of the disease status of member countries on a voluntary basis.

The World Animal Health is a yearly publication on the occurrences of animal disease throughout the world. It also contains information on the most important control, prevention, and prophylaxis measures adopted and the number of animals slaughtered, destroyed, or vaccinated. Figures on animal population are also provided. Other sections provide detailed information on human cases of the OIE-listed zoonotic diseases, veterinary personnel, national reference laboratories, and vaccine production. This publication is unique in the world.

The Scientific and Technical Review is a peer-reviewed journal that contains in-depth studies devoted to current scientific and technical developments in animal health and veterinary public health worldwide. The particular distinction of this publication lies in relating specialized research to practical problems encountered in safeguarding animal health and veterinary public health, an essential aspect for the improvement of animal production and the protection of public health. It appears 3 times per year.

Other technical publications include technical series on a variety of topics such as assessment and management of pain in animals, or epidemiology, and global or regional scientific conference proceedings.

International Solidarity

More than 120 members are developing countries or countries in transition. These countries often find it difficult to free themselves from epizootics, including zoonoses. This leaves a reservoir of pathogens that threatens the status of countries that have attained disease freedom, often at great expense.

The OIE influences the wealthier countries to help developing countries and offers its expertise and that of the networks as well as its own resources to help them meet the OIE standards. This results in a 'win-win' situation because the control of diseases in developing countries also results in reduction of poverty and increases food security, market access, and public health while contributing to help free countries safeguard their free status.

OIE offers to developing countries independent evaluation of their animal health policies and infrastructures, gap analysis, and donor opportunities if needed (*see* 'Strengthening Veterinary Services').

International Trade in Animal and Animal Products

As described above, the OIE is the international organization given the responsibility by the WTO for establishing standards in animal diseases and zoonoses. The standards contained in the Terrestrial and Aquatic Code are intended to prevent and control the spread of animal disease while avoiding unjustified sanitary barriers to the international trade of animals and animal products.

The OIE certifies countries free of four diseases (rinderpest, foot-and-mouth disease, contagious bovine pleuropneumonia, and bovine spongiform encephalopathy) according to specific guidelines by which a country can demonstrate that the disease is not present in its animal population. This allows importing countries to take decisions without having to control the situation in the exporting country directly in the field. For other diseases, such as avian influenza, there are specified criteria by which a country can certify itself as free from a disease.

The OIE can also play a role in mediating trade disputes between countries by offering a voluntary dispute settlement mechanism. This is a science-based approach to finding alternative solutions and resolving differences, as distinct from the legalistic approach used in the formal WTO system. The mechanism is voluntary and the agreement of both parties is needed before the OIE can initiate the process.

Animal Production Food safety

Preventing or eliminating hazards at their source, at the farm level, is clearly more effective than trying to detect and eliminate them downstream. A permanent working group on food safety was established in 2002, sharing membership with Codex Alimentarius, FAO, and WHO, to establish standards for food safety from the farm to the abattoir in order to eliminate hazards existing during production at the farm and prior to the slaughter of animals or the primary processing of animal products (meat, milk, eggs, etc.) that could pose a risk to consumers. This group is also working to prevent gaps and duplications between Codex Alimentarius and the OIE standards.

Veterinarians have an established role at the farm level. Under OIE guidelines, veterinarians working at the abattoir screen for diseases particularly during ante- and post-mortem inspection. They verify that animal welfare standards are met, and assure the humane slaughter. VSs are well placed as part of a multidisciplinary team of professionals, to work for the safe production of food, including dairy products from the farm to the fork.

As part of the effort to ensure the safety of food of animal origin, and indeed for the purpose of controlling animal disease outbreaks, there must be a reliable and effective way to trace the animal back to the farm of origin. This should be based on the identification of farms, individual animal identification, or identification of groups of homogeneous animals, the ability to track movement of animals, and a record-keeping system. Traceability has important implications for trade as well as for animal health, disease control, and food safety. Therefore, the OIE developed standards for animal traceability. In addition, the OIE organized a world conference in 2009 bringing together governments, international organizations, industry, and primary producers with the purpose of supporting the implementation of the relevant international standards for identification and traceability of live animals and facilitating the bridge of traceability between animals and animal food products globally.

Animal Welfare

Animal welfare was identified as a priority when OIE member countries mandated the organization to take the lead internationally on animal welfare and to elaborate recommendations and guidelines covering animal welfare practices. This is all the more relevant to the OIE since animal health is a key component of animal welfare. The Permanent Animal Welfare Working Group was inaugurated at the 70th World Assembly of Delegates in May 2002.

To date, the OIE has developed guidelines for the transport of animals by land, sea, and air, for the slaughter of animals, and for killing animals for disease control purposes. The next standards to be developed are on the control of stray dog populations, livestock production systems, and laboratory animal welfare.

To further progress on animal welfare standards, the OIE has held two global conferences, in 2004 and 2008, in order to promote the worldwide implementation of OIE animal welfare standards, to raise the profile of animal welfare, and to encourage veterinarians and VSs to take greater responsibility for animal welfare.

Strengthening Veterinary Services

In order to adequately implement OIE standards, a country requires a VS with adequate human, physical, and financial resources, technical authority and capacity, interaction with stakeholders, and access to markets. However, more than 120 of the 175 OIE members are developing countries where VSs may not always comply with international OIE standards on the quality and performance of VS. The OIE sees VSs as a global public good and their compliance with international standards as a priority for public investment. The OIE is therefore actively engaged in the evaluation and improvements of the capacities of national VS.

The process chosen by the OIE consists of the democratic adoption of quality standards contained in the Terrestrial Animal Health Code, and the creation of a tool to analyze the conformity of the countries to the standards.

The OIE's tool for the evaluation of the performance of VSs, the PVS tool, is designed to assist VSs to establish their current level of performance, to identify gaps and weaknesses regarding their ability to comply with standards described above, and to establish priorities and carry out strategic initiatives. This tool is the principal lever of the OIE to bring compliance with quality standards in the governance of VSs of all countries.

The PVS establishes a diagnostic. The OIE also offers a gap analysis in collaboration with FAO and various key funding agencies, permitting members to define detailed priorities for investment in order to be able to comply using their national budget and priorities and, if needed, soliciting aid from the international community.

For member countries requesting assistance with capacity building, the OIE also provides expertise and training for national senior officials, both to improve sanitary governance and to help prepare and implement animal disease control and eradication programs.

Standard Setting Procedures and Publication of International Animal Health Codes

The *Terrestrial Animal Health Code*, now in its 17th edition (2008), and the *Aquatic Animal Health Code*, in its 10th edition, are intended to assure the sanitary safety of international trade in terrestrial and aquatic animals and their products and to provide surveillance methods for important animal diseases. This is achieved through the detailing of health measures to be used by veterinary authorities to avoid the transfer of agents pathogenic to animals or humans, while avoiding unjustified sanitary barriers and while implementing surveillance of major diseases.

They are written in two sections: the first contains recommendations that apply to a wide range of topics, production sectors, and/or diseases (so-called 'horizontal standards') and the second contains recommendations on specific diseases (so-called 'vertical standards') including recommendations on agent inactivation and on surveillance and risk assessment.

The horizontal standards include most notably the general and ethical obligations for importing and exporting countries, methodologies for risk analysis, and the criteria by which diseases are included on the list and by which countries are to report disease outbreaks to the OIE. Other horizontal standards are animal welfare standards, veterinary public health measures such as the role of VSs in food safety, and the responsible use of antimicrobials in veterinary medicine.

The second section of the Codes consists of recommendations applicable to specific diseases on the OIE list. The diseases selected for inclusion in this list affect fish, shellfish, mammals, birds, or bees. These include diseases that are considered the most serious due to their potential for rapid spread beyond national borders, or for transmission to humans, as well as diseases that are less highly contagious but whose economic or health importance justifies their being taken into consideration in international trade. Each disease is dealt with in a separate chapter. Diseases are grouped as those that affect multiple species and those that affect a single species. There are more than 100 terrestrial and aquatic animal diseases for which standards have been developed.

These standards are related to the risks of transmission of the diseases or disease-causing agents linked to animal and animal products. But certainly it should be noted that certain products or commodities subjected to specific treatments may in fact pose no risk, no matter the sanitary status of the country.

The recommendations contained in the OIE Animal Health Codes are developed with the active participation of member countries, knowing that these will apply equally to themselves and to others. They are the fruit of a consensus of very senior veterinary authorities of member countries, thus accounting for their value and their very wide practical application.

Procedures for Updating the Codes

All standards are prepared and submitted by the elected specialized commissions to the World Assembly of National Delegates. They are adopted following the rule of 'one country – one vote'.

Other OIE Standards and Guidelines

While the Codes are highly important documents, it should be noted that they must be used with the companion documents, the *Manual of Diagnostic Tests and Vaccines for Terrestrial Animals (Terrestrial Manual)* and the *Manual of Diagnostic Tests and Vaccines for Aquatic Animals*, the reference standards for veterinary laboratories. Their purpose is to contribute to the international harmonization of methods for the surveillance and control of the most important animal diseases. Standards are described for laboratory diagnostic tests and the production and control of biological products (principally vaccines) for veterinary use across the globe, providing internationally agreed diagnostic laboratory methods. The Manuals set laboratory standards for all OIE-listed diseases as well as several other diseases of global importance. In particular, they specify those 'prescribed tests' that are recommended for use in health screening for international trade or movement of animals.

Other OIE Activities

Communication

In recognition of the centrality of communication for the VSs, which underpins everything they do, including disease surveillance, prevention, control and response, animal welfare, public health, and food safety, guidelines on communication useful for national VSs are being developed for inclusion in the Code.

Veterinary Education

In line with OIE's efforts to strengthen VSs is the recognition that veterinary education is basic to an effective VS. Society has placed increasing demands on veterinarians in the fields of food security, food safety, public health, and animal welfare. The OIE recognizes these, seeing them as integral to veterinary education. The harmonization and quality of veterinary curricula are a crucial component of sound national animal health systems.

A principal mandate of the regional representations and the subregional representations is to develop programs for capacity building in the members for the benefit of the delegates, and their national focal points, the people officially identified as national contacts with the OIE in specific areas.

As part of its multifaceted approach to improve VSs, the OIE has organized a meeting of all the world's veterinary schools with the aim of helping them incorporate into their curricula the concepts with the international public good principles expected from veterinary missions and activities.

Conclusion

A Global Public Good

Among the many challenges facing the world, the dramatic increase of human and domestic animal populations, globalization and the unprecedented movement of people and commodities worldwide, and the increasing encroachment on natural ecosystems are leading to increasing disease threats. As the interrelationships between animal and human health and the health of the ecosystem are better understood, it becomes clear that the consequence of an effective VS is a healthier animal and human population, less afflicted by zoonotic diseases, better nourished, and participating in an improved world economy. This entails prevention and control of emerging diseases at the human–animal interface. The concept of 'One World, One Health' has been developed jointly by the WHO, FAO, UNICEF, World Bank, and OIE, and accepted by most other international health organizations. It is based on more preventative actions, increased cooperation between VSs and public health authorities, and on strengthening emergency response capabilities while helping the poorest nations and strengthening animal and public health systems. The result should be a better capacity to respond to emerging disease situations. All countries must be prepared in face of these new disease threats and it is widely accepted that the work of the VSs is a global public good.

Since its inception in 1924, the OIE has been the global leader in animal disease prevention and control, has served as a focal point for international cooperation on animal health issues, has promoted global safe trade in animal products, has promoted transparency on the global situation of animal diseases including zoonoses, and has shared veterinary expertise among member countries.

With increasing trade, growing demand for foods of animal origin, growing disease threats, unprecedented movements of people and animals, and a changing climate, the role of the OIE has increasing importance. The larger vision of the OIE of contributing to improving public health, food safety and security, and the livelihoods of poor farming communities can only be achieved if governments agree to foster closer cooperation between all the sectors in the health system, to support VSs, and to share information.

ORGANIC DAIRY PRODUCTION

K Shea, Horizon Organic, Longmont, CO, USA

This article is reproduced from the previous edition, Volume 4, pp 2193–2199, © 2002, Elsevier Ltd.

History

In the early days of organic agriculture, products were sold at farmers' markets, cooperatives and directly from the farm. The definition of 'organic' and the actual methods for raising the products as organic varied from place to place and farm to farm. Gradually private and public institutions began emerging to set organic farming standards and provide third-party verification of label claims. Many producers turn to organic farming systems in order to take advantage of the high-value niche market and improve farm income, thereby enabling themselves to compete in today's vertically integrated agriculture system. Organic producers have an intense belief that their farming system is superior in its ability to care properly for the land and its finite resources. Today, organic production is well defined and has matured into a significant market segment.

Market Trends

According to the US Department of Agriculture, the amount of farmland managed under certified organic practices has expanded dramatically, as has consumer demand for organically grown food. In the United States, organic farming became one of the fas test-growing trends in agriculture during the 1990s. Certified organic cropland more than doubled from 1992 to 1997, and two organic livestock sectors – eggs and dairy – grew even faster. Organic foods are one of the top consumer trends today, accounting for more than US$7.8 billion in annual sales, and doubling every 4 years since 1990.

The Western Agricultural Economics Association published information on sales of organic milk in mainstream supermarkets showing a growth over the last 8 years, reaching US$75.7 million in 1999. Organic dairy products can be found in conventional supermarkets and natural-food stores across the United States and in the United Kingdom, where the demand for organic milk and dairy produce is now growing strongly. One leading retailer is predicting a 10-fold increase in its sales over the next 5 years. The Soil Association shows the United Kingdom organic food market currently growing at around 40% year^{-1} and by 2002 it is expected to top £1 billion.

The organic sector in Canada is small but growing rapidly. According to industry sources, farm cash receipts from this industry reached about Can$500 million in 1999, with an estimated retail value of Can$1 billion, including processed and nonprocessed products. Canadian organic retail sales growth is expected to rise from Can$0.7 billion in 1997 to Can$3.1 billion in 2005, which equates to an average growth of 20% annually. The industry anticipates that its market share will increase to 10% of the Canadian retail market by 2010.

Worldwide, growth in organic retail sales is between 20% and 30% per annum. At this rate, 30% of the land in Europe is predicted to be in organic production or in conversion to organic by 2010. In Europe, organic retail sales are estimated at approximately US$7.5 billion, in the United States at US$6.5 billion and in Japan at US$1.5 billion. It is predicted that, by 2005, the industry in Japan will hit the US$10 billion mark. Although still fledgling in Australia, the organic industry turns over US$250 million per year in retail sales of organic food and it exports approximately US$25–30 million worth of organic produce.

The Organic Products Exporters of NZ Inc. (OPENZ) was formed to encourage and support companies and organizations, which have an interest in the New Zealand organic export industry. OPENZ reported a significant increase in the value of organic exports to June 2000. Survey results showed that New Zealand certified organic exports reached over NZ$60 million for the year 1999–2000. This was an increase of 77% on the previous year's figure of NZ$34.08 million. The survey was administered by Trade New Zealand and received responses from 34 out of the 40 exporter members of OPENZ.

A report suggesting organic dairy products will become a profitable, long-term niche market worth up to NZ$200 million a year within a decade has convinced the Dairy Board to foster organic farming in New Zealand. New Zealand currently exports about NZ$60 million-worth of organic products, mostly fruit and vegetables. It has been estimated that the organic market will be unlikely to exceed 5% of the board's NZ$7.6 billion business, but it is a niche that the board wishes to exploit.

International Organic Standards Comparisons

There have been organic standards in the European Union (EU), and EU regulation 2092/91 has been in force since 1991. In many European countries, organic agriculture is known as ecological agriculture, reflecting the reliance on ecosystem management rather than external inputs. According to the Codex Alimentarius Commission:

Organic agriculture's increased momentum is due to consumer demand and to positive environmental impact. Many aspects of organic farming are important elements of a systems approach to sustainable food production, including in developing countries, both for domestic consumption and export.

The Committee on Food Labeling of the Codex Alimentarius Commission has developed *Guidelines for the Production, Processing, Labelling, and Marketing of Organically Produced Foods* (**Table 1**).

The International Federation of Organic Agriculture Movements (IFOAM) represents, internationally, the organic movement in parliamentary, administrative and policy-making forums. IFOAM has consultative status with the UNO and FAO. It sets and regularly revises the international *IFOAM Basic Standards of Organic Agriculture and Food Processing*, which are translated into 19 languages. IFOAM also operates the International Organic Accreditation Services, Inc. (IOAS), in order to administrate the IFOAM Accreditation Program to ensure equivalency of certification programs worldwide.

In the United Kingdom, the integrity of organic food is safeguarded by international legislation. Organic livestock production is regulated by EU Regulation 804/1999. The United Kingdom Register of Organic Food Standards (UKROFS) is the British control body for the organic sector. Food sold as organic anywhere in the EU must be certified as produced under an approved system authorized by an official inspection and certification service. The Soil Association is the best known of the UKROFS validating bodies.

Canadian organic dairy products have been widely distributed since 1995 and, in Canada, there is more information available on organic dairy farming, than on other types of livestock farming. The Canadian Organic Advisory Board Inc. (COAB) was established in 1992 as a national, nonprofit advisory body to represent the interests of organic production and certification groups across Canada. The Board is a vehicle for collaboration of stakeholders within the organic industry and, notably, agencies within the federal and provincial government that have been involved in the development of organic standards.

The Certified Organic Associations of British Columbia (COABC) works on a voluntary basis to maintain a credible set of organic production and processing standards. COABC ensures compliance with the standards by administrating the accreditation and auditing process in partnership with the British Columbia Ministry of Agriculture, Fisheries and Food (BCMAFF).

The United States signed into law the Organic Foods Production Act (OFPA) in 1990. The final rule implementing OFPA was published in the Federal Register in December of 2000. This final rule establishes the National Organic Program (NOP) under the direction of the Agricultural Marketing Service (AMS), an arm of the US Department of Agriculture. The goal of this national program is to facilitate domestic and international marketing of fresh and processed food that is organically produced and to assure consumers that such products meet consistent, uniform standards.

To ensure that access of New Zealand organic products into the EU is maintained, the Organic Products Exporters Group Inc. (OPEG) has requested that the Ministry of Agriculture and Forestry (MAF) Food establish an Official Organic Assurance Program for organic products exported to the EU. The objective of this program is to provide an official assurance to the EU that organic products exported from New Zealand comply with the requirements of Council Regulation 2092/91.

Japan's Ministry of Agriculture, Forestry and Fisheries (MAFF) have completed the development of their own national standard for organic production using the Codex *Guidelines for the Production, Processing, Labelling, and Marketing of Organically Produced Foods* as a base. The Japan standard covers plant products only and Japan's MAFF have advised that imported products labeled as organic will need to comply with the standard by April 2001.

A comparison of standards around the world shows that they are mostly consistent but do vary in a few areas. These areas are pasture requirements, percent of total feed which must be organic and the use of antibiotics.

Table 1 Standards for organic dairying

	International Federation of Organic Agricultural Movements	*Codex (1999 Draft only, not agreed upon)*	*Canada June 1999*	*Certified Organic Associations of British Columbia 1997*	*US Department of Agriculture NOP 2000*	*Soil Association UK 1998*
Living conditions as related to access to pasture or free range	Access to open air and/or grazing appropriate to type of animals and season	Herbivores must have access to pasture. May allow exceptions in certain circumstances	Environment suited to their needs that provides regular access to pasture, free-range open-air runways or other areas subject to weather and ground conditions	Free access to pastures, paddocks or runways. Access to grazing land 120 days of the year	Access to outdoors and direct sunlight. Access to pasture for ruminants. Allows temporary exemptions in case of certain circumstances or to protect soil	All stock must have access to pasture during grazing season unless specifically exempted
Conversion: dairy herds	Not less than 30 days 12 months organic feed, 90 days health and living conditions	Still under discussion	In accordance with the standards for at least 12 months	12 months incorporating all required practices. Replacements 90-day transition if certified livestock not available but must be heifers or 120-day dry-treated cows	12 months incorporating all required practices. New herd conversion, 80% organic feed for first 10 months	12 weeks
Feed	100% organically grown feed, with 50% coming from farm or produced within the region. If impossible, allowance for 15% of feed from nonorganic sources	Should be 100% organically grown. If operator can demonstrate such feed is not available, livestock will maintain status with 85% organic feed	100% from organic sources. May be 85% for ruminants in the short term only	Certified organic required, certified transitional feed is regulated	Certified organically produced feed and pasture required	Livestock systems should be planned to provide 100% in accordance with standards. Allowed 90% on a daily basis, or 85% dairy stock
Health care	Natural medicines and methods emphasized. Use of conventional veterinary medicines allowed when no alternatives are available	Use of veterinary drugs prohibited in absence of an illness. If no alternative permitted treatment or management, vaccinations and therapeutic uses permitted. Should not withhold necessary treatment to maintain organic status	Vaccination and use of veterinary drugs allowed only when disease cannot be combated by other means. Withholding of necessary treatments to maintain organic status is not permitted	Vaccinations allowed as appropriate to each bioregion. Withholding of necessary medical treatment that would disqualify organic status is prohibited	Vaccinations allowed. Administrations of medications in absence of illness prohibited. Withholding treatment to maintain organic status causing suffering or death shall be grounds for decertification	Use of veterinary medical products where no known problem exists prohibited. Medications must never be withheld where it will result in unnecessary suffering. Vaccines restricted to known disease risk that cannot be controlled by other means

(*Continued*)

Table 1 (Continued)

	International Federation of Organic Agricultural Movements	*Codex (1999 Draft only, not agreed upon)*	*Canada June 1999*	*Certified Organic Associations of British Columbia 1997*	*US Department of Agriculture NOP 2000*	*Soil Association UK 1998*
Use of antibiotics	When conventional veterinary medicines are used the withholding period shall be at least double	Withdrawal periods double that required by legislation. After 2005 antibiotics not allowed	If veterinary drugs used, withdrawal period at least double	Not permitted for slaughter animals. Allowed for breeding animals but not in a subtherapeutic manner. Use on animals in 3rd trimester or during lactating will disqualify offspring for slaughter. Milk to be withheld for 30 days or twice withdrawal period if longer	Not permitted	Permitted in clinical cases where no other remedy is effective. Withdrawal at least three times that permitted on product license and not less than 14 days
Use of parasiticides	When conventional veterinary medicines are used the withholding period shall be at least double	Withdrawal periods double that required by legislation	If veterinary drugs used withdrawal at least double	Not permitted for slaughter animals. Allowed for breeding herd use but use in 3rd trimester or during lactation disqualifies offspring as organic for slaughter purposes	Not permitted for slaughter stock. Allowed in breeder stock if sickness or infection present; routine use not allowed. Progeny can be sold as organic but not if used during 3rd trimester of gestation or during lactation. 90-day withdrawal or dairy animals	Permitted when used therapeutically when clinical symptoms appear. Restricted use on routine basis over a specific time period as part of the disease reduction program. Ivermectin-based products prohibited

Before the NOP rule was published, certification agency standards in the United States varied in regards to antibiotics. Some allowed none; other allowed their use with a 30–90-day withdrawal period. During this withdrawal period, the milk or milk products could not be sold as organic, and the meat could never be used as organic. Today under the NOP, antibiotics are never allowed on organic cattle. Under COABC regulations, cows can be brought back into the milking string after 30 days.

Though the particulars of organic livestock production may vary between nations, around the world the standards emphasize proactive health care, the principle of prevention versus treatment. Healthy cow care and early sick-cow recognition are crucial. By doing the utmost to control the animals' environment, and thereby prevent illness and lower stress, the animals remain healthier than similar cows where these preventative practices are not performed. Standards usually require access to the outdoors, fresh air, sunlight and shelter, and they recognize species-appropriate behavior and make allowances for it.

Using the NOP as a model, here is a glimpse into organic certification requirements:

The farmland itself must have no prohibited materials applied to it for at least 36 months before the harvest of organic crops. It must have distinct, defined boundaries and buffer zones such as runoff diversions to prevent the unintended application of a prohibited substance to the crop or contact with a prohibited substance applied to adjoining land that is not under organic management. The producer must select and implement tillage and cultivation practices that maintain or improve the physical, chemical and biological condition of soil and minimize soil erosion. The producer must manage crop nutrients and soil fertility through rotations, cover crops, and the application of plant and animal materials.

Milk or milk products must be from animals that have been under continuous organic management beginning no later than 1 year prior to the production of such products, except for the conversion of an entire, distinct herd to organic production. For the first 9 months of the year of conversion, the producer may provide the herd with a minimum of 80% feed that is either organic or produced from land included in the organic system plan and managed in compliance with organic crop requirements. During the final 3 months of the year of conversion, the producer must provide the herd with 100% organic feed.

The producer of an organic livestock operation must maintain records sufficient to preserve the identity of all organically managed livestock and all edible and nonedible organic livestock products produced on his or her operation.

The producer must not use animal drugs, including hormones, to promote growth in an animal or provide feed supplements or additives in amounts above those needed for adequate growth and health maintenance for the species at its specific stage of life.

The producer of an organic livestock operation must establish and maintain preventive animal health care practices. The producer must establish appropriate housing, pasture conditions and sanitation practices to minimize the occurrence and spread of diseases and parasites. Animals in an organic livestock operation must be maintained under conditions that provide for exercise, freedom of movement and reduction of stress appropriate to the species. Additionally, all physical alterations performed on animals in an organic livestock operation must be conducted to promote the animals' welfare and in a manner that minimizes stress and pain.

The producer of an organic livestock operation must administer vaccines and other veterinary biologics as needed to protect the well-being of animals in his or her care. When preventive practices and veterinary biologics are inadequate to prevent sickness, the producer may administer medications included on the National List of synthetic substances allowed for use in livestock operations. The producer may not administer synthetic parasiticides to breeder stock during the last third of gestation or during lactation if the progeny is to be sold, labeled, or represented as organically produced. After administering synthetic parasiticides to dairy stock, the producer must observe a 90-day withdrawal period before selling the milk or milk products produced from the treated animal as organically produced. Every use of a synthetic medication or parasiticides must be incorporated into the livestock operation's organic system plan subject to approval by the certifying agent.

The producer of an organic livestock operation must not treat an animal in that operation with antibiotics, any synthetic substance not included on the National List of synthetic substances allowed for use in livestock production, or any substance that contains a nonsynthetic substance included on the National List of nonsynthetic substances prohibited for use in organic livestock production. The producer must not administer any animal drug, other than vaccinations, in the absence of illness. The use of hormones for growth promotion is prohibited in organic livestock production, as is the use of synthetic parasiticides on a routine basis. The producer must not administer synthetic parasiticides to slaughter stock or administer any animal drug in violation of the Federal Food, Drug, and Cosmetic Act. The producer must not withhold medical treatment from a sick animal to maintain its organic status. All appropriate medications and treatments must be used to restore an animal to health when methods acceptable to organic production standards fail. Livestock that are treated with prohibited materials must be clearly identified and shall not be sold, labeled or represented as organic.

A livestock producer must document in his or her organic system plan the preventative measures he or she has in place to deter illness, the allowed practices he or she will employ if illness occurs, and his or her protocol for determining when a sick animal must receive a prohibited animal drug. These standards will not allow an organic system plan that envisions an acceptable level of chronic illness or proposes to deal with disease by sending infected animals to slaughter. The organic system plan must reflect a proactive approach to health management, drawing upon allowable practices and materials. Animals with conditions that do not respond to this approach must be treated appropriately and diverted to nonorganic markets.

The producer of an organic livestock operation must establish and maintain livestock living conditions for the animals under his or her care which accommodate the health and natural behavior of the livestock. The producer must provide access to the outdoors, shade, shelter, exercise areas, fresh air and direct sunlight suitable to the species, its stage of production, the climate, and the environment. This requirement includes access to pasture for ruminant animals. The producer must also provide appropriate clean, dry bedding, and, if the bedding is typically consumed by the species, it must comply with applicable organic feed requirements. The producer must provide shelter designed to allow for the natural maintenance, comfort level, and opportunity to exercise appropriate to the species. The shelter must also provide the temperature level, ventilation and air circulation suitable to the species and reduce the potential for livestock injury. The producer may provide temporary confinement of an animal because of inclement weather; the animal's stage of production; conditions under which the health, safety, or well-being of the animal could be jeopardized; or risk to soil or water quality. The producer of an organic livestock operation is required to manage manure in a manner that does not contribute to contamination of crops, soil or water by plant nutrients, heavy metals or pathogenic organisms and optimizes nutrient recycling.

Future of Organic Dairying

Nitrogen self-sufficiency through the use of legumes and biological nitrogen fixation, as well as effective recycling of organic materials, including crop residues and livestock manure, will positively affect the impact of the farming system on the wider environment. These practices, coupled with conservation of wildlife and natural habitats, are some of the many benefits of organic production practices.

Livestock manures are one of the most valued resources on an organic farm or ranch. Conservation of manure and its proper application are a key means of recycling nutrients, building soil and improving the sustainability of an organic operation. Ideally, manures for organic crop production are composted. However, uncomposted manures are allowed with restrictions. Raw, uncomposted livestock manures may not be applied to crops destined for human consumption unless incorporated into the soil a minimum of 120 days prior to harvest.

At the same time, water resources must be protected. Fertilizers and manures must be applied to prevent runoff and leaching, fields must be managed to prevent erosion, and 'catch crops' must be used where necessary to soak up excess nitrogen. Riparian zones must be stabilized and protected, natural wetlands must be maintained and protected, and waterways must be protected from livestock and livestock waste through the use of fencing and water tanks to prevent fouling natural streams.

Fliebach, Mader, Pfiffner, Dubois and Gunst recently released results of a 21-year field trial in Switzerland, comparing organic and nonorganic farming systems. The study shows dramatic differences in soil health. It was reported that there were more microorganisms (which play a role in soil fertility and delivering nutrients to roots) in the organically managed field than in the conventionally managed field.

Consumers have become increasingly aware of these environmental issues. The alleged liberal use of pesticides by farmers and the purported suffering of livestock have been highlighted in the press over recent years, and caused rising numbers of consumers to turn to organic products.

The organic sector is growing with sales projected to increase from $US1.31 billion in 1995 to $US4.37 billion in 2005. At present highest demand in the market is for single ingredients in the form of organic milk, cheese or yogurt. An increase in unit shipments of organic dairy desserts and organic ready-made meals is expected and should increase revenues over the rest of the forecast period.

P

PACKAGING

V B Alvarez and M A Pascall, The Ohio State University, Columbus, OH, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The packaging of food can be traced to ancient times although its early beginning was with crude materials. Early reports document wine being stored in animal skin and various liquids including water being packaged and stored in earthen vessels. Increases in the complexity of human civilization also saw the development and use of diverse types of packages made from varying types of materials. The Industrial Revolution, which started during the 1700s, also had an effect on food packaging because the new industrial workers demanded a more convenient manner for transporting and storing meals. Beginning in the 1950s and within modern times, the growth of the fast-food industry has significantly influenced the food-packaging industry. Examples of foods in this category include gravy preparations, dry cake mixes, boil-in-bag foods, and TV dinners. These developments created a demand for new types of packages. The packaging of fluid milk started prior to the 1950s when Gail Borden discovered and patented the process for condensed milk. This occurred in 1856 and was followed by the development of the glass milk bottle in 1884, the invention of the automatic bottle filler and capper in 1886, and the introduction of the first plastic-coated paper milk carton in 1932. Due to the properties of milk and dairy products, packaging is considered to be a critical step in the processing operations. The reason is that packaging is the last link in the processing chain. If the choice of packaging is inappropriate or its failure occurs during handling, transportation, and storage of milk products, the processing steps would be useless, even if they were properly executed. In an attempt to minimize food safety hazards associated with inadequately processed and/or packaged milk products, the Pasteurized Milk Ordinance (PMO) enacted by the US government mandates regulatory guidelines for the dairy industry. **Figure 1** shows a typical fluid milk filling room that complies with the PMO's requirements. The filling room is separated from other processing operations, and the equipment and facilities have the infrastructure to prevent any contamination of milk.

Purpose of Packaging of Dairy Products

The systems and requirements for packaging of dairy products are similar to those of other foods. Milk and dairy products are packed in various types of packaging materials depending on the specific product properties, processing conditions, storage, handling, and end use. The primary purposes of packaging are to preserve and protect dairy products against spoilage and harmful factors in the outside environment, to contain specific amounts of the product in units that are easy to handle during production, storage, transportation, and consumption, and to provide information about the product to the consumer and regulators. Important considerations about materials used to package dairy products are toxicity and compatibility with the product, resistance to impact, maintenance of sanitation, odor and light protection, tamper resistance, size specifications, shape and weight requirements, marketing appeal, printability, and cost. Examples of packaging types used for dairy products include glass and plastic bottles, gable-top and brick-type cartons, bags, pouches, two- and three-piece cans, aerosol containers, plastic tubs, and other containers.

Table 1 lists the common packaging materials, their properties, advantages, and disadvantages, and dairy products that are packaged in containers fabricated from them.

Packaging of Dairy Products

Fluid Milk

This is currently marketed as standardized low-fat milk with 0.5, 1.0, 1.5, or 2.0% fat content. It is also marketed as skim milk with <0.5% fat and as homogenized whole milk with a fat content of 3.25%. Milk flavor results mainly from proteins, lipids, and carbohydrates, and small amounts of other components. Depending on the way milk is handled, processed, and stored, its quality and flavor can deteriorate. This decline may be due to bacterial growth, enzymatic activity, and environmental factors such as oxygen and temperature. Additionally, milk is susceptible to the development of light-activated or light-induced off-flavors and vitamin A degradation. Therefore, the properties of the selected packaging materials are important if the quality and nutritional value of milk are to be maintained during storage.

Glass bottles were introduced in 1884 and were the first modern packaging material for fluid milk. An important property of glass that makes it suitable for milk and other foods in general is its fairly inert nature. As a result, it is not associated with the leaching of chemicals that might alter the taste of the product. Its impermeability makes it desirable for long-term storage of foods that are susceptible to volatile loss or the ingression of spoilage gases. Flint glass is transparent and allows product visibility. Due to its rigidity, glass maintains its shape and volume under vacuum or pressure. Glass is stable at high temperatures and has good consumer appeal. In spite of these advantages, glass is breakable and relatively heavy, and has a high manufacturing energy requirement and high cost of production.

Several types of laminated materials are used to package fluid milk. Single-use containers made of plastic/paper laminates (polyethylene (PE)-coated to paperboard) have been used widely because of their low cost, easy printability, and forming versatility. However, they have poor barrier properties against moisture and gases. Since this type of milk package is single use, only the carrying crates used to transport the unit containers require washing and reuse. Another type of laminated material that is used for milk packaging generally consists of seven separate layers that may include PE/adhesive/paperboard/adhesive/aluminum foil/adhesive/PE (or an ionomer). The heat-sealing material in this structure is the PE or ionomer that is bonded to the aluminum foil. The paperboard layer provides rigidity and strength while the aluminum is the oxygen barrier film. Packages made from this type of material are capable of extending the shelf life of the product at ambient temperatures if it is aseptically processed. In these materials, individual films are combined into a single structure to provide physical strength, resistance to puncture, machinability, sealability, environmental resistance, and barrier against moisture, oxygen, carbon dioxide, odor, and light.

High-density polyethylene (HDPE) blow-molded bottles are the single biggest types of milk package used in the United States. HDPE is easy to shape and mold into dispensers; it can be extruded into films to make pouches, or laminated with other materials such as aluminum foil, paper, and other packaging films. HDPE is a good barrier to moisture and is resistant to most solvents; however, it is a poor barrier to carbon dioxide and oxygen and offers little protection against light. To make HDPE opaque, colored resin or shrink-wrapping

Table 1 Properties of common materials used to fabricate packaging for dairy products

Material	*Water vapor transmission*[a]	*Gas permeability constant*[b]			*Advantages*	*Disadvantages*	*Products*
		O_2	*N_2*	*CO_2*			
Glass	Low	Low	Low	Low	Impermeable, easily recycled, inert	Heavy weight, breakable, high energy costs of manufacturing	Fresh milk, yogurt, cream
Metal	Low	Low	Low	Low	Excellent gas barrier, rigid, easily recycled	Requires coatings to prevent corrosion	Milk powder, condensed and evaporated milk
Films							
PVDC (Saron)	3.1	0.91	0.91	0.78	Excellent barrier to water vapor, gases, fatty and oily products	Produces toxic compounds when incinerated	Chesses, MAP[c]
Cellophane, nitrocellulose coated	4.7	0.07	0.07	0.07	Excellent clarity and sparkle, can be used in coatings and laminations	Not strong for heavy products	Cheeses
Polymer coated	7.8	0.03	0.03	0.03			
Plastics							
Low-density polyethylene	20.2	28.60	28.60	11.38	Very flexible, highly resistant to most solvents, good moisture barrier	Useless for rigid containers, poor barrier for gases	Liquid milk (pillow packs), condensed milk (squeeze bottles)
High-density polyethylene	4.7	7.15	7.15	3.25	Moderately flexible, stiffer, tasteless, odorless	Poor barrier for oxygen and other gases, softness, low softening point, poor clarity	Milk, yogurt, sour cream, ice cream
Polyvinyl chloride	62.0	9.75	9.75	-	Versatile material, compounded with a wide range of additives (plasticized)	Difficult to recycle, poor moisture barrier properties	Cheese, yogurt, MAP
Polyethylene terephthalate	Low	Low	Low	Low	High tensile strength, low gas and moisture permeability, high use-temperature range, high scuff resistance, excellent oil barrier	Lack of heat sealability	Milk
Paper							
Laminated papers	Low	Low	Low	Low	Laminated to aluminum foil and extrusion coated with PE offers barrier to moisture, flavor, and UV light	Poor barrier for gases	Butter
Coextruded laminated (aseptic)	Low	Low	Low	Low	Barrier against moisture, gas, odor, light, and UV light	Cost	Milk, milk powder, yogurt
Waxed papers	High	Low	Low	Low	Moisture barrier, low cost, good resistance, good heat-sealing characteristics	Difficult to keep folded	Tubs for ice cream or cream, butter

[a] g per m^2 · day at 38 °C and 90% RH.

[b] cc·mil per m^2 · day · atm at 25 °C and 50% RH (cm^3 per m^2 · day).

with a suitable label is used to protect against UV or fluorescent light in display cases.

Evaporated Milk

Evaporated milk is manufactured by a process of evaporation, concentration, homogenization, and sterilization of whole milk. The approximate composition of evaporated low-fat milk is 7.5–9.0% fat and 18–22% non-fat milk solids. In this process, the whole milk is exposed to an ultra-high temperature (UHT) process and then packaged aseptically. To prevent contact and reaction with the metal in tin cans, a protective coating is used. The base material in these cans is steel, but most cans are tin-plated, or coated with enamel, epoxy, or lacquers to prevent rusting or attack from the packaged product. Cans used to package milk are sealed by locking the curl on the lids to the flange on the body of the opened can. Once the seal is accomplished, it is called a double seam. Hermetically sealed cans are capable of safely storing evaporated milk for several months without refrigeration.

Sweetened Condensed Milk

Sweetened condensed milk is a product that has been concentrated by evaporation, to which sucrose is added to form an almost saturated sugar solution, after which it is canned. Concentration is usually done by evaporation, but reverse osmosis can also be used. The approximate composition of sweetened condensed milk is 8–9% fat, 20–22% non-fat milk solids, 10–11% lactose, 43–45% sucrose, and 25–27% moisture. This high sugar content helps to maintain the quality of the product during its shelf life. Normally, sweetened condensed milk is packaged in metal cans. In addition, sweetened condensed milk can be kept in the refrigerator for a brief period of time in order to prevent mold growth after it has been opened.

Properties of Coated Cans

Cylindrical cans are the most commonly used containers for condensed and evaporated milk. They are made from rigid steel or aluminum, and are capable of withstanding pasteurization and sterilization processes and still act as good gas and light barriers. Important characteristics of these containers are their design for easy opening, inexpensive costs, ease of processing on high-speed lines, and recyclability. There are several disadvantages associated with the use of metal cans for milk packaging. These include interactions between the metal and packaged products, and susceptibility of the empty container to damage, which could subsequently compromise the safety of the product.

Powder Milk

Non-fat milk powders and whole milk powders (WMPs) are made by evaporating fluid milk to dryness. Dried whole milk contains 26–40% fat and up to 5.0% moisture (by weight). This high fat concentration is a major cause of deterioration due to lipid oxidation during processing and storage. Thus, materials selected to package dried whole milk must limit photodeterioration in order to maintain the product's quality for extended shelf life (ESL).

Metal Cans

The use of three-piece tinplate cans was the traditional method for dried milk packaging for retail marketing. After filling but before sealing these containers, air is withdrawn from the powder and replaced by an inert gas such as nitrogen. This serves to reduce rancidity and extends the product shelf life. Metal cans are popular in many parts of the world due to their mechanical strength, ease of transport and handling, and the possibilities of reuse. Resealable cans usually have a pressure plug lid that provides a gas-tight seal. These types of cans usually have an aluminum foil diaphragm that is affixed to the underside of the sealing rim. This diaphragm provides an extra layer of protection to the unopened can.

Laminates

Within recent time, composite cans made from aluminum foil/polymer/paperboard laminates and pouches made from aluminum foil/polymer have been replacing metal cans for powdered milk packaging. Some of these laminated packages could be fabricated on form–fill–seal (FFS) machines. Gas flushing of the product is not uncommon prior to sealing the package. This is done by saturating the powder with inert gas (nitrogen) prior to filling the container. These materials have a light weight but have the disadvantage of not having the mechanical strength or durability of rigid metal containers. Also, they are difficult to recycle and sealing could be problematic for pouches if the dry powder contaminates the sealing area. The strength of a laminate is dependent upon the composition of the material. For instance, a laminate made from aluminum foil, paperboard, and low-density polyethylene (LDPE) has a lower burst strength than a similar laminate in which the paperboard is replaced by a PET film. These laminates could be mounted as roll-stock on FFS machines where they could be used to make gusseted or nongusseted pouches. Typically, a pouch used for dried milk packaging, and made on an FFS machine, would have a laminate made with a PET (17 μm)/LDPE (9 μm)/aluminum foil (9 μm)/LDPE (70 μm) structure.

Composite Cans

Composite cans are made by the spiral winding of paperboard strips. They can be produced with a wide variety of liners. Cans made from these materials have mechanical strength comparable with aluminum foil/LDPE/paper bags and metal cans. Composite packages have the added advantages of being lighter than metal cans and do not corrode under high-humidity conditions. Composite cans are filled in the same manner as metal cans but they cannot be cleaned with hot water. The material specifications for cans used to package whole or skim milk powders are 0.9 mm thick paperboard and 0.5 μm thick aluminum foil coating with a nitrocellulose lacquer to protect it from abrasion by the powder. An outer decorative label incorporating a fiber sealing material gives increased protection against moisture penetration. When compared with the filling of metal cans, the occluded air trapped in vacuoles within the milk powder is not removed during the gas flushing phase of fiber cans or laminate package filling. This means that the headspace oxygen in these composite packages is higher than in milk stored in metal cans. This has the potential to cause milk in composite packages to spoil faster. For ESL of milk power, residual oxygen concentrations should not exceed $0.02 - 0.03\,\mathrm{ml\,g^{-1}}$. A reduced oxygen environment could be created by conditioning the milk powder under vacuum for 24–48 h before gas flushing to remove the occluded air.

Ice Cream

The packaging of ice cream is often a complicated operation, especially if mixed flavors or exceptional shapes are required. Frozen dessert packages are designed to contain bulk product for the sale of dipped products such as ice cream cones or to package ice cream product into small containers for direct retail sale. The packaging steps may start in the hardening area to retain the shape of the portioned dessert. Practically all frozen desserts for bulk use are packaged in single-service containers made of paperboard or plastic. Some are packaged in reusable plastic containers, but the use of steel cans is limited. Packages for retail sale vary in size (US sizes vary from 100 ml to 1 l). The most common retail size package is the 250 ml carton. Typical metric package sizes are 100 ml, 250 ml, 500 ml, 1 l, 2 l, and 4 l with shapes that are rectangular, cylindrical (round), or conical (tapered cylinder). A relatively new shape called square/round (squround) is a modification of the conical container. The shape is rectangular, tapered, and rounded at the corners. Ice cream packaged in these containers is easier to scoop out when compared with ice cream in either the round or rectangular containers. Also, these squround containers have tighter seals and tend to fit better in the freezer compared with the round ones. The traditional rectangular 250 ml carton is made of plastic-coated paperboard. During the fabrication process, the label is printed on the carton, which is folded into a collapsed shape and then sealed on one side. Ice cream mixes are regularly packaged in polymeric cups or tubs, flexible plastic bags, or wax-coated paper. All types are distributed in either cartons or plastic shipping cases.

Cheese

Cheesemaking is a complex system with different reactions taking place during the manufacturing, maturation, and storage stages. In unpackaged cheese, quality and water loss depend on the chemical properties of the cheese and on the storage conditions. In packaged cheeses, quality and water loss depend not only on the storage conditions, but also on the permeability and protection provided by the packaging material. Factors that may be considered when selecting a package are the type of cheese and the resulting resistance to mechanical damage (hard or soft cheese); the presence of a specific microorganism; wholesale or retail packaging; permeability to water vapor, oxygen, CO_2, NH_3; and light; and labeling facilities.

Waxing can be applied to low-moisture cheese shortly after manufacturing. In the past, semi-hard cheese was often covered with paraffin wax. However, a latex emulsion is currently used to coat this type of cheese. Soft cheese is commonly wrapped in a three-layer film consisting of a wax/paper/varnish structure; in this material, the wax is in contact with the cheese. This combination results in a packaging material with low O_2 and water vapor transmission rates.

Fresh and cream cheeses are susceptible to photooxidation. Therefore, they require a packaging material that protects against transmitted light. Genuine vegetable parchment or grease-proof paper was frequently used to package fresh cheese but is currently being used for Petit Suisse. Paper coated with paraffin or polyvinyl chloride/polyvinylidene chloride (PVC/PVDC) copolymer is sometimes used in the form of a banderole. While a number of plastics have been introduced over the years, the standard material is polystyrene (PS), which is thermoformed on FFS machines. PS is also co-extruded or extrusion coated with PVC or PVC/PVDC co-polymer to improve its barrier properties. The coated PS is sometimes pigmented with TiO_2 to provide a better barrier against light.

Yogurt

Yogurt is a highly perishable product and packaging protects it during handling and helps to maintain its physicochemical, nutritional, and sensory characteristics. The package should also prevent loss of volatile flavors and/or the absorption of undesirable odors. Packaging for yogurt is classified into three main categories depending on the physical strength of the container.

Semi-rigid Containers

These types of containers are normally manufactured from plastic. The properties of different types of plastic materials that are important for yogurt packaging are water vapor, oxygen, and nitrogen transmission rates. Furthermore, yogurt containers must be acid resistant and prevent the loss of volatile flavors. Materials that are used to package yogurt are PE, polypropylene (PP), PS, PVC, and PVDC laminates.

Flexible Containers

These types of yogurt containers are mainly in the form of paperboard cartons and plastic pouches. Paper-based cartons are made from laminates (PE/aluminum foil/PE or PE/paper/aluminum foil/PE) and are used only to package dehydrated yogurt. An important property of flexible containers for yogurt packaging is permeability to gases and water vapor. Paperboard cartons had been used for yogurt packaging in the past. This type of container was susceptible to leakage. Consequently, its use as a yogurt container is limited despite improvements in its manufacture.

Rigid Containers

Glass bottles are still used in some countries (France and eastern Europe) to package yogurt. Although glass is an excellent packaging material, its high cost of manufacture and current market trends that favor single-use containers limit the use of glass for yogurt packaging. Other rigid containers that are used to package some yogurt-based products (e.g., dried yogurt) are metal cans.

Butter

Butter has a minimum milk fat content of 80–82%, total fat-free dry milk solids of 2%, and a maximum moisture content of 16%. Butter may also have some approved additives such as beta-carotene, sodium chloride, and cultures of harmless lactic acid-forming bacteria. Butter is very susceptible to light-induced flavors, as a result of its susceptibility to lipid oxidation. It is well known that fluorescent light and sunlight are the cause of oxidation of milk fats found in butter. Thus, the selection of an appropriate packaging material can significantly reduce the incidence of oxidation caused by light and the development of oxidized flavors.

Butter is normally wrapped in wet waxed, dry waxed, grease-proof, or vegetable parchment paper, or aluminum foil laminated with vegetable parchment or grease-proof paper. Dairy spreads are usually packaged in thermoformed PP or LDPE containers with lids of, for example, aluminum foil, PVC, or PE. Bulk butter is packed in 25 kg LDPE-lined paperboard cartons. For long-term storage, it is sometimes packaged in cans.

Several components of butter are known to influence its spoilage. These include free fatty acids, fat-soluble amino acids, and carotene, which promote autoxidation under the influence of light. Spoilage by microorganisms may cause several off-flavors (putrid, volatile acid, etc.). Therefore, the packaging material must not have a high permeability to water vapor because this could increase the risk of surface mold growth in areas where pockets of moisture could accumulate. Lipolysis also produces a soapy-rancid flavor and the degree of its formation depends on the light source, wavelength of the light, exposure time, distance from the light source, and carotene content of the butter. These conditions should be taken into account when selecting an appropriate packaging material.

Probiotic Dairy Foods

The selection of packaging materials to protect and assure the therapeutic activity of these foods is important for the commercialization of these products. It is also important that the level of oxygen within the package should be minimized in order to avoid toxicity and death of the microorganism and a resultant loss of product functionality. Glass bottles provide the best protection for probiotic products, with plastic being the second best alternative. Active and intelligent packaging is becoming increasingly important as a choice for these products. These packages function by (1) absorption of compounds that induce spoilage, (2) release of compounds that extend the shelf life of the product, and (3) monitoring of the shelf life.

Trends and New Concepts

Both the dairy and the wider food industries face similar challenges with respect to product packaging. Some of these challenges are related to the need to maintain efficiency and sustainability of the manufacturing process and to respond to current market trends. Food safety, governmental regulations, and the demand to use sustainable packaging are the issues that seem to be influencing the direction in which the industry is heading. The following are examples of current trends in packaging that are impacting the dairy industry.

The increased use of bio-based materials such as polylactic acid (PLA) to fabricate pouches has influenced packaging manufacturers to use ultrasonic sealing as the method of choice for these materials. The traditional method of heat-sealing used for PLA packages causes it to distort at the sealing areas. This is so because PLA shows poor heat stability. The use of ultrasonic sealing solves this problem because it is considered a cold-sealing technique. Containers made from PLA are compostable and/or biodegradable. Using PLA, a British company developed a milk bottle with a smart two-part system to aid its recyclability. The outer layer consists of recycled cardboard, which is lined with an inner sleeve of PLA made from corn starch. The outer layer protects the paperboard from becoming wet and soggy, but upon emptying, it decomposes in landfills.

The protection of milk, yogurt, and dairy beverages from the oxidative effects of light is still a concern because of its potential to reduce quality and lower the shelf life of the products. Lactra™ is an opaque white liquid technology that has been developed primarily for dairy packaging applications, and it is suitable for both single- and multilayered containers. This technique blocks the transmission of light at wavelengths of up to 550 nm while maintaining the aesthetics of the container. Lactra™ protects and extends the shelf life of dairy products packaged in PET and complies with the European Union (EU) and Food and Drug Administration (FDA) food contact regulations (**Figure 2**).

In another example, an aseptic flexible pouch developed in Europe was made with a polymeric film having calcium carbonate as two-fifths of its volume. This film is stronger and significantly lighter than currently used materials. This new aseptic pouch is sterilized with an electron beam emitter before shipment and this eliminates the need for chemicals and water sterilization before use.

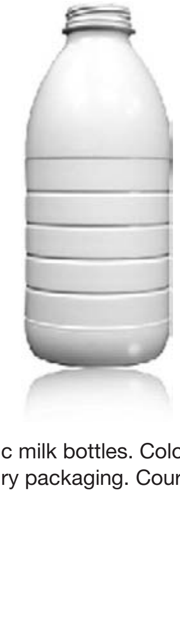

Figure 2 New plastic milk bottles. ColorMatrix's Lactra barrier protection for PET dairy packaging. Courtesy of color Matrix Europe Ltd.

Another recent development is a new aseptic PET bottle for shelf-stable UHT milk. The package is sterilized by a system that uses a dry decontamination technique in which vaporized hydrogen peroxide is applied to sterilize preforms just before they are blown into bottles. These bottles can be made of 20% less plastic because the blown bottle never has to withstand the rigors of conventional hydrogen peroxide sterilization and the thermal abuse associated with it. This dry decontamination provides additional energy-saving benefits because it virtually eliminates the use of a water rinse or hot air drying.

Active packaging is a relatively new technology for powdered milk. Active packaging (also called smart packaging) is the response of a package to a change in the internal or external environment. This response is designed to change the environment within the package and extend the shelf life of the product. As an example, an active package was created by the use of a plastic sachet made with PVC and PS materials. This system was designed to release α-tocopherol in the powdered milk at a controlled rate if the storage temperature exceeded a given threshold. Since α-tocopherol is an antioxidant, its controlled release reduces the potential for rancidity of the milk. In a second example of active packaging, a saturated salt solution was incorporated into the package of a cheese product. When this system absorbs oxygen, it adjusts the humidity within the package. This humidity control was accomplished by a two-way system that continually responded and adjusted to match the outside relative humidity (RH) by either adding or removing water to maintain a predetermined level of RH inside the package.

The FDA's approval of a linear aseptic filler for HDPE bottles for low-acid food and beverages is a significant recent event that has influenced food packaging. Consequently, the traditional paperboard and laminated box packages are being replaced by blow-molded plastic bottles. Products such as flavored milk shakes and coffee drinks that are packed in this linear aseptic filler can now be shipped at ambient temperatures with a 180-day shelf life. This feature is found in an ESL system that has a new sanitary valve without O-rings that does not come in contact with the bottle during filling. This eliminates the possibility of bacterial contamination. High speed is another feature found in two new fillers. One has 64 valves with 32-pocket starwheels. This filler is designed to fill plastic and glass bottles with a maximum diameter of 3.0′ (76 mm) at speeds of up to 800 bottles per minute. The other ESL high-speed filler is designed for half gallon and 2 l sizes at speeds of up to 120–140 cartons per minute,

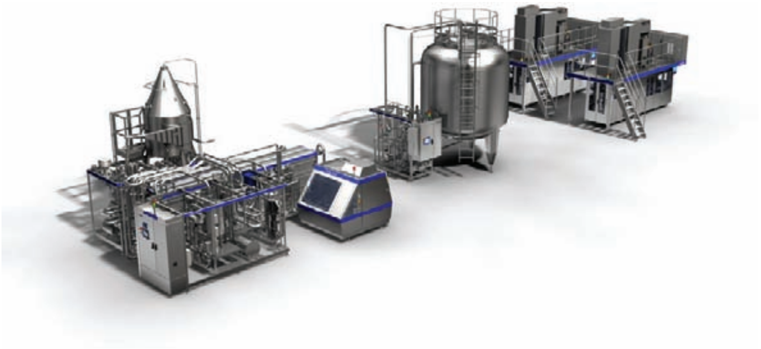

Figure 3 Tetra Lactenso production solutions are engineered to meet the product interacting areas of food safety, quality, efficiency, and sustainability. Courtesy of Tetra Pak.

depending on the carton size. An example of the new fillers is the aseptic system shown in **Figure 3**. The important features of the filler are the automated instrumentation, longer running time capabilities, shorter presterilization times, easy cleaning, and low maintenance.

Bacillus cereus

A Christiansson, Swedish Dairy Association, Lund, Sweden

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Bacillus cereus is an aerobic spore-forming bacterium, whose spores are commonly present at low levels in raw milk. In the 1960s and earlier, *B. cereus* was clearly a quality problem, due to coagulation (sweet curdling) of pasteurized milk and formation of flakes in cream when added to coffee (bitty cream). This was due to poorly cleansed equipment (e.g., milk cans) at the farm and in dairy factories and a lack of adequate refrigeration. Nowadays, these problems are rarely seen in countries where milk is kept at temperatures below 6 °C. However, when pasteurized milk is stored at higher temperatures, *B. cereus* may still be a limiting factor for the keeping quality. *Bacillus cereus* can produce several enterotoxins causing diarrhea and vomiting. There are few dairy-related cases, but milk and cream have been incriminated in both types of illnesses.

Characteristics

Morphology and Cultivation

Bacillus cereus is a Gram-positive, rod-shaped, motile bacterium with peritrichous flagella. The cells tend to grow in chains but may occur singly as well. The length of the bacterium varies between 3 and 5 μm and the diameter is more than 1 μm. Spores are oval or cylindrical, located centrally or paracentrally/subterminally, and do not distend the cell. A typical trait of the *B. cereus* group is the presence of storage granules of poly-*β*-hydroxybutyrate in the cytoplasm. These are easily seen by phase contrast microscopy. *Bacillus thuringiensis*, *B. mycoides*, *B. weihenstephanensis*, *B. pseudomycoides*, and *B. anthracis* have similar characteristics, except that *B. mycoides*, *B. pseudomycoides*, and *B. anthracis* are nonmotile. The species concept within the *B. cereus* group (which includes the genetically very closely related entities mentioned above) is still under debate. *Bacillus weihenstephanensis* and *B. mycoides* are better adapted to growth at low temperature than the other members within the *B. cereus* group. If not mentioned specifically in the text, '*B. cereus*' refers to the entire group (*B. cereus sensu lato*) except *B. anthracis*. *Bacillus cereus* forms colonies with typical appearance on agar media, generally with dull or frosted, grayish/whitish surface. *Bacillus mycoides* and *B. pseudomycoides* form rhizoid colonies. Widely used selective agar media for cultivation from food are mannitol egg yolk polymyxin agar (MYP) and polymyxin pyruvate egg yolk mannitol bromothymol blue agar (PEMBA). The detection of *B. cereus* is based on the absence of mannitol fermentation and positive egg yolk reaction (lecithinase). *Bacillus cereus* can also be enumerated on blood agar with polymyxin added. Colonies with clear zones of hemolysis and a very sharp margin are a useful diagnostic feature. Strains producing emetic toxin have a narrow zone of hemolysis or none at all. The zone does not enlarge upon further incubation, which is the case with nonemetic isolates. A chromogenic selective plating agar (BCM, *B. cereus* group plating medium) that stains colonies expressing phosphatidylinositol-specific phospholipase C turquoise blue has proven to be a good alternative to standard media. It is not possible to differentiate between the species of the *B. cereus* group based on colony morphology only.

Physiology

Bacillus cereus is a versatile microorganism with respect to growth substrates. Most strains produce proteases that can degrade casein and gelatin and enzymes for starch hydrolysis. Enzymes such as lecithinase and sphingomyelinase for degradation of phospholipids and lipase, with activity against triglycerides, can also be produced. Sweet curdling of milk is due to a protease and bitty cream due to phospholipase activity. Several carbohydrates are utilized, for example, glucose, fructose, trehalose, *N*-acetylglucosamine, and maltose. Others are utilized by only certain strains, for example, salicin, cellobiose, inositol, and mannose. A majority of strains do not grow on lactose. Mannitol is generally not used. *Bacillus cereus* is in general Voges–Proskauer (VP) positive and utilizes citrate, but not urea. Most strains can reduce nitrate.

The minimum growth temperature differs among strains and is generally not lower than 5–6 °C, although a few strains have been shown to grow at 4 °C. Increased temperature from 6 to 9 °C markedly affects the growth rate among psychrotrophic (psychrotolerant) isolates (**Table 1**). Some strains have temperature minima as high as 10–15 °C. The optimum growth temperature is 30–37 °C and the maximum growth temperature is 37–50 °C. Strains producing emetic toxin do not grow below 10 °C and are able to grow at 48 °C. The psychrotolerant *B. weihenstephanensis* and *B. mycoides* are able to grow at 7 °C or below and do not grow at 43 °C. These species possess a cold-shock protein (CspA) that is detectable by PCR. Some strains that grow with a minimum temperature of 7 °C and above do not have *cspA* and are classified as *B. cereus* (*sensu stricto*).

The minimum pH for growth is 4.3–4.9 and the upper limit is 9.3. However, in the presence of organic acids, the minimum pH is higher, for example, pH 5.6 in 0.1 mol l^{-1} lactate. Although *B. cereus* grows best under aerobic conditions, anaerobic growth by fermentation of glucose or other carbohydrates or by anaerobic respiration with nitrate is possible. *Bacillus cereus* is able to grow in media with up to 7% NaCl if other conditions are optimum. Minimum water activity for growth is 0.92–0.95.

The values represent average data for pasteurized milk from 10 Swedish dairy plants in August. One milk package was collected from each plant and the milk from each package was divided aseptically into four aliquots, which were incubated in glass bottles in water baths with accurate temperature regulation (±0.1 °C).
Original data from Christiansson A.

Spores

Spores are formed on a variety of growth media under aerobic conditions, upon starvation. The presence of manganese and magnesium ions stimulates sporulation. Sporulation is a fairly lengthy and complicated process, occurring in the late logarithmic and early stationary phase of growth. Even under favorable conditions, sporulation may take up to 16–24 h to complete. Spores are never formed as a result of chilling if nutrients are available, that is, refrigeration of milk does not induce sporulation. For example, high levels of spores are not found in refrigerated pasteurized milk although the *B. cereus* counts may grow to 10^7 ml^{-1}. On the other hand, milk diluted 1:50 with water is still a good growth medium, but nutrients will be depleted after growth and spores are formed abundantly, particularly if the milk is present in thin layers. This is relevant to the cleaning situation in a dairy plant. The spores may germinate and grow out to vegetative cells again under favorable conditions. Germination is much faster than sporulation. The germination rate is highly temperature dependent and may occur within much less than an hour at favorable temperature. In milk, it is stimulated by high-temperature, short-time (HTST) pasteurization, that is, heat treatment. The spores become activated and substances that stimulate germination may be formed as a result of heat treatment. Increased pasteurization temperature in the range of 72–85 °C will lead to activation and germination of more spores. However, initiation of growth in refrigerated milk will occur only after a lag phase of several days.

The heat resistance of *B. cereus* spores is comparatively low. However, there is considerable variation in heat resistance among strains. Although not inactivated by HTST pasteurization, *B. cereus* spores are easily killed upon ultra-high temperature (UHT) treatment. Typical *D*-values at 100 °C are in the range of 0.3–10 min. For comparison, $D_{100\,°\mathrm{C}}$ for *Bacillus stearothermophilus* has been estimated to be approximately 3000 min. Strains producing emetic toxin produce spores that are among the most heat resistant within the *B. cereus* group. Generally, psychrotrophic strains tend to be less heat resistant than mesophilic strains, for example, with *D*-values of 2–9 min at 90 °C. Vegetative cells are easily killed by pasteurization.

Milk-Borne Illness

Bacillus cereus is a common contaminant in many food types, including milk, and a significant cause of foodborne illness worldwide. *Bacillus cereus* can cause diarrhea and/or vomiting when food (most often) containing large numbers of *B. cereus* is consumed. The symptoms are generally mild and transient, lasting no more than 24 h, generally without sequelae. Two types of outbreaks are known: diarrheal-type outbreak and emetic-type outbreak.

Diarrheal-Type Outbreak

The illness is characterized by a fairly long incubation period of 8–22 h. Watery diarrhea is very common, together with abdominal cramps, rectal spasms, and moderate nausea. Vomiting is rare. The duration of illness is generally 12–24 h. The delayed onset of symptoms indicates that illness is most likely due to growth of *B. cereus* in the small intestine, since the toxin(s) are very susceptible to inactivation by low pH and degradation by proteases. Preformed toxin in food will thus be inactivated in the stomach and ileum. Foods associated with diarrheal outbreaks generally contain high numbers of *B. cereus*, that is, 10^5–10^8 per gram food. Foods incriminated in diarrheal outbreaks include meat products, soups, vegetables, puddings, and milk products.

Emetic-Type Outbreak

The incubation period is short, that is, 0.5–5 h. The rapid onset of nausea and vomiting is due to a preformed toxin in the food. Abdominal cramps and diarrhea occur occasionally. Recovery is rapid, within 6–24 h. The level of *B. cereus* in incriminated food can vary between a few thousand and up to more than $5 \times 10^{10}\,\mathrm{g}^{-1}$, although it is generally high. Fried and cooked rice are typical foods frequently involved, but milk-borne cases are also known.

Toxins

The nature of the enterotoxins produced by *B. cereus* has remained elusive for decades. However, during the last 15 years, the knowledge about these toxins has increased considerably.

At least three types of enterotoxins capable of causing diarrhea have been identified. Two of these, hemolysin BL (HBL) and the nonhemolytic enterotoxin (NHE), are protein toxins consisting of three subunits each. All subunits are needed for full activity. Both toxins have been isolated from *B. cereus* strains involved in food poisoning. The third toxin, cytotoxin K (cytK), is a single protein toxin. CytK was involved in a rare foodborne outbreak, which caused the death of three persons, where the symptoms included bloody diarrhea. Additional toxins have been described but their involvement in foodborne illness is uncertain. The enterotoxin genes can be found in all species of the *B. cereus* group as judged by various PCR methods. Most strains are able to produce more than one toxin. *Nhe* genes are present in almost all strains, whereas *Hbl* and *cytK* genes can be found in approximately 50% of all strains, including strains in raw milk. However, *cytK* genes were not found in strains growing in pasteurized milk at refrigeration temperature. The toxin production potential (expression of the genes) varies considerably between strains and toxins. Strains involved in foodborne illness are generally more toxigenic than the average food or environmental isolate. They are often mesophilic, that is, they have a minimum growth temperature above 10 °C, but food poisoning strains growing at or above 7 °C are also known. However, strains belonging to *B. weihenstephanensis* and *B. mycoides* are generally less toxic than the other members of the *B. cereus* group. *Bacillus thuringiensis* and *B. cereus* (*sensu stricto*) have similar toxigenicity. From the point of food safety, there is therefore no need to differentiate between these two species as far as milk products are concerned. The toxins are heat labile and are considered to be inactivated by heating above 60 °C for 5 min. PCR primers have been published for detection of all enterotoxin subunits. However, the mere presence of the genes is not sufficient to judge the pathogenicity of *B. cereus*. Monoclonal antibodies have been developed for all subunits of NHE and HBL and can be used for evaluation of the toxin production potential. Cytotoxicity tests using, for example, Vero cells or Caco cells can be employed to assess the overall cytotoxicity of strains. NHE seems to be the most cytotoxic toxin followed by HBL and cytK.

The emetic toxin is a cyclic peptide, cereulide, which contains 12 modified amino acids and resembles the ionophore valinomycin. The molecular weight is

1.2 kDa. The toxin is quite heat resistant and cannot be destroyed even by heating at 121 °C for 1 h. Unlike the diarrheal toxins, the emetic toxin is encoded by a plasmid. The expression of the toxin varies strongly among strains and also depends on the composition of the food. The emetic toxin is a more serious health hazard than the diarrheal toxins and has been the cause of death in rare cases. Strains producing emetic toxin are rare in the dairy production chain (less than 1% of all isolates). Emetic strains do not grow in pasteurized milk that is kept refrigerated. A large number of cells (more than 5 log cfu g^{-1}) are needed for toxin production. Recently, a real-time PCR method with PCR primers for detection of genes has been developed. Furthermore, a detection method for the toxin, based on the motility of boar sperm, has become available and can be used for foodstuffs.

In addition to enterotoxins, several proteases, phospholipases, and hemolysins may have a role in the pathogenesis of *B. cereus*.

Outbreaks Related to Dairy Products

Outbreaks related to dairy products are rare. Some cases are presented in **Table 2**. Both diarrheal and emetic symptoms have been recorded. Consumption of (refrigerated) raw milk is never associated with illness, due to the low numbers of *B. cereus* present. Growth to high numbers is always necessary in order to cause food poisoning. From the table, it seems that young people and elderly may be at higher risk than the general population. Several factors may explain why milk-borne cases are few: Milk is generally kept at refrigeration temperature and growth of *B. cereus* is slow, thus the risk of exposure to high levels of bacteria is limited, although significant. In addition, sweet curdling often occurs when the product contains 10^6–10^7 *B. cereus* per ml of milk, with decreased risk of consumption. Psychrotrophic strains, in particular *B. weihenstephanensis*, will be enriched in pasteurized milk upon cold storage and these strains seem to be less toxigenic than *B. cereus* (*sensu stricto*). Psychrotrophic strains have a slower growth rate at the temperature of the human intestine (37 °C; close to their maximum temperature of growth) than mesophilic strains, which grow faster. They are therefore less likely to cause food poisoning. However, temperature abuse will increase the risk of illness. Highly toxigenic (mesophilic) strains have been found in raw milk and they may be important in other products such as milk powder.

Incidence in Dairy Products

Vegetative *B. cereus* cells are found in raw milk at <10 ml^{-1} to a few hundred per ml. These cells are killed by pasteurization. Spores are found from <10 l^{-1} to a few thousand per liter milk, that is, at much lower levels. There is a marked seasonal variation in psychrotrophic

Table 2 Outbreaks of milk-borne illness caused by *Bacillus cereus*

Product	*Year*	*Country*	*People ill*	*Symptoms*	*Analytical data*
Unpasteurized milk (heated and then kept at room temperature overnight)	1972	Romania	221 school children	Diarrhea and abdominal cramps after 8–11 h	20×10^6 *B. cereus* per ml in milk. *Bacillus cereus* found in children's feces
Cream, pasteurized	1975	England	Two 15-year-old girls	Vomiting after 8–10 h. One girl had diarrhea	5×10^6 *B. cereus* per gram in cream
Milk, pasteurized	1981	Denmark	1-year-old boy	Vomiting after 1.5 h, no diarrhea	2.6×10^6 *B. cereus* per ml in milk. Remaining milk was sweet curdled 1 h after consumption
Milk powder, infant formula	1981	Chile	35 neonate children	Diarrhea	*Bacillus cereus* found in stool cultures
Human breast milk	1981	India	Child, 6 months	Diarrhea, occasional vomiting	*Bacillus cereus* found in breast milk
Milk, pasteurized	1988	The Netherlands	42 elderly people	Nausea and vomiting after 2–14 h	0.4×10^6 *B. cereus* per ml in milk
Ultra-high temperature milk (process failure)	1991	Japan	201 people	Vomiting 95%, average after 5 h Diarrhea 55%	Milk distributed at room temperature

Compiled from Christiansson A (1992) The toxicology of *Bacillus cereus*. *International Dairy Federation Bulletin* 275: 30–35; Van Netten P, van de Moosdijk A, van Hoensel P, Mossel DAA, and Perales I (1990) Psychrotrophic strains of *Bacillus cereus* producing enterotoxin. *Journal of Applied Bacteriology* 69: 73–79; Shinagawa K (1993) Serology and characterization of toxigenic *Bacillus cereus*. *Netherlands Milk and Dairy Journal* 47: 89–103; Cohen JV, Marmabio E, Lynch B, and Moreno A (1984) *Bacillus cereus* in food poisoning amid newborns. *Revista Chilena de Pediatrica* 55: 20–25.

spores, with the highest levels in summer and early autumn.

Milk and Cream

The number of *B. cereus* in pasteurized milk and cream depends on the quality of the raw milk, the process hygiene at the dairy plant, the storage temperature of the product, and age of the product at the sampling time. *Bacillus cereus* grows slowly at temperatures below 6 °C and will not be a quality problem, unless the sell-by date is set at several weeks. After 7 °C storage for 7 days, the incidence of *B. cereus* can typically vary between 5 and 90% (winter and summer) at <10 to 10^5 ml^{-1} (including differences in dairy hygiene). When stored below 5 °C, *B. cereus* is rarely detected unless there is a cleaning problem in the dairy plant.

Fermented Milks and Cheese

Bacillus cereus is rapidly inactivated in traditional yogurt manufacture as well as in the manufacture of fermented milk with lactococci. Some growth is possible within the first hours of fermentation. Multiplication in semihard cheese is likewise restricted to the first hours in the cheesemaking process. Inhibition occurs due to lactic acid at pH 5.6 but other inhibitors are also active. As the pH is lowered, vegetative *B. cereus* cells will die whereas spores that have not germinated may still be present. When present in these products, *B. cereus* seldom exceeds 100 g^{-1}.

Milk Powder

Bacillus cereus is frequently found in low numbers in milk powder and infant formula. The frequency of isolation varies between 30 and 100% of samples with origin worldwide. Under certain circumstances, there may be some opportunity for growth of *B. cereus* in the evaporation process. Most samples contain <10 cfu g^{-1} but samples with more than 10^3 cfu g^{-1} have been found. These are due to hygienic problems in the factory or due to raw milk with a high degree of contamination. High levels of *B. cereus* in infant formula may constitute a health risk. Regulation (EC) 1771/2007 on microbiological criteria for foodstuffs in the European Union defines process hygiene criteria for presumptive *B. cereus* in dried infant formulae and dried dietary foods for special medical purposes intended for infants below 6 months of age. These are n (sample size) = 5, c (number of sample units giving values between m and M) = 1, acceptable limits (m) = 50 cfu g^{-1}, and unsatisfactory limits (M) = 500 cfu g^{-1}. In standard 1.6.1 of the Australia New Zealand Food Standards Code, which specifies microbiological standards for powdered infant formula products, the limits for *B. cereus* are $n = 5$, $c = 0$, and $m = 100$ cfu g^{-1}.

Source

At the Farm

Bacillus cereus is a ubiquitous microorganism. The spores are present in soil from 10^2 cfu g^{-1} and up to more than 10^5 cfu g^{-1}. Consequently, food products of plant origin frequently contain *B. cereus* spores. Soil is an important source of contamination for milk. There is a marked seasonal variation in the spore content of raw milk, with higher levels during the pasture period, when the teats of the cow may be contaminated with soil. Dirty teats that are not cleansed before milking are an important contamination source, particularly during wet weather. *Bacillus cereus* is able to grow and sporulate on insufficiently cleaned milking equipment, so equipment may be a secondary source of contamination. Used bedding material and feed may also contain spores of *B. cereus*.

In the Dairy Plant

There has been considerable disagreement whether the occurrence of *B. cereus* in dairy products is caused by recontamination of milk at the dairy plant or by contamination at the farm. To some extent, this was due to the inability to detect the low levels of spores in raw milk, whereas *B. cereus* was easily detected in pasteurized milk after storage. It is now generally agreed that the original contamination occurs at the farm from soil. The seasonal variation in the occurrence of *B. cereus* in dairy products, kept at temperatures above 6 °C, can to a large extent be explained by the increased contamination rate of the milk during the grazing period. However, additional contamination may occur from the dairy plant equipment. Since spores survive pasteurization, they will be present in the milk throughout the dairy process. Spores of *B. cereus* are very hydrophobic and will attach to surfaces of equipment, where they may germinate and form biofilms at sites that are difficult to clean. Several strain-typing methods (e.g., Random Amplified Polymorphic DNA-Polymerase Chain Rection analysis (RAPD-PCR), Amplified Fragment Length Polymorphism analysis (AFLP), riboprinting, Repetitive element sequence polymorphism-PCR analysis (rep-PCR), and pulsed field gel electrophoresis (PFGE)) have recently been applied to strains of *B. cereus*. These methods demonstrate a high discriminatory power and could be helpful in finding contamination sites in dairy plants. There is a very strong diversity among strains of *B. cereus* in raw milk. Recontamination of milk by *B. cereus* has been demonstrated in silo tanks, pasteurizers, milk pipelines

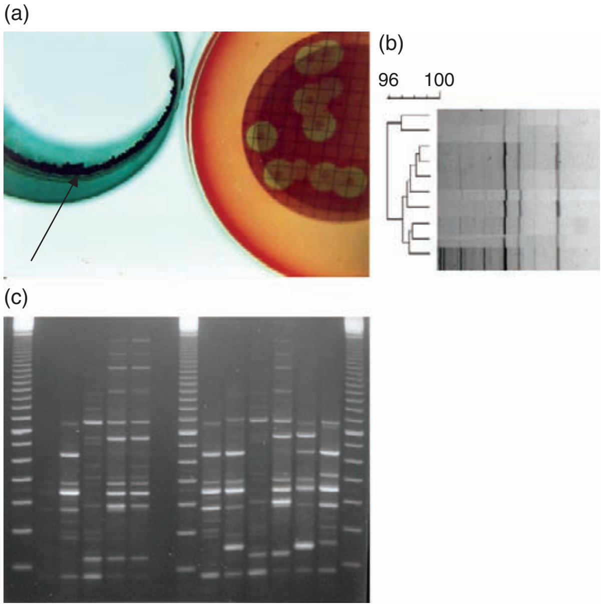

Figure 1 Examples of strain typing of *Bacillus cereus* isolates. (a) A milk stainless-steel pipeline with a very rough welded seam (arrow) was replaced at a dairy plant (to the left). Spores were recovered from the seam by rinsing with water and ultrasonication, collected by filtration, and then grown on blood agar plates (to the right). (b) All isolates showed the same RAPD fingerprint, which indicates that the welded seam was a source of recontamination. Similar fingerprints were found in pasteurized milk. (c) Examples of various RAPD fingerprints of strains from pasteurized milk. Lanes 1, 8, and 15 are molecular weight markers. A Christiansson, unpublished data.

with bad welding, and in packaging machines using RAPD-PCR (**Figure 1**). Automated ribotyping and rep-PCR have been used to identify surfaces of dairy equipment involved in recontamination of milk.

Control

The Farm

At the farm, measures to control *B. cereus* include careful teat cleansing before milking and proper cleaning and disinfection of the milking equipment. Since the teats become dirty with soil when the cows are outdoors during the grazing period, it is essential that they are clean before attaching the teat cups. During the indoor season, high levels of *B. cereus* spores may be found in used bedding material, if not replaced daily, and may contaminate the teats. The best cleansing routine includes the use of one moistened cloth per cow, followed by a dry paper towel. In addition, the milking equipment must be kept clean by careful cleaning after milking. Teat liners and other rubber material must be replaced regularly since aged rubber with cracks can harbor milk residues where *B. cereus* can propagate and sporulate.

The Dairy Plant

At the dairy factory, cleaning and maintenance is essential. Attention must be given to proper concentrations of cleaning agents, sufficiently high cleaning temperature (at least 75 °C for alkaline cleaning agents with 1–1.5% NaOH and at least 60–65 °C for acid cleaning agents with 0.6–0.9% nitric acid), and proper flow rates during cleaning, since spores are difficult to remove and to kill. *Bacillus cereus* is considerably more resistant in a biofilm with spores than in a planktonic state. The spores are not killed by hot water disinfection, but sodium hypochlorite at pH 6–7 is effective. Regular replacement of gaskets and other rubber parts is important.

In Dairy Products

The best control measure for *B. cereus* in pasteurized milk and cream is to keep a low storage temperature in the whole chain from the dairy plant to the customer. Below 5–6 °C, growth of most strains of *B. cereus* is insignificant. If the temperature is higher, the sell-by date must be shortened. Suitable time/temperature combinations may be found by storage tests. Seasonal variation, occurrence of recontamination at the dairy plant as well as possible moderate temperature abuse by the customer must be taken into consideration when choosing the recommended last consumption date of the products.

Milk powder is microbiologically stable and no growth of *B. cereus* can occur in the powder, although occurrence of contamination with *B. cereus* is frequent. However, milk powder is frequently used in infant formulae and in infant foods. When such powders are reconstituted, it is important that the product is consumed shortly after preparation unless it is not cooled to below 8 °C. Spores of *B. cereus* are able to germinate rapidly at the reconstitution temperature and will grow rapidly if the product is kept at room temperature. Young children may be more susceptible to toxins that may be produced than adults.

Brucella spp.

B Garin-Bastuji, French Agency for Food, Environmental & Occupational Health Safety (ANSES), Maisons-Alfort, France

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Brucella spp. are the causative agent of brucellosis, a zoonosis of worldwide importance. Human brucellosis is usually characterized by an intermittent influenza-like clinical pattern, which may be severe and may be followed by chronic, intermittent relapses. The main manifestations of animal brucellosis are reproductive failure, for example, abortion and birth of unthrifty offspring in the female, and orchitis and epididymitis in the male, and rarely arthritis. Persistent infection with shedding of *Brucella* in reproductive and mammary secretions is common.

Genetic and immunological evidence indicates that all members of the genus *Brucella* are closely related. However, due to relevant differences in host preference and epidemiology displayed by the major variants, as well as molecular evidence of genomic variation, the classification of the genus includes nine species (**Table 1**).

Brucella abortus primarily infects cattle but may be transmitted to buffaloes, camels, deer, dogs, goats, horses, pigs, sheep, and humans. *Brucella melitensis* causes a highly contagious disease in sheep and goats although cattle and other species can be infected. It is the most important species in human infection. *Brucella suis* covers a wider host range than most other *Brucella* species. *Brucella canis* causes epididymo-orchitis in the male dog and abortion and metritis in the bitch. It has not been reported in other animals except humans. *Brucella ovis* is responsible for epididymitis in rams and occasionally infects ewes, but does not infect other animals or humans. *Brucella neotomae* is only known to infect the desert wood rat under natural conditions, and no other cases have been reported. In the last decade, isolations of previously unidentified species of *Brucella* have been reported from sea mammals (*B. ceti* and *B. pinnipedialis*). Finally, a new species, *Brucella microti*, was recently isolated in central Europe from the common vole (*Microtus arvalis*).

Characteristics

Morphology

Bacteria included in the genus *Brucella* are Gram-negative coccobacilli or short rods (0.6–1.5 μm × 0.5–0.7 μm) arranged singly and rarely in pairs or small groups. The morphology of *Brucella* spp. is fairly constant except in old cultures, where pleomorphic forms may occur. Brucellae are nonmotile and do not form spores, and flagella, pili, or true capsules are not produced. They usually do not show bipolar staining and resist decolorization by weak acids.

Culture and Growth Characteristics

Brucella spp. are aerobic, but many strains require an atmosphere containing 5–10% added CO_2 for growth (**Table 2**). The optimum pH for growth varies from 6.6 to 7.4, and culture media should be adequately buffered near pH 6.8 for optimal growth. The optimal growth temperature is 36–38 °C, but most strains can grow between 20 and 40 °C. Growth in liquid media favors dissociation of smooth-phase cultures to nonsmooth forms and is usually poor unless the culture is vigorously agitated. On suitable solid media, colonies are visible after 2 days of incubation. After 4 days of incubation, the colonies are round, 1–2 mm in diameter, with smooth margins, translucent, and a pale honey color when plates are viewed in the daylight through a transparent medium. When viewed from above, the colonies appear convex and pearly white. Later, the colonies become larger and slightly darker. Smooth *Brucella* spp. cultures have a tendency to undergo variation during growth, especially with subcultures, and dissociate to rough (R) forms, and sometimes mucoid (M) forms.

Biochemical Characteristics

The metabolism of *Brucella* spp. is oxidative, and cultures show no ability to acidify carbohydrate media in conventional tests. The *Brucella* species are catalase-positive and usually oxidase-positive (except otherwise stated in **Table 1**), and reduce nitrates to nitrites (except *B. ovis* and some *B. canis* strains). *Brucella suis* biovar 1, *B. neotomae* and biovars 1–4 and 9 of *B. abortus* produce H_2S from sulfur-containing amino acids (**Table 2**). Urease activity varies from fast to very slow. Indole is not produced from tryptophan, and acetylmethylcarbinol is not produced from glucose.

Antigenic Characteristics

All smooth *Brucella* spp. strains show complete cross-reaction with each other, but not with nonsmooth variants,

[a] Dye concentration in serum dextrose medium: $20\,\mu g\,ml^{-1}$.
[b] Usually positive on primary isolation.
[c] Some basic fuchsin-sensitive strains have been isolated.
[d] Some basic fuchsin-resistant strains have been isolated.
[e] Negative for most strains.
[f] Growth at a concentration of $10\,\mu g\,ml^{-1}$ thionin.

in agglutination tests with unabsorbed polyclonal antisera. Cross-reactions between nonsmooth strains can be demonstrated as well with unabsorbed anti-R sera. Lipopolysaccharide (LPS) comprises the major surface antigens of the corresponding colonial phase involved in agglutination. The S-LPS molecules carry the A and M antigens, which show different quantitative distribution among the smooth *Brucella* spp. strains (**Table 2**).

Serological cross-reactions have been reported between smooth brucellae and various other Gram-negative bacteria, and especially *Yersinia enterocolitica* O:9, which can induce significant levels of antibody cross-reacting with S-LPS *Brucella* spp. antigens in diagnostic tests.

Susceptibility to Phages

Over 40 phages have been reported to be specifically lytic for *Brucella* spp. Thus, lysis by specific phages is a useful test to confirm the identity of *Brucella* spp. and for speciation within the genus. The phages mainly used for *Brucella* spp. typing are Tbilisi (Tb), Weybridge (Wb), Izatnagar$_1$ (Iz$_1$), and R/C (**Table 1**).

Susceptibility to Dyes and Antibiotics

Susceptibility to the dyes thionin and basic fuchsin, which varies between biovars, is one of the routine typing tests of *Brucella* spp. (**Table 2**). On primary isolation, all brucellae are usually susceptible *in vitro* to gentamicin, rifampin, and tetracyclines. Most strains are also susceptible to ampicillin, chloramphenicol, cotrimoxazole, erythromycin, kanamycin, novobiocin, spectinomycin, and streptomycin, but variation in susceptibility may occur. *In vivo*, most strains are resistant at therapeutic concentrations to amphotericin B, bacitracin, β-lactamins, cephalosporins, clindamycin, cycloheximide, lincomycin, nalidixic acid, nystatin, polymyxin, and vancomycin.

Resistance and Survival

The ability of *Brucella* spp. to persist outside its mammalian host is relatively high as compared with most other non-spore-forming pathogenic bacteria, under suitable conditions. Thus, when conditions of pH, temperature, and light are favorable, that is, pH > 4, cool temperature, high humidity, and absence of direct sunlight, brucellae may retain infectivity for several months in aborted fetuses and fetal membranes, feces and liquid manure, water, wool, and hay, and on equipment and clothes. Brucellae are able to withstand drying particularly in the presence of extraneous organic material and will remain viable in dust and soil. Survival is prolonged at low temperatures, especially when freezing.

The persistence of brucellae in milk and dairy products is related to a variety of factors including the type and age of product, humidity level, temperature, changes in pH, moisture content, biological action of other bacteria present, and conditions of storage. The results of several studies are presented in **Table 3**. At low numbers in liquid media, brucellae are fairly heat-sensitive. Thus, dilute suspensions in milk are readily inactivated by pasteurization (high-temperature short-time or flash methods) or prolonged boiling (10 min).

Brucellae do not remain viable for prolonged periods in ripened fermented cheese. The optimal fermentation time to ensure safety is not known but is estimated at 3 months. However, in normally acidified soft cheese, the strictly lactic and short-time fermentation and drying increase the survival of *Brucella*. Pasteurization of milk or cream is the only means to ensure safety of these products.

Brucellae are fairly sensitive to ionizing radiation and are readily killed by normal sterilizing doses of gamma rays, under conditions that ensure complete exposure, especially in colostrum. In contrast to dairy products, the survival time of brucellae in meat is extremely short, due to acidic fermentation of the meat except in frozen carcasses where the organism can survive for many years. Therefore, meat consumption is less likely to be a source of infection. Direct contamination of abattoir workers and carcasses by milk and uterovaginal secretions is prevented by a proper and hygienic removal of mammary glands, reproductive organs, and lymph nodes, which are the most heavily contaminated organs.

Most commonly available disinfectants readily kill brucellae at normally recommended concentrations (phenol $10\,\mathrm{g\,l^{-1}}$, formaldehyde, xylene $1\,\mathrm{ml\,l^{-1}}$), except in the presence of organic matter or at low temperature, which drastically reduce their efficacy. Where possible, decontamination should be carried out by heat treatment, especially for surfaces. Diluted hypochlorite solutions, ethanol, iodophors, or isopropanol, and optimally substituted phenols, but not the alkyl quaternary ammonium, are effective for decontamination of exposed skin.

Animal Brucellosis

Brucellosis in Cattle

Brucella-infected cattle generally develop granulomatous inflammatory responses often located within lymphoid tissues and organs with a prominent reticuloendothelial component. There is a predilection for selected body sites

Table 3 Studies on *Brucella* survival time in dairy products

Product	*Species of Brucella*	*Survival time*	*Temperature (°C)*	*pH*

such as reproductive organs, udder, and supramammary lymph nodes, and sometimes joints and synovial membranes. The localization and persistence of brucellae in these organs and tissues follow in the wake of a widespread distribution of *Brucella* during a generalized stage of infection. During this first stage of infection, the major clinical symptom is abortion but other signs due to a localization of brucellae may be observed (e.g., orchitis, epididymitis, hygroma, arthritis, metritis, subclinical mastitis). However, numerous animals develop self-limiting infections or they become asymptomatic latent carriers and potential excretors.

The second stage is characterized by the elimination of brucellae or, more frequently, by a persistent infection of the mammary glands and supramammary and genital lymph nodes, with a constant or intermittent shedding of the organisms in the milk and genital secretions. Animals generally abort once, from 5 to 8 months of gestation, but reinvasion of the uterus occurs in subsequent pregnancies through shedding of the microorganism in fluids and membranes. The pregnancy can also be full-term. Vaginal discharges after abortion or normal calving are the main source of contamination of congeners, other animal species, and man. The interherd spread of infection generally follows the movement or gathering of infected animals.

Persistent infection of mammary glands is associated with constant or intermittent shedding of the organisms in the milk in succeeding lactation periods and a drop in milk production estimated at 10%. The number of brucellae excreted in milk is relatively low and does not allow transmission through direct contact, except through the milker's hands.

In the male, localization in the reproductive organs generally results in brucellae being shed in the semen.

Congenital infection is of major epidemiological significance, since 2–20% of heifer calves born to infected cows may be persistently infected. Other calves fed with infected milk usually become infected, but most recover from these infections.

Brucellosis in Small Ruminants (Specific Features)

Brucella melitensis is the main causative agent of brucellosis in sheep and goats, but sporadic cases due to *B. abortus* have been observed. Pathologically and epidemiologically, *B. melitensis* infection in sheep and goats is very similar to *B. abortus* infection in cattle. The excretion from the vagina is more copious and prolonged than in the case of cows and last in goats for at least 2–3 months. In goats, about two-thirds of acute infections acquired naturally during pregnancy lead to infection of the udder and excretion of the organisms in the milk during the next lactation. Excretion may cease during a lactation period. Infection reduces milk production more drastically than in cattle.

Brucellosis in Other Species

In other milk-producing domestic ruminants (buffaloes, camels, reindeer, yaks), the risks associated with the shedding of brucellae in milk are comparable with those in cattle, sheep, and goats.

Human Brucellosis

Humans are accidental and almost always dead-end hosts of *Brucella* infections. The disease is primarily an occupational hazard in professionals who work with animals and their products, namely, veterinarians, farmers, laboratory technicians, abattoir workers, and others. The primary route of infection is through either direct or indirect contact on skin or mucous membranes. Another source is the ingestion of contaminated fresh dairy products. Humans are susceptible mainly to *B. abortus*, *B. melitensis*, and *B. suis*. *Brucella melitensis* and *B. suis* often give rise to the most severe form of infection. After an average 8- to 20-day (up to several months) incubation period, illness occurs in different forms. The asymptomatic form is frequent and mainly due to *B. abortus*, and is characterized by serologic evidence in persons with no symptoms consistent with brucellosis. The acute form is also common and symptoms include lassitude, headache, and muscular or joint pain, and drenching sweats, especially at night, are characteristic. The manifestations of brucellosis are sometimes most pronounced in or limited to a specific system or organ. Complication occurs in the course of acute infection, and localized brucellosis occurs in the absence of other signs of systemic illness (spondylitis and peripheral arthritis, especially of the hip, knee, and shoulder, epididymo-orchitis and thrombophlebitis). Nervous, genitourinary, hepatosplenic, and cardiovascular complications may be observed as well. Chronic brucellosis includes one or more of the signs described above and persists or recurs over a period of 6 months or more. Finally, *Brucella* dermatitis has traditionally been ascribed to allergy to brucellae. Brucellosis may be diagnosed on medical history but definitive diagnosis needs bacteriological and serological tests. Bacteriological studies consist essentially in blood cultures. However, cultural examinations are time-consuming, hazardous, and not sensitive, and cultural analysis must be performed in well-equipped laboratories with highly skilled personnel and are generally limited to hospital laboratories. Thus, diagnosis is frequently based on the detection of high or rising titers in serological tests such as serum agglutination test and the Rose Bengal test (RBT) as screening tests, and

Coombs' or complement fixation tests, or ELISA for confirmation.

Treatment of choice in acute brucellosis consists of antibiotic therapy. The best results are now achieved with rifampin (600–900 mg day^{-1}) combined with doxycycline (200 mg day^{-1}) given orally for at least 6–7 weeks. Treatment generally needs to be prolonged or repeated in persistent forms before a cure is achieved.

Diagnosis of Animal Brucellosis

In the absence of pathognomonic signs, the specific diagnosis of brucellosis can only be made on the basis of laboratory testing, especially in domestic animals.

Bacteriological Methods

There is no single test by which a bacterium can be identified as *Brucella* spp. A combination of growth characteristics, and serological and bacteriological methods is usually required.

Staining methods

Stamp's modification of the Ziehl–Neelsen method is the usual procedure for the examination of smears of organs or biological fluids. However, this method shows a low sensitivity on milk and dairy products where brucellae are often present at low numbers and interpretation is frequently impeded by the presence of fat globules. Furthermore, staining methods are not specific, and other organisms causing abortion, for example, *Chlamydophila abortus* (formerly *Chlamydia psittaci*) or *Coxiella burnetii*, are very difficult to differentiate from *Brucella* spp. organisms. The results, whether positive or negative, should be confirmed by culture.

Culture

Basal media

Direct isolation and culture of *Brucella* spp. are usually performed on solid media that enable the developing colonies to be isolated and recognized clearly, and limit the establishment of nonsmooth mutants and overgrowth of contaminants. However, the use of liquid media may be recommended for specimens where brucellae may be in small numbers. A wide range of commercial dehydrated basal media is available, for example, *Brucella* medium base, Tripcase or Trypticase soy agar, and Bacto™ tryptose. Addition of 2–5% bovine or equine serum is necessary for the growth of strains like *B. abortus* biovar 2, and many laboratories systematically add serum to the basal media, with excellent results. Other media such as serum dextrose agar or glycerol dextrose agar can be used satisfactorily. A nonselective, biphasic medium, known as the Castañeda medium, is recommended for the isolation of *Brucella* spp. from blood and other body fluids or milk, where enrichment culture is usually advised.

Selective media

All the basal media mentioned above can be used for the preparation of selective media. Appropriate antibiotics are added in order to suppress growth of organisms other than *Brucella* spp. The selective medium most widely used is Farrell's medium, which is prepared by the addition of six antibiotics to a basal medium. A freeze-dried antibiotic supplement is available commercially. A selective biphasic medium made of the basal Castañeda medium with the addition of antibiotics to the liquid phase is sometimes recommended for isolation of *Brucella* spp. in milk.

These media allow the isolation of most strains of *Brucella* spp.; however, some strains of *B. melitensis* may be partially inhibited by bacitracin, included in the supplement. Sensitivity increases significantly by the simultaneous use of both Farrell's and the modified Thayer–Martin's medium.

Collection and culture of specimens

Brucellosis is one of the most easily acquired laboratory infections; hence, safety precautions for sampling, and shipping, handling, and processing of the samples are extremely important, and work should only be carried out under level 3 containment (biosafety) conditions and by personnel adequately trained and made aware of the risks.

Milk

Samples of milk have to be collected aseptically after washing and drying of the whole udder and disinfection of the teats. It is essential that the samples contain milk from all quarters, and 10–20 ml of milk should be taken from each teat, avoiding contact of milk with the milker's hands. The first few streams are discarded and the sample is directly milked into a sterile vessel. Milk specimens should be cooled immediately after they are taken and sent to the laboratory by the most rapid route. If they are to spend more than 12 h in transit, they should be treated with boric acid (0.1%), or preferably frozen. On arrival at the laboratory, samples are frozen if they are not to be cultured immediately. Then, milk is centrifuged at 5–700 g for 15 min, and cream and deposits are spread on solid selective medium, separately or mixed. Brucellae are usually present in low numbers in bulk tank samples, and isolation from such specimens is very unlikely.

Dairy products

These materials are likely to contain small numbers of organisms, and enrichment culture is advised. Sampling methods are those classically recommended for bacteriological examination of dairy products and adapted to each sort of product. Specimens need to be carefully homogenized before culture, after they have been ground in a tissue grinder or macerated and pounded in a stomacher or an electric blender, with an appropriate volume of sterile phosphate-buffered saline. The superficial strata (rind and the underlying parts) and core of the product should be cultured. Brucellae grow, survive, or disappear more or less rapidly according to the local physicochemical conditions linked to specific process technologies, and their distribution among the different parts of the product varies. A previous inoculation into guinea pigs or mice may sometimes provide the only means of detecting the presence of *Brucella* spp., especially when the specimens are heavily contaminated or likely to contain a low number of brucellae. Spleen is then cultured and, if possible, a serum sample is subjected to specific tests.

Other specimens

The most valuable other specimens include aborted fetuses (stomach contents, spleen, and lung), fetal membranes, vaginal secretions, semen, and arthritis or hygroma fluids. On animal carcasses, the tissues preferred for culture are those of the reticuloendothelial system (i.e., head, mammary and genital lymph nodes, and spleen), the pregnant or early postparturient uterus, and the udder.

Identification and typing

Species identification is routinely based on lysis by phages and on simple biochemical tests (oxidase, urease, etc.). For *B. melitensis*, *B. abortus*, and *B. suis*, the identification at the biovar level is currently performed by four main tests: carbon dioxide requirement, production of hydrogen sulfide, dye (thionin and basic fuchsin) sensitivity, and agglutination with monospecific A and M antisera.

The polymerase chain reaction (PCR), including the real-time format, based on selected sequences of the *Brucella* spp. genome, provides an additional means of *Brucella* detection and identification, which is unaffected by the colonial phase. A number of other methods including a multilocus sequencing scheme and several typing schemes based on the use of multiple locus VNTR analysis (MLVA) have recently been described, which can add useful epidemiological information allowing isolates to be differentiated to the species level or to be further subdivided at the subspecies level.

Serological Diagnosis

Diagnosis of *Brucella* spp. infection often has to be based on serological methods, in situations where bacteriological examination is not practicable. In routine veterinary tests, anti-*Brucella* antibodies are detected in serum and milk. The most widely used and recommended serum-testing procedures are (1) buffered *Brucella* antigen tests (BBAT), that is, card test and the RBT, or buffered plate agglutination test (BPAT), (2) complement fixation test (CFT), and (3) indirect ELISA tests. The milk ring test (MRT) or indirect ELISA performed on bulk tank samples have great usefulness for locating infected herds or flocks (the MRT is not usable in small ruminants). These tests are also of great interest to identify infected animals. The World Health Organization, the World Organization for Animal Health (OIE), the US Department of Agriculture, and the European Union have adopted specific recommendations for standardization of performance of the tests and interpretation of the results for all the different methods mentioned above. In small ruminants RBT and CFT are the most effective and the most widely used methods.

Allergic Tests

Delayed-type hypersensitivity reactions associated with cell-mediated immunity may be induced by either infection or immunization with living or adjuvant killed vaccines. Thus, a number of skin tests have been developed. Antigens free of S-LPS, such as Brucellin-INRA, should be preferred to crude preparations that interfere with serological diagnosis. Reactions are thus specific to the genus *Brucella*. Allergic skin test is now more and more widely used for nonvaccinated cattle, sheep, and goat herd surveillance, notably as a complementary test.

Control

Control, eradication, and prevention of brucellosis require the implementation of regional programs based on vaccination and/or test and slaughter of infected animals, and general nonspecific management practices and hygienic measures that reduce exposure potential. These measures would not be effective without health education, training, and mobilization of livestock owners and others engaged in animal production, and if animal identity is not well recorded and stock movements are not well controlled.

General Measures

General nonspecific control measures help to reduce the spread of infection. Field personnel should be aware of simple safety measures to prevent human contamination and passive intra- and interherd transmission. Isolation of females at parturition, and incineration or deep burying of nonliving products and fetal membranes are essential to limit the spread of infection. Contaminated materials and premises should be disinfected by heat treatment or by the use of the chemicals previously mentioned. All personnel handling contaminated material should wear disinfected or single-use protective clothing. Body surfaces that have been accidentally exposed to infection should be systematically washed and then decontaminated. Abattoir workers should take similar precautions, especially when handling udder and uterus, which should be systematically destroyed when infection is suspected.

In the laboratory, *Brucella* spp. present a very serious risk to workers handling heavily infected materials and cultures. Even when processing milk or dairy products risk exists but is lower. However, special safety precautions are not required for personnel engaged in routine serological diagnosis.

All personnel regularly exposed to infection should be kept under close clinical and serological surveillance. Currently no vaccine is efficient or safe enough to be recommended.

In infected areas, trade in fresh milk and dairy products should be strictly controlled and limited to officially declared brucellosis-free farms. The milk produced on infected farms should be heat treated whatever its commercial purpose.

Eradication by Test and Slaughter

Considering the low efficacy and the cost of antimicrobial chemotherapy in farm animals, test and slaughter of sero-positive animals is one of the two major forms of control and prevention of brucellosis. Such a strategy of eradication is justified on economic grounds when the prevalence rate of infected herds is 1% or below. The epidemiological surveillance of brucellosis-free herds is generally based on regular control by the use of bulk MRT (in cattle only) and/or individual serological testing. All susceptible animals should be permanently identified and movements of animals closely controlled. Eradication programs usually require an abortion notification and investigation scheme as well to detect infection. When positive results or abortions occur, safety measures should be undertaken and reactors or aborted females slaughtered. In some circumstances, for example, in free areas or in heavily infected herds, slaughter of the whole herd is advisable. Herd replacement should not subsequently occur and contaminated premises or pastures should not be used for animal housing or grazing, for 2–3 months.

Immunization

In high-prevalence areas or where the herds are large, or in extensive pastoral areas, it may be impossible to conduct the test-and-slaughter regime outlined above. Therefore, mass immunization is the only way to reduce the rate of infection. At present, the most widely used vaccines are the live attenuated vaccines S19 in cattle and Rev.1 in small ruminants. These vaccines have proved to be effective in reducing the number of abortions and also limiting the spread of infection. The RB51 vaccine, usable only in cattle, has become the official vaccine for the prevention of brucellosis in cattle in some countries. However, its efficacy as compared to the reference S19 vaccine remains controversial.

Vaccination cannot be expected to eradicate the disease from a herd. Furthermore, when used in adult animals, these vaccines induce long-term serological reactions and sometimes abortions. To reduce these reactions, immunization is generally restricted to young animals between the ages of 3 and 6 months and the conjunctival route is preferred to subcutaneous delivery. When the epidemiological situation improves, a combined scheme including immunization of young animals and test and slaughter of infected adults may be applied. Then, when the prevalence rate of infected herds becomes sufficiently low, test and slaughter as outlined above may be applied.

Introduction to *Campylobacter* and Relevance to Milk

Introduction and History

Campylobacter spp. have been associated with disease in animals for many years. More recently, their role in human disease was established when they were isolated from stool samples of individuals with diarrhea using a direct technique developed by Skirrow in 1977. Thermotolerant species, in particular *Campylobacter jejuni* and to a lesser extent *Campylobacter coli*, have since emerged as major zoonotic human enteropathogens in most developed countries, being more frequently recovered from patients than salmonellae. These are predominantly transmitted to humans via the handling or consumption of contaminated foods of animal origin (particularly poultry meat and raw milk) or untreated surface water. Reported incidences of human campylobacteriosis tend to be single cases or small clusters, with larger outbreaks of disease seldom observed. The infective dose for *Campylobacter* is thought to be low, and clinical disease following infection varies from a mild self-limiting enterocolitis lasting 24 h to severe illness lasting in excess of 10 days. Sequelae to *Campylobacter* infection can manifest as meningitis, pneumonia, miscarriage, and a severe form of Guillain–Barré syndrome (GBS).

The epidemiology of *Campylobacter* spp. in livestock and wildlife, and contamination of foods of animal origin at harvest and postharvest phases of the food chain is highly complex with many data gaps remaining despite considerable research efforts made internationally over the last 30 years. Also due to the fastidious nature of these organisms, it is likely that much progress remains to be made in relation to optimal isolation and identification. Furthermore, with advances in molecular subtyping of zoonotic pathogens, it has become evident that considerable genotypic diversity in *C. jejuni* populations circulating in animals and foods of animal origin exists, making progress in understanding their epidemiology difficult.

It is likely that these organisms were first observed in 1886 by Theodor Escherich as nonculturable spiral-shaped bacteria. In 1913 McFadyean and Stockman isolated *Vibrio*-like organisms from aborted ovine fetuses, while in 1918 Smith observed spiral bacteria in aborted bovine fetuses and suggested that they belonged to the same *Vibrio* species as those recovered by McFadyean and Stockman 5 years earlier and proposed the name *Vibrio fetus*. In 1931, Jones and coworkers discovered a new *Vibrio* species in calves with dysentery and subsequently named the organism *Vibrio jejuni*. Another *Vibrio* species was isolated from pigs with diarrhea in 1944 by Doyle and was named as *Vibrio coli*.

In 1963, Sebald and Véron created a new genus, *Campylobacter*, and transferred *V. fetus* and *V. bubulus* to this new genus based on their DNA base composition, microaerophilic growth requirements, and nonfermenting metabolism. Subsequently in 1973, Véron and Chatelain published a taxonomic study of microaerophilic *Vibrio*-like organisms and suggested four species within the genus *Campylobacter*: *C. fetus*, *C. coli*, *C. jejuni*, and *C. sputorum*.

As the intestinal tracts of livestock are frequently colonized by *C. jejuni* and *C. coli*, including bovines, milk may be exposed to fecal contamination and hence to these enteropathogens during harvest. As a consequence, there are significant risks to public health associated with the consumption of contaminated milk, and the implementation of management interventions is required at both harvest and postharvest phases of the food chain.

Detection of *Campylobacter* in Milk

Growth Conditions

Campylobacter species are Gram-negative, curved, rod-shaped bacteria. They are motile by a single flagellum attached to either or both poles. They can become coccoid following prolonged culture or exposure to oxygen.

Campylobacter species have an optimal growth temperature range of 37–42 °C. They require microaerophilic conditions (5% oxygen, 10% carbon dioxide, and 85% nitrogen). The optimum pH for growth is 6.5–7.5, and these organisms do not grow below pH 4.9. Survival at acid pH values is temperature dependent, but inactivation is rapid at pH values less than 4.0, especially above refrigeration temperatures.

Thermal Resistance

Campylobacter species are heat sensitive and the cells are destroyed at temperatures above 48 °C. *Z*-values for *C. jejuni* are in the range of 5.07–8.02 °C. A *Z*-value of 6.10 °C has been reported for *C. coli*. Continuous change in morphology from the spiral to coccoid form has been observed during heating. *Campylobacter* species are destroyed by commercial pasteurization treatments.

Susceptibility to Antibiotics

Campylobacter jejuni are generally susceptible to erythromycin and gentamicin. Resistance of *C. jejuni* and *C. coli* to other antibiotics varies between strains and has been reported at low rates for clindamycin, azithromycin, and meropenem. Resistance to ciprofloxacin, nalidixic acid, and particularly tetracycline is on the increase. *Campylobacter upsaliensis* and *C. fetus* have been reported as being resistant to nalidixic acid along with many strains of *C. jejuni* and *C. coli.* The use of antibiotic susceptibility for differentiating between strains is less reliable due to the increasing frequency and variability of resistance among *Campylobacter* species.

Biochemical Properties

Biochemical tests can further confirm and differentiate between different *Campylobacter* species; however, some biochemical properties are dependent on the age of culture and test conditions applied. Rapid catalase and cytochrome oxidase tests suggest presence of *C. jejuni*, *C. coli*, and *C. lari.* Only the two subspecies of *C. jejuni* possess the enzyme hippuricase (hippurate hydrolase) and can hydrolyze sodium hippurate to benzoic acid and glycine. *Campylobacter coli* and *C. jejuni* can also be differentiated based on polymorphism in a number of gene sequences including *ceuE*, the GTPase gene, the 16S rDNA gene, and the 23S rDNA gene. *Campylobacter* spp. do not utilize carbohydrates.

Serology

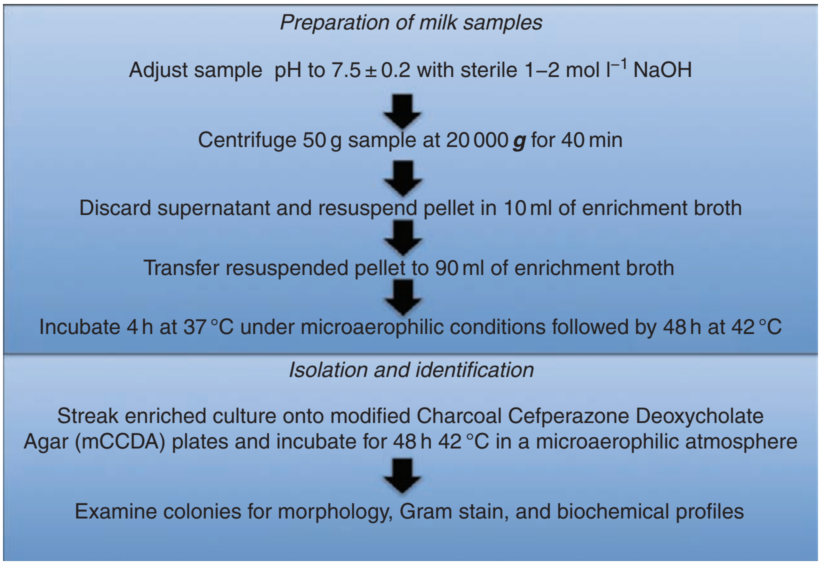
Penner (1980) and Lior (1982) described two methods of serotyping for *Campylobacter.* The Penner serotyping scheme involves detection of the heat-stable *O*-polysaccharide antigen by an indirect hemagglutination assay. The Lior serotyping scheme involves detection of the heat-labile flagellar and capsular antigens by a slide agglutination assay.

Campylobacter serology is poorly standardized and various crude bacterial antigen preparations have been used in the detection of *C. jejuni*-specific antibodies in patients suffering with GBS. The *Campylobacter* flagellar protein is the dominant immunogen recognized during *C. jejuni* infection in humans. Complement fixation assays (CFAs), immunoblotting, and enzyme-linked immunosorbent assays (ELISAs) have all been used for detecting these antibodies. Antigenic cross-reactivities, however, can result in low specificity of assays.

Isolation and Identification

The United States Food and Drug Administration (US-FDA)-recommended procedure for isolating *Campylobacter* from milk is extensively used and is outlined in **Figure 1**.

This particular method proposes the Bolton formulation as the enrichment broth, but others including Preston broth, Brucella broth, and Campy pack broth can also be used. Some procedures recommend that the initial



Preparation of milk samples

Adjust sample pH to 7.5 ± 0.2 with sterile 1–2 mol l^{-1} NaOH

Centrifuge 50 g sample at 20 000 ***g*** for 40 min

Discard supernatant and resuspend pellet in 10 ml of enrichment broth

Transfer resuspended pellet to 90 ml of enrichment broth

Incubate 4 h at 37 °C under microaerophilic conditions followed by 48 h at 42 °C

Isolation and identification

Streak enriched culture onto modified Charcoal Cefperazone Deoxycholate Agar (mCCDA) plates and incubate for 48 h 42 °C in a microaerophilic atmosphere

Examine colonies for morphology, Gram stain, and biochemical profiles

Figure 1 Procedure for isolation and identification of *Campylobacter* from milk. From US-FDA (2010) Bacteriological Analytical Manual. http://www.fda.gov (accessed 22 April).

enrichment be carried out at 37 °C for 4–6 h in the absence of selective supplements, in order to allow damaged cells to recover. Following incubation of selective plates, *Campylobacter* species appear as round- to irregular-shaped colonies with smooth edges. They can show thick translucent white growth to spreading, film-like transparent growth. Colonies are confirmed by Gram stain, catalase, oxidase, and other biochemical tests. This procedure can be lengthy, requiring 4–5 days to complete. Nucleic acid methods can be used and these are giving a more reliable and conclusive result. Such methods have been applied for the identification and quantification of *Campylobacter* in a wide range of food samples, including milk. They can be used to identify *Campylobacter* at the species level, which is often difficult and unreliable by traditional methods. In addition, samples with very low numbers of viable, but nonculturable cells may go undetected on agar media but may be detected by molecular methods.

Real-time PCR assays can be performed on enriched samples in as little as an hour with a detection limit of 1 cfu per PCR. An immunocapture PCR method that uses an avidin capture assay to detect PCR products also exists. This quantitative method does not require an enrichment step, requires 8 h to complete, and has a detection limit of 1 cfu ml^{-1}.

A rapid hybridization assay using a fluorescently labeled specific DNA probe can be applied for detecting *C. jejuni* at very low levels (3–10^5 cfu per PCR) in milk and poultry rinse samples. This method involves filtering samples through 0.22-μm hydrophobic grid membrane filters (HGMFs) and labeling with a 1475-bp chromagen-labeled DNA probe (pDT1720). Hybridized cells are subsequently detected in a colorimetric immunoassay. *Campylobacter jejuni* in food and clinical samples can also be detected by an immunomagnetic-hybridization technique. This method involves directing a monoclonal antibody against a specific outer membrane protein of *C. jejuni*. Captured *C. jejuni* cells are subjected to lysis by ultrasonication and the genomic DNA is reacted with a microtiter plate-immobilized RNA probe. Detection of the RNA–DNA hybrids formed in wells is then carried out using a monoclonal anti-RNA–DNA hybrid antibody. Overall, molecular-based methods are more specific, reliable, and faster at identifying *Campylobacter* at the species level compared with conventional identification methods.

Molecular Characterization of *Campylobacter*

Detection

Although food laboratories generally use conventional culture methods for the detection and identification of *Campylobacter*, more rapid alternative methods are available, including molecular methods. Alternative methods can be used as a screening tool to quickly assay a large number of samples and eliminate negatives at an early stage. Molecular methods can also be used to confirm the identity of a particular *Campylobacter* strain.

In addition to commercially available kits/assays, a number of publications report on the use of traditional PCR or, more recently, real-time PCR to screen for *Campylobacter*. A useful feature of nucleotide-based assays is the ability to speciate the strain.

Subtyping Approaches

Epidemiological investigations often benefit from rapid, reliable subtyping techniques. Several methods have been used to subtype *Campylobacter*. Subtyping methods based on analysis of the flagellin A gene include *fla*A restriction fragment length polymorphism (*fla*A-RFLP) and sequencing of a 321 bp short variable region (SVR). RFLP has sufficient discriminatory power to be considered a valuable epidemiological tool. However, DNA sequence based methods have advantages over RFLP. The *fla*ASVR typing protocol is useful for discriminating between even closely related *Campylobacter* strains and is widely employed because of its speed and simplicity.

Multilocus sequence typing (MLST) is a nucleotide sequencing technique that characterizes *Campylobacter* spp. based on the sequence heterogeneity present in seven housekeeping genes. These genes evolve slowly due to their critical role in central metabolism and are therefore particularly useful for the long-term analysis of diverse bacterial populations with weak clonal population structures. Sequence data determine the allelic profiles or sequence types (STs), which are then grouped into clonal complexes (CCs). MLST has confirmed the genetic diversity of *C. jejuni* and shown its population structure to be weakly clonal. MLST is a highly discriminatory typing system and is the current ‘gold standard’ for molecular typing of *Campylobacter*.

Whole-genome microarray analysis is a robust and sensitive method to determine genetic relatedness of bacterial populations. A whole-genome DNA microarray containing all 1654 genes from *C. jejuni* NCTC 11168 was constructed in 2001. Comparisons with 11 different strains identified 1300 core genes common to all, and 354 genes (21%) that were absent or highly divergent in at least 1 of the 11 samples. Core genes appear to encode proteins with a housekeeping function, while many of the remaining 21% encode surface-located structures including flagella, lipooligosaccharide, and the capsule. Whole-genome analysis offers the potential to identify genes encoding pathogenic factors and could prove useful as an epidemiological and/or diagnostic tool.

Antibiotic Resistance

Epidemiology of Resistance

Treatment of campylobacteriosis with antibiotics may be required in cases of immunocompromised patients or those showing no signs of improvement once the diagnosis has been made. Macrolides and fluoroquinolones are the antimicrobial agents currently chosen when therapeutic intervention is required. Resistance to erythromycin is low in most countries, and in general it remains the drug of choice. Fluoroquinolones such as ciprofloxacin may also be used, but resistance can be a problem in some regions. The frequency of fluoroquinolone resistance has been reported to be as high as 90% in Spain, Thailand, and Taiwan. Although lower rates of up to 45% have been reported elsewhere, current trends show that resistance is increasing. Antibiotic use in both animal production and human medicine can influence the development of antibiotic-resistant *Campylobacter*. Therefore, the emergence of antimicrobial resistance in enteric *Campylobacter* spp. due to the use of antimicrobial agents in husbandry is a matter of concern.

Resistance to Fluoroquinolones and Macrolides

Fluoroquinolones are a subgroup of quinolones, derived from nalidixic acid, and have a fluorine at the C-6 position of the quinolone structure. The targets of these agents are the type II topoisomerase DNA gyrase and topoisomerase IV. These enzymes are essential for DNA replication, recombination, and transcription. Inhibition appears to occur by interaction of the drug with complexes composed of DNA and either of these two target enzymes.

Resistance to fluoroquinolones is mainly due to chromosomal mutations in the *gyrA* and *gyrB* genes encoding the subunits of DNA gyrase, in genes that affect the expression of porin channels in the outer membrane, and in the genes encoding multidrug resistance efflux systems. Efflux was first postulated as a mechanism of multidrug resistance in *Campylobacter* in 1995. In 2002, a chromosomally encoded multidrug resistance–nodulation–cell division (RND) efflux system CmeABC was identified and characterized in *C. jejuni*, and later in *C. coli*.

Erythromycin is a protein synthesis inhibitor that binds to the ribosome causing dissociation of the peptidyl-tRNA, rather than blocking the peptidyltransferase activity as in the case of larger macrolides. In *C. jejuni* and *C. coli*, erythromycin resistance is chromosomally mediated and can be due to an alteration of the 23S rRNA gene, modification of the antibiotic, or efflux. Sequencing of the 23S rRNA genes from erythromycin-resistant *Campylobacter* spp. identified mutations that are associated with high-level resistance.

Methods to Determine Resistance

A lack of any agreed standardized approach for the testing of antimicrobial resistance in *Campylobacter* led to the issue being addressed by the Clinical and Laboratory Standards Institute (CLSI). Subsequently, an agar dilution reference method for *Campylobacter*, establishing quality control (QC) ranges for five agents, was introduced. In 2006, a new approved broth microdilution method, with QC ranges for 13 agents, was developed.

The aim of broth and agar dilution methods is to determine the lowest concentration of the antimicrobial compound (minimal inhibitory concentration (MIC)) that, under defined test conditions, inhibits the visible growth of *Campylobacter*.

Agar dilution involves the incorporation of different concentrations of the antimicrobial substance into an agar medium followed by the application of a standardized number of cells to the surface of the agar plate. Plates are read by observing the lowest drug concentration that inhibits visible bacterial growth.

The broth microdilution test is the standard method for determining levels of resistance to an antibiotic. Bacteria are inoculated into a liquid growth medium in the presence of different concentrations of an antimicrobial agent. Growth is assessed after incubation for a defined period of time and the MIC value is determined. The lowest concentration (highest dilution) of antibiotic preventing appearance of turbidity is recorded as the MIC.

The epsilometer test (E-test) has been found to compare favorably with agar dilution and broth microdilution methods, although economic reasons can prevent its use in routine laboratory screening. The E-test consists of a plastic strip containing a predefined gradient of antimicrobial compound concentrations. In this method, the strip is applied directly onto the surface of an inoculated agar plate. The drug on the strip then diffuses into the agar. Following incubation, an elliptical zone of inhibition is visible around the test strip. The point at which the zone edge intersects the plastic strip at a specific drug concentration is taken as the MIC.

Campylobacter and Disease

Clinical Disease

Experimental *C. jejuni* infections in humans have revealed that a low infectious dose of approximately 500 cells is sufficient to induce illness. Approximately 30% of patients experience an influenza-like prodrome of fever, headache, and myalgias lasting up to 24 h. The actual incubation period after ingestion is typically 2–5 days, but can range from 1 to 10 days. Symptoms include profuse diarrhea (often bloody), fever, and acute abdominal pain that may mimic appendicitis. Vomiting is uncommon, but nausea, headache, backache, and aching of the limbs may be experienced. The peak of the illness usually lasts for 24–48 h, with the symptoms resolving themselves within a week. The vast majority of patients suffering from *Campylobacter* enteritis do not require chemotherapy. Fluid and electrolyte replacement should enable a full recovery. Stools remain positive for several weeks, and minor relapses can occur. Approximately 1 in 1000 cases of *C. jejuni* infection develops GBS, an acute, autoimmune, polyradiculoneuropathy affecting the peripheral nervous system.

Pathogenesis

Bacterial gastroenteritis results from a complex set of interactions between the host and the invading organism. Consequently, the mechanisms by which *Campylobacter* spp. cause disease are not well understood. Pathogenesis will depend on the susceptibility of the patient as well as the virulence of the infecting strain. The role of several virulence factors has been studied and the mechanisms of pathogenicity are becoming clearer. Factors such as motility, chemotaxis, colonization, adherence, invasion, translocation, and toxin production, including the holotoxin cytolethal distending toxin (Cdt), have been implicated in the pathogenesis of *Campylobacter* enteritis.

Epidemiology of Outbreaks Associated with Milk

The main reservoir of *Campylobacter* is the gastrointestinal tract of warm-blooded animals, with studies describing the isolation of *Campylobacter* spp. from a broad range of animals. While Campylobacter spp. are commonly recovered from food animals, they have also been isolated from other vectors such as insects, wild birds, marine mammals, and both wild and domestic animals. Furthermore, these pathogens are also routinely isolated from environmental sources in close proximity to livestock and poultry farms. These sources include rivers, streams, lakes, sewage, drinking water, livestock and poultry farms, as well as slaughter line environments.

Transmission of *Campylobacter* to humans can occur through direct contact with infected animals or fecal matter and indirectly by the consumption of contaminated food or water. The primary source of foodborne campylobacteriosis seems to be from raw poultry meat through cross-contamination of ready-to-eat foods during food preparation, with the consumption of undercooked poultry being an alternate but less common source of infection.

Unpasteurized milk is commonly implicated in *Campylobacter* outbreaks. Cow's milk typically contains bacterial loads in the range of 10^3–10^4 cfu ml^{-1}. These numbers may represent bacteria on the lower end of the teat, organisms that have colonized the teat canal, and those from fecal contamination on the outside of the teat. The use of good hygiene practices when milking can significantly reduce the prevalence and levels of bacterial contamination in milk; these practices may involve thoroughly washing and drying udders before milking. However, the principal risk factor associated with milkborne gastrointestinal illnesses such as campylobacteriosis is insufficient or no heat treatment, with the consumption of unpasteurized milk and milk products a well-documented source of *Campylobacter* infection. Cases of campylobacteriosis associated with pasteurized milk have generally been linked with postpasteurization contamination or a failure in the pasteurization processing step.

Prevalence data on *Campylobacter* from 21 different countries showed that 30% (mean positives) of dairy cows sampled were positive for *Campylobacter* spp., with prevalence ranging from 6 to 64%. The same study also reported 3.2% (mean positives) of raw milk samples positive for *Campylobacter* spp., with prevalence ranging from 0 to 9.2%.

There is little evidence to suggest that *Campylobacter* poses a significant threat in fermented dairy products such as cheese and yogurt. The low prevalence of these pathogens in such products is due to their poor survival in acidic conditions. Other cases of campylobacteriosis outbreaks from milk have come from milk contaminated by bird pecking through the packaging.

Control of Milk Quality at Pre- and Postharvest Phases

Milk is an important nutritional component for humans in many societies throughout the world. It is a natural secretion of the mammary gland and is not a sterile commodity in this state. Milk derived from animals can contain pathogens and historically has been identified as a vehicle responsible for transmitting a significant burden of disease to humans in both developing and developed countries. Recent analysis of human outbreak data and other estimates suggest that milk is responsible for a small but substantial proportion of foodborne infectious disease (~2–9%) in Ireland and the United Kingdom. Interestingly, *Salmonella*, *Campylobacter*, and enterohemorrhagic *Escherichia coli* were the most frequently implicated agents in milkborne disease. Differences in the burden of human disease attributed to milk consumption are likely to vary widely due to regional or cultural differences, jurisdictional/legislative restrictions on the marketing of raw milk, and differences in consumer preferences for drinking raw milk or dairy products. In countries where the marketing of liquid raw milk is prohibited, consumption by families on dairy farms is still prevalent even in developed regions.

The subclinical carriage and intermittent shedding of *C. jejuni* and *C. coli* in bovines and other animal species from which milk is derived is a public health concern. Raw milk is frequently found to contain these significant *Campylobacter* species and is primarily indicative of fecal contamination during milking. In addition, less frequent reports of subclinical infection of mammary glands have also been observed, which can result in preharvest contamination of milk. The milking of animals is not a sterile process and contamination of milk with organisms of fecal origin is common and to an extent unavoidable even with the implementation of high standards of hygiene. Milk may also be contaminated with fecal organisms, including *Campylobacter* spp., at any stage postharvest, for example during bulk storage on-farm, transportation, processing, or postprocessing.

Integrated control and intervention is required along the milk production chain to manage risks and adequately protect public health. At farm level, good farming and husbandry practices are essential so that feed quality is controlled, waste is effectively managed, mastitis is prevented and managed in herds, and adequate standards of housing and stocking are maintained. In addition, drinking water should be of a potable standard and drinking troughs should be designed to minimize fecal contamination. Fecal soiling of hides, tails, and udders should be minimized as much as possible by, for example, adequate provision of clean bedding and prevention of enteritis within the herd. During harvesting of milk from cows, visibly contaminated teats should be cleaned and dried prior to attaching clusters. Milking equipment should be well maintained and adequate cleaning and sanitizing should be carried out between milking sessions using recommended cleaning agents, procedures, and a potable water supply. All milk should be pumped through a milk filter or ‘sock’ to remove any visible traces of fecal material or other suspended particulates, and milk should be cooled and stored appropriately before transportation to the processing plant.

The main public health intervention for liquid milk in developed countries is pasteurization, which involves the rapid heating of milk using plate heat exchangers to a minimum of 71.7 °C and holding at that temperature for 15 s. Once satisfactorily heated, the milk is then rapidly cooled again using plate heat exchangers, thus largely preserving the desired organoleptic properties of raw milk. Individual processing operations can vary this time–temperature treatment to achieve an equivalent reduction in bacterial populations. Pasteurization is sufficient to eliminate bacterial pathogens, including *C. jejuni* and *C. coli*, in milk. In terms of food safety assurance in a commercial processing facility, it is imperative that the pasteurization conditions are met consistently by monitoring time–temperature recording equipment, for example, thermographs, and the completion of routine microbiological testing to detect fecal indicator organisms (Enterobacteriaceae, *E. coli*). In addition, levels of the phosphatase enzyme, which is naturally found in raw milk, can be readily measured in pasteurized samples. This enzyme is relatively heat labile and is denatured at pasteurization temperatures; therefore, detection of active phosphatase indicates incomplete pasteurization or post-pasteurization contamination with raw milk.

Several studies have highlighted the risks of inadequate pasteurization or postprocess contamination of liquid milk associated with the transmission of *Campylobacter* spp. to humans. For example, an outbreak in the United Kingdom in which 110 people became ill (41 were confirmed to be infected with *C. jejuni*) was associated with the consumption of inadequately pasteurized milk from a local dairy. Other studies have highlighted the risk of equipment failure in the dairy plant resulting in the mixing of raw with pasteurized milk. The phenomenon of wild birds pecking the foil caps on milk bottles delivered to consumer’s doorsteps resulting in contamination of milk with *Campylobacter* spp. and infection in humans have also been well reported, again highlighting the risks associated with postprocess contamination and human health.

Although documented, the transmission of *Campylobacter* spp. to humans via the consumption of dairy products is rare and is considered to be a minor route of exposure to humans. The survival of *C. jejuni* in cheeses (including soft varieties) and fermented products such as yogurt is poor, most likely a result of the organisms intolerance to high salt concentrations and low pH, respectively. In soft cheeses artificially inoculated with 7 $\log_{10}$ cfu ml^{-1}, a 1 $\log_{10}$ reduction can be achieved within 4 h, the reduction increases to 3 $\log_{10}$ following 24 h storage and the organism is not detected after 336 h storage. For fermented dairy products with a pH of 4.2, the inoculated cells (7 $\log_{10}$ cfu ml^{-1}) did not survive beyond 3 days storage. These data suggest that such products manufactured from raw milk would not pose any substantial risk to consumers once products were sufficiently processed (e.g., to ensure adequate salt concentrations or pH levels were achieved) and matured/aged before being marketed for consumption.

Finally, in order to adequately and consistently protect public health, it is imperative that an integrated approach is taken based on the principles of hazard analysis critical control point (HACCP) systems at all stages of milk production (preharvest, harvest, and postharvest). This approach should be adapted by all stakeholders, including producers, processors, retailers, and legislators, so that increased levels of food safety assurance are achieved for liquid milk and dairy products.

Future Issues

The complex epidemiology of campylobacteriosis is widely acknowledged and the extensive dissemination of *Campylobacter* spp. within livestock and the environment has made its control difficult. In addition, molecular subtyping studies, using techniques such as pulsed-field gel electrophoresis, MLST, and others, have revealed the highly diverse nature of strains of this zoonotic agent in circulation in these animal and environmental reservoirs. Ongoing research is required in a number of areas to ascertain how this pathogen is introduced to livestock and to identify effective interventions to reduce its prevalence and potential transfer to raw milk and dairy products.

Further work is also required in relation to food attribution studies so that more accurate and detailed estimates of numbers of human cases of campylobacteriosis caused by the consumption of contaminated milk can be completed. Such data on the associated public health burden would provide valuable information for health professionals, the dairy industry, regulatory agencies, and other risk managers. It would also facilitate an impetus to communicate such risks to consumers of raw milk and other dairy products made from unpasteurized milk.

The standardization and dissemination of laboratory techniques used to detect, quantify, and characterize *Campylobacter* spp. in animals, foods of animal origin, and humans would also be beneficial, enabling the generation of more accurate and reproducible prevalence data and risk assessments.

In recent years, the prevalence of antimicrobial resistance among *Campylobacter* spp. of animal and food origin has increased. The corresponding antibiotic resistance profile of *Campylobacter* spp. implicated in human disease is similar. Antimicrobial therapy may be required in a minority of human campylobacteriosis cases where the drugs of choice are often macrolides and fluoroquinolones. Therefore, increased and multidrug resistance now represents a significant health risk where drug therapy is necessary. Strict licensing and prudent use of antibiotics in animal production and treatment are recommended. This strategy must be supported by the development and application of standardized methods to monitor antimicrobial resistance in *Campylobacter* populations, allowing reliable surveillance data to be generated on an ongoing basis, review of resistance trends and making interventions as required. This is an important component of public health protection, given the more recent hypotheses, for example, that infection in humans by quinolone-resistant strains of *C. jejuni* tends to cause more prolonged and severe symptoms. In addition, the development and promotion of herd health management programs on dairy farms should be encouraged so that a preventive approach to disease is taken, thus reducing the dependence on antimicrobials.

This article is a revision of the previous edition article by P. Aureli and G. Franciosa, Volume 1, pp 456–463, © 2002, Elsevier Ltd.

Introduction

The interest in *Clostridium* spp. in milk products mainly pertains to two aspects, sanitary and technological. Of utmost importance is the presence of pathogenic clostridia in milk products because of their potentially harmful effects on human health: although cases of food-borne diseases attributed to clostridia in dairy products are rare (<70 cases in the last 10 years), some have even recently been reported, including a few related to commercial foods, which makes the risk more threatening due to the wide distribution such products can reach on the market. However, most of the *Clostridium* species relevant to dairy products are nonpathogenic to humans, yet their multiplication can cause deterioration and/or serious defects in the final products with consequent economic losses.

Clostridia are widely distributed in soil, dust, water, sediments, sewage, animal carcasses, and vegetation; healthy animals and humans normally carry low numbers of spores in their intestines ($\sim$100 g^{-1} feces). Contamination of feeds and especially silage, where clostridia can grow under certain conditions of water activity (a_w), pH, and temperature, contributes to the spread of spores. Raw milk can become contaminated with spores during the milking process, as a result of environmental cross-contamination. *Clostridium sporogenes*, *Cl. perfringens*, *Cl. butyricum*, *Cl. tyrobutyricum*, and *Cl. beijerinckii* are the most frequently encountered species, along with other rare species such as *Cl. botulinum*. Usually, processing of raw milk either kills the spores of clostridia or inhibits their multiplication in the dairies; however, depending upon the conditions applied and the characteristics of the strains, some can occasionally survive and grow.

This article will focus on *Clostridium* spp. commonly found in milk-based products and the control measures to be taken to ensure the wholesomeness and integrity of such widely consumed foods.

Morphology and Physiology

Clostridium spp.

The genus *Clostridium* comprises a heterogeneous group of microorganisms. They are Gram-positive, anaerobic, rod-shaped, and endospore-forming bacteria: the shape and length of the rods, and the position of the spores may vary considerably. Spores are very resistant to extreme chemical/physical conditions and therefore are widely distributed in terrestrial environments where they can germinate when conditions become favorable, that is, in low oxygen tension areas and in the presence of sufficient nutrients. The growth temperatures vary from 3.3 to 80°C, with an optimum between 25 and 40 °C for most clostridia.

Historically, the taxonomic definition of species within the genus has relied on the phenotypic characteristics displayed by the bacteria, such as metabolic activities, cultural conditions, chemical composition of the bacterial cell wall, and toxicity and pathogenicity. Some distinctive phenotypic features of the *Clostridium* spp. relevant to dairy products are given in **Table 1**.

Subsequent studies of the microbial genetic material allowed a more precise classification of species. Although the overall DNA base composition is of limited value for determining the relatedness of groups – the G + C content of members of the genus ranging from 22 to 50% – more recent phylogenetic studies based on similarities of 16S rRNA/DNA sequences have confirmed many of the preexisting species, while excluding others. Moreover, *Clostridium* spp. are distributed into 19 different clusters (I–XIX), the first of which essentially includes the clostridia most frequently found in milk and dairy products, often referred to as *Clostridium sensu stricto.*

Pathogenesis of *Clostridium* spp. Contaminating Dairy Foods

The pathogenic *Clostridium* spp. that can potentially spoil milk products are those associated with botulism (*Cl. botulinum* and neurotoxigenic *Cl. butyricum*), enterocolitis (*Cl. perfringens*), and possibly sudden infant death syndrome (SIDS) (*Cl. perfringens*, *Cl. botulinum*) and neonatal necrotizing enterocolitis (NE) (*Cl. butyricum*). Additionally, *Clostridium* spp. must be regarded as potential producers of harmful biogenic amines in cheese products.

The highly potent neurotoxin (lethal dose for humans: 1 ng kg^{-1} body weight) produced by *Cl. botulinum* is responsible for the serious neuroparalytic disease of botulism.

Table 1 Some metabolic and physiological features of clostridia associated with milk products

[a] v, variable.
[b] d, digested (proteins are totally metabolized, with consequent clarification of the medium).
[c] c, clotted (proteins are partially metabolized and tend to aggregate, causing formation of ‘clots’ in the medium).
[d] D_{100} (min) = time in minutes required to inactivate 90% of the specific clostridial population at 100 °C.

Although seven serologically distinct botulinum toxins (A–G) exist, all have common protein structures and mode of action, consisting of zinc endopeptidase activity against specific protein targets of the presynaptic vesicles that contain the neurotransmitter acetylcholine. Cleavage of these proteins blocks the neurotransmitter release at the nerve terminal ends and ultimately produces the flaccid paralysis of botulism. Generally, one strain of *Cl. botulinum* produces a single type of neurotoxin: type A, B, and E botulinum neurotoxins account for nearly all of human botulism. Two forms of botulism may result from ingestion of food contaminated with either preformed toxin (food-borne botulism) or neurotoxigenic clostridial spores, which subsequently may colonize the intestine of the host – generally infants under 1 year of age and adults suffering from gastrointestinal distress – and synthesize the toxin *in vivo* (intestinal toxemia botulism).

Enterotoxin-producing *Cl. perfringens* type A is responsible for a form of mild enteritis. Classical symptoms include diarrhea, abdominal cramps, and, less frequently, nausea, vomiting, and fever, which follow shortly after ingestion of food contaminated with at least 10^8 *Cl. perfringens* cells per gram. The ingested microorganisms that succeed in surviving the high acidity of the stomach sporulate within the small bowel and release the enterotoxin by cell lysis into the intestinal lumen. Here, it rapidly binds the intestinal epithelial cells, causing cytotoxic effects by alterations to membrane permeability.

In addition, a role for *Cl. perfringens* type A in SIDS has been proposed, because many SIDS infants have symptoms of gastrointestinal infections prior to death, and *Cl. perfringens* and its enterotoxin are found in a significantly high number of feces from such infants.

Clostridium butyricum has been hypothesized as a causative agent of neonatal NE, a disease mostly affecting premature infants even though neonates with no predisposing factors may also be affected. Mucosal necrosis of the ileum and colon is the main symptom: although the exact etiology of the disease is still unknown, different bacteria are thought to cause the intestinal lesions, including *Cl. butyricum.* This microorganism is normally considered a harmless saprophyte: typically, it does not produce any toxin but an *in vitro* cytotoxic effect due to the production of butyrate has been demonstrated on various cells. Besides, unique strains of *Cl. butyricum* producing botulinum toxin type E have been implicated in intestinal toxemia botulism and food-borne botulism in Italy and China. These peculiar strains seem to have acquired the genetic information coding for botulinum toxin type E through DNA mobile vectors from an ancestral strain at some point during evolution.

Although the actual roles of *Cl. perfringens* type A and *Cl. botulinum* in SIDS, and *Cl. butyricum* in neonatal NE, are still questionable, it has been recommended to maintain the number of spores of *Clostridium* low in products intended for use by infants.

Finally, different *Clostridium* spp. commonly found in cheese products are decarboxylase-positive microorganisms and may thus contribute to the decarboxylation of free amino acids to biogenic amines, such as histamine from histidine. High levels of these substances may exert toxic effects, including dilatation of peripheral blood vessels resulting in hypotension, flushing, and headache, and induction of contraction of intestinal smooth muscle, which may be the cause of vomiting and diarrhea.

Significance of *Clostridium* spp. in Dairy Foods

Incidence of Clostridia in Milk and Dairy Products

Raw milk usually contains large numbers of bacteria. Of these bacteria, clostridia represent a minority, the contamination levels being around $10–10^2$ spores ml^{-1}. These levels can increase to $>10^3$ spores ml^{-1} when lactating animals are fed on heavily contaminated silage. Percentages of the different *Clostridium* spp. are variable, but *Cl. sporogenes*, *Cl. perfringens*, *Cl. butyricum*, and *Cl. tyrobutyricum* generally predominate, accounting for about 75% of the whole anaerobic spore-forming flora; other species of importance, such as *Cl. botulinum*, may be present at levels of less than 1 spore l^{-1}. The redox potential of raw milk does not allow for growth of clostridia in this medium.

Clostridia in dairy products mainly originate from the raw milk. They have been recovered from a variety of cheeses, cheese sauces and creams, pasteurized milk, powdered milk, sweetened condensed milk, yogurt, and ice cream: numbers generally do not exceed $10–10^2$ spores g^{-1}, reflecting those in the original milk even for species composition. The intrinsic properties of some dairy products, that is, pH, a_w, redox potential (E_h), nutrient availability, and microflora, can be compatible with the germination and multiplication of certain clostridial strains, especially when the extrinsic factors such as storage temperature and time are also suitable for growth (see section ‘Control’). The consequences of growth of clostridia in dairy foods are described below.

Technological Problems

Both texture and flavor quality of dairy products may be affected by growth and metabolism of clostridia. One of the major concerns in cheese manufacturing is the so-called ‘late blowing’ defect, consisting of formation of holes, which can crack the cheese, accompanied with undesirable off-flavors. It appears during the course of cheese ripening in a large variety of hard and semihard cheeses, including Parmesan, Grana Padano, Emmental, Gruyère, Gouda, and Provolone. Processed canned cheese and cheese spreads can also be affected.

Considerable amounts of CO_2 and H_2 are responsible for the appearance of holes and blowing of cheese, while butyric acid and minor organic volatile acids negatively affect the flavor and taste of cheese. Gas and acids in the cheese result from fermentation of lactate mainly by *Cl. tyrobutyricum* and, to a lesser extent, by other *Clostridium* spp. (*Cl. sporogenes*, *Cl. butyricum*, and *Cl. beijerinckii*).

The occurrence of 'late blowing' in cheese depends on different factors, including the number and species of clostridia originally contaminating the milk, the manufacturing process, and the characteristics of the final product. Silage is identified as the main source of milk contamination. When silage fermentation conditions are not prone to rapid decrease in pH and maintenance of uniformly anaerobic conditions, germination of clostridial spores and subsequent multiplication of vegetative cells can occur. In grass silage, clostridial numbers range from below the detection limit to a maximum of 6.89 $\log_{10}$ CFU g^{-1}, whereas for maize silage, clostridial counts range from below the detection limit to a maximum of 4.69 $\log_{10}$ CFU g^{-1}. Defective cheeses generally result from milk originally contaminated with at least 200–10^3 *Cl. tyrobutyricum* spores per liter. The growth of clostridia is critically influenced by ripening time and temperature, lactic acid concentration, salt concentration, pH values, fat content, and presence of other microorganisms. The shape, size, and structure of the cheese, including normal eye formation, can also play a significant role. The numbers of spores detected in defective cheeses vary from 10^4 to 10^7 g^{-1} for *Cl. tyrobutyricum*, and from 10^3 to 10^6 g^{-1} for *Cl. sporogenes*. Although the latter microorganism causes more frequent spoilage of milk, its growth requirements and predominantly proteolytic metabolism are the possible reasons why it is more rarely involved in the 'late blowing' of cheese.

Diseases Associated with Clostridia in Dairy Foods

Botulism

Dairy products have rarely been involved in outbreaks of food-borne botulism, probably because their intrinsic and extrinsic properties are generally unsuitable for growth of *Cl. botulinum*. However, some outbreaks have been reported, the more recent being listed in **Table 2**. Raw milk was the likely source of spores in all outbreak-related dairy foods, except for the Brie cheese, the commercial cheese sauce implicated in the 1993 US outbreak, the hazelnut yogurt, contaminated with botulinum spores and/or toxin from different sources (specifically, the straw used for cheese ripening; potato skins; and the hazelnut conserve added to the yogurt), formula milk powder, and *süzme* (condensed) yogurt buried under soil.

Numbers of *Cl. botulinum* spores naturally contaminating raw milk are very low (~1 spore l^{-1}); however, the preliminary steps used in dairy production, such as centrifugation and filtration, contribute to the concentrating of microbial spores to 10 or more per gram of cheese product, depending on the manufacturing procedures. Even low numbers of *Cl. botulinum* spores per gram of product can be harmful, if conditions are met for their growth and toxin production.

Some common features can be traced for all the outbreaks of food-borne botulism linked to consumption of dairy products. First, proteolytic strains of *Cl. botulinum* were always the causative agents: spores of these microorganisms are more heat- and acid-resistant than the nonproteolytic ones (**Table 1**). Second, both commercial and homemade milk products were made from pasteurized milk: the temperatures and times generally used for thermal treatment of these products are not sufficient to kill the proteolytic spores of *Cl. botulinum*, but they do eliminate viable cells of nonsporing organisms, which are potential competitors of *Cl. botulinum*, such as lactic acid bacteria, thus facilitating the growth of *Cl. botulinum* in the product. Finally, the intrinsic factors (pH, a_w, Eh) of the cheese products, as well as abused storage temperature/time, and packaging conditions in the case of commercial products, were suitable for the outgrowth of spores and consequent toxin production.

Although the source of *Cl. botulinum* spores is rarely detected in intestinal toxemia botulism, an infant formula milk powder contaminated with *Cl. botulinum* type B

Table 2 Most recent outbreaks of botulism caused by consumption of spoiled dairy products

Year	*Location*	*Food source*	*Botulinum toxin type*
1974	Argentina	Commercial cheese spread with onions	A
1974	France and Switzerland	Soft ripened cheese (Brie)	B
1978	France	Soft cheese	B
1989	UK	Hazelnut yogurt	B
1993	USA	Commercial cheese sauce	A
1996	Italy	Commercial soft-spread cheese	A
1997	Iran	Locally made cheese	A
2001	UK	Formula milk powder	B
2005	Turkey	Condensed yogurt	A

spores has very recently been associated with a case of infant botulism.

Finally, it must be noted that type E neurotoxigenic *Cl. butyricum* has not yet been involved in any case of botulism from consumption of contaminated dairy products. However, since *Cl. butyricum* is a frequent spoiler of milk, the risk posed by the neurotoxigenic variant of the species does exist, particularly since it has already been implicated in both food-borne botulism and intestinal toxemia botulism.

Clostridium perfringens *enteritis*

Although the food most frequently involved in *Cl. perfringens*-associated diarrhea is undercooked meat, other foods including dairy products have also been implicated in outbreaks. Precise epidemiological data are lacking because hospitalization is not necessary in most cases and sporadic cases remain unknown, as does the source of illness.

Histamine poisoning

Cheese is the second leading source of histamine poisoning, after fish. However, the problem is largely underestimated because of the mild symptoms; hence, the incidence is difficult to determine. Moreover, many species of bacteria can contribute to the production of amines such as histamine in cheese, and the main role played by each one can be hardly determined.

Safety of Milk and Dairy Products from Cattle Affected by Botulism

Since the recent marked increase in the reported incidence of suspected cattle botulism, the potential human health risk associated with consumption of meat or milk derived from animals from herds affected by botulism has been raised. Using current scientific evidence, the Food Standards Agency (FSA) recently considered the restrictions (movement of the cattle and meat and milk from affected herd into the food chain) previously adopted on unaffected animals within the flock to be overprecautionary. In addition, FSA recommends that in the absence of other signs, there should be no restrictions on milk or meat from healthy cattle, sheep, and goats from affected farms.

Detection and Enumeration of *Clostridium* spp.

Analyses for clostridial contamination are performed not only on defective cheeses and milk products or those implicated in disease outbreaks, but also on the milk intended for dairy production, as a significant preventive measure. Hence, methods of choice should be able to detect very high as well as very low numbers of spores; in addition, they should be rapid, specific, reproducible, and easy to perform. Although such methods are needed for routine assessment of clostridial contamination in milk and its derivative products, no standardized technique is yet available for this purpose.

In theory, isolation and enumeration should be equally suitable for both vegetative cells and spores of clostridia; in practice, killing of viable cells cannot be completely avoided, because all samples are generally subjected to a heating step before incubation, in order to eliminate vegetative cells of other microorganisms and stimulate spore germination. For this reason, only the total number of clostridial spores can be determined. Different heating temperature/time conditions can be applied, taking into account that spores of some species are less heat-resistant than others (**Table 1**), and they might be inactivated as well.

For adequately sensitive detection and enumeration of clostridia in fluid milk, concentration of microorganisms by membrane filtration or centrifugation may be required. Alternatively, direct incubation of the milk under anaerobic conditions after thermal treatment has been proposed. However, milk is not an ideal substrate for supporting growth of clostridia, due to the absence of any reducing agent, or because of the growth and metabolism of other thermal-resistant bacteria, resulting in a decrease in pH values to inhibitory levels. Certain *Clostridium* spp. that are not able to ferment lactose, specifically *Cl. butyricum* and *Cl. tyrobutyricum*, do not grow in milk unless their appropriate carbon sources – lactate and acetate – are added.

Because clostridia include organisms with very different cultural and metabolic characteristics, selective agents that equally favor all relevant species while inhibiting other microorganisms are hard to find. However, since sulfite reductase activity is a common property among clostridia, broth and agar media used for their detection and enumeration often depend on sulfite reduction as a key differential criterion. These media generally include sodium sulfite (<0.05%, because some *Clostridium* strains are sensitive to this substance) and an iron salt in their formulations. Reducing conditions are maintained by inclusion of cysteine or thioglycolate in the medium. Precipitation of dark iron sulfide in these media, or gas formation in lactate-containing media, is presumptive for clostridial growth, even if confirmation is desirable since a few other bacteria also reduce sulfite or ferment lactate.

Enumeration of clostridia may be achieved by both direct counting and most probable number (MPN) methods. Direct counting is carried out by streaking dilutions from the original product onto selective solid media, such as sulfite–polymixin–sulfadiazine (SPS) agar. Polymyxin is the only antibiotic that appears to be partially, but not entirely, selective for clostridia. Black colonies are enumerated after anaerobic incubation of plates at 30 or 37°C for up to 3 days. The MPN method consists of inoculating serial dilutions of the test food in three or five replicates of broth medium, such as differential reinforced clostridial medium (DRCM) or lactate RCM. After thermal treatment of the inoculated tubes and subsequent incubation under anaerobic conditions for 5–7 days, blackening or production of gas (depending on the medium used) is suggestive of clostridial growth. Numbers of clostridia are then extrapolated from appropriate tables. Although the MPN test is more sensitive in detecting low numbers of spores than the direct counting, because of the larger inoculum, it is less accurate because it assumes that blackening and production of gas are due to clostridia only, and it is also more time consuming.

Recently, several PCR assays (i.e., PCR-DGGE nested PCR, real-time PCR) for detection and quantification of cluster I clostridia, identified as the major causal agent of late blowing in cheese, have been reported.

Identification of *Clostridium* spp. may be necessary in some investigations: this relies on recognition of differential characteristics of strains, such as the metabolic or genetic properties. Biochemical tests including sugar fermentation patterns and enzymatic activities have proven useful for identification at the species level. Amplification through PCR of species-specific DNA sequences, such as those coding for toxins in toxigenic clostridia or those for nonconserved ribosomal RNA in other *Clostridium* spp., is also widely applied for early detection and identification of these microorganisms. For toxin-producing species, such as *Cl. botulinum* and *Cl. perfringens*, demonstration of toxicity is required in any case. Conventional methods for botulinum toxin detection involve the use of animals and specific antitoxins: many alternative *in vitro* tests, including enzyme-linked immunosorption assay (ELISA) tests and assays for the detection of the enzymatic activity of botulinum toxins, have been devised, some of the most recent ones approaching the sensitivity and specificity of the standard *in vivo* assay. *Clostridium perfringens* type A toxin is also commonly demonstrated by *in vivo* tests or by cytotoxicity in cultured cells: slide latex agglutination and ELISA tests are also applicable.

Control

Several control measures are effective in preventing or minimizing contamination of milk with clostridia and inhibiting their growth in dairy products.

Good Manufacturing Practices

Selection of high-quality raw milk with low levels of clostridial spores helps ensure that the final products are safe and wholesome. Special attention should be paid to the quality of the silage fed to animals, since preservation of crops by lactic acid fermentation and maintenance of anaerobic conditions may facilitate the growth of contaminating clostridia, particularly *Cl. tyrobutyricum* because of its ability to ferment lactic acid. Spores ingested by animals concentrate in the feces, which is one of the main sources of milk contamination.

In many countries, regulations specify requirements relating to the health and care of milk-producing animals and to the hygiene of milking, handling, and transportation. Raw milk intended for Parmesan and traditional Swiss-type cheese production is collected from cows not fed on silage.

Reduction of Spores in Raw Milk

High-speed centrifugation (bactofugation) removes most spore-forming organisms from milk and does not affect the composition, flavor, and nutritional value of milk: efficacy in reduction of spores is a function of initial contamination in the milk and the operating conditions.

Heat treatment is effective only at the temperature/time conditions of sterilization (>135 °C for 2–3 s), but sterilized milk is unsuitable for the manufacture of most dairy products. Pasteurization includes a variety of temperature/time combinations, but generally temperatures do not exceed 90 °C, which is destructive to vegetative cells but not to bacterial spores; besides, this thermal treatment might activate spore germination and outgrowth, especially in the absence of microbial competition, if intrinsic and extrinsic properties of the pasteurized processed milk product are permissive.

Prevention of Spore Outgrowth in Dairy Products

Depending on the type of milk product, milk product technology, and duration of storage or ripening, inhibition of clostridia may be achieved by use of chemical additives, biopreservation, refrigerated storage, a_w and pH reduction, and combination of preservative factors, according to the 'hurdle' concept.

Nitrates, hexamethylenetetramine (HMT), and polyphosphates are the chemicals more commonly used against clostridia in cheese technology. Nitrates are converted into the functional nitrites through the metabolic activity of other contaminating microorganisms in the product; small amounts of nitrites (10–50 ppm) exert inhibitory effects against clostridial spores, possibly by enhancing their heat sensitivity. However, there are concerns on the use of these substances, due to the production of carcinogenic and mutagenic nitrosamines by chemical and/or microbial transformation, and for this reason their use in cheesemaking is not allowed in some countries; in other countries, 10–30 g of nitrates per 100 l of milk is permitted for the manufacture of some hard cheeses, such as Gouda.

HMT is used in the production of the Italian hard cheese Provolone. HMT is a precursor of formaldehyde, since under acidic conditions it is decomposed to ammonia and formaldehyde. The latter compound inhibits spore development in cheese because it reduces the availability of certain macromolecules by combining with them. However, because of its high reactivity with nucleic acids also, its use is allowed only within certain limits, that is, 15–25 ppm in the milk at the beginning of the production; at the end of ripening, formaldehyde in the product must be <0.5 ppm, set as the upper limit for safe human consumption.

Polyphosphates have been demonstrated to control clostridial growth in pasteurized processed cheese spreads stored at refrigeration temperatures, but their mechanism of action is still unknown. In the European Union, the maximum level of total phosphate permitted in processed cheese and cheese spreads is 2%, even if lower quantities may be sufficient to completely inhibit clostridia.

Biopreservatives such as lysozyme and bacteriocins, especially nisin, also show some effectiveness against clostridia, thus representing valuable alternatives to the use of chemical additives in cheese. Egg white lysozyme, added '*quantum satis*', disrupts microbial vegetative forms and delays the germination of spores by cleavage of the bacterial cell wall. Some clostridial strains, however, are resistant to lysozyme. Its anticlostridial activity has been well demonstrated in hard cheeses, such as Grana Padano and Emmental. On the other hand, nisin – a bacteriocin produced by *Lactococcus lactis* – has been widely used to prevent clostridial germination in pasteurized processed and spread cheeses, with high moisture and reduced salt contents. Nisin is directly added during cheesemaking to levels up to 250 ppm, depending on a_w and pH of the product.

Lactic acid bacteria starter cultures used to ferment milk products such as yogurt consistently inhibit clostridia by lowering the pH of the food, and thus represent another means of biopreservation.

Low-temperature storage, pH and a_w reduction, and other factors, including many of the preservative substances listed above, often function in synergy to control clostridia in dairy products. A combination of techniques leads to establishment of multiple barriers ('hurdles') more restrictive than that achieved with individual factors. Refrigerated storage of dairy products, for instance, cannot prevent by itself the growth of psychrotrophic clostridia; also, any storage temperature abuse might be risky in the absence of other inhibitory agents. a_w and pH reduction has classically been applied for inhibiting growth of any microorganisms in foods: however, addition of salts and various acidulants to reach values that are inhibitory for most clostridia (**Table 1**) is possible only to a certain extent in some dairies, in order to obtain organoleptically acceptable products.

In conclusion, given the wide distribution of clostridia in nature, keeping the contamination level as low as possible or inactivating contaminating spores as early in processing as possible should be ensured through appropriate quality control procedures, specifically by proper application of HACCP (hazard analysis critical control point) programs.

Coxiella burnetii

C Heydel and H Willems, Justus Liebig University, Giessen, Germany

© 2011 Elsevier Ltd. All rights reserved.

Characteristics

Coxiella burnetii is the etiological agent of the zoonosis Q fever, which was first described in Australia. It is a pleomorphic, Gram-negative bacterium with a size of 0.2–0.7 µm with obligate intracellular propagation and worldwide distribution.

Studies based on comparison of 16S rRNA encoding gene sequences demonstrate that this pathogen is most closely related to *Legionella* spp. and resides within the γ-subdivision of the Proteobacteria while members of the family Rickettsiaceae, the former family of *C. burnetii*, are grouped in the α-subdivision.

Genotyping of *C. burnetii* isolates revealed the heterogeneity of this organism. Pulsed-field gel electrophoresis (PFGE) of *Not*I-restricted DNA was the first method applied for differentiation of North American *C. burnetii* isolates, which could be classified into four groups. With the same technique, 80 *C. burnetii* isolates derived from animals and humans within Europe, the United States, Africa, and Asia could be distinguished in 16 additional restriction patterns. Genome sizes, calculated by summing up the *Not*I restriction fragment sizes, ranged from 1.6 to 2.4 Mbp. With the availability of whole genome sequences of *C. burnetii*, typing methods were developed based on markers consisting of variable numbers of tandem repeats (VNTRs). This method, termed multiple loci variable number of tandem repeat analysis (MLVA), was found to be highly discriminatory. Thus, out of 42 isolates investigated with MLVA, 36 different genotypes were identified.

In mammals, *C. burnetii* propagates in alveolar macrophages before disseminating and infecting other cells of the mononuclear phagocyte system, and infrequently fibroblasts or endothelial cells. *In vitro*, *C. burnetii* may be cultivated in a broad range of epithelial, fibroblast, and macrophage-like cell lines. *Coxiella burnetii* is internalized into host cells by microfilament-dependent, parasite-directed endocytosis after engaging the leukocyte response integrin a_vb_3 (phase 1) or the CR3 receptor (phases 1 and 2). The pathogen then resides and multiplies within the harsh and acidic environment (pH 4.8) of parasitophorous vacuoles resembling secondary lysosomes.

During multiplication, *C. burnetii* undergoes a unique developmental cycle with two cellular types termed small cell variants (SCVs) and large cell variants (LCVs). It has been suggested that metabolically dormant SCVs are phagocytosed by eukaryotic host cells. Conditions in the vacuole trigger vegetative differentiation of SCVs into metabolically active LCVs. Apart from size, SCVs and LCVs differ markedly in ultrastructure, antigenicity, and metabolic capability.

Furthermore, specific small, spore-like particles (SLPs) are described, which are supposed to be responsible for the high resistance of *C. burnetii* against environmental conditions. SCVs and SLPs are considered as extracellular survival stages. Viable organisms can be recovered after heating at 63 °C for 30 min, exposure to 10% salt solution for 180 days at room temperature, exposure to 0.5% formalin for 24 h, or sonication in distilled water for >30 min.

After serial cell culture passages, *C. burnetii* undergoes a phase variation. Virulent phase I coxiellae, synthesizing amphiphilic full-length lipopolysaccharides (LPSs), are replaced by low-virulent phase II variants producing truncated LPSs. The isolation of virulent phase I *C. burnetii* from specimen homogenates is accomplished by inoculation into immunocompetent hosts (e.g., guinea pigs). Subsequently, homogenates of infected spleens are passed serially in cell culture or yolk sacs of embryonated hen's eggs to generate less virulent phase II *C. burnetii.*

The size of the *C. burnetii* genome is less than 40% that of *Escherichia coli*, that is, about 1.2×10^9 Da or 2.0×10^6 bp. The G + C content is 43 mol%. Until now, genomes of five *C. burnetii* isolates have been sequenced completely. Progress in understanding the genetics of *C. burnetii* has been hampered because of the inability to genetically manipulate the organism. Intracellular dependence, slow growth rates, and the tendency to infect persistently rather than lyse host cells made application of known genetic techniques fairly difficult. Recently, *C. burnetii* was transformed after electroporation and the cloning and characterization of a mutant generated by transposon mutagenesis were reported. This may facilitate the study of the unique and exemplary biology and pathogenicity of *C. burnetii.*

Five different plasmid types (36–56 kb) and one plasmid-homologous sequence integrated into the chromosome may be distinguished, which comprise about 2% of the genome. Although their function is still cryptic, they are supposed to be of essential importance, since every isolate contains exactly one type of plasmid or plasmid-homologous sequence. In contrast to initial studies, *C. burnetii* plasmids are no longer considered to be responsible for either acute or chronic Q fever. Epidemiological studies confirm that host factors play a key role in the clinical outcome of the disease.

Symptoms

Acute Q fever in humans is most often described as influenza-like, self-limited, febrile illness, although the majority of *C. burnetii* infections are asymptomatic (~60%). After an incubation period of 2–6 weeks, high fever, rigor, profuse sweats, fatigue, severe headache with retroorbital pain, photophobia, nausea, general malaise, myalgia, and arthralgia are characteristic. In more severe cases, pneumonia or hepatitis can occur. Rare manifestations include encephalitis, pericarditis, and myocarditis. Illness normally lasts 1–6 weeks, but can show a prolonged course. In more than 10% of cases, especially after repeated exposure to the infective agent, acute disease fades to the mostly afebrile Q fever fatigue syndrome. It is characterized by fatigue, muscle aches and pains, night sweats, headaches, photophobia, sleep disorder, loss of libido, and weakness of short-term memory, and can last for more than 1 year.

Some patients, probably about 2%, develop chronic disease 1–20 years after the initial illness or exposure. The most frequent manifestation of chronic Q fever, particularly in patients with underlying valvulopathy, is endocarditis. Most cases involve the aortic valve and about 30% the mitral valve. Further occasional symptoms of chronic Q fever can be vasculitis, osteomyelitis, and granulomatous hepatitis, especially under immunocompromising conditions. In women, premature delivery or spontaneous abortion has also been reported.

Similar to humans, in animals the most common route of infection seems to be inhalation of aerosols. They, however, usually do not develop illness from *C. burnetii* infection. *Coxiella burnetii* infection does not induce respiratory pathology in any animal species. Furthermore, chronic infection with cardiac or hepatic localization does not occur in animals.

After infection, *C. burnetii* can be isolated from the organs of clinically healthy animals. The colonization of the female reproductive system and proliferation of *C. burnetii* in both uterus and mammary gland often lead to spontaneous abortion, stillbirth, or premature delivery, and shedding of *C. burnetii* by birth fluids and milk. Miscarriages due to *C. burnetii* are most frequently seen in small ruminants. In sheep, late abortions occur sporadically and rarely epidemically in as many as 60% of gravid ewes. In goats, abortion is predominantly seen 15 days before term. Flocks with an abortion history also show an increase of weak newborns. Although ovine and caprine *C. burnetii* infection is often described as transient and tends to spontaneous cure as in dogs, cats, and humans, some studies suggest that it has rather an enzootic character as in cattle where *C. burnetii* circulates from generation to generation.

In cattle, abortion and generally reduced fertility due to *C. burnetii* are described. The infection may cause subclinical mastitis with elevated somatic cell counts and might have an effect on coinfection with common mastitis pathogens. Manifest mastitis has rarely been seen but there are some descriptions in sheep and goats. In a mass outbreak in Bulgaria, sheep developed a progressive severe inflammation of the milk gland, with disappearance of the milk secretion, and general intoxication leading to death of some animals.

Coxiella burnetii in Milk

After initial infection and bacteremia, *C. burnetii* may be detected in the udder during successive lactations. As confirmed by real-time PCR, 10^1–10^4 cells ml^{-1} can be excreted with the milk. A common shedding pattern could not be identified. Shedding can be continuous, intermittent, sporadic, or even absent in infected animals. In a follow-up study comprising 7 concomitant milk samplings of 139 dairy cows of which 60% showed positive PCR results in feces, vaginal mucus, or milk samples, approximately 40% were detected as milk shedders. Two predominant milk shedding patterns, persistent (34.5%) and sporadic (51.7%), were found. Shedding was not restricted to the time following parturition and could not be linked to shedding by feces or vaginal mucus. Another PCR analysis of samples from 110 shedder cows revealed that 53.6% shed the *C. burnetii* via milk. Parallel detection in feces and/or vaginal mucus was possible in 11.9 and 25.4% of these, respectively; 62.7% shed only via milk. The study claims that excretion via milk might be more important in cows and goats than in sheep where fecal and vaginal excretion prevailed.

The serological status of an animal does not allow prediction of milk shedding. It seems, however, that animals with high titers in enzyme-linked immunosorbent assay (ELISA), immunofluorescent assays (IFAs), or complement fixation tests (CFTs) have a higher probability of being shedders or even heavy shedders spreading large amounts of particles.

In an infected herd, between 15 and 76% of the lactating animals were shown to excrete Coxiellae with milk. This wide margin is probably not only due to a regional clustering of *C. burnetii* infection but also due to the method of preparation of the milk samples and the sensitivity of the applied detection method. In a major PCR study testing the bulk tank milk of dairy herds from all over the United States over 3 years, more than 94% of the samples were tested positive.

Due to the high prevalence of *C. burnetii* in the milk of domestic ruminants, the zoonotic risk of oral infection is of special interest. Most reported Q fever cases can be assigned to airborne infections. When milk is suspected as the source, different probable modes of transmission occur at the same time. Therefore, distinguishing true oral infections and evaluating the risk potential of contaminated milk are difficult.

The efficiency of oral infection, that is, occurrence and proportion of associated illness, is doubted. In guinea pigs, experimental oral infection led to seroconversion in 8 of 25 animals and in 5 of these *C. burnetii* was found in internal organs. The manifestation of infection probably depends on the infective dose and virulence of the strain. Administration of high doses of corticoids favored the infection, whereas alternating the intestinal permeability by chemical or mechanical means had no influence upon antibody formation or distribution of the infective agent in the host. *Coxiella burnetii* was estimated to be less efficiently transmitted by the oral route than by aerosols. Effective infection in mice requires 10 000 times more Coxiellae by oral versus intraperitoneal administration.

In humans particularly, the ingestion of contaminated raw milk is suspected of causing Q fever. This is still a matter of controversy as no conclusive evidence proves the alimentary infection of humans. This issue gains relevance as there are efforts under way in the United Kingdom, Canada, and the United States to promote increased human consumption of fluid raw milk. Pasteurization is generally accepted as sufficient for inactivating *C. burnetii* in milk. Mandatory pasteurization parameters were adjusted to the heat stability of *C. burnetii* when it was recognized as the most heat-resistant organism of public health significance.

It is largely accepted that ingestion of *C. burnetii*-contaminated food can result in serological conversion, but cases of Q fever have been documented rarely. In addition, it is likely that seroconversion follows the ingestion of inactivated cells as well as of live cells.

A study undertaken among hundreds of individuals, living several miles away from dairy farms, revealed that persons consuming raw milk had a higher rate of seropositive reactions. In a group of prisoners, some showed seroconversion after ingestion of contaminated raw milk for more than half a year, but the majority of the inmates remained seronegative. In another study, a small number of volunteers did not develop symptoms or an immunologic response after drinking contaminated, unpasteurized milk.

Q fever was observed in creamery workers with practically no contact with the livestock but exposed to large amounts of contaminated milk. Unpasteurized goats' milk has been described as a potential source of infection during a Q fever outbreak among patients and staff of a psychiatric institution in southern France.

To summarize, the possibility of oral infection by *C. burnetii* via milk cannot be denied. Possibly a relatively high oral infective dose impedes outbreaks of Q fever. Single cases in not yet identified risk groups could easily be overlooked because of the flu-like character of the disease. Furthermore, it is unclear whether milk infection might evoke the chronic form of Q fever after years of incubation.

Reservoirs and Routes of Infection

Coxiella burnetii exhibits extreme geographical distribution and is endemic in every part of the world except for New Zealand and Antarctica. Its broad host range includes mammals, birds, and arthropods. However, the most common animal reservoirs are cattle, sheep, and goats, in which *C. burnetii* infections are far more frequent than generally expected. Studies in the 1960s and 1970s demonstrated that 10% of US dairy cows are constantly infected with an increasing seroprevalence among cattle. In herds with reported infertility problems, the proportion of infected animals may be up to 80%. Today, *C. burnetii* must be regarded enzootic in US dairy herds with more than 90% of bulk tank milk samples testing positive via PCR.

Infection cycles may occur among arthropods and mammals in nature, and numerous species of ticks are considered as reservoirs for *C. burnetii.* Ticks acquire the organism by bloodsucking and transmit it with their feces. However, various investigations suggest that only some species, like *Dermacentor reticulatus*, might be of importance as reservoirs.

Although infection cycles may occur among arthropods and mammals in nature, *C. burnetii* maintains an independent and more important airborne infection cycle among domestic livestock. Domestic ruminants shed the desiccation-resistant organism in urine, feces, and especially birth products, contaminating the environment. Parturient placentas of infected ruminants were shown to contain as many as 10^{12} cells g^{-1}. Dissemination of contaminated straw and manure or birth products rotting on pastures may cause the spread of the organism via dust especially in periods of dry and windy weather. The highly infectious particles (minimal infectious dose by aerosol transmission is one *Coxiella* cell per individual) can be spread by the wind over distances of several kilometers. In this way, subsequent Q fever occurs even in distant urban areas. In Europe, the majority of Q fever outbreaks can be assigned to airborne infections originating from birth products of sheep and goat flocks during lambing season.

Diagnostics

Prior to implementation of specific control measures, precise and reliable diagnosis of *C. burnetii* infection in animals and humans is required.

For the detection of *C. burnetii*, the most relevant techniques include isolation, immunodetection in tissue samples, and DNA amplification. Initially, *C. burnetii* was isolated by inoculation of specimen into laboratory animals (i.e., guinea pigs, mice) or embryonated hen's eggs. Nowadays, isolation and propagation are mainly carried out by means of conventional, permanent cell cultures. The recent development of a new medium, suitable for cultivation of *Coxiella* in the absence of host cells, will probably further simplify cultivation.

Since isolation of *C. burnetii* requires much time and experience, immunodetection of *C. burnetii* antigen in tissue samples, smears, or secretions is applied increasingly in routine diagnostics. To increase sensitivity and specificity of *C. burnetii* detection, DNA amplification methods were established. Several procedures have been described for PCR detection of *C. burnetii* in milk. Meanwhile, several real-time PCR assays were developed not only to detect but also to quantify *C. burnetii* cells in clinical specimens.

Despite improved methods for the detection of the pathogen, the diagnosis of Q fever and *C. burnetii* infections still relies mainly upon serology. Particularly, surveys with large numbers of specimens are most commonly performed serologically. Usually, IFA or CFT and ELISA techniques are applied. To summarize, CFT is very specific but lacks sensitivity; moreover, a prozone phenomenon is present with specimens of chronic cases that could lead to false negative results. ELISA tests in general are satisfactory for diagnosis. Nevertheless, for Q fever, diagnostic IFA is still the reference method, since it is both sensitive and highly specific. No cross-reactions with other organisms have been documented. Antibodies against *C. burnetii* can also be detected in milk by capillary tube agglutination tests.

For the diagnosis of Q fever, sera should be tested at different time points to demonstrate seroconversion. A fourfold increase in anti-*Coxiella* titers is considered to be characteristic of acute Q fever. Alternatively, antibody subclasses against *C. burnetii* should be differentiated and additionally phase I and phase II antigens may be applied in the test system. The results of serology are positive between 2 and 4 weeks after the onset of disease. In acute Q fever, IgM antibodies against phase II antigen rise prior to antiphase I IgM or IgG antibodies. IgM persists for 6–8 months and diagnosis can be made even when a single sample is IgM positive. In chronic Q fever, antiphase I antibodies predominate at very high levels. *Coxiella burnetii* serology in animals is predominantly carried out by CFT or ELISA.

Treatment

If Q fever is diagnosed early during illness, a regimen of tetracycline compounds especially doxycycline (200 mg day^{-1}) for 15–21 days is still recommended. Quinolones, like ofloxacin (600 mg day^{-1}) and pefloxacin (800 mg day^{-1}), were reported to be effective in Q fever pneumonia and Q fever meningoencephalitis. In prolonged Q fever, a combination of pefloxacin (800 mg day^{-1}) and rifampicin (1200 mg day^{-1}) applied for 15 days has been successful. In chronic Q fever (i.e., mainly endocarditis), tetracycline is usually combined with either rifampicin or quinolones and even chloroquine. However, since antimicrobial treatment ranges from 1 year to unlimited administration, valve replacement is often proposed for hemodynamic reasons.

So far, no satisfactory treatment scheme for coxiellosis exists in animals. Cattle and sheep, treated with tetracycline, continued to shed the organism. Nevertheless, a potential protective effect on pregnancies was not excluded.

Prevention

To prevent Q fever and coxiellosis, vaccination and hygiene management strategies must be applied. Despite great efforts to develop Q fever vaccines, only one vaccine, Q-Vax®, is commercially available and is restricted to Australia. The formalin-inactivated whole cell vaccine provides reliable protection. Unfortunately, it can induce mild to severe adverse reactions, especially when administered to individuals with prior exposure to the agent. Thus, strict prevaccination screening, for example, exclusion of persons with positive skin reactions, is necessary. Booster inoculations are problematic for the same reason.

In the area of veterinary medicine, two vaccines against coxiellosis of ruminants, Chlamyvax FQ® and Coxevac®, are commercially available. Chlamyvax FQ®, a whole cell vaccine containing inactivated *C. burnetii* phase II particles and a *Chlamydia* component, is solely approved in France. For Coxevac®, which contains inactivated phase I particles, European registration is in progress.

Generally, vaccines prepared with phase II particles are considered to be less protective. This was confirmed by a recent comparative study in which goats were challenged after vaccination. Only vaccination with Coxevac® led to a reduction of abortion incidence and shedding. The complete effectiveness of the vaccine against bacterial shedding in milk led the authors to suggest that vaccination might represent the microbiological quality assurance awaited by the producers of raw milk.

Possibly, the effectiveness of Coxevac® in small ruminants can be finally evaluated when results of obligatory vaccination programs for goat and sheep holdings in southern regions of the Netherlands, ordered to control a large Q fever outbreak, become available.

Coxevac® reduced the probability of susceptible (i.e., noninfected) dairy cattle becoming a shedder to one-fifth. This result was not seen if vaccinees were pregnant. Furthermore, Coxevac® failed to prevent or reduce *C.burnetii* shedding in cows that were infected prior to vaccination. Thus, vaccination with the phase I vaccine might protect noninfected herds. Nevertheless, infected herds need further hygienic and medical measures to reduce effectively the bacterial burden.

During Q fever outbreaks, predominantly originating from small ruminants, official recommendations regulate hygiene management measures in most countries. Following for example the recommendations of the German Robert Koch institute, sheep and goat herds must be kept at a distance of >500 m from inhabited areas. For disinfection of contaminated stables, solutions of 10–20% bleaching powder, 1% Lysol, or 5% hydrogen peroxide are recommended. Contaminated manure should be ploughed under after decontamination for 5 weeks with quicklime packages.

Special care has to be taken with the highly infectious birth products, which must be eliminated from stables or pastures immediately for proper disposal. After lambing, dams and offspring must be kept in closed stables for 2 weeks.

Shearing and storage of wool are restricted to closed rooms outside residential areas. Shearing personnel are obliged to wear dusk masks. If ticks are suspected as vectors, acaricides should be administered.

As discussed above, it is difficult to evaluate the risk originating from contaminated raw milk. Following the precautionary principle, pasteurization should be advised.

Meat, unlike udder and placental tissue, is not regarded as a source of infection. Eradication of *C. burnetii*-infected livestock is discussed periodically when Q fever outbreaks occur but cannot be recommended due to the high prevalence of coxiellosis in general, the environmental stability of the infective agent, and the unavoidable contact with wildlife reservoirs. Nevertheless, identification and culling of persistently heavy shedding individuals could reduce the bacterial burden.

Altogether, identification and proper disposal of material potentially contaminated with *C. burnetii* are the main objectives in Q fever prevention. Besides, physicians should be encouraged to include Q fever in their differential diagnosis to promote early and efficient therapy or control measures if infection occurs.

Introduction

The genus *Escherichia* derives its name from Theodor Escherich, who first isolated this organism from feces in 1885. The type strain of the genus is *E. coli*, a common bacterium found in the gastrointestinal tract of humans and other vertebrates where most strains are nonpathogenic commensals. However, there are several groups of *E. coli* that can be pathogenic, causing a variety of diseases, some of which are fatal. The three clinical syndromes resulting from *E. coli* infection are urinary tract infections caused by uropathogenic *E. coli*, meningitis and septicemia resulting from necrotoxigenic *E. coli* infection, and diarrheal diseases. In food safety, the most important *E. coli* are those that cause diarrheal diseases. *E. coli* can also cause spoilage in dairy products, for example, blowing of cheese and ropiness in milk and cheese brines can be caused by *E. coli* growth.

General Characteristics

E. coli is a member of the family Enterobacteriaceae, which includes Gram-negative facultatively anaerobic rod-shaped bacteria (possessing both a fermentative and respiratory metabolism) and which do not produce the enzyme oxidase. *E. coli* cells are typically 1.1–1.5 μm wide, 2–6 μm long and occur as single straight rods. They can be either motile or nonmotile, and when motile produce lateral, rather than polar, flagella. In addition to flagella, many strains produce other appendages such as fimbriae or pili, which are proteinaceous structures (or appendages or fibers) that extend outward from the bacterial surface and play a role in attachment to surfaces including other cells or host tissues.

E. coli have strain-specific O lipopolysaccharide antigens on their cell wall (at least 181 O antigens are currently recognized) and flagella or H antigens if present (53 H types are recognized). There are also 80 different capsular polysaccharide (K) antigens. *E. coli* are serotyped based on the combination of O, H, and K antigens, although generally only the O and H types are listed, for example, *E. coli* O157:H7. Serotyping of *E. coli*, together with genome, virulence, and phage typing, is a useful epidemiological tool.

E. coli is closely related to *Shigella* spp., although *Shigella* tends to be less biochemically active than most strains of *E. coli*. *Shigella* and *E. coli* can be considered to be within a single genus based on genetic relatedness, but historically the two have remained separate to prevent confusion in medical diagnosis.

Pathogenic Types of *E. coli*

E. coli causing human diarrhea are assigned to groups based on their virulence properties and clinical manifestations.

Enterohemorrhagic *E. coli* and Shiga Toxigenic *E. coli*

The enterohemorrhagic *E. coli* (EHEC) group have a common ability to produce cytotoxins that are active on monkey kidney (Vero) tissue culture cells. These cytotoxins are mediated by genes carried by lysogenic bacteriophages and act in a similar manner by interfering with protein synthesis in eukaryotic cells. The toxins belong to two major antigenically distinct groups, Stx1 and Stx2, with various subgroups. Stx1 is similar to the Shiga toxin produced by *Shigella dysenteriae*; consequently, Shiga toxin-producing *E. coli* are referred to as both STEC (Shiga toxin-producing *E. coli*) and VTEC (verotoxigenic *E. coli*). EHEC is a term commonly used to refer to those STEC that cause enterohemorrhagic disease.

Since their recognition in the 1980s, EHEC have become the most notable of the enteropathogenic *E. coli* (EPEC) that are transmitted by food, including dairy products. They can cause illness in humans and diarrheal illness in young animals. Human EHEC infection can be asymptomatic or result in symptoms ranging from mild diarrhea to hemorrhagic colitis and life-threatening hemolytic–uremic syndrome (HUS). Strains causing hemorrhagic syndromes frequently, but not exclusively, carry accessory virulence factors to the Shiga toxins located on a chromosomal pathogenicity island, the locus for enterocyte effacement (LEE). The LEE encodes genes that lead to the formation of attaching and effacing lesions typically seen in the intestinal epithelium in both EHEC and EPEC (see below) infections. EHEC strains also frequently carry a unique 92-kb plasmid, pEHEC, that encodes several potential virulence factors, although none is considered essential in EHEC pathogenesis at this time. The pEHEC carries genes encoding an EHEC hemolysin that is used as a differential characteristic for putative EHEC in some agar isolation media.

There are many serotypes of STEC, although a limited number are commonly associated with HUS. The most common is the O157:H7 serotype and others include O26, O111, O45, and O103. Clinical isolates of these types often carry the same virulence determinants, for example, Stx1 and/or Stx2, the LEE, and pEHEC.

Enterotoxigenic *E. coli*

Enterotoxigenic *E. coli* (ETEC) produce the *E. coli* heat-labile (LT) and/or heat-stable (ST) toxins. ETEC are important causes of diarrhea among children in developing countries and of traveler's diarrhea. Symptoms include acute watery diarrhea that may be mild and of short duration and which in some cases is similar to cholera. ETEC strains are host specific, that is, some strains can cause diarrhea in young animals (e.g., calves, lambs, and piglets), while other strains will specifically infect only piglets, and others only humans.

The major virulence factors of ETEC are intestinal colonization factors, for example, fimbriae, and the enterotoxins. The host specificity of individual strains is determined by the type of colonization factors and fimbriae produced. The LTs are high-molecular-weight proteins similar to cholera toxin and consist of five enterocyte-binding B subunits and a biologically active A subunit. The internalized A subunit causes electrolyte imbalance and a net fluid loss to the gut lumen by activation of adenylate cyclase and accumulation of cyclic adenosine monophosphate. The STs are small polypeptides that act similarly through activation of guanylate cyclase and accumulation of cyclic guanosine monophosphate.

Enteropathogenic *E. coli*

EPEC are a major cause of acute or chronic enteritis in children in developing countries. EPEC typically produce attaching and effacing lesions on the intestinal epithelium. The genes encoding this activity are carried on a 60 MDa EPEC adherence factor plasmid and the LEE pathogenicity island, which is also present in many EHEC. The clinical symptoms are a consequence of the ensuing electrolyte loss and epithelial damage. There have been a limited number of outbreaks of EPEC disease linked to food- and waterborne transmission.

Enteroinvasive *E. coli*

Enteroinvasive *E. coli* (EIEC) invade the host intestinal epithelial cells where they multiply, causing cell destruction and an acute inflammatory response similar to shigellae. Patients may first develop watery diarrhea prior to onset of dysentery with a low volume of stools containing blood and mucus. Other symptoms are headache, fever, and cramping. Humans appear to be the main reservoir of EIEC, with little evidence to support EIEC carriage in animals or foods of animal origin. EIEC outbreaks are usually associated with water or food contaminated with human feces or person-to-person transmission. The incidence of the disease caused by EIEC is generally low in developed countries.

Enteroaggregative *E. coli* and Diffusely Adherent *E. coli*

Two other groups of diarrheagenic *E. coli* characteristically adhere to Hep-2 tissue cells. Those that adhere in an aggregative pattern resembling microcolonies are termed enteroaggregative *E. coli* (EAEC) and those producing a more diffuse adherence on the Hep-2 cell surface are known as diffusely adherent *E. coli* (DAEC). The mechanisms of pathogenesis of these groups are poorly understood, as is their epidemiology. Both groups are isolated from diarrheal cases in children in developing countries and there is limited evidence of foodborne outbreaks.

E. coli Outbreaks from Milk and Dairy Products

Milk and Cream

Raw milk has been implicated as the vehicle of sporadic cases and several outbreaks of EHEC-associated illness in North America, Europe, and the United Kingdom. While cows' milk is the most common source, goats' and sheep milk has been implicated in *E. coli* O157 infection. Outbreaks of EHEC infection have been associated sheep with raw milk and pasteurized milk contaminated postprocessing. In an outbreak of EHEC infection where nine children developed HUS in the United Kingdom, *E. coli* O157 was found in pipes and on a discarded rubber gasket from a milk-bottling machine, suggesting postpasteurization contamination. Postpasteurization contamination was also believed to have caused an outbreak of *E. coli* O104:H21 linked to pasteurized milk in the United States.

Cheese

Outbreaks of illness caused by EAEC, EIEC, ETEC, and EHEC have been attributed to the consumption of cheese. Cases of EAEC O92:H33 were associated with Pecorino cheese made from raw milk thought to be inadequately processed. An outbreak of EIEC O124 involved 387 people following consumption of Camembert cheese. Contamination was traced to river water used for cleaning processing equipment that had been filtered through a malfunctioning treatment system. ETEC serotype O27:H20 was isolated in an outbreak caused by the consumption of French Brie and Camembert that had been mishandled during shipping and distribution.

Cheese has been the attributed vehicle in several EHEC outbreaks. Outbreaks of *E. coli* O157:H7 have been attributed to a variety of cheeses such as farm-produced cheese, fresh cheese curds, a semihard Lancashire cheese, and a Gouda made from unpasteurized milk. Other serotypes have included EHEC O103:H2 contaminating soft cheese made from a mixture of unpasteurized cows' and goats' milks; O119 EHEC in fromage frais; and O26 EHEC from a raw milk Camembert cheese in France. The use of contaminated raw milk or post-processing contact with raw milk and subsequent survival of the EHEC during the cheesemaking process have been the major contributing factors.

Other Milk Products

An outbreak of *E. coli* O157:H7, which affected 16 people and caused 5 HUS cases among children, was linked to a live yogurt made on a farm from pasteurized milk. Postpasteurization contamination of milk was likely due to either inadequate cleaning or contamination from farmyard material. Ice cream contaminated with STEC O145:H28 and O26:H11 has been attributed to cases of HUS. Cases were guests at two birthday parties on the same farm where the ice cream was also made. STEC of the same serotypes were isolated from calves and the farm environment. There have been no documented cases of *E. coli* infection caused by dried or condensed dairy products, or by butter.

Incidence in Milk and Dairy Products

The primary source of *E. coli* on a farm is the animals and wildlife. Although EHEC and STEC are the most studied pathogenic *E. coli* in farm environments, other types (EAEC and EPEC) have been detected. Humans may be a significant source of other pathogenic types. Animal isolates of *E. coli* are dispersed via feces and can be found on hides and hair and in saliva. Fecal contamination is widely disseminated on dairy farms in soil, dust, non-potable water, and on pastures and dissemination is assisted by wildlife, for example, rodents, birds, and flies, and personal and farm equipment. Animal excretion of specific *E. coli* types may be intermittently varying with season and animal age, for example, EHEC O157:H7 may be carried by up to one-third of dairy herds and 4–10% of cattle within the herd may be excreting at any time.

Milk can be contaminated during collection indirectly via udders soiled with contaminated feces, soil, water, feed, and bedding, or directly if the animal has *E. coli* mastitis. Workers, either asymptomatic or ill, may excrete *E. coli* in their feces and poor personal hygiene practices can lead to contamination of dairy products and equipment. Equipment at farms and factories can become contaminated by raw milk, water, and soil, and contamination can be transferred from farm to factory via soil on bulk milk tankers and other transport vehicles.

Table 1 lists various studies on the incidence of *E. coli* in dairy products. Generally, dairy products produced from pasteurized milk and with good hygiene and sanitation protocols, as expected, are less often contaminated with *E. coli*.

Growth and Survival

Information on the growth and survival of *E. coli* in foods is generally not specific to the individual pathogenic types. Where this is available, this information is specified.

The optimal temperature for growth of *E. coli* is 35–40 °C, the minimum being 7–8 °C and the maximum about 46 °C. O157 EHEC have a more limited growth range and will not grow below 8 °C and grow poorly or not at all at 44–45.5 °C, the temperature often used in routine methods for detecting *E. coli*. The growth medium used can limit the ability of a particular strain to grow or produce gas at temperatures above the optimum.

E. coli is sensitive to heat and this depends on the composition, pH, and water activity (a_w) of the suspending medium or food matrix. The *D*-value or time required to reduce *E. coli* numbers by one log cycle in cows' milk at 58 °C (D_{58}) is 0.78 min, while in nonfat dry milk powder, the D_{58} value increases with the increasing percentage of milk solids. As the a_w decreases, the heat resistance can increase depending on the solute; for example, at an a_w of 0.98, sodium chloride has a greater effect than glucose. *E. coli* is somewhat more sensitive to heat than other enteric pathogens, for example, *Salmonella*, and will not survive adequate pasteurization. *E. coli* survives well in chilled and frozen foods. In pasteurized, unpasteurized, and skim milk, *E. coli* O157:H7 does not grow at 5 °C, although at 8 °C, 1–2 and 2–3 log increases may occur after 4 and 7 days, respectively. After initial freezing, there is normally a decrease in viable *E. coli*, and then the population can remain stable for periods greater than 12 months.

E. coli can grow at a pH between 4.4 and 10, the optimal being 6–7. The minimal pH allowing growth is influenced by the type of acidulant, the presence of inhibitory substances, for example, nitrite, temperature, and a_w. For example, strains of *E. coli* O157 will grow at 37 °C in a medium of pH 4.5 acidified with hydrochloric acid but

Table 1 A summary of some surveys of milk and milk products for *E. coli*

Product	*E. coli group*	*Number tested*	*Percent positive for E. coli*	*Country*	*References*
Raw milk	EPEC[a]	Unknown	19	India	Singh *et al*. (1970)
Milk products	Generic *E. coli*	5760	29	Europe	Otenhajmer *et al*. (1989)
Raw milk	Generic *E. coli*	1154	46	Europe	Otenhajmer *et al*. (1989)
Raw milk (bulk tank)	Generic *E. coli*	175	47	Trinidad	Adesiyun *et al*. (1997)
Raw milk (bulk tank)	*E. coli* O157:H7	268	0.8	United States of America	Murinda *et al*. (2002)
Raw milk	Toxigenic *E. coli*[b]	12	17	Zimbabwe	Gran *et al*. (2003)
Raw milk	*E. coli* O157:H7	930	34	Malaysia	Chye *et al*. (2004)
Raw milk	*E. coli* O157:H7	250	0.4	Hungary	Hucker *et al.* (2006)
Raw milk (milk filters)	*E. coli* O157:H7	536	3	Ireland	Murphy *et al*. (2005)
Naturally soured milk	Toxigenic *E. coli*[b]	21	33	Zimbabwe	Gran *et al*. (2003)
Cultured pasteurized milk	Toxigenic *E. coli*[b]	27	26	Zimbabwe	Gran *et al*. (2003)
Pasteurized milk	EPEC and ETEC	32	0	Brazil	Jakabi and Franco (1991)
Pasteurized milk and cream	Generic *E. coli*	430	6	Sweden	Lindberg *et al*. (1998)
Raw milk cheese (soft)	Toxigenic *E. coli*[b]	221	1.4	Spain	Quinto and Cepeda (1997)
Raw milk cheese (soft and semisoft)	*E. coli* O157:H7	153	0	Belgium	Vivegnis *et al*. (1999)
Raw milk cheese (soft, hard, unripened, and blue)	STEC	1039	3	France	Vernozy-Rozand *et al.* (2005)
Raw milk cheese (Castellano)	STEC	83	2	Spain	Caro and Garcia-Armesto (2007)
Raw milk cheeses (soft, semihard, and hard)	STEC	796	2	Switzerland	Stephan *et al.* (2008)
Camembert	Generic *E. coli*	102	3	Japan	Takeba *et al*. (1996)
Pasteurized milk soft cheese	Toxigenic *E. coli*[b]	75	0	Spain	Quinto and Cepeda (1997)
Butter (pasteurized and unpasteurized)	Generic *E. coli*	60	22	Italy	Bianchi and Geminiani (1994)
Ice cream	Generic *E. coli*	73	30	Turkey	Arslan *et al*. (1996)
Frozen yogurt	Generic *E. coli*	170	0	Spain	Lopez *et al*. (1997)
Cream confectionery	Generic *E. coli*	92	10	Italy	Simoni *et al*. (1983)

[a] Uncertain definition of enteropathogenic *E. coli* (EPEC).

[b] Enterotoxigenic *E. coli* (ETEC), Shiga toxigenic *E. coli* (STEC), and necrotoxigenic *E. coli* were isolated.

not with lactic acid. *E. coli* have several different regulatory systems that enable cells to adapt to and survive acid stress. Both acid-resistant and acid-sensitive strains have been found among nonpathogenic *E. coli*, and EIEC, EPEC, EHEC, and ETEC groups.

The minimum a_w allowing growth of *E. coli* is 0.95 (∼8% sodium chloride) and the optimal a_w is 0.995, with variations between strains. Combinations of parameters are often present as hurdles for controlling growth of *E. coli* in dairy products. For example, during cheese manufacture, low pH produced by starter cultures metabolizing lactose into lactic acid, low a_w developed with the addition of salt and during ripening, and temperature control inhibit *E. coli* growth. Curd cooking temperatures of 30–38 °C (for soft and semisoft cheeses) and 38–55 °C (for hard cheeses) can provide conditions suitable for the growth of *E. coli*; therefore, careful control of pH and a_w is essential to limit the growth of any pathogens present. In the initial stages of fermentation of soft and semisoft cheeses, any *E. coli* present (including pathogenic types) can grow until the pH drops, salt is added, and the temperature is reduced. However, it is possible for *E. coli* to survive beyond the ripening stages of some semihard, soft, and fresh cheeses. Zones of these intrinsic parameters are established during processing, for example, in soft and mold-ripened cheeses, and the behavior of any *E. coli* strain varies accordingly.

Control

Common factors causing outbreaks of *E. coli* disease due to dairy products include the use of contaminated raw milk, faulty pasteurization or failure of processing equipment, starter culture failure, and postpasteurization contamination. The application of a hazard analysis critical control point (HACCP)-based approach together with the prerequisites of good manufacturing practices (GMPs) and good hygiene practices (GHPs) is now required through the dairy food chain in many countries. Effective sanitation and cleaning of equipment at all processing steps and meticulous personal hygiene of food handlers are essential, whether on farm, during transport, or in factories. Equipment sanitation is important, as any residues of product on equipment or machinery may allow growth of *E. coli* contaminants at ambient temperatures, leading to subsequent product contamination. Use of potable water for cleaning and during manufacture is important and failures to adhere to this have resulted in outbreaks of *E. coli*. Effective monitoring at control points and corrective action in the event of a deviation are fundamental in this process.

Processing plants should be designed to ensure that contamination is not transferred from raw to final products. Movement of personnel and equipment between milk receival bays and processing areas should be prevented with similar separation of raw and pasteurized product areas. Specific control measures for particular products are discussed below.

Milk and Cream

As *E. coli* is part of the bacterial flora in feces of healthy dairy animals, contamination of raw milk can easily occur during collection. On-farm controls include the supply of safe feed and water, maintenance of animal health, and removal and rapid treatment of any animals with mastitis. GHPs on farm, including cleaning and disinfecting of udders before milking and effective cleaning of surfaces and equipment in the dairy parlor and on milk transport tankers, are essential to minimize contamination of the raw milk during collection and storage. Preventing environmental contamination of raw milk via dust and other particulate matter and ensuring personal cleanliness and hygiene are also important. Raw milk contains various antimicrobial factors that may restrict microbial growth (lysozyme, lactoferrin, lactoperoxidase, immunoglobulin); however, this alone is insufficient and chilling is also required. Chilling raw milk to below 4 °C within 2 h of collection restricts growth of *E. coli*, and regulations for milk storage are established in most countries.

Raw milk is potentially contaminated with *E. coli* and consumption of raw milk poses a threat to human health, particularly for young children, the elderly, and those who are immunocompromised. Heat treatment is the most common method for enhancing the safety of liquid milk. Any *E. coli* present in pasteurized milk is a consequence of ineffective pasteurization or postprocessing contamination. Pasteurization at 63 °C for 30 min and high-temperature, short-time (HTST) pasteurization at 72 °C for 15 s or equivalents are effective in reducing *E. coli* contamination to levels considered safe for human consumption. The effect of thermization varies depending on the temperature and time used. Low treatments (57 °C for 15 s) sometimes used in cheesemaking will have little or no effect in destroying *E. coli* compared with higher temperatures (62–65 °C for 15–20 s). Similar measures apply to cream, although the higher fat content can protect bacteria from the effects of heat, and higher temperature limits of these treatments are required. After pasteurization, considerable care is required to prevent recontamination, and pasteurized milk and cream are held chilled (preferably at less than 5 °C) to prevent growth if contamination occurs.

Critical controls include storage and pasteurization conditions (temperature and holding time), with prerequisites being effective cleaning and sanitation of all product contact surfaces, controlled airborne contamination, personal and environmental hygiene.

Cheese

The likelihood of *E. coli* contamination of cheese depends largely on the quality of the milk used and the performance criteria for the process. If milk is adequately pasteurized, the risk is minimal. When raw milk or low temperature thermised milk is used, there may be some loss of viability of *E. coli*; however, whether they survive or grow and their presence in the final product will depend on the combined effect of subsequent processing hurdles. Therefore, raw milk cheeses may pose similar threats to health as raw milk, depending on the method of cheese processing. The health risk has to be weighed up against cheese quality benefits when making raw milk cheese.

There is a diversity of cheese types and processes, each of which has control points with critical limits that have to be monitored. Use of starter cultures for rapid acidification contributes significantly to controlling pathogens; therefore, ensuring the activity of the starter culture is essential. Ensuring adequate temperature control during fermentation, cooking, and storage, and control of moisture and salt are required. In some countries, holding cheese made from raw milk for more than 60 days is required to ensure safety. This can no longer be relied on for control of some pathogenic *E. coli*, as O157:H7 strains have been found to survive, for example, in Cheddar cheese, beyond this time.

Fermented Milk Products

Production of fermented milk products, like cheese, relies principally on the production of organic acids from the activity of starter cultures. The resultant level of acid varies among products. Control of starter culture activity and the resultant pH is essential. This may need to be combined with other hurdles such as refrigeration in ensuring the safety of fermented products. Some strains of *E. coli* are capable of surviving at low pH and prevention of contamination of the product after pasteurization is essential. Fruits, nuts, and other flavorings added after pasteurization must be of high microbiological standard. Aseptic packaging of products is also important in reducing postprocessing contamination.

Ice Cream and Other Frozen Dairy Desserts

In addition to milk and other dairy products, ingredients such as sugar, eggs, fruits, nuts, flavors, and colors are used in the manufacture of ice cream and other frozen dairy products. These additional ingredients may introduce *E. coli* contamination, especially if added after pasteurization of the milk or dairy mix. Growth of *E. coli* in ice cream and frozen dairy desserts is limited by low a_w and storage temperature; however, growth of *E. coli* can occur if products are in the liquid state. Freezing may have little effect on the number of bacteria present; it is therefore important to maintain good hygiene and sanitation throughout manufacture. Control measures for ice cream and frozen dairy desserts include provision of raw ingredients of good microbiological quality (especially those that cannot be pasteurized), appropriate pasteurization or heat treatment, prevention of postpasteurization contamination, and storage at low temperatures. Attention to hygiene in serving frozen dairy products is important, as *E. coli* have been found contaminating ice cream and ice cream scoop water.

Dried and Concentrated Products

The heat treatment used in the manufacture of dried and concentrated dairy products is equivalent to, if not greater than, pasteurization and is sufficient to destroy viable *E. coli*. Such products, due to their low a_w, do not support the growth of *E. coli*. Prevention of postprocessing contamination is an important control measure in the manufacture of these dairy products.

Other Products

Butter has not been directly implicated as a source of human *E. coli* infections. Pasteurization of cream in the manufacture of commercial butter and the inhibitory qualities of the product ensure that it is unlikely to be a vehicle of *E. coli* infection. The addition of ingredients, for example, fresh herbs, may introduce contamination as described for frozen products (above).

Enterobacteriaceae

S K Anand, South Dakota State University, Brookings, SD, USA

M W Griffiths, University of Guelph, Guelph, ON, Canada

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The family Enterobacteriaceae comprises a very large group of morphologically and physiologically similar bacteria. They are of great importance, as some of these organisms are involved in food spoilage, some are foodborne pathogens, and some are indicators of fecal contamination of food products.

The genera belonging to the Enterobacteriaceae family are often associated with intestinal infections, but can be found in almost all natural habitats. They are the causative agents of such diseases as meningitis, bacillary dysentery, and typhoid.

The most commonly encountered members of the Enterobacteriaceae in dairy products belong to 27 genera and include *Escherichia*, *Salmonella*, *Shigella*, *Yersinia*, *Klebsiella*, *Enterobacter*, *Serratia*, *Citrobacter*, *Proteus*, *Edwardsiella*, *Erwinia*, *Morganella*, and *Providencia.* Several of the genera contain species that are psychrotrophic. Typically, Enterobacteriaceae can be isolated from 6% of pasteurized milk samples, and among the predominant species are *Hafnia alvei*, *Rahnella aquatilis*, and *Serratia liquefaciens.*

Morphology and Physiology

The Enterobacteriaceae are Gram-negative, non-spore-forming, non-acid-fast, straight rods (0.3–1.0 × 1.0–6.0 μm). They lack cytochrome oxidase and are referred to as oxidase negative. They are nonhalophilic facultative anaerobes, with optimal growth between 22 and 37 °C. Being chemoautotrophs (i.e., able to grow on simple organic carbon and nitrogen compounds), they have both respiratory and fermentative metabolism. The base composition of the DNA is 38–60 mol% GC.

An important distinguishing feature splitting the Enterobacteriaceae into two groups is the type of fermentation, either the mixed acid fermentation carried out by the *Escherichia*–*Salmonella*–*Shigella* group that is characterized by the production of acetate from pyruvate through acetyl-CoA, or the butanediol fermentation characteristic of the *Erwinia*–*Enterobacter*–*Serratia* group resulting in the formation of butanediol as the end product of fermentation.

All members of Enterobacteriaceae ferment glucose with acid production and reduce nitrates (NO_3 to NO_2 or all the way to N_2). Certain physiological groups of organisms may be recognized within the family Enterobacteriaceae. The most important of these are ‘coliforms’, which ferment lactose vigorously to acid and gas at 35–37 °C within 1 or 2 days. Most strains found in the genera *Escherichia*, *Enterobacter*, and *Klebsiella* fit the description of coliforms and are used as indicators of hygiene in food analysis. In addition, many strains of *Citrobacter* are also considered coliforms. Certain other enterics may ferment lactose, but minimal gas production and/or a lower temperature optimum for most of these organisms preclude them from being termed ‘coliforms’. In contrast, *Salmonella* and *Shigella*, which stand out as the major pathogens of the family, do not ferment lactose or sucrose. Therefore, inclusion of these sugars in plating media assists in their isolation, as nonfermenting colonies can be selected for further testing.

Another physiological group comprises the genus *Proteus* and its relatives, *Morganella* and *Providencia.* These organisms often appear on plating media used for the isolation of *Salmonella* and *Shigella* and may appear nonfermenting. A distinguishing characteristic of these organisms is their possession of the enzyme phenylalanine deaminase, for which a test can be easily carried out. Many organisms in this group also hydrolyze urea rapidly.

The members of Enterobacteriaceae are motile via peritrichous flagellae, with the exception of *Shigella* and *Klebsiella*, which are nonmotile. The Enterobacteriaceae also possess fimbriae (pili) and may have a capsule or slime layer. The cell wall is complex and the antigenic structure plays an important role for some species in epidemiology and classification.

Significance in Milk and Dairy Foods

Although milk may be contaminated by a number of routes like bovine feces, udder infection, milking personnel, and environmental sources, the most important with respect to Enterobacteriaceae is the contamination of milk by feces, which usually occurs at milking. Even with modern milking practices, it is impossible to entirely eliminate the possibility of contamination of milk. *Escherichia coli* and other Enterobacteriaceae have often been used as indicators of microbial quality and hygienic processing methods.

Milk

Consumption of raw milk is considered a risk factor for enteric infections including salmonellosis. The commercial distribution of raw milk in California has led to continuing outbreaks caused by *Salmonella* Dublin, while, in Scotland, the introduction of mandatory pasteurization eliminated the problem of milk-borne salmonellosis. However, there have been some outbreaks of salmonellosis caused by pasteurized milk, primarily due to poor plant design and incorrect operation of the pasteurizer. The largest salmonellosis outbreak where pasteurized milk was identified as the vehicle occurred in Chicago, USA in 1985, and involved 16 284 known cases, while the actual number of people affected might have been as high as 250 000. In another study of bulk tank milk in US dairies in 2004, coliforms were detected in 95% (818 of 860) of the samples. Twenty-two samples (2.6%) were found to be culture-positive for *Salmonella*, and eight serotypes identified were Montevideo, Newport, Muenster, Meleagridis, Cerro, Dublin, Anatum, and 9,12: nonmotile. A study conducted in downgraded Danish bulk tank milk during 2004 also reported the presence of coliforms in 20% of the samples.

Enterobacteriaceae were also found to be present in 212 (61.6%) goat's milk samples and 45 (71.4%) ewe's milk samples in ewe's bulk tank milk in Switzerland. *Campylobacter* spp. and *Salmonella* spp. were not isolated from any of the samples. However, 16.3% of goat's milk samples and 12.7% of ewe's milk samples were polymerase chain reaction-positive for shiga toxin-producing *E. coli*.

On the other hand, foodborne shigellosis almost invariably involves contamination by a food handler or from sewage-contaminated environmental sources such as water or soil. Thus, any dairy product that has been handled by a *Shigella*-infected person, and that is not to be heated directly before consumption, is a potential vehicle of foodborne shigellosis.

Although *Yersinia enterocolitica* is well established as an enteric pathogen, the number of cases that are associated with dairy foods remain small. Milk has been responsible for at least three large outbreaks of yersiniosis in the United States. In one such outbreak, chocolate milk was involved. The organism was introduced with the chocolate syrup, which was added after the milk was pasteurized. Pasteurized milk was linked to at least two other outbreaks among hospitalized children. The general consensus is, however, that the *Y. enterocolitica* strains isolated from milk belong to nonpathogenic serotypes.

As far as spoilage is concerned, coliforms cannot compete well at refrigeration temperatures and at a pH below 5.5, but *Klebsiella*, *Enterobacter*, *Citrobacter*, and *Serratia* do grow well in refrigerated milk and are responsible for several milk defects that include significant proteolysis and lipolysis. These genera produce heat-stable proteases and lipases that have similar properties to those synthesized by *Pseudomonas* spp.

Dried Milk

Infant dried milk was the cause of a significant outbreak involving *Salmonella* Ealing in the United Kingdom during 1985. Insulation surrounding the drying chamber was found to be the source of contamination. A similar outbreak, involving infant formula, was reported in Australia, where the causative agent was *Salmonella* Bredeney. A survey conducted following these events suggested that *Salmonella* contamination in the environment of spray-drying plants was common.

Enterobacter sakazakii has been implicated in a rare but severe form of neonatal meningitis, with dried infant formula being implicated as the mode of transmission. The high mortality rate (40–80%) and the lack of information about this organism led to a study of the heat resistance of *E. sakazakii* in reconstituted dried infant formula. *Enterobacter sakazakii* strains (five clinical and five food isolates) were used to determine the heat resistance of this organism at 52, 54, 56, 58, and 60 °C in reconstituted dried infant formula and *D*-values of 54.8, 23.7, 10.3, 4.2, and 2.5 min were obtained for each temperature, respectively. The overall calculated *z*-value was 5.82 °C. In a comparison of the *D*-values of several members of the Enterobacteriaceae in dairy products, *E. sakazakii* was among the most thermotolerant organisms.

Cheese

Salmonella is normally destroyed or inactivated during fermentation of high-acid products (lactic acid *c.* 1%, pH value less than 4.55) such as yogurt and soft cheese. The degree of inactivation, however, was found to be less in cheese due to protection provided by casein and possibly fat. Also, *Salmonella* may grow in the curd of low-acid cheese (pH value greater than 4.95). As a small number of salmonellae may persist for significant periods, the practice of aging of raw milk cheese for 60 days at not less than 4.4 °C would not be an effective control measure.

Although cheese-borne salmonellosis is often associated with raw milk cheese, a large outbreak that occurred in Canada in 1984 was attributed to improper pasteurization. An estimated 10 000 people were affected, and the causative serovar was identified as *Salmonella* Typhimurium PT10.

Similarly, *Citrobacter freundii* in Camembert cheese was suspected in a diarrhea outbreak in Washington. In addition to being potential pathogens, Enterobacteriaceae can cause spoilage of low-acid cheeses. *Enterobacter* spp. have been shown to be involved in slimy curd spoilage of Cottage cheese and *Enterobacter aerogenes* is able to oxidize diacetyl to acetoin, a flavorless compound. This results in a cheese with a flat, bland taste.

A number of amines, such as tyramine and histamine, formed by members of the Enterobacteriaceae are toxic to humans. Cheeses, especially Swiss cheeses, can contain these biogenic amines. Amines were determined in the Emmental cheese milk, in cheese before brining, in cheese ripened for up to 49 days, and in cheese blocks or grated cheese stored for up to 5 months at 5 or 15 °C. Amine concentrations increased throughout cheesemaking, ripening, and storage. Histamine and tyramine dominated up to the end of ripening, and the concentration of putrescine and cadaverine increased during storage. Amine formation increased at higher storage temperatures, and was higher in grated than in intact cheese. Formation of biogenic amines in Emmental cheese was strongly influenced by the microflora, with high counts of Enterobacteriaceae being associated with high concentrations of putrescine and cadaverine.

Other Milk Products

Enterobacteriaceae infections have been occasionally associated with other dairy products like ice cream. In addition, cream-filled pastries are also known to constitute a foodborne disease problem. In a survey of 439 outbreaks in the United States associated with milk products, about 12.5% were attributed to *Salmonella*. Similarly, caprine raw colostrums were also found to be positive for Enterobacteriaceae.

A study conducted during the milk fermentation and preparation of buffalo's milk yogurt revealed that *S. enterica* Typhimurium PT8 had longer generation times in mixed cultures. *Lactobacillus bulgaricus* or its combination with *Streptococcus thermophilus* was found to be more inhibitory to the growth and survival of *Salmonella* than *Str. thermophilus* alone. In a recent study, *E. coli* 0157:H7 was found to survive in different yogurt products like yogurt drink, plain yogurt, and salted yogurt (yogurt native to Hatay, Turkey) at both 4 and 22 °C.

At least 2.13 $\log \text{cfu}\,\text{g}^{-1}$ of Enterobacteriaceae was reported in 'Kurut', a dairy product obtained by drying yogurt under the sun in rural areas of Turkey. Similarly, *Klebsiella*, *Escherichia*, and *Enterobacter* were found to be predominant among Enterobacteriaceae in Ethiopian traditional dairy products that included milk, butter, buttermilk, naturally fermented milks, and Cottage cheese.

Enumeration

Enterobacteriaceae are often isolated from fecal matter on agar containing lactose and a pH indicator. Colonies that ferment lactose would produce sufficient acid to cause a color shift in the indicator. For example, *E. coli* is a fermenter of lactose, while *Shigella*, *Salmonella*, and *Yersinia* are nonfermenters. Several commercial media, including ready-to-use petrifilms manufactured by 3M, are available for the detection of Enterobacteriaceae, and the International Dairy Federation has approved standard methods for their enumeration. Several tests relying on the detection of β-glucuronidase are also approved for the detection of *E. coli*, although not the enterohemorrhagic serovars.

A hydrophobic grid membrane filtration (HGMF) method for the enumeration of coliforms has also gained the status of an official method.

All Enterobacteriaceae isolates are identified biochemically using systems like API 20E manufactured by bioMérieux. Important serotypes can also be differentiated by their O (lipopolysaccharide), H (flagellar), and K (capsular) antigens.

Sources

Due to problems caused by recontamination of pasteurized milk with Gram-negative psychrotrophs, critical contamination sites for psychrotrophic Enterobacteriaceae were investigated. Milk samples were collected in three dairy plants at the silo tank; just before and just after the pasteurizer; from the buffer tank of pasteurized milk; just before the filling machine; and as filled and sealed consumer packages. There was a relatively high frequency of recontamination of refrigerated milk with psychrotrophic bacteria. Gram-negative bacteria were isolated from 40% of 87 packages, with pseudomonads being isolated from all contaminated packs, and Enterobacteriaceae from 9%. Recontamination occurred mainly during filling procedures, and it is considered that efforts to improve hygiene should be concentrated in this area.

Control

The vast majority of milk consumed in developed nations is cow's milk, although goat's milk is increasing in popularity in the United Kingdom and significant quantities of sheep's milk are consumed in Australia. In developing countries, sheep and goat may be of greater importance than cattle as sources of milk, while other sources of milk are buffalo, camels, and mares. The chemical composition of milk of different species varies considerably, but although this affects the organoleptic properties and, possibly, the development of the spoilage microflora, there is no evidence that the survival or growth of pathogenic microorganisms is significantly affected, except in camel milk.

Hazards from Enterobacteriaceae can be prevented by heating milk sufficiently to kill the bacteria, holding chilled milk and dairy products below 4.4 °C (40 °F), preventing postpasteurization cross-contamination, and prohibiting people who are ill from working in dairy food operations. The infective dose of virulent members of Enterobacteriaceae is dependent upon the particular strain, and it varies from only a few organisms to millions. For this reason, time/temperature abuse of food products may or may not result in illness.

Pasteurization is an essential process in providing milk that is free of hazardous microorganisms. Alternatively, ultra-high temperature (UHT) treatment wherein a temperature of 132 °C for not less than 1 s is employed is another popular process that has a good safety record. The microbiological problems in UHT milk are usually restricted to spoilage due to the heat-stable proteolytic enzymes alone. The same is true for milk products like cream and butter as well.

Thermal stress (curd cooking at 55 °C) during the production of Grana cheese was found to be only partially effective in the control of selected pathogens including *E. coli* 0157:H7 and *Salmonella* Typhimurium. Similarly, differences in pH values due to temperature-dependent whey retention accounted for the effect of cooking temperature on coliforms and fecal coliform counts during the manufacture and ripening of Manchego cheese prepared from ewe's milk. Although brine-salting had no effect on Enterobacteriaceae counts, a significant effect of salting time on Enterobacteriaceae and fecal coliform counts was detected. In addition to this, ripening temperature was the most important manufacturing variable with greatest influence on Enterobacteriaceae and fecal coliform counts during the whole curing period.

In concentrated milk preparation, the milk is heated to a high temperature prior to entry into the evaporator and this, together with operating temperatures in the first stages of the evaporator, would kill any vegetative pathogens present. Furthermore, the higher sugar levels in condensed milk lead to lowering of water activity, thereby preventing the growth of pathogenic organisms.

Dried milk may be made by either the roller process or the spray process. Due to the extensive heat treatment, the products generally do not pose any threat from the presence of Enterobacteriaceae in such products.

In Caprine colostrums, heat (56 °C for 60 min and 63 °C for 30 min) and high pressure (400 and 500 MPa for 10 min at 20 °C) were found to significantly reduce Enterobacteriaceae.

In addition to this, in the case of fermented milk products like hard and soft cheeses, yogurt, and several intermediate products, the heat treatment of milk and the controlled fermentation are important to prevent the growth of Enterobacteriaceae. Even in traditionally made yogurt and some unripened soft cheeses, the high acidity of the final product is sufficient to inactivate many pathogens including members of the Enterobacteriaceae. Moreover, these pathogenic contaminants are unable to grow in hard cheeses during ripening, and conditions of storage are intended to maximize the inactivation of any pathogen present. In the case of Ragusano cheese, presalting of curd (with 2% added salt) before stretching reduced the coliform counts in cheese by 1.41 log and also resulted in major reduction in early gas formation. Another approach is the addition of bacteriocin-producing adjunct cultures during cheesemaking that can help in inhibiting Enterobacteriaceae.

Prevention of recontamination is, however, the key factor in the safety of such products.

Introduction

Enterobacter species are widely dispersed in nature and exist in a diverse range of environments such as soil, water, households, food processing establishments, vegetation, and vertebrate and invertebrate hosts. *Enterobacter* are also increasingly recognized as potential human pathogens, especially as agents of nosocomial infections in the clinical environment. Currently, only *Enterobacter sakazakii* (*Cronobacter*) are considered foodborne pathogens and have been associated with cases of bacteremia, meningitis, and necrotizing enterocolitis (NEC) in infants. Powdered infant formula (PIF) has been identified as a major route of infection, and therefore these organisms are of particular concern to manufacturers of formula milk powders and milk derivatives that supply this industry.

Classification

The genus *Enterobacter* comprises a heterogeneous group of organisms in the Enterobacteriaceae family. They are Gram-negative, generally motile, oxidase-negative, nonsporing, flagellated, rod-shaped, facultative anaerobes. The genus *Enterobacter* was derived from members of the genus *Aerobacter* in 1960 when the motile and ornithine decarboxylase (ODC)-positive strains were separated as *Enterobacter* from the nonmotile and ODC-negative *Klebsiella* strains. Originally genera and species were defined based on phenotypic characteristics. The development of techniques such as DNA–DNA hybridization and nucleic acid sequence analysis has enabled the measurement of evolutionary distances and made it possible to determine more accurately the relationships between organisms. This has led to the proposed reclassification of several *Enterobacter* species and the transfer of *E. intermedius* to the genus *Kluyvera* as *K. intermedia*, *E. agglomerans* to the genus *Pantoea*, and *E. sakazakii* to the genus *Cronobacter* (**Table 1**). Species closely related to *E. cloacae*, such as *E. dissolvens*, *E. asburiae*, *E. hormaechei*, *E. kobei*, *E. ludwigii*, and *E. nimipressuralis*, are often referred to as belonging to the '*Enterobacter cloacae* complex'. All species within this complex are of clinical significance and are increasingly being implicated in cases of hospital-acquired infections. However no link has been established between ingestion of contaminated food and infection due to these species.

Enterobacter sakazakii, which was previously referred to as 'yellow-pigmented *E. cloacae*', has now been recognized as a group of multiple genomospecies and a novel genus, *Cronobacter*, has been proposed. *Cronobacter* consists of *C. sakazakii*, *C. dublinensis*, *C. malonaticus*, *C. muytjensii*, *C. turicensis*, and the as yet unnamed *Cronobacter* genomospecies 1. The genus *Cronobacter* is contaxic (synonymous) with *E. sakazakii*, and these organisms are known to cause serious invasive disease and are recognized as a particular problem for infection in neonates and, to a lesser extent, in older infants and immunocompromised adults. Neonatal infections have been epidemiologically linked to consumption of contaminated reconstituted PIF in neonatal intensive care units (NICUS).

Physiology

Growth

Enterobacter spp. generally grow well, aerobically and anaerobically, between 20 and 37 °C on nonselective laboratory media at neutral pH. The growth ranges of different species vary; *Cronobacter* can grow between 6 and 47 °C with a pH range of 4.5–10 at 37 °C. Most *Enterobacter* strains will grow and produce typical colonies on selective media for Enterobacteriaceae, such as Violet Red Bile Agar (containing glucose or lactose) and Hektoen or MacConkey agar. Some strains of *Enterobacter/Cronobacter* are reported to be unusually sensitive to antimicrobial agents commonly used in Enterobacteriaceae selective media, including antibiotics, brilliant green, crystal violet, bile salts, and sodium lauryl sulfate. *Cronobacter* are the only species for which specific isolation media have been developed.

Resistance

Water Activity

In general *Enterobacter* are not considered particularly resistant to low-water activity (a_w) environments. However, *Cronobacter* are noted for their ability to survive during desiccation and their persistence in dried formula for 1–2 years. High concentrations of osmolytes and humectants have been proposed as selective strategies. *Cronobacter* strains can grow in media containing up to 7% sodium chloride or 20% sucrose.

Table 1 Nomenclature of *Enterobacter* spp. and relevance to foodborne disease

Enterobacter *species*	*Taxonomic note*	*Clinical source*	*Food/environment sources*
E. aerogenes	*Klebsiella mobilis*	All sites	Ubiquitous (dairy)
E. agglomerans	*Pantoea agglomerans*[a]	All sites	Ubiquitous (dried food, PIF)

pH

Cronobacter is classified as a moderately resistant member of the Enterobacteriaceae that can withstand transitory exposure to a pH of 3.0. It can survive for extended periods of time (>5 h) at a pH of 3.5.

Thermal Inactivation

Enterobacter do not survive pasteurization; however, there is a great diversity of thermotolerance among strains. Use of water at 70 °C has been recommended for reconstitution of powdered formula to inactivate possible *Cronobacter*/*Enterobacter* contaminants.

Antibiotic Susceptibility

Enterobacter species are naturally susceptible to a range of antibiotics. *Enterobacter hormaechei* is the species most susceptible to fosfomycin. Natural antibiotic resistance in *Enterobacter* spp. is similar to that of other Enterobacteriaceae. High-level cefoxitin resistance is also seen in species of the *E. cloacae* complex. Increasing prevalence of antibiotic resistance among *Enterobacter* spp. is an emerging problem worldwide. An increase in the use of antimicrobial agents within the hospital setting has led to the development of resistance to many β-lactam antibiotics via extended-spectrum β-lactamases (ESBLs), with ~25% of *Enterobacter* spp. being resistant to extended-spectrum cephalosporins. *Cronobacter* is notably more sensitive to antibiotics than other *Enterobacter* species.

Prevalence and Distribution

Environment and Host Reservoirs

Enterobacter are ubiquitous in the environment, and *E. cancerogenous*, *E. cloacae*, *E. asburiae*, and *Cronobacter* have been isolated from environmental and domestic water sources. Plants (including crops and trees), soil, and the microbial rhizosphere can harbor *Enterobacter* spp. They can be recovered from vertebrate and invertebrate hosts, and species of the *E. cloacae* complex can routinely be found in the feces of humans and animals. Although there are a few reports of *Cronobacter* isolates from fecal samples of asymptomatic colonized individuals, these organisms are not recognized as normal inhabitants of the human gut. In a farm environment, *Cronobacter* have been found in dried pellets of animal feed but not in cattle feces. *Cronobacter* strains were previously tested in a model of a bovine gut to establish whether they can survive a bovine digestive system. No survival of strains was recorded, which indicates that cattle may not be an important vector in the transmission of *Cronobacter*.

Food Contamination

Enterobacter species can be found on a wide range of foods. These include fresh, frozen, or powdered fruits and vegetables, legume products, tea, herbs, spices, animal feed (dried pellets), grains, nuts, seeds, flour, pasta, chocolate, beverages, and water. Other food sources include meat, fish, eggs, dairy products, and PIF. *Enterobacter cloacae* is a recognized contaminant of raw milk and dairy produce such as yogurt and cheese. Although they do not survive pasteurization, *Enterobacter* have been found in pasteurized milk and cream and in dried dairy products, possibly due to postprocess contamination.

PIF is used as an alternative to breast milk to provide nutritional requirements in addition to breast-feeding or where breast-feeding is not feasible. While ready-to-use liquid formula is marketed as sterile, the powdered form (including dried bovine milk and milk products) often contains bacterial spores and may contain low levels of pathogenic microorganisms. The most frequently isolated Enterobacteriaceae species from powdered milk products are *E. cloacae*, *Cronobacter*, *E. agglomerans* (*Pantoea*), *E. pulveris*, *E. helveticus*, and *Klebsiella pneumoniae.* Currently the recovery of *Cronobacter* from PIF is reported to be at approximately 2% of commercially available packages, and illness is reported to be at approximately six incidents per year. Therefore, the vast majority of contaminated formula consumed does not result in infection and the organisms have relatively low pathogenicity. Investigation of potential contamination routes in infant formula factories has indicated that raw milk and liquid ingredients are probably not the primary hazard. A diverse range of Enterobacteriaceae enter as contaminants in dry raw ingredients, via inefficient air filtration, water leaks, and human carriage. The majority of factory environment samples contaminated with *Cronobacter* appear to be found around spray dryer towers; this may be related to the relatively high desiccation resistance of *Cronobacter* as compared to other Enterobacteriaceae.

Foodborne Outbreaks

The earliest report of *Cronobacter* contamination in powdered milk was in 1950. The first case of neonatal illness attributed to *Cronobacter* occurred in London in 1958. The link between neonatal illness and PIF was first proposed in 1983. A number of outbreaks in NICUs have been epidemiologically linked to consumption of contaminated food, particularly reconstituted infant formula (**Table 2**).

In Iceland (1986), three neonatal cases shared identical biotypes, plasmid DNA profiles, and antibiograms with strains isolated from infant formula. In Belgium (1998), arbitrarily primed PCR typing partially confirmed strain similarity between isolates from milk and those from patients in an outbreak of necrotizing entercolitis. In the United States (2001), pulsed-field gel electrophoresis (PFGE) showed that *Cronobacter* isolates from opened and unopened containers of a nutritional supplement were indistinguishable from the isolate obtained from a neonate with meningitis. Finally, in France (2004), cases occurring in five hospitals were linked to the use of a hypoallergenic formula, which was subsequently recalled by the manufacturer. Investigation revealed failures in hospital practices with regard to the preparation, handling, and storage of feeding bottles. In some instances no direct link has been made to batches of PIF. In these cases extrinsic contamination of prepared formula and horizontal transmission from other infected/colonized hosts are the possible causes of infection. Multiple strains of *Cronobacter* have simultaneously been isolated from the

same food containers, or single infected children, further complicating the epidemiology.

Clinical Relevance

Enterobacter spp. are increasingly recognized as opportunistic pathogens in a wide variety of settings and rarely cause disease in healthy individuals. They are common contaminants of hospital surfaces, medical supplements, catheters, and other medical and feeding equipment, as well as medical staff. In general, *Enterobacter* organisms are responsible for around 50% of nosocomial infections, mostly in immunocompromised patients, and can affect people of all ages. Community-acquired infections can occur through open wounds or severe crush injuries. *Enterobacter aerogenes* and the *E. cloacae* complex are the most frequently encountered *Enterobacter* species in clinical samples. Immunocompromised individuals are at particular risk of acquiring infection. *Enterobacter cloacae*, along with *E. aerogenes*, *E. hormaechei*, *E. gergoviae*, and *Cronobacter*, has been associated with infections in neonates. Risk factors in neonates include premature birth and low birth weight. Infants of normal gestational age and birth weight infected during the first month postpartum are more likely to develop meningitis, with high case fatality rates as compared to premature, low-birth-weight infants, who usually develop later onset of infections resulting in bacteremia. This may be due to sterile, parenteral initial feeding and administration of prophylactic antibiotics prior to exposure to contaminated nutritional products. *Cronobacter* infections are uncommon in adults and mainly comprise cases of wound infection, bacteremia, and aspiration pneumonia in elderly patients.

Necrotizing Enterocolitis

NEC is an inflammatory process of the small and large intestine. This condition is one of the most common causes of death in NICUs and the most relevant acquired intestinal complication during the neonatal period. NEC has an incidence of 2–5% in all preterm infants and up to 13% in those with low birth weight. The reported case fatality rates range between 0 and 20% in infants weighing >2500 g and between 10 and 55% in low-birth-weight infants (<1500 g). Initial symptoms include feeding intolerance, delayed gastric emptying, abdominal distension and/or tenderness, decreased bowel sounds, and bloody stools. NEC has no definitive known cause, and research suggests involvement of a combination of factors leading to intestinal damage, including intestinal mucosal immaturity/dysfunction, ischemia and/or reperfusion injury, the release of inflammatory mediators and bile acids, and downregulation of cellular growth factors. Empirical antibiotic use and intestinal bacteria are thought to be associated factors, though no common infectious agent has been identified. Decreased levels of bactericidal/permeability-increasing protein (BPI), particularly in premature low-birth-weight neonates, may be significant in cases where bacterial invasion is a contributing factor. BPI binds to lipopolysaccharides produced by Gram-negative organisms neutralizing the endotoxin and reducing intestinal wall disruption. NEC is rarely seen in infants prior to initiation of oral feeding. The use of infant formula as opposed to breast milk greatly increases the risk of NEC. Infant formula contaminated with *Cronobacter* has been associated with outbreaks of NEC.

Bloodstream Infections

Bacteremia is the presence of viable bacteria in the bloodstream, whether associated with active disease or not. When associated with the release of bacterial toxins into the circulation, bacteremia can elicit a vigorous immune response resulting in systemic inflammatory response syndrome. This is characterized by rapid breathing, low blood pressure, and fever, which may lead to multiple organ failure (septic shock). *Enterobacter* cause 3–9% of all bloodstream infections and up to 15% of bacteremia in the elderly. Case fatality rates for *Enterobacter* sepsis range from 20 to 50%. *Enterobacter cloacae*, followed by *E. aerogenes*, is the species most frequently isolated in *Enterobacter* bacteremia and is responsible for over 90% of all cases. *Enterobacter asburiae*, *E. cancerogenous*, *E. amnigenus*, and *Cronobacter* have also been reported to cause bacteremia in adults. *Enterobacter* are estimated to account for up to 8.7% of all bacteremia and approximately 20% of Gram-negative sepsis cases in children, with case fatality rates of 6–20%. Most infections are nosocomially acquired, with molecular fingerprint epidemiology suggesting that horizontal transmission plays a significant role. Risk factors associated with *Enterobacter* sepsis in children include parenteral nutrition and use of antibiotics and catheters. As with adults, *E. cloacae* and *E. aerogenes* are responsible for over 90% of cases. However, *Cronobacter* are notable for their association with cases in neonates and links to ingestion of contaminated infant food. *Enterobacter hormaechei* and *E. gergoviae* have also been responsible for outbreaks in NICUS.

Central Nervous System Infections

Enterobacter are rare aetiological agents of central nervous system (CNS) disease. Bacterial meningitis is a serious and frequently fatal infection of the protective membranes covering the brain and spinal cord. Infections can increase inner cranial pressure, requiring aspiration of fluid and drainage of cerebral infarction to prevent cerebral damage. Meningitis can lead to long-term complications in survivors, including mental and motor disabilities, convulsive disorders, hydrocephalus, and deafness. Common symptoms include headache, neck stiffness, fever, confusion/delirium, vomiting, and photophobia. These symptoms may not be obvious in young children, who may present with irritability and lethargy. *Enterobacter* spp. are estimated to cause 2.4–4.5% of meningitis cases in adults and up to 10.4% of cases in children. In adults the main species implicated are *E. cloacae* and *E. aerogenes* with a case fatality rate of 16–20%. However, in children *Cronobacter* are the most frequently reported species with case fatality rates of up to 80%. Ingestion of contaminated infant formula has been implicated in several outbreaks. Low birth weight, prematurity, length of hospital stay, invasive procedures, and overuse of antibiotics put infants at an increased risk. Patients with *Cronobacter* neonatal meningitis may suffer more severe outcomes than those with meningitis attributed to *E. cloacae* and other Gram-negative bacteria. *Cronobacter* causes cystic changes, abscesses, fluid collection, dilated ventricles, and infarctions. Cases of *Cronobacter* meningitis have been reported in children between the ages of 3 days and 4 years, with half of the cases occurring in the first week after birth and almost three-quarter during the first month. A retrospective study of 46 infants with *Cronobacter* infections indicated that meningitis was more prevalent in infants of normal gestational age and birth weight, with the onset of disease usually occurring within the first week following birth. In contrast, low-birth-weight, premature infants were more likely to develop bacteremia with no progression to CNS disease, and the age of onset was usually over 1 month. It is probable that *Cronobacter* has a developmental dependence on access to the CNS.

Other Infections

Enterobacter species cause up to 5% of nosocomial pneumonias, being a significant cause of ventilator-associated and early post-lung transplant pneumonia. They are also associated with other lower respiratory tract infections. Case fatality rates are particularly high in elderly patients. *Enterobacter* skin and soft-tissue infections include cellulitis, fasciitis, myositis, abscesses, and wound infections (including burns and crush injuries). *Enterobacter* species can infect wounds in any body site. Most are nosocomially acquired, with surgical complications and cephalosporin prophylaxis being associated with increased risk of infection. *Enterobacter* species that colonize the digestive tract may be isolated from intraabdominal sites following intestinal perforation or surgery and are responsible for approximately 10% of postsurgical peritonitis cases. A few examples of endocarditis due to *Enterobacter* have been reported. In most cases there was underlying cardiac disease, particularly mitral valve infection. *Enterobacter* cause up to 4% of nosocomial urinary tract infections (UTIs), usually associated with urinary catheters and/or prior antibiotic therapy. They are also occasionally associated with osteomyelitis and septic arthritis in adults and children. *Enterobacter* bone and joint infections can be difficult to cure, with relapses requiring additional treatment.

Isolation, Identification, and Subtyping

Detection Methods

There are no microbiological media specifically designed for the genus *Enterobacter*. These organisms grow well on nonselective laboratory media and can be easily cultured from clinical samples. All *Enterobacter* species ferment glucose, and the majority ferment sucrose (except *E. cancerogenous*) and lactose (except *E. cancerogenous* and *E. hormaechei*). Therefore most *Enterobacter* isolates will appear as typical Enterobacteriaceae colonies on selective media for this family, such as Violet Red Bile, MacConkey, or Hektoen Enteric agars. *Enterobacter* are not generally considered foodborne pathogens but contribute to the overall microbial presence in foods and, as members of the Enterobacteriaceae, are relevant as hygiene indicators in food production processes. The process hygiene criteria for pasteurized milk, milk/whey powder, and dried infant formula allow only very low levels of Enterobacteriaceae (less than 5 cfu ml^{-1}, and 10 and 0.01 cfu g^{-1}, respectively). The EC regulation for the detection of Enterobacteriaceae refers to ISO 21528-1:2004, which entails preenrichment in buffered peptone water (BPW), followed by selective enrichment in Enterobacteriaceae enrichment (EE) broth, streaking on Violet Red Bile Glucose (VRBG) agar, and confirmation of typical colonies based on negative oxidase activity and positive glucose fermentation.

Owing to their status as neonatal pathogens associated with infant formula, specific isolation methods have been developed for *Cronobacter*. Initially these were based on ISO 21528-1:2004 mentioned above, followed by culturing of Enterobacteriaceae isolates on nonselective media at a low temperature (25 °C) and biochemical confirmation of yellow-pigmented colonies. In recent years various fluorogenic and chromogenic media have been developed for the detection of *Cronobacter*. These are mainly based on detection of the enzyme α-glucosidase, which is constitutively expressed in *Cronobacter* spp. However, *E. helveticus*, *E. pulveris*, and *E. turicensis*, which can be found in the same ecological niches as *Cronobacter* (including dried food products and factory environments), can also produce presumptive colonies on these agars.

There is currently an ISO technical specification for the detection of *Cronobacter* in milk-based infant formula (ISO/TS 22964:2006). This entails preenrichment in BPW and selective enrichment in a modified lauryl sulfate tryptose (mLST) broth (incorporating 0.5 mol l^{-1} NaCl and 10 mg ml^{-1} vancomycin hydrochloride), followed by streaking on a chromogenic agar. It has been reported that some *Cronobacter* strains do not grow well in selective media commonly used for Gram-negative organisms, and a differential method, incorporating *Cronobacter* screening broth (10 g l^{-1} peptone, 3 g l^{-1} meat extract, 5 g l^{-1} NaCl, 0.04 g l^{-1} bromocresol purple, 10 g l^{-1} sucrose, and 10 mg l^{-1} vancomycin hydrochloride) in place of mLST, has been proposed for the EN ISO horizontal standard currently in development. Carbohydrate fermentation results in a color change from purple to yellow, and only positive (yellow) broths are streaked onto chromogenic media.

The US Food and Drug Administration (USFDA) proposes a method involving preenrichment, centrifugation, plating on two chromogenic agars (one containing a chromogenic β-D-cellobioside in addition to α-D-glucopyranoside), and a real-time PCR assay based on the *dna*G gene, which is a component of the macromolecular synthesis (MMS) operon.

Alternative methods for the detection of *Cronobacter* include the MATRIX® PSAK50 cationic paramagnetic particle capture technique and enzyme-linked immunoassays (Assurance® and TECRA HELIX®). Genetic-based assays include the BAX® and foodproof® Enterobacteriaceae plus *E. sakazakii* detection systems. The latter simultaneously qualitatively detect Enterobacteriaceae DNA and the presence of *Cronobacter*. Both DNA-FISH (Vermicon®) and PNA-FISH techniques have been developed for the detection of viable *Cronobacter* cells in infant formula.

Phenotypic Identification

The *Enterobacter* genus is heterogeneous and difficult to define using biochemical criteria. Owing to their close relationships, phenotypic identification of individual *Enterobacter* species can also be unreliable. To ensure the safety of infant formula and at the same time to reduce unnecessary disposal of product, it is important to identify between *Cronobacter* and *Enterobacter* species. *Cronobacter* can generally be distinguished from *Enterobacter* species based on hydrolysis of 5-bromo-4-chloro-3-indolyl-α-D-phosphate, ornithine decarboxylation, and use of the 2,3 butanediol fermentation pathway (determined by Methyl Red and Voges–Proskauer reactions). Individual *Cronobacter* species can be separated by their different phenotype profiles using fermentation of 1-0-methyl-alpha-D-glucopyranoside and dulcitol combined with production of indole and utilization of malonate (**Table 3**). The reliability of some biochemical confirmation galleries such as API 20 E has been questioned as species of the *E. cloacae* complex can be misidentified as *E. sakazakii* (*Cronobacter*). The ID 32 E kit has been proposed as a more accurate alternative, successfully confirming 90% of isolates with no false positive or false negative results. The use of yellow pigmentation as an identification for *Cronobacter* is unreliable and has been discontinued.

Molecular Identification

Oligonucleotide probes have been designed to detect the 16S and 23S rRNA gene sequences of the family Enterobacteriaceae; however, there are no molecular probes designed specifically to identify the genus *Enterobacter*. Multilocus sequence analysis (MLSA) using the *recN*, *rpoA*, and *thdF* genes can be used to extrapolate genetic similarities between the species of Enterobacteriaceae. The *rpoA* and *rpoB* gene sequences provide useful diagnostic tools to identify and differentiate species of this family and can be more discriminatory than 16S rRNA sequencing. A number of molecular approaches have been developed to identify *Cronobacter*. Targets for conventional PCR assays include the 16S rRNA gene, the *ompA* gene, the gene coding for the 1,6 α-glucosidase, and a gene encoding a zinc-containing metalloprotease. Real-time PCR assays target the 16S rRNA gene, the region located between the 16S and 23S rRNA genes, the region between the tRNA-glu and 23S rRNA genes, and the *dna*G gene in the MMS operon. The α-glucosidase and *dna*G gene-based methods have proved to be 100% sensitive and specific for *Cronobacter* using a broad panel of target as well as non-target strains.

Subtyping Methods

A number of approaches have been developed that can be used to characterize strains of *Enterobacter*, including antibiograms, biotyping, serogrouping, plasmid profiling, ribotyping, random amplification of polymorphic DNA (RAPD), arbitrarily primed PCR (AP-PCR), repetitive sequence-based PCR (rep-PCR), enterobacterial repetitive intergenic consensus (ERIC) PCR, amplified fragment length polymorphism (AFLP), and PFGE. Typing techniques are more discriminatory and reliable than classic techniques such as biotyping or antibiograms. Although there is frequent plasmid carriage within *Enterobacter* species, problems can arise due to plasmid instability and lack of extrachromosomal elements in some strains. PFGE has been used to investigate outbreaks in NICUs involving *E. cloacae*, *E.aerogenes*, *E. gergoviae*, and *Cronobacter* and is currently seen as the ‘gold standard’ for molecular subtyping of

foodborne pathogens. The most common restriction enzymes used for *Enterobacter* are *Xba*I, *Spe*I, *Not*I, and *Sma*I. PFGE has been successfully used to analyze the dissemination of *Cronobacter* strains within infant formula and milk protein factories. A standard protocol for *Cronobacter* PFGE typing is currently being developed by the PulseNet International Program.

Prevention and Control

Manufacture

Owing to the high costs associated with product recalls, the risk associated with an unsafe product, and the impact of negative media attention, it is critical that *Enterobacter* and *Cronobacter* spp. are kept under control along the infant formula production chain. Hygienic standards within facilities are key to keeping contamination events to a minimum. Accumulation of food residues on structural surfaces can harbor potential pathogenic bacteria and act as continuous culture systems. Air is a potential source of contamination, and *Cronobacter* and *Enterobacter* spp. have been isolated from air filters. Contamination in infant formula production facilities has been previously found in the form of dust, water droplets, and airborne microorganisms. General handling of materials, spray drying, and milling and cleaning operations can create aerosols that disseminate through the plant. Molecular profiling of isolates from production facilities can identify the persistence of clonal strains and key contamination points within the manufacturing environment. This provides a basis to develop and implement continuous quality control and prevention strategies.

Contamination of milk powders by *Enterobacter* spp. may occasionally be due to failures in the pasteurization process or more likely due to postdrying contamination during mixing with other ingredients, packing, and filling. Over three-quarters of raw milk concentrate and 85% of the nonproduct processing line may be positive for Enterobacteriaceae. It is not possible with current technology to eliminate Enterobacteriaceae from a manufacturing plant but effective cleaning-in-place (CIP) strategies and limited passage of personnel into high-risk areas can act as control measures. Sampling protocols should be implemented to monitor plant hygiene and presence of potential pathogens. Reduction in Enterobacteriaceae levels in many factories has been achieved by implementing a policy of systematic dry cleaning when possible. It is critical to maintain a low-moisture environment postpasteurization, and the absence of water prevents proliferation and dissemination of microorganisms. PIF has a low water activity (∼0.2); therefore, this desiccated state limits the survival of many Gram-negative organisms. *Cronobacter* have been previously seen to be very resistant to osmotic stress and drying in comparison to other *Enterobacter* spp.

Ineffective cleaning of the processing equipment promotes the buildup of residues where the bacteria can grow and proliferate and subsequently contaminate the powder. Adhesion of microorganisms and the formation of biofilms are a concern in the food industry. Bacterial biofilms that are difficult to remove via CIP procedures can form within the equipment and be a constant source of contamination. They may compromise food quality and represent a significant public health risk. It is known that several groups of bacteria can attach to surfaces commonly found in the manufacturing environment, such as stainless steel and rubber. Bacterial within a biofilm may be more resistant to disinfectants and sanitizers when compared to bacteria in a planktonic state.

Consumers

Education of end users is an important factor in preventing foodborne illness due to contaminated infant foods. There is an ongoing debate as to the inclusion of warnings on packaging that powdered breast milk substitutes are not sterile products. The FAO/WHO recommends that powdered breast milk substitutes be reconstituted with water at 70 °C to reduce the risk posed by any contaminating *Enterobacter*.

In several outbreaks in hospital settings the feed preparation equipment has been found to be the likely source of contamination. Guidelines on preparation, storage, and feeding times have been issued to professionals to reduce the risk of further outbreaks in NICUs. These include the recommendation that sterile ready-to-use products be used whenever possible and appropriate hygiene and sterilization protocols be in place.

Conclusions and Future Perspectives

The WHO recommends exclusive breast-feeding for up to 6 months and then complementary feeding with continued breast-feeding for 2 years and above. Natural breast milk has been shown to enhance the neonatal gut barrier and protect against infection, diarrheal disease, and also NEC. PIF is used as an alternative to breast milk to provide nutritional requirements in addition to breast-feeding or where breast-feeding is not feasible. PIF constitutes over 80% of the infant formula used worldwide.

The focus to date has been on *Cronobacter* (*E. sakazakii*) in infant formula, with contamination by other *Enterobacter* being given less consideration. *Enterobacter* spp. have the ability to cause infections and have been previously seen to contaminate infant formula. The FAO/WHO categorizes *Cronobacter* and *Salmonella enterica* as Category A organisms with a clear evidence of causality, whereas Category B organisms (causality plausible, but not yet demonstrated) include *E. cloacae* and *E.* (*Pantoea*) *agglomerans*. For organisms that are regularly acquired by vertical transmission during birth or are endemic in the hospital environment, it is less likely that sufficient epidemiological evidence may be found to link cases of infection to powdered breast milk substitutes. However, measures implemented to control *Cronobacter* contamination also reduce the likelihood of the presence of other Enterobacteriaceae.

Understanding of the physiology and survival strategies of *Cronobacter* is an important step in the efforts to eliminate this bacterium from the critical food production environments.

Listeria monocytogenes

E T Ryser, Michigan State University, East Lansing, MI, USA

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Listeria monocytogenes, the causative agent of listeriosis in humans and animals, was first isolated by British researchers at Cambridge University in 1924 from the blood of infected rabbits. These animals exhibited a typical monocytosis, after which the bacterium was named. Although widely recognized as a cause of miscarriage in pregnant women and meningitis, encephalitis, and septicemia in newborn infants and immunocompromised adults, this organism did not emerge as a serious foodborne pathogen until 1985. Unlike most other foodborne illnesses, the outcome of listeric infections can be particularly devastating with a mortality rate of about 20%. During the 1980s, three major dairy-related outbreaks of listeriosis – two in the United States and one in Switzerland – were linked to consumption of pasteurized milk, Mexican-style cheese, and Vacherin Mont d'Or soft-ripened cheese, which together resulted in over 100 fatalities. These outbreaks, combined with a then presumed low oral infectious dose for susceptible individuals, prompted the United States to institute a policy of 'zero tolerance' for *L. monocytogenes* in all cooked/ready-to-eat foods, including dairy products. Since 1985, over 112 Class I recalls have been issued in the United States for *Listeria*-contaminated domestic and imported cheeses with an additional 58 Class I recalls involving unfermented dairy products, principally ice cream, at a financial cost exceeding $120 million. Although *L. monocytogenes* accounted for 13 of 18 (72%) dairy-related Class I recalls issued during 1994 and 1995, only 1 of 36 *Listeria*-related Class I recalls in 2000 involved a dairy product (domestically produced Cheddar cheese). Furthermore, the fact that only 29 *Listeria*-related recalls involving 27 cheeses and 2 other dairy products were issued since 2001 indicates that dairies in the United States and elsewhere have generally taken sufficient measures to minimize *Listeria* contamination within their processing facilities. However, in the United States the availability of Queso Fresco and other soft Mexican-style cheeses that have been illegally prepared from raw milk or have been illegally imported has become an increasing public health concern among the growing Hispanic population.

Characteristics of *Listeria* spp.

The genus *Listeria*, which is included among the coryneform bacteria, contains six species: *L. monocytogenes*, *L. ivanovii*, *L. seeligeri*, *L. innocua*, *L. welshimeri*, and *L. grayi*; the first three species are β-hemolytic on laboratory media containing blood. *Listeria monocytogenes* is the only *Listeria* species that is of public health significance as a foodborne pathogen. *Listeria ivanovii*, widely recognized as pathogenic to domestic livestock, only rarely infects humans as is also true for *L. seeligeri*. *Listeria innocua*, the most commonly isolated species, is nonpathogenic as is also generally true for *L. welshimeri* and *L. grayi*.

Listeria monocytogenes is a Gram-positive, non-spore-forming, facultatively anaerobic, short, rod-shaped bacterium that occurs singly or in short chains. The organism is psychrotrophic, generally growing in nonselective laboratory media at temperatures between 1 and 45 °C with optimal growth occurring at 30–37 °C. However, *L. monocytogenes* strains reportedly can grow at temperatures as low as −0.1 °C in pasteurized milk during extended storage. At 4 °C, growth of *Listeria* is somewhat faster with generation times of 30–40 h. However, the growth rate triples (generation times of 10–13 h) when milk is held at mildly abusive temperatures (8 °C). When incubated at room temperature, broth cultures of *Listeria* exhibit a characteristic tumbling motility, which can be seen microscopically. Colonies on clear laboratory media are small, smooth, and bluish-gray when examined under obliquely transmitted light. Biochemically, all listeriae produce catalase and ferment glucose to acid without producing gas, whereas typical *L. monocytogenes* isolates ferment rhamnose but not xylose. All *Listeria* species hydrolyze aesculin, which leads to a characteristic blackening of commonly used *Listeria*-selective enrichment (e.g., Fraser broth) and plating media (e.g., modified Oxford agar) that contain aesculin and ferric ammonium citrate. In addition to a wide range of commercial biochemical-, antibody-, and DNA-based test kits for identifying *L. monocytogenes*, several chromogenic plating media have become available that can differentiate *L. monocytogenes* from other *Listeria* species.

Of particular concern to the dairy industry is the ability of *L. monocytogenes* to tolerate environmental extremes found in dairy processing facilities, grow at pH 4.3–10.0, grow in the presence of up to 10% NaCl (a_w 0.92), survive for several months in refrigerated 25.5% NaCl brine tanks, and develop limited tolerance to heat and acid. Based on somatic (O) and flagellar (H) antigens, 13 different *L. monocytogenes* serotypes have been identified. Serotype 4b has been most commonly associated with outbreaks of human illness followed by serotypes 1/2b and 1/2a, with most of the major dairy-related outbreaks traced to just a few strains of serotype 4b that have now been well characterized by various genetic typing methods including pulsed-field gel electrophoresis (PFGE) and ribotyping.

Symptoms of Listeriosis

Listeriosis, the disease caused by *L. monocytogenes*, is a relatively rare infection that most often occurs in three well-defined risk groups, namely pregnant women, newborn infants, and immunocompromised adults, with the last group including the elderly and individuals with predisposing conditions such as cancer, organ transplants, cirrhosis of the liver, and HIV/AIDS infections. Approximately 2500 cases occur annually in the United States, with 1–4 cases per 10^6 population reported in most developed countries. Unlike other more common foodborne illnesses caused by *Campylobacter* and *Salmonella*, listeriosis has a mortality rate of approximately 20%, making it among the deadliest of the foodborne diseases with an estimated annual cost of $2.33 billion in the United States. In addition to host susceptibility, development of listeriosis in humans is also affected by gastric acidity, inoculum size, and variations in virulence between different strains of *L. monocytogenes*. Despite repeated exposure of the general population to *Listeria* through the food supply, individuals not included in the three well-defined risk groups seldom develop invasive listeriosis, with healthy individuals rarely infected. However, a far less severe form of noninvasive listeriosis characterized by symptoms of gastroenteritis has also been described, including one well-documented outbreak traced to highly contaminated chocolate milk. Based on several recent risk assessments, ingestion of foods containing $>10^6$ organisms g^{-1} is now presumed to be responsible for the majority of invasive listeriosis cases among susceptible individuals.

Invasive listeriosis in immunocompromised adults frequently leads to meningitis, encephalitis, or septicemia. Symptoms that develop suddenly after an initial incubation period of 2–70 days include severe headache, dizziness, stiff neck or back, incoordination, and other disturbances of the central nervous system. Without proper antibiotic therapy, approximately 20% of those infected will die, with some survivors developing permanent neurological complications. In pregnant women, *L. monocytogenes* produces a mild flu-like illness characterized by sudden chills, fever, sore throat, headache, dizziness, lower back pain, discolored urine, and occasionally diarrhea. While expectant mothers almost invariably recover without complications, infection of the fetus can result in miscarriage, stillbirth, or premature delivery of an infant with perinatal septicemia – a severe infection of the respiratory, circulatory, and central nervous systems that can either terminate fatally or lead to permanent mental retardation.

Two factors, namely the growth of *L. monocytogenes* as an intracellular pathogen within macrophage cells of the spleen and liver and the inability of many antibiotics to effectively penetrate the blood–brain barrier, complicate treatment of listeric infections. Hence, a favorable prognosis depends on rapid diagnosis and appropriate antibiotic therapy, with oral administration of large doses of amoxicillin together with an aminoglycoside (e.g., gentamicin) for 2–4 weeks now the recommended treatment.

Outbreaks

The oral route for listeriosis was established from animal feeding studies conducted during the 1920s. However, evidence for *L. monocytogenes* as a human foodborne pathogen did not emerge until the 1950s when a sharp increase in stillbirths was observed among pregnant women in post–World War II Germany who consumed raw milk, sour milk, cream, and Cottage cheese (**Table 1**).

The eventual isolation of identical *L. monocytogenes* serotypes from a mastitic cow and stillborn twins whose

Quebec, Canada	2002	17	Raw milk cheese
Quebec, Canada	2008	22	Raw milk soft cheese

mother consumed the same raw milk before delivery confirmed raw milk as the source of infection. Despite the presence of *L. monocytogenes* in about 2.5–5% of the raw milk supply from the United States and most other developed countries, current pasteurization practices are sufficient to destroy *Listeria* in raw milk. Few additional cases have been traced to raw milk since most milk is now pasteurized before consumption to eliminate *Listeria* and other pathogens.

In 1981, the status of *L. monocytogenes* as a foodborne pathogen began to change following a major outbreak in the Maritime Provinces of Canada that was traced to consumption of contaminated coleslaw. Two years later, one particular brand of pasteurized milk in the United States was epidemiologically linked to 42 adult and 7 infant cases of listeriosis in Massachusetts. Fourteen patients died, giving a mortality rate of 29%. Inspection of the milk-processing facility failed to uncover any evidence of improper pasteurization or postpasteurization contamination. Although the dairy factory received milk from farms on which veterinarians diagnosed several cases of bovine listeriosis during the outbreak, *L. monocytogenes* was never recovered from the incriminated milk, which in turn raises questions concerning the role of pasteurized milk in this outbreak. In 1994, an unusual outbreak was reported in the United States in which consumption of pasteurized chocolate milk was directly traced to 66 cases of illness in Illinois, Wisconsin, and Michigan. Unlike previous outbreaks, symptoms of gastroenteritis predominated, with only four individuals requiring short-term hospitalization. Postpasteurization contamination of the chocolate milk followed by repeated episodes of temperature abuse allowed this atypical strain of *L. monocytogenes* serotype 1/2b to attain populations of 10^8–10^9 cfu ml^{-1} in the milk at the time of consumption. Except for one additional outbreak recently traced to consumption of butter in Finland, repeated attempts have generally failed to confirm culturally other unfermented dairy products, including fluid milk and ice cream, as vehicles of listeric infection.

Ingestion of *Listeria*-contaminated cheese has been more commonly linked to listeriosis, with seven major outbreaks and numerous sporadic cases having been reported. The first and largest of these outbreaks occurred in the United States in the Los Angeles area during the first half of 1985 and involved an estimated 300 cases. Consumption of California-made Jalisco brand Mexican-style cheese contaminated with *L. monocytogenes* serotype 4b was linked to 142 listeriosis cases in Los Angeles County alone, including 48 deaths (mortality rate of 34%). The contaminated cheese was subsequently recalled nationwide. Factory records indicated that raw milk may have been intentionally added to pasteurized milk used in cheesemaking. Although not isolated from the incoming raw milk supply, the epidemic strain was widespread in the factory environment, which also suggests ample opportunity for postpasteurization contamination.

In the second of these outbreaks, consumption of Vacherin Mont d'Or – a soft surface-ripened cheese – contaminated with *L. monocytogenes* serotype 4b was traced to 122 listeriosis cases in Switzerland from 1983 to 1987. Thirty-four patients died, giving a mortality rate of 28%. Two different epidemic-associated strains of *L. monocytogenes* serotype 4b were isolated from patients and the incriminated cheese as well as from the wooden shelves and brushes used in 40 different cheese ripening cellars. Surface samples from the cheese contained the epidemic strain at levels of 10^4–10^6 cfu g^{-1}, thus suggesting both contamination and growth of *L. monocytogenes* on the cheese surface during ripening. The outbreak ceased after installation of metal ripening shelves and thorough cleaning/sanitizing of the ripening rooms.

During the mid-1990s, two major dairy-related listeriosis outbreaks in France were traced to different varieties of soft surface-ripened cheese. In 1995, 20 individuals including 11 pregnant women developed listeric infections after consuming Brie de Meaux cheese that was prepared from raw milk. Unlike previous outbreaks, no geographic clustering was observed, with cases reported in 8 of 22 French regions. Isolates from patients were identical to those from the incriminated cheese, with this organism likely present in the raw milk used for cheesemaking. Two years later, 14 cases of listeriosis were linked to consumption of Pont l'Évêque cheese manufactured in Normandy. The implicated raw milk cheese contained *L. monocytogenes* serotype 4b at a level of >1000 cfu g^{-1}.

Improper manufacture of soft and semihard cheese is now responsible for the majority of both outbreak and sporadic cases that have been traced to dairy products, with consumption of such cheeses best avoided by high-risk individuals. One 2002 outbreak in Quebec, Canada, involving 17 cases of listeriosis (5 pregnant and 12 nonpregnant adults) was linked to consumption of commercially produced raw milk soft and semihard cheese that had undergone less than the legally required 60 days of aging. In late August and September of 2008, 22 cases of listeriosis (7 pregnant and 15 nonpregnant adults), including 1 adult fatality, 1 stillbirth, and 6 premature deliveries, were again traced to consumption of several soft French-style cheeses that were commercially produced from raw milk in Quebec, Canada.

In the United States, concerns surrounding consumption of soft cheese have generally focused on soft, unripened Mexican-style varieties that are frequently homemade and either illegally produced from raw milk in the United States or illegally imported from Mexico. In 2000, 13 cases of listeriosis including 11 perinatal infections and 5 stillbirths were traced to soft Mexican-style cheese that was locally prepared from raw milk and then sold either door-to-door or through small markets or street vendors to Mexican immigrants in North Carolina. Unlike the previous outbreaks, this epidemic strain of *L. monocytogenes* serotype 4b exhibited a rarely seen PFGE profile. Another similar but smaller outbreak in 2003 was also traced to raw milk Queso fresco cheese that was illegally produced in Texas. These outbreaks along with a growing number of sporadic cases among Hispanics have prompted renewed efforts to curtail the illegal importation, production, and sale of such raw milk cheeses in the United States.

Sources

Primary reservoirs for *Listeria* include soil, feces, water, and decaying vegetation. Consumption of aerobically spoiled and improperly fermented silage having a pH >4.5 has been routinely linked to listeriosis outbreaks in ruminant farm animals. Numerous wild and domestic animals, including cows, sheep, and goats, are susceptible to listeric infections, with large numbers of healthy asymptomatic carriers excreting high numbers of *L. monocytogenes* in their feces. Long-term survival of *Listeria* under adverse environmental conditions typically leads to further spread of this pathogen through the food chain. The hardy nature of this ubiquitous psychrotrophic food-borne pathogen, along with its ability to colonize, multiply, and persist in food production facilities for months or years, makes *L. monocytogenes* a major threat to manufacturers of dairy products as well as ready-to-eat meat and poultry products, smoked fish, prepared sandwiches, and delicatessen products, all of which have been frequently found to harbor *Listeria*. Being unable to survive pasteurization, this pathogen most often enters dairy products and other ready-to-eat foods as a postpasteurization contaminant. While most frequently isolated from floor drains, conveyor belts, and areas with condensate, *L. monocytogenes* has also been recovered from cheese vats and filling machines, which lends further support to this pathogen being a postpasteurization contaminant.

Incidence and Behavior in Milk and Dairy Products

Dairy cattle, sheep, and goats can intermittently shed *L. monocytogenes* in their milk at levels of up to 10^4 cfu ml^{-1} as a result of *Listeria*-related mastitis, encephalitis, or abortion. Milk from severely infected cows is unlikely to reach consumers due to a variety of overt symptoms, including excessive salivation, inability to eat or drink, impaired locomotion, and 'circling disease', all of which are related to disturbances of the central nervous system. However, mildly infected and apparently healthy animals can shed *L. monocytogenes* in their milk for many months and are thus of far greater public health concern. Composite results from numerous bulk tank surveys conducted since 1983 indicate that 2.5–5% of the North American and European raw milk supply can be expected to contain low levels (i.e., <10 cfu ml^{-1}) of *L. monocytogenes* at any given time. Hence, proper refrigeration is important, given several reports indicating that *L. monocytogenes* populations in naturally contaminated raw milk can increase 1000-fold after 4 and 10 days of storage at 10 and 4 °C, respectively.

Listeria monocytogenes is more thermally tolerant than most other non-spore-forming foodborne pathogens. However, current vat (63 °C for 30 min) and high-temperature–short-time pasteurization (72 °C for 15 s) practices will ensure total destruction of *L. monocytogenes*. Despite the ability of *L. monocytogenes* to attain populations of 10^6 cfu ml^{-1} in commercial skim milk, whole milk, chocolate milk, and whipping cream after 8 days of storage at 8 °C (a not uncommon temperature of home refrigerators), this organism has been rarely detected in pasteurized fluid milk products. While *L. monocytogenes* has been occasionally recovered from commercially produced butter with survival up to 70 days being reported in butter prepared from inoculated cream, this pathogen is a far more frequent postpasteurization contaminant of ice cream. Since May 1986, 47 of 58 *Listeria*-related Class I recalls issued in the United States for unfermented dairy products involved ice cream, ice cream novelties, and related frozen desserts containing very low levels of *L. monocytogenes*. Increased prevalence of this pathogen in frozen rather than fluid dairy products coincides with the relatively complex handling of such products, particularly ice cream novelties, during manufacture and packaging. However, given the presumed low levels of contamination, the inability of *Listeria* to grow in frozen dairy products, and the recall of over 3.1 million gallons of ice cream without incident, consumption of such products does not appear to pose a major public health threat.

As one might surmise from the aforementioned outbreaks, *L. monocytogenes* is a more frequent contaminant of cheese, most notably soft surface-ripened varieties such as Brie, Camembert, and certain Mexican-style varieties, which support growth of the organism during cheese ripening. Since 1986, 81 Class I recalls were issued in the United States for domestically produced cheese, principally Mexican-style cheese, contaminated with *L. monocytogenes*. During this same period, 31 imported cheeses, including French Brie, Danish Esrom, and Anari (goat's milk cheese from Cyprus), were also recalled. Results from extensive surveys suggest that about 1–5% of cheeses produced in Europe, primarily soft and semisoft varieties surface-ripened by mold or bacteria, may contain *L. monocytogenes*, with this pathogen seldom found in aged hard cheeses (e.g., Cheddar) or cheeses that undergo severe heat treatments during manufacture (e.g., Cottage, Mozzarella, Parmesan, Swiss, processed cheese).

Following the 1985 outbreak in California involving Mexican-style cheese, work was initiated to assess the behavior of *L. monocytogenes* during the manufacture and storage of yogurt, buttermilk, and a wide range of cheeses, with most of these studies describing the outcome of preparing these products from artificially contaminated pasteurized milk. *Listeria* populations generally increase <10-fold when milk is fermented with a traditional starter culture containing mesophilic or thermophilic lactic acid bacteria at an inoculum level of 1%, with growth ceasing at pH <5.2. In one of several studies that examined postpasteurization contamination, *L. monocytogenes* persisted an average of 3 weeks in refrigerated cultured buttermilk and yogurt inoculated to contain 10^3–10^4 cfu g^{-1} of *L. monocytogenes*. Regardless of the cheese variety manufactured, physical entrapment of *Listeria* in the curd during milk coagulation results in a 10-fold increase in numbers. Thereafter, the behavior of *Listeria* is dictated by the manufacturing steps for the particular cheese. The extent of acid development and curd cooking during cheesemaking along with pH, salt content, moisture content (water activity), and type/extent of ripening will determine the ultimate fate of *L. monocytogenes* in the final product. Growth of *Listeria* in cheese is primarily confined to soft/semisoft varieties ripened by mold (e.g., Brie, Camembert, Roquefort) or bacteria (e.g., French cheeses, Brick) and certain Mexican-style cheeses (Queso Fresco) with populations increasing to >10^6 cfu g^{-1} as the cheese attains a pH >6.0 during ripening (**Table 2**).

Although *L. monocytogenes* is generally unable to grow in cheeses having a pH <5.2, it can survive in many such cheeses for weeks or months and has even been recovered from experimentally produced 434-day-old Cheddar cheese. These findings raise legitimate concerns regarding the adequacy of the mandatory 60-day holding period at >1.7 °C to completely inactivate *L. monocytogenes* (and other pathogens) in Cheddar and other hard cheeses that can be legally prepared from raw milk or milk subjected to subpasteurized heat treatments. However, barring contamination during packaging, cheeses such as Cottage and Mozzarella that undergo severe heat treatments during manufacture should be free of *Listeria.*

Control

Given the widespread distribution of *Listeria* in the environment, control of *Listeria* must begin at the farm level with attention given to good animal husbandry practices, use of only high-quality feed/silage, hygienic milking practices, and proper refrigeration to minimize growth of the pathogen during bulk tank storage of milk. Current vat and high-temperature–short-time pasteurization practices are the only commercially practical means for destroying *L. monocytogenes* in raw milk. Thus, barring postpasteurization contamination, properly pasteurized fluid milk products will be free of *Listeria.* Well-designed sanitation programs that include weekly sampling for *Listeria* in problem areas within the factory are essential if the incidence of this pathogen is to be minimized in the production facility and in the finished product. Postpasteurization contamination most frequently occurs during extruding, filling, and packaging operations when the product is exposed to airborne contamination and

Introduction

The genus *Mycobacterium* is a member of the Actinobacteria. Mycobacteria are aerobic, acid-fast, nonmotile (with the exception of *Mycobacterium marinum*), nonspore forming bacilli (although recent findings indicate that some strains such as *M. marinum* may have the ability to form spores), which are widely distributed in the environment. There are over 100 different species of mycobacteria, most of which are nonpathogenic to humans and are found mainly in soil and water. However, tuberculosis and leprosy, two of the most notorious diseases known to man, are caused by members of this genus. While they are generally considered to be Gram positive, this is not strictly true. The unique cell envelope of mycobacteria contains a very high proportion of lipids that give the members of this genus unique characteristics such as resistance to acid, alcohol, and chlorination. It is the thick, waxy, lipid-rich cell wall that gives mycobacteria their characteristic pink/red color following acid-fast staining procedures (e.g., Ziehl-Neelson, see **Figure 1**). Although most mycobacteria live in soil, water (including chlorinated tap water supplies), and foodstuffs, some members of the genus are not free-living bacteria but are instead found living in animal hosts. These include *M. tuberculosis* and *M. bovis*, both of which are pathogens in both humans and cattle.

Mycobacteria consist of both fast- and slow-growing members, with the quicker-growing species usually being nonpathogenic saprophytes (feeding on dead or decaying organic matter) and the majority of the pathogenic strains belonging to the slower-growing species. Mycobacteria that form colonies visible to the naked eye on suitable substrates within a period of seven days are generally classified as fast-growing species (e.g., *M. smegmatis*), while species that take longer than this are considered to be slow growers (e.g., *M. tuberculosis*). From a clinical perspective, mycobacteria are classified into two groups: the *M. tuberculosis* complex (e.g., *M. tuberculosis*, *M. bovis*, *M. africanum*) and the nontuberculous mycobacteria (e.g., *M. avium*, *M. intracellulare*, *M. avium paratuberculosis*).

Mycobacterium tuberculosis Complex

The members of the *Mycobacterium tuberculosis* complex (MTC) (with the exception of strain BCG) are all pathogenic and capable of causing a deadly disease of the pulmonary system, tuberculosis, in a variety of hosts. Its members include *M. tuberculosis*, *M. bovis*, *M. africanum*, *M. microti*, *M. canetti*, *M. caprae*, and *M. bovis* Bacille Calmette-Guérin (BCG). Strains of the MTC are approximately 99.9% similar at a genetic level but there are distinct differences phenotypically with regard to the level of their pathogenicity. Approximately one-third of the world's population is infected with mycobacteria capable of causing tuberculosis, but most of these are asymptomatic and will never develop the disease. Nonetheless, tuberculosis is a leading global cause of death due to infectious disease. Although primarily a disease of the lungs, infections of the gastrointestinal tract are not uncommon. All members of this group are reportable to public health authorities, although many laboratories are not equipped to distinguish between the different species. As a result the exact number of tuberculosis cases caused by each species is not available.

Tuberculosis has been prevalent in human society since ancient times. Large-scale outbreaks such as the White Death have been recorded throughout history. With the development of antimycobacterial antibiotics, tuberculosis disease was thought to be under control. However, a resurgence in tuberculosis has been seen in recent times, especially among immunocompromised individuals, such as those affected by HIV (AIDS).

Mycobacterium bovis

The most commonly reported mycobacterial infection in cattle is caused by *M. bovis*. It causes bovine tuberculosis characterized by the development of granulomatous lesions in the lung tissue, lymph nodes, intestine, and other tissues. The primary hosts of *M. bovis* are cattle species, but it has the ability to infect a very wide range of mammalian hosts such as humans, deer, goats, pigs, dogs, cats, and badgers. *M. bovis* can cause tuberculosis in humans, with AIDS patients being the most at-risk group. Infection usually occurs through ingestion of contaminated milk, especially raw milk. Upon oral infection the bacterium can cause localized infections in the gut, and through infection of macrophages can establish infections of the lymph nodes and disseminate throughout the body, which can also lead to pulmonary disease. Symptoms of *M. bovis* infection include weight loss, fever, and general weakness. It is thought to have

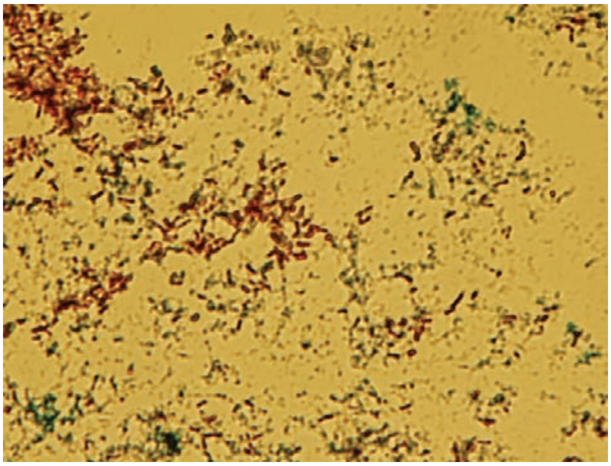

Figure 1 Acid-fast stain of *Mycobacterium avium paratuberculosis* (MAP). MAP cells appear stained red.

originally derived from an ancestral soil-dwelling saprophyte that lived in cow dung.

It has been estimated that *M. bovis* accounts for approximately 3.1% of all human tuberculosis disease with the vast majority being nonpulmonary infections. Infection is greatest in developing countries; *M. bovis* tuberculosis is quite rare in developed countries, accounting for less than 1% of infection.

Members of the MTC have a pattern of pathogenesis distinct from most other bacteria. Unless a host has an underdeveloped or compromised immune system the mycobacteria will not initially cause disease. Upon entering the body, bacteria encounter macrophages, cells of the immune system that engulf and kill bacteria. Mycobacteria can survive this process and replicate inside the macrophage. They can subsequently exist in a quiescent state for many years. This is referred to as latent infection. In 90% of the cases of infection with *M. tuberculosis*, the infection will not lead to disease in the host. However, in the remaining 10% of infected individuals the mycobacteria can reactivate and cause disease. This leads to active disease, and it is at this point that individuals in turn become infective. The reasons for reactivation of the mycobacterium are unknown, but it is more likely to occur in an individual who is malnourished or whose immune system has become impaired. This can be due to infection with the human immuno deficiency virus (HIV), which can cause a breakdown in the capability of the immune system to fight disease; old age; or the use of corticosteroids which inhibit the immune system. In the developed world mortality from tuberculosis is approximately 10% of those with active disease; in the developing world this percentage is much higher.

Mycobacterium tuberculosis

This bacterium is the etiological agent of most tuberculosis in humans. Although pulmonary infection is more common with *M. tuberculosis*, intestinal infection can also occur and is more common in immunocompromised hosts. Any part of the gastrointestinal tract can become infected. *M. tuberculosis* shows a strong tropism for lung tissue, and when injected intravenously it can translocate to the lungs and cause pulmonary infection. It is primarily associated with human disease, although it can also colonize cattle and a wide variety of other mammals. *M. tuberculosis* is thought to have evolved from *M. bovis*, gradually developing into a different species. Symptoms of intestinal infection include ulcers, thickening of the bowel wall, weight loss, diarrhea, and fatigue. Infection from dairy products usually occurs due to the consumption of contaminated, unpasteurized milk or cheese.

Mycobacterium africanum, M. microti, M. canetti, and *M. caprae*

M. africanum is commonly found in West African countries and, although it is rarely identified outside of this region, it has been detected in a small number of tuberculosis patients worldwide. Both humans and cattle are susceptible to colonization and infection. Its contribution to tuberculosis disease in the above regions is thought to be up to 50%. While its infectivity in humans is comparable to that of *M. tuberculosis*, the extent of its virulence is unknown. Again, it causes disease in a large number of HIV-positive patients. *M. microti* primarily infects small rodents, in which it causes tuberculosis. It has also been reported to be present in cattle. It very rarely causes disease in humans but has been reported both in immunocompetent and in immunosuppressed patients. *M. canetti* was first described in 1969. It grows more quickly than *M. tuberculosis* and forms smooth, shiny colonies. Infection in humans has only rarely been reported. Locations include the Horn of Africa, France, Madagascar, and French Polynesia. It is unknown if this species can infect cattle and cause infection through contaminated milk. *M. caprae* is the most recent addition to the MTC, and was only identified in 1999. It has been isolated from symptomatic cattle and very infrequently from humans.

Nontuberculous Mycobacteria

Nontuberculous mycobacteria (NTM) consist of species not part of the *M. tuberculosis* complex or *M. leprae.* They are also known as 'mycobacteria other than tuberculosis'

(MOTT). These bacteria are usually saprophytic but they can be opportunistic pathogens and can cause deadly infections in a susceptible host. Unlike in *M. tuberculosis* complex bacteria, person-to-person contact is not the primary source of infection. Infection normally occurs through contact with the bacteria from environmental sources via ingestion, inhalation, or through exposed wounds.

Detection of infections of humans by these bacteria has increased in recent years for several reasons. Better diagnostic and culturing techniques have allowed for better isolation of these bacteria from infected individuals; there has also been a rise in the numbers of susceptible hosts (such as individuals suffering from AIDS) which has led to this increased infection. In contrast to *M. tuberculosis* complex infections, NTM infections are not reportable to public health bodies, possibly resulting in an underestimation of the extent to which they cause disease.

NTM can cause both local infections and body-wide disease depending on the strain, host physiology, and point of entry. NTM infections were initially thought to cause disease only in the immunocompromised, but they are now also recognized as being capable of causing disease in immunocompetent hosts. They can cause a wide range of diseases, which can be pulmonary, intestinal, and disseminated throughout the host. NTM have been found in both raw milk and pasteurized samples. These include the following:

M. avium complex
M. avium paratuberculosis
M. ulcerans
M. fortuitum
M. gordonae
M. marinum
M. kansassii
M. scrofulaceum

Mycobacterium avium Complex

The *Mycobacterium avium* complex (MAC) consists of a group of closely related mycobacteria that are difficult to identify and differentiate. The members are very similar at a genetic level but they vary greatly in their host tropisms, disease phenotypes, and pathogenicity. The MAC consists of both saprophytes and opportunistic pathogens. Members of the MAC include *M. avium*, *M. avium avium*, *M. intracellulare*, *M. avium paratuberculosis*, *M. haemophilum*, and *M. avium hominis.*

Symptoms of a MAC infection can include the following:

- Fever
- Abdominal pain
- Weight loss
- Fatigue
- Diarrhea
- Night sweats

These mycobacteria are capable of survival and replication under a wide variety of environmental stresses which include large variations in temperature, low pH, and chlorination. Members of the MAC are slow-growing and usually nonpigmented. MAC bacteria are common in the environment and can cause infection in a susceptible host when inhaled or swallowed. Diarrhea and abdominal pain are associated with gastrointestinal involvement. Members of the MAC are pathogens of low virulence, but infections are common in immunocompromised individuals. In AIDS the risk of infection by these bacteria is inversely related to the CD4 count of a patient. Unlike other opportunistic infections in AIDS, infection by members of the MAC is not thought to be a result of the reactivation of a latent infection but rather a new infection. Infections by members of the MAC are difficult to eradicate with antibiotics and many are resistant to antituberculosis antibiotics.

Mycobacterium avium paratuberculosis

Mycobacterium avium paratuberculosis (MAP) was first described in 1895 and originally named Johne's bacillus. It is a member of the MAC and is very similar to the other members of this group. Unlike other members of MAC and NTM, it is a specific agent of intestinal inflammation in a wide variety of animals. It is the causative agent of Johne's disease, which is primarily a disease of ruminants but which can also be seen in some nonruminants such as birds, foxes, dogs, and some primates. It causes an intestinal infection that results in a chronic wasting disease that ultimately ends in the death of the animal. Infection usually occurs years before the animal displays symptoms of the disease. Chronic inflammation may emerge after a long latent period. This emergence of disease has been linked to stress on the animals and hormonal changes. Hundreds of millions of dollars are lost annually due to infection by MAP on account of decreased milk yields and culling of infected animals.

Like many mycobacteria, it is capable of surviving and replicating inside macrophages. The principal route of infection is through ingestion, with calves being at greatest risk. MAP can be passed from mother to calf in both the colostrum and milk, and *in utero* transmission of MAP has also been observed. MAP bacteria are also shed intermittently in high numbers in the feces of the infected cattle, contaminating bedding, pasture, and water sources. However MAP displays a strong tropism to the intestine and will cause intestinal inflammation if experimentally administered intravenously or subcutaneously. The primary symptoms of Johne's disease include diarrhea, weight loss, and decreased milk yield. Unlike all other mycobacteria, MAP requires the presence of mycobactin, an iron chelating agent, for growth in laboratory media.

Detection of the incidence of MAP in cattle herds has risen in the mid-twentieth century, which is possibly due to better laboratory cultivation techniques. Cattle displaying Johne's symptoms are usually culled to prevent further infection in the herd. Subclinically infected cattle are seen to secrete MAP in their milk, exposing the young with an underdeveloped immune system to the pathogen at an early age. The presence of MAP has been demonstrated in pasteurized retail milk, perhaps as a result of postpasteurization contamination. Some studies have shown a high degree of tolerance in MAP toward the pasteurization process, unlike in *M. tuberculosis* or *M. bovis*, which are effectively killed during standard high temperature short time (HTST) pasteurization. An increase in the hold time in HTST pasteurization has been shown to have a greater killing effect on MAP compared to an increase in temperature. MAP has also been shown to be capable of surviving in some cheeses for long periods in the environment. Amoebae have been shown to be a host in pastureland and allow for replication outside of a bovine host.

MAP has been linked to Crohn's disease, a gastrointestinal disorder in humans that is currently thought to be autoimmune in nature. Symptoms of Crohn's disease include weight loss, abdominal pain, diarrhea, and ileac obstruction. This link has proven to be controversial and no firm consensus has been reached on the matter. The link was first postulated in the early twentieth century, when the first comparisons were made between the pathology and symptoms of Crohn's and Johne's diseases (see **Table 1**). MAP strains have been detected and isolated from the blood, feces, and tissue biopsies of patients with Crohn's disease. MAP bacteria isolated in this way have been shown to cause Johne's disease in goats after experimental infection.

Table 1 Comparison of the major symptoms of bovine Johne's disease and Crohn's disease

	Johne's disease	*Crohn's disease*
Cause	MAP	Unknown

GI, Gastro intestine; MAP, *Mycobacterium avium paratuberculosis*.

Other Nontuberculous *Mycobacterium* of Relevance to Dairy Production

A number of other NTMs are capable of causing skin infections and opportunistic wound infections. Several mycobacterial species have been reported to cause mastitis in cattle, including *M. chelonei*, *M. fortuitum*, *M. phlei*, and *M. smegmatis*. Infections of this nature in cattle can result in the pathogen contaminating the milk, leading to possible infection of young calves. The recently identified strain *M. avium silvaticum* has been suspected of causing chronic enteritis in calves, possibly being spread from cow to calf *via* contaminated milk. Other species of NTM have been isolated from raw milk products from cattle not suffering from any clinical infection. *M. flavescens*, *M. gordonae*, *M. abscessus*, *M. mucogenicum*, *M. marinum*, *M. terrae*, *M. kansassii, M. haemophilum*, and *M. agri* as well as several unidentified species have all been observed. Not much is known about how infectious these mycobacteria are when orally ingested by humans, but several have been shown to cause infections in immunocompromised individuals, especially transplant patients on immunosuppressing agents and those with AIDS. The NTM group has doubled in number since 1990, probably due to the increasing use of modern genetic techniques and improvements in mycobacterial culture techniques. Though the virulence of these organisms is generally considered very low, they can still play a role in infections of immunocompromised individuals through contaminated milk supplies.

Mycobacterial Contamination of Milk

Milk supplies can become contaminated at many stages of milk collection and processing. Cattle infected with pathogenic strains can secrete bacterium in milk itself. The bacterium can also be shed in huge numbers in the feces of the animal, leading to contamination of the external surface of the udder due to contact with the feces itself or with contaminated bedding. Washing of the udders before milking has been shown to decrease bacterial contamination; however, some contamination still does occur. Contamination can also take place postpasteurization. Some mycobacterial pathogens such as *M. tuberculosis* and *M. bovis* have been shown to be capable of establishing infections at very low doses. Most data pertains to pulmonary infection, however, and the numbers required to establish intestinal infection are unknown.

Infection within the Herd

Cattle can become naturally infected with mycobacteria through the respiratory or oral route. Infection via the respiratory system is the most common route in cattle, especially in the context of intense farming. Oral infection is more common in suckling calves. Cows can shed the bacterium in their colostrum and milk, or teats can become contaminated with feces, thus passing it on to calves. Apart from infection from inside the herd, a number of other avenues exist for the transmission of this disease.

Drinking water can easily become contaminated and lead to infection. Mycobacteria survive quite well in treated water supplies. Apart from oral infection, aerosols could also lead to respiratory infection.

Many mycobacterial species have been detected in the milk of the infected cattle, including *M. bovis* and MAP. Other sources of mycobacteria include the urine and feces of infected cattle. As a result bedding, pastures, and water can easily become contaminated. Shedding can be intermittent and occurs in sublinically infected cattle. The minimum dose of mycobacteria required to establish a lasing infection in cattle varies from species to species, and also depends on the route of infection and the health of the animal. Infected cattle are most likely to have been repeatedly exposed to a variety of doses.

Prevalence of Mycobacteria in Dairy Herds

Cattle are susceptible to colonization and infection by a wide variety of mycobacteria, *M. bovis* being the most commonly reported species. Prevalence varies depending on a number of factors, including the following:

- eradication programs
- farming policy
- wildlife reservoirs of mycobacterium
- geographical location

Eradication programs in industrialized countries have greatly reduced the prevalence of *M. bovis* infection in both animals and humans. This is a result of the monitoring programs that identify and eliminate the infected cattle, vaccination, and widespread pasteurization of milk. Farming policy can greatly impact *Mycobacterium* levels. Regulation of animal movement, animal identification systems, and coordination between agricultural and health authorities all play a part in the control of disease spread. Conversely a lack of these systems or breakdown in established systems can lead to an increased prevalence in the national herd of a country. As already mentioned, mycobacterial species have wide host ranges, and apart from infecting domesticated animals they can also infect wildlife. Other species can act as reservoirs of infection, reintroducing the bacterium to pasturelands and water supplies. Reported reservoirs of mycobacteria include badgers, possums, ferrets, wild deer, and assorted domesticated animals. Control measures have at times focused on this area as a means to control spread of mycobacterial disease. Culling of infected wildlife has been attempted in several species with varying degrees of success. Culling of badger populations has been shown to decrease levels of *M. bovis* in cattle inside the culling regions. However, in some instances this was seen to lead to an increased infection of cattle in adjacent regions.

Mycobacterial infection in humans due to contamination of dairy supplies has become less relevant in developed countries. With improvements in milk hygiene and mass pasteurization of dairy supplies, these countries have a vastly decreased mycobacterial load as compared to the prepasteurization era. These improvements in conjunction with vaccination, monitoring, and eradication programs for the tuberculosis complex bacterium have led to retail milk supplies that are safe from pathogens such as *M. bovis* and *M. tuberculosis*. A small percentage of the dairy in developed countries still involves making use of raw milk in the cheese-making process. Although the process itself can kill mycobacteria, this alone would not be sufficient to protect the consumer. If the process is coupled with effective monitoring and control programs the risk is greatly reduced. Even though the monetary cost of such surveillance is high, it is essential to safeguard human health and consumer confidence. This holds true for the majority of the NTM group of mycobacteria. However, the potential zoonotic capability of MAP continues to be a possible threat to the dairy industry. Its possible resistance to pasteurization process is a cause for concern should a link between MAP and Crohn's disease be proven. Even without the link to Crohn's disease, MAP still represents a substantial danger to economically important farmed animals through its presence in milk.

The main danger to human health as a result of mycobacterial contamination of milk supplies lies in the developing world where pasteurization is not practiced to as great an extent as is common in the developed world. Infections by mycobacteria of importance to human health are higher in cattle in these regions due to a lack of regulation in the industry coupled with a lack of effective monitoring and control programs. In the developed world the incidence of AIDS infection has remained low in the general population. However, this is not the case in the developing world, where the numbers of infected individuals have been seen to rise steadily. This, coupled with malnutrition, exacerbates the problem of mycobacterial disease in these countries.

Culture and Identification of *Salmonella* in Milk and Dairy Products

Different methods have been used for the isolation and identification of *Salmonella* bacteria in milk and dairy products. A standard cultural procedure is the ISO 6785:2001 method of the International Organization for Standardization whereby 25 ml of milk or milk product is preenriched in 225 ml of buffered peptone water (BPW), incubated for 16–20 h at 37 °C, after which 0.1 ml of the preenriched BPW is added to 9.9 ml of prewarmed Rappaport Vassiliadis (RV) selective enrichment broth and incubated at 42 °C for 20 ± 2 h and then plated onto selective agars for determination of the presence or absence of *Salmonella*. Presumptive *Salmonella* isolates are further confirmed by biochemical testing and serologically by typing with poly- and monospecific *Salmonella* somatic and flagellar antisera. Polymerase chain reaction (PCR)-based methods are increasingly used to detect the presence of DNA sequences, such as a part of the *invA* or *spaQ* gene (both required for invasion) located within the *Salmonella* Pathogenicity Island (SPI) 1 or the *ttrRSBCA* gene complex (required for tetrathionate respiration) located adjacent to the SPI 2. These genes are specific for nearly all *Salmonella* serovars. The cultural and identification methods employed have a significant impact on the percentage of samples that test positive for the presence of *Salmonella* or a DNA sequence thereof. An advantage of cultural methods is that an isolate is obtained that can be further examined for characteristics including the phage type (PT), antimicrobial susceptibility, the presence of plasmids, and the plasmid profile; the presence of virulence and other genes; and the pulsed field gel electrophoresis (PFGE) pattern. Determination of the PFGE pattern is commonly done in the case of outbreaks to determine if the isolates can be traced to the same source or sources and to direct the institution of control and preventative measures. An advantage of PCR-based methods is that they have attained a high level of sensitivity and specificity and often result in a higher percentage of samples that are identified as contaminated with *Salmonella* than the cultural methods.

Incidence of *Salmonella* in Milk and Dairy Products

Raw or Nonpasteurized Milk

Raw milk may contain a variety of food-borne pathogens including *Salmonella* spp., verotoxigenic *Escherichia coli* (VTEC), *Campylobacter* spp., *Listeria monocytogenes*, and *Yersinia* spp. Before pasteurization and the institution of eradication and control programs for brucellosis and tuberculosis, *Brucella* spp. and *Mycobacterium* spp. could also occasionally be isolated from raw milk.

Studies have been conducted to determine the incidence, prevalence, and occurrences of *Salmonella* bacteria in milk and dairy products. During a 2002 survey of 854 farms in 21 US states, *Salmonella* were isolated from 2.6% of the raw milk samples, whereas a real-time PCR indicated that *Salmonella* were present in 11.8% of the samples. In another study conducted in 2007 in 17 US states, 541 raw bulk tank milk samples and 523 in-line milk filters were collected and examined for the presence of *Salmonella* by a cultural method and by real-time PCR. *Salmonella* isolates were cultured from 6.7% of the milk samples and 19.9% of the milk filters, while PCR analysis indicated that *Salmonella* were present in 13.9% of the milk samples and 33.3% of the milk filters. Twenty-five *Salmonella enterica* subsp. *enterica* (hereafter denoted as *Salmonella*) serovars were identified; the most common serovars were *S.* Cerro (34 isolates), *S.* Kentucky (20), *S.* Muenster (14), *S.* Newport (10), *S.* Anatum (10), *S.* Montevideo (8), and *S.* Mbandaka (8). In a recent study in California, samples of bulk tank milk were taken at intervals of 2–3 months during a 29-month period and cultured for *Salmonella*. At each sampling period, 10–21% of the dairy farms were positive for *Salmonella*. The most commonly isolated *Salmonella* serovars in that study were *S.* Montevideo (33%), *S.* Typhimurium (14%), *S.* Dublin (13%), and *S.* Give (11%).

Pasteurization of milk is a process whereby the milk is heated at 72 °C for at least 15 s or at other temperature and time combinations. It is very effective in killing *Salmonella* and other pathogens in milk. Occasionally, pasteurized milk becomes contaminated as a result of faulty processing procedures. Investigation of a large outbreak of salmonellosis in the United States in 1984 showed that

2% low-fat pasteurized milk processed at the dairy plant in northern Illinois had become contaminated with *S.* Typhimurium. The likely cause of contamination was a cross-connection of a skim milk transfer line between tanks containing raw milk and a tank with pasteurized skim milk. Examination of the possible sources of contamination of the raw milk showed that 28 (5.5%) of pooled raw milk samples from 2786 milk producers in Wisconsin and Illinois contained *Salmonella.*

Certified Milk

Certified milk is raw nonpasteurized milk produced under conditions that comply with standards of sanitation. In California, outbreaks of salmonellosis due to *S.* Dublin occurred when people consumed certified milk.

Cheese

Soft cheeses or cheeses made from unpasteurized or insufficiently pasteurized milk may be contaminated with *Salmonella.* The largest food-borne outbreak of salmonellosis in Canada occurred during the spring and summer of 1984, affecting about 2700 people in the four Atlantic provinces (Newfoundland, New Brunswick, Prince Edward Island, and Nova Scotia) and in the more central province of Ontario, and the affected were note to have consumed Cheddar cheese contaminated with *S.* Typhimurium PT10. Production of the cheese was traced to a single plant on Prince Edward Island. Cheese was manufactured from either pasteurized (16 s at 73.8 °C) or heat-treated (16 s at 66.7 °C; not pasteurized) milk. The contamination level of the cheese was low. The level ranged from 0.36 to 9.3 *Salmonella* bacteria per 100 g of cheese made from the heat-treated milk, and it ranged from 0.36 to 4.3 *Salmonella* bacteria per 100 g of cheese manufactured from the pasteurized milk. Up to 60 samples per lot of cheese had to be examined to find a positive lot. Examination of raw milk samples from 327 farms on Prince Edward Island, Canada, supplying milk to the cheese processing plant showed that the bulk tank milk of one farm contained *S.* Typhimurium PT10. One of 24 cows in the herd, although clinically healthy, shed the same *S.* Typhimurium PT10 intermittently in the milk from one quarter of the udder during a 36-day observation period. Not all the milk used to produce the cheese was properly pasteurized since manual turning of an electronic flow diversion valve in the plant allowed some raw milk to flow into vats used for cheesemaking. The presence of alkaline phosphatase (a temperature-sensitive enzyme that is inactivated during pasteurization) in samples of cheese associated with human illness indicated that the milk had not been fully pasteurized. Examination of the isolates of *S.* Typhimurium by plasmid profiling and digestion of plasmid DNA with restriction endonucleases showed that two subgroups (I and II) of *S.* Typhimurium PT10 contaminated the cheese. *Salmonella* Typhimurium PT10 subgroup I was isolated from raw milk and cattle associated with the incriminated dairy, whereas subgroups I and II were recovered from employees at the dairy plant, from cheese obtained at the plant and in stores, and from consumers who became ill after consumption of the cheese. Investigation of the outbreak suggested that only a few *Salmonella* bacteria might cause infection in consumers. Studies on the fate of *S.* Typhimurium in the manufacturing and ripening of low-acid Cheddar cheese showed that after a rapid initial decline, the number of *Salmonella* remains the same and can survive refrigerated storage for more than 40 weeks. Similarly, during an outbreak of *S.* Newport in 2007 in northeastern Illinois, samples of 85 patients, a Mexican-style aged cheese (cotija) obtained at a local Hispanic grocery store, and raw milk from a bulk tank at a local dairy farm consumed by the patients tested positive for *S.* Newport. The isolates had indistinguishable PFGE patterns.

Raw goats' milk may also contain *Salmonella*, and the drinking of raw goats' milk and consumption of cheese made from raw goats' milk have resulted in several outbreaks of salmonellosis in humans. In a large outbreak in France in 1993, consumption of goats' milk cheese made from unpasteurized milk caused a large number of consumers to be infected with *S.* Paratyphi B. The organism was isolated from milk at the processing plant on 2 of 5 occasions and was found in the milk from only 1 of 40 farms that supplied the plant.

Dried Milk Products

Dried milk products are occasionally contaminated with *Salmonella.* In an outbreak of salmonellosis in infants in the United Kingdom, all infected infants had been fed a reconstituted dried milk product from one manufacturer. *Salmonella* Ealing was isolated from 4 of 267 sealed packets that were examined. Other outbreaks of salmonellosis due to *S.* Tennessee or *S.* Anatum have occurred in infants after consumption of powdered milk products and infant formula in England, Wales, Belgium, France, Canada, and the United States.

The prevalence of *Salmonella* serovars in dairy products is undoubtedly influenced by, but does not appear to entirely coincide with, the prevalence of *Salmonella* serovars causing infection or shedding in dairy cattle. The reason the two parameters are not in complete congruence with one another may lie in the fact that dairy products are commonly produced on a very large scale and contamination with a less common serovar may result in widespread outbreaks of salmonellosis. Also, the *Salmonella* serovar isolated from the milk or processed dairy product is whatever serovar happens to be present or has survived in the product when samples are taken for analysis, whereas differences among serovars in geographic distribution, host specificity, virulence, and infectious dose influence whether infection and shedding in cattle occur.

Sources

Excretion of *Salmonella* in the Milk

Excretion of *Salmonella* by cows in the milk occurs when the animal is febrile and experiencing an acute episode of salmonellosis. This happens most frequently during the *postpartum* period. Cows infected with the host-adapted *S.* Dublin may shed *Salmonella* bacteria with the milk, but shedding of *Salmonella* via this route has also occurred with a number of other *Salmonella* serovars including *S.* Typhimurium, *S.* Muenster, *S.* Give, *S.* Heidelberg, and *S.* Enteritidis. Occasionally, mastitis occurs in infected cows. Nonsymptomatic carrier animals may excrete *Salmonella* intermittently with the milk. *Salmonella* bacteria may be shed for prolonged periods of time from one quarter of the udder. In one study, *S.* Enteritidis PT8 was repeatedly isolated over a period of 7 months from the right hindquarter of the udder of a 5-year-old Holstein cow. The milk appeared normal at all times. In a study in the United Kingdom, 26 of 70 milk filters examined during a 4-year period (1983–86) tested positive for *S.* Typhimurium PT49a. At the end of the study period when milk samples were collected from 131 lactating cows, *Salmonella* bacteria were found in one milk sample. Milk samples taken 3 months later from 152 cows in milk at the same farm showed the same results; one milk sample cultured positive for *S.* Typhimurium. The affected cow shed *Salmonella* from one quarter of the udder.

The number of *Salmonella* bacteria shed in the milk may vary considerably. During an outbreak of *S.* Muenster infections in dairy cattle, one cow in midlactation in a herd of 35 cows shed *S.* Muenster at a rate of approximately 200 cfu ml^{-1}. The cow continued to shed the organism during the rest of the lactation period and at the next calving *S.* Muenster was again isolated. One of the quarters of the udder showed signs of clinical mastitis at calving. During the same outbreak affecting more than 200 herds, 3 other cows in 3 herds continued to shed *S.* Muenster in the milk, although the fecal samples were negative. Chronically infected carriers may shed 10–30 bacteria per ml of milk, but shedding of as many as 10^5 bacteria per ml of milk has been reported.

Contamination of Milk from Other Sources

Milk is most often contaminated after it leaves the cow by various means including fecal matter, contaminated equipment, dust, and other environmental sources. Adult cattle that recover from clinical disease may become active carriers and such apparently healthy animals may excrete *Salmonella* in large numbers in the feces for prolonged periods. Carrier animals are a major source of environmental contamination and infection of animals and humans. Cows excreting *Salmonella* may infect neighboring cows in a barn, which then in turn may excrete *Salmonella* in the milk and the feces. During an outbreak of salmonellosis in dairy cattle in Quebec, Canada, *S.* Give was isolated from the feces of cows with clinical salmonellosis and from the bulk tank milk of two herds. In one herd, the infection was so widespread that *S.* Give was isolated from the feces of 41% of the cows. Milk production was considerably reduced. Ten of 24 positive cows shed *Salmonella* in their feces for more than 6 weeks, and 5 of 23 cows for 11 weeks or longer. The only clinically affected cow had profuse diarrhea in its *postpartum* period. *Salmonella* Give was isolated from 2 of 5 cats that frequented the feeding alley in the barn. In a neighboring dairy herd, a febrile and diarrheic cow excreted *S.* Give in the feces, and a week later the two adjacent cows shed the same *Salmonella* serovar in the feces. The distribution of the infection appeared to be limited to the immediate environment of the clinically ill animal since feces from none of the other cows in the herd tested positive for *Salmonella*. One cow in this herd shed *S.* Give in the feces for at least 26 weeks.

Milking equipment may be contaminated with *Salmonella* before and during milking the cows. Dust, bedding, manure, other debris, and aerosols may be aspirated by the vacuum pump of the milking systems and contaminate the milk with *Salmonella* and other pathogens. Plant fibers and other particulate debris have been found on milk filters, suggesting that fecal matter, bedding, and other debris may have contaminated the milk. Farmers and farm workers may be infected and transfer *Salmonella* from themselves or from sources in the immediate environment to the milking equipment and the milk. *Salmonella*-infected cats and dogs on the farm may play a role in contaminating the milk. Direct or indirect contamination of the milk may occur when cows drink *Salmonella*-contaminated water or when the water contaminates the udder or the milking equipment. Farmers and their helpers may also contract the disease by direct transfer of *Salmonella* from infected cattle or calves via feces or saliva.

Cattle that drink from contaminated streams and creeks may ingest *Salmonella* and the water may contaminate the udder and teats. In the United Kingdom, cattle and calves grazing on pasture contaminated with human sewage became infected and *S.* Dublin, *S.* Typhimurium, and other *Salmonella* serovars were repeatedly isolated from milk filters.

Dried milk products may be contaminated with *Salmonella*. In one outbreak, the source of contamination was traced to a spray-dryer that had a hole in its inner lining, allowing contamination of the milk powder to occur.

Utensils used for cheesemaking may be contaminated with *Salmonella*. In an outbreak of salmonellosis caused by the consumption of cheese contaminated with *S.* Berta, the unpasteurized soft cheese was made by ripening the skim milk curds at room temperature in large buckets. One of the buckets had previously been used for the soaking of chicken carcasses before they were frozen for later consumption. *Salmonella* Berta was also isolated from the chicken carcasses.

Control Measures

There are many measures that can be taken to prevent salmonellosis. The most important public health control measure is undoubtedly pasteurization of the milk; if properly done, pasteurization is extremely effective in eliminating the risk of infection. Regulations under the US Public Health Service and a variety of state and local regulatory agencies requiring pasteurization of milk and a comprehensive set of sanitary procedures resulted in a decrease in the outbreaks of milk-borne illness from approximately 25% of all reported food-borne illness outbreaks in 1938 to less than 1% in 2008. Measures other than pasteurization include prevention of contamination, inhibition of bacterial growth, prevention of gastrointestinal infection in infants and adults by the consumption of fermented milk products, and control of the feeding of *Salmonella*-contaminated feeds to animals. The growth of *Salmonella* can be inhibited by lowering the pH of foods, by treating foods with organic acids or sodium chloride, and by refrigeration. Such preventative measures have been described in the literature (see 'Further Reading'). Vaccination of cattle is also used to prevent and control salmonellosis (*see* **Diseases of Dairy Animals**: Infectious Diseases: Salmonellosis).

Measures to curtail the drinking of unpasteurized milk have been highly successful in preventing infections. The implementation of legislation in 1983 in Scotland prohibiting the retail sale of untreated cows' milk effectively controlled the large general community outbreaks of milk-borne salmonellosis and *Campylobacter* enteritis. However, the drinking of raw milk by dairy farmers and their families and friends continues to be a common practice in many countries. It has caused numerous cases of salmonellosis among these groups. Dairy farmers and their families should be informed about the dangers of drinking of raw milk and the ensuing cases of illness and number of deaths due to infections with *Salmonella*, *Campylobacter*, *Listeria*, and VTEC. Such information can be provided by placing articles about milk-borne illnesses and measures to control such illnesses in dairy producers' magazines and other publications for farmers and their families.

The public at large, and especially chronically ill elderly patients and the parents of young children, should be cautioned against the drinking of raw milk, an increasingly popular 'health food'. Some consumers claim that drinking raw milk has health benefits including decreased risks for artherosclerosis, arthritis, and lactose intolerance. However, such claims are not supported by scientific evidence.

Large outbreaks in the United States and Canada of milk- and cheese-borne salmonellosis in humans occurred as a result of misdirecting the flow of raw milk into containers and vats intended to receive pasteurized milk. It is therefore imperative to maintain proper control of the flow of pasteurized milk and to maintain a strict separation of unpasteurized and pasteurized products in dairy processing plants.

Outbreaks of salmonellosis after consumption of reconstituted dried milk products prompted recommendations to manufacturers such as increased monitoring of the drying process so that defects in the process may be readily recognized and remedied, not to blend products with high counts of bacteria with batches with a low viable count, and not to keep raw milk and whey on-site at milk-drying plants.

The average number of milking cows per dairy worker has increased significantly during the last few decades in many countries and less time is available for attention to the hygiene of individual animals. In the process, the potential exposure of milk to contamination during production has also increased. Thus, strict hygienic measures before, during, and after milking the cows should be maintained. Such measures include a clean milking parlor, proper disinfecting and cleaning of the udder and teats, good maintenance, cleaning and disinfecting of milking equipment before and after use, and the institution of other measures to promote hygiene and prevent contamination of milk during production.

Good manufacturing practices must be maintained in order to produce cheese free from *Salmonella* contamination. Investigation of an outbreak of salmonellosis due to *S.* Heidelberg in Denver and Pueblo, CO, showed that the raw milk used at the dairy processing plant to make the cheese contained more than 3 million bacteria per ml. The raw milk was stored for 1–3 days in insulated but unrefrigerated holding tanks and the milk was filtered only after pasteurization, a violation of guidelines for pasteurization. Also, bacterial culturing and determination of the presence of phosphatase in the milk used to make the cheese were not carried out. The manufacturer was urged to take appropriate corrective measures.

Salmonellosis in Humans

Throughout the world, much of the milk consumed is still not pasteurized. In many countries, unpasteurized milk or certified milk is available for sale or can be obtained directly from the farm. In Canada, the sale of raw milk directly to consumers is prohibited. The distribution of raw milk is illegal also in Scotland. However, in England, registered producers are allowed to sell raw milk directly to the consumer. Although Food and Drug Administration (FDA) regulations in the United States require mandatory pasteurization of packaged milk and milk products for human consumption in interstate commerce, in 27 US states raw milk can still be bought directly from the farmer. Raw milk is sometimes available to the consumer through a 'cow share' purchasing program. The drinking of unpasteurized milk and the consumption of soft cheeses made from raw or improperly pasteurized milk or milk contaminated after the pasteurization process have resulted in numerous single case and small and large outbreaks of salmonellosis. Cases of food-borne outbreaks due to consumption of *Salmonella*-contaminated raw milk have been reported in many countries. The majority of milk-borne epidemics of salmonellosis in humans in the United Kingdom have been caused by *S.* Dublin and *S.* Typhimurium. These two *Salmonella* serovars have also been the most commonly isolated serovars from cattle in the western European countries, whereas in the United States and Canada *S.* Typhimurium has been the most frequently isolated serovar from bovine sources. Such outbreaks continue to occur. For example, the consumption of Mexican-style soft cheese made from raw milk caused several outbreaks of *S.* Typhimurium DT (definitive phage type) 104 infection in people in California and Washington State. In another recent outbreak of salmonellosis in Pennsylvania, 29 cases of diarrheal illness, 16 of them in children less than 7 years of age, occurred as a result of drinking raw milk or consuming a soft cheese (queso fresco) made from raw milk; all isolates had the same PFGE pattern (the DNA was digested using the *Xba*I restriction enzyme) and could be traced to the same dairy farm that held a state-issued permit to sell raw milk to customers.

Symptoms

The symptoms observed in cases of human salmonellosis are diarrhea, abdominal cramps, nausea, vomiting, fever, headache, and blood in the feces. The frequency and severity of the symptoms may vary. In the soft cheese-related outbreaks of infection with *S.* Typhimurium DT 104 mentioned above, diarrhea was observed in 100%, abdominal cramps in 93%, fever in 93%, bloody stools in 72%, and vomiting in 53% of cases, while 9% of patients were hospitalized. In California, during the period 1971–74, there were 79 cases of human salmonellosis due to *S.* Dublin; 74 of these 79 cases drank certified raw milk produced at a single large dairy farm. In 52 of the 79 cases, the organism was isolated from blood, urine, or deep tissue sites, demonstrating the invasiveness of the pathogen. Sixteen of the 79 patients died, of whom 13 had preexisting chronic debilitating diseases. In 1993, in France, consumption of a raw goats' milk cheese was associated with a *S.* Paratyphi B infection in 273 patients; in 240 patients the organism was isolated from the feces, in 15 from blood, in 14 from tissues, and in another 4 the site was unknown. Thirty-seven percent of the patients were hospitalized and one died. The largest single food-borne epidemic in the United States affected an estimated number of more than 160 000 persons who became ill as a result of *S.* Typhimurium infection from contaminated 2% low-fat milk produced by a dairy plant in Illinois in 1985. There were more than 16 000 culture-confirmed cases, 2777 patients were hospitalized, and 14 associated deaths occurred.

Patients infected and shedding *Salmonella* with the stool may experience sequelae to the primary infection such as extraintestinal salmonellosis and isolation of the *Salmonella* from the blood, from cases with septicemia, cystitis, and pyelonehritis, and from cases with abscesses and tissues. Sterile or reactive arthritis of the knees and occasionally of the ankles and other joints is not uncommon in patients who experienced a bout of diarrhea and from whom previously or concomitantly *S.* Typhimurium, *S.* Enteritidis, or other *Salmonella* serovars were isolated from the stool. Human leukocyte antigen (HLA) typing of such patients shows that they are usually B27 positive.

Susceptibility to *Salmonella* Infection and Severity of Illness

Susceptibility to, and severity of, *Salmonella* infection in humans depends on various factors including the dose and virulence of the pathogen for the human host, the type of food contaminated with *Salmonella* that was consumed, the age of the host, and factors known to affect the immune status of the host, such as infection with the human immunodeficiency virus (HIV), leukemia, and/or the use of immunosuppressive drugs. Other host-associated risk factors include diabetes, partial gastrectomy, and the low gastric acidity associated with these conditions. The very young and the elderly are most susceptible to the infection. The fat content of contaminated foods such as cheese may influence the dose required to cause an infection. *Salmonella* present in foods with a high fat content such as cheese may be trapped in hydrophobic lipid moieties and survive the acidic conditions of the stomach to subsequently attach to and invade the enterocytes lining the intestines. Cases in which humans became infected after ingestion of an estimated dose of 100–500 *S.* Heidelberg or, in another outbreak, less than 10 *S.* Typhimurium in Cheddar cheese, support this hypothesis.

Shigella spp.

E Villalobo, Universidad de Sevilla, Seville, Spain

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Dysentery is an intestinal disorder caused by microorganisms: bacteria, amoebas, or viruses. Bacillary dysentery or shigellosis refers to the disease caused by bacteria of the genus *Shigella.* This name was adopted in 1950 in honor of Kiyoshi Shiga, the scientist who first differentiated amoebic from bacterial dysentery, and who isolated *Bacillus dysenteriae* in 1898.

Shigella spp. are enteric bacteria essentially found in humans and primates, but they spread into the environment, especially into water and food, due to human activities. Milk and dairy products are susceptible to being contaminated by shigellae, causing thousands of outbreaks a year. Indeed, outbreaks are more and more common, due to adoption of new life styles. Consequently, dysentery is an emerging disease of worldwide public dimension that attracts the attention of food and health administrations in an attempt to minimize its societal impact. The following sections are devoted to the bacteriology of *Shigella* spp. and their occurrence in milk. Special attention is paid to pathogenesis, outbreaks, safety, and detection/identification methods.

Bacteriology

Shigellae (genus *Shigella*, family Enterobacteriaceae, according to Bergey's Manual, Section 5: "Facultatively Anaerobic Gram-Negative Rods") are straight rod-shaped, facultatively anaerobic, oxidase-negative bacteria that stain Gram-negative. Shigellae, unlike their closest relative *Escherichia coli*, are nonmotile, and do not ferment lactose or produce gas from glucose, nor reduce sulfate to hydrogen sulfide. However, enteroinvasive *E. coli* (EIEC), which also causes dysentery, is practically indistinguishable from shigellae. Infective dose, 1000-fold higher for EIEC than for shigellae, is perhaps one difference between these two pathovars. The four species of the genus *Shigella* are *Sh. dysenteriae*, *Sh. flexneri*, *Sh. boydii*, and *Sh. sonnei.* A few serovars have been differentiated in each species, even though all serovars within each species share a specific O side chain in their lipopolysaccharide (LPS). This is the reason why *Sh. dysenteriae*, *Sh. flexneri*, *Sh. boydii*, and *Sh. sonnei* are usually referred by epidemiologists as subgroups A, B, C, and D, respectively.

The natural hosts of shigellae are humans and monkeys, with the intestinal tract being their common habitat. However, these pathogens remain viable in the skin. Person-to-person transmission by the fecal/oral route is common, though sexual transmission is also possible. They are also viable in food, water, and beverages; consequently, these are additional modes of transmission. Special attention must be paid to asymptomatic carriers and flies, as both serve as silent transmission vehicles.

Pathogenesis

The main pathogenicity or virulence property of *Shigella* is cell invasion, which is responsible for most of the symptoms of dysentery. The invasion occurs mainly in the colon, though it can also be observed in the last part of the ileum. The process starts with the adhesion of pathogens to the surface of M cells of the follicle-associated epithelium. The host–pathogen contact causes internalization of the bacteria into vacuoles, in a process resembling macropinocytosis. After lyzing the vacuolar membrane, the pathogens escape to the cytoplasm, move to the edge of the nucleus, where they grow and form a microcolony. Cell-to-cell spreading occurs via bacteria-containing protrusions phagocyted by the adjacent cells. Spreading is not limited to the epithelial lining but proceeds to the lamina propria, where the bacteria are released and ingested by macrophages. The pathogens, rather than being killed by macrophages, escape the phagosome, induce release of interleukin-1β, and cause apoptotic death of the macrophages. The overall result is an inflammatory response that attracts polymorphonuclear leucocytes, which loosen the cellular junctions. Now, the pathogens at the colonic lumen are free to pass through the epithelial lining and to gain access to the basolateral surface. Then, more epithelial cells are invaded and the inflammatory response is amplified. This recurrent event results in the formation of colonic ulcers, a macroscopic hallmark of dysentery. The dysenteric stool is bloody and mucoid due to the infiltration of red blood cells and serum proteins.

Genetic Determinants of Virulence

Virulence is a multifactorial property in which both a nucleoid and a plasmid are involved. All pathogenic shigellae and EIEC bear a large plasmid ranging from 180 to 220 kb, called the virulence plasmid. This plasmid contains a pathogenicity island, needed for invasion and essentially composed of three operons: *ipa* (invasion plasmid antigens), *mxi* (membrane expression of invasion plasmid antigens), and *spa* (surface presentation of invasion plasmid antigens). While *mxi* and *spa* genes code for subunits of the type III secretion system, the *ipa* genes code for the effectors secreted by this system. Some other genes located in the virulence plasmid, such as *virG* (*icsA*), which codifies for an outer membrane protein, are also needed for invasion. The nucleoid-encoded genes, mainly responsible for the survival of the pathogen in the host, are also organized in a few pathogenicity islands. Enumerating all the nucleoid-encoded genes would require extensive discussion; but, due to its significance, the locus *stx* stands out, as it codifies for the shiga toxin in *Sh. dysenteriae* 1. This toxin is a potential inhibitor of mammalian protein synthesis and is responsible for the most severe pathogenic phenotypes. Recently, two new enterotoxins responsible for the clinical manifestation of dysentery have been characterized. Shigella enterotoxin 2 is codified in the virulence plasmid and is present in most shigellae isolates.

Disease Symptoms and Complications

Clinical manifestation of dysentery varies greatly from asymptomatic infections to fulminating dysentery, though mild diarrhea is also common. The severity of the disease depends not only on the person but also on the shigellae strain. For obvious reasons, immune-compromised or malnourished individuals and children are prone to suffer more severe infections. By species, *Sh. dysenteriae* and *Sh. flexnery* produce severe infections, while *Sh. sonnei* is more benign. The typical symptoms of dysentery are fever, permanent emission of bloody and mucopurulent stools that leads to dehydration, and intestinal discomfort characterized by cramps and tenesmus. Complications can cause death, due to septicemia and hypoglycemia, especially in children.

Reiter's syndrome is a common sequela of dysentery in individuals expressing the HLAB127 histocompatibility antigen. Hemolytic uremic syndrome, with renal failure, is not infrequent when infected with *Sh. dysenteriae* 1. Though very infrequent, ulcerative keratitis due to shigellae infection has also been reported.

Occurrence in Milk

Milk is a rich substance that supports bacterial growth; therefore, after contamination, bacterial counts increase within a wide range of time and temperatures. Consequently, the shelf life, quality, and safety of raw milk are determined by the types and load of bacteria. High loads of spoilage flora imply high enzymic activity of lipases and proteases, sometimes thermostable, that reduce the fat and protein content, consequently lowering the quality of raw milk. These enzymic activities have other undesirable organoleptic effects: bitterness, rancidity, and off-flavors. Pathogenic bacteria, such as *Shigella* spp., primarily affect food safety; hence, pathogen contamination must simply be avoided in milk.

Shigella spp. remain viable for at least 72 h at 4 °C or proliferate at 15–37 °C in raw milk. As the infective dose is very low – 10 to 100 bacteria are enough to trigger an infection – special care must be taken to avoid contamination of raw milk and dairy products by these pathogens. Occurrence of *Shigella* spp. is sometimes reported in milk, as in Sudan, where analysis of bulk tank cow milk indicates that 20% of the samples contain *Shigella* spp. in the range of 1×10^6 cfu ml^{-1}. Occurrence of *Shigella* spp. in dairy products is lower than in raw milk, due to the special properties of these foods, as discussed below.

Outbreaks

There are no accurate data available regarding the total number of dysentery outbreaks each year, but most likely millions of humans are affected worldwide. Estimates indicate 145 million cases per year, with mortality reaching between 0.5 and 1.5 million; children below 5 years of age are the main victims. Outbreaks take place worldwide, with the majority occurring in countries suffering from poor sanitation, hunger, wars, or catastrophes. There is also a general seasonal trend: in tropical areas the incidence is higher in the rainy season, due to flooding, while in subtropical areas the incidence is higher in summer, due to high temperature and drought.

Shigella flexneri and *Sh. dysenteriae* account for most cases of dysentery in developing countries. The former relates to the endemic disease, and the latter to epidemics. *Shigella sonnei* essentially affects well-developed countries. Finally, *Sh. boydii* rarely causes outbreaks except in the Indian subcontinent. An epidemiological transition from flexneri to sonnei is considered an indicator of economic development; such a transition should be seen in the near future in emerging economies such as India.

Milk and dairy products are suspected of being responsible for several dysentery outbreaks. Between 1998 and 2007, 83 foodborne pathogen-related outbreaks were publicly reported, of which 14.5% had been associated with dairy products. One of the recent outbreaks occurred in 2004 in Vilnius, Lithuania. Of the 41 cases detected, 36 were diagnosed as dysentery; 50% of the patients were children under 14 years of age, and 16% of the affected individuals were above 65 years.

As expected, all patients were positive for *Sh. sonnei.* Unpasteurized milk curd was the vehicle for transmission, and contamination of this product was due to handlers either in the dairy facility or in the market. Indeed, the same *Sh. sonnei* serotype was confirmed in patients, workers, and inhabitants of the dairy facility, and workers of the market. This case clearly shows the importance of microbiological safety measures needed in dairy production.

Microbiological Safety

There are several ways to reduce shigellae in raw milk, the most effective one being thermal treatment. Pasteurization and ultra-high temperature (UHT) treatment are very effective. For *Sh. dysenteriae*, the decimal reduction time (D value) in milk at 82.2 °C is 0.8 s, while in nutrient broth at 63 °C it is 5 min. Thus, the common thermal treatments applied to milk significantly reduce the total counts of *Shigella.*

Detection, Enumeration, and Identification Methods

Coliform bacteria are indicative of fecal contamination; therefore, a milk sample with a high coliform count is suspicious of harboring enteric pathogens also, such as *Shigella* or *Salmonella.* The prevalence of shigellae in milk is not negligible, and from time to time they appear in the dairy industry. When this occurs, it is important to monitor the possible sources of contamination in order to adopt control measures. Thus, it is worthy to review the traditional and molecular methods for detection and identification of shigellae.

There are no specific media for growing *Shigella* spp. Normally, the media used to cultivate these pathogens are of a broad bacterial spectrum, or designed either for enterobacteria or *Salmonella.* Typical enrichment media are Hajna (Gram-negative) broth, buffered-water peptone, selenite cystine broth, tetrathionate broth, and brilliant green bile glucose broth. As the counts of shigellae in milk are high, enrichment is not only unnecessary but contradictory, given that these pathogens outgrow in the presence of other enteric bacteria. If enrichment is needed, addition of novobiocin to the media greatly improves the recovery of *Shigella* spp. A successful strategy is to use this antibiotic along with a low carbohydrate concentration in the medium. Typical isolation (selective) media are Salmonella–Shigella agar, xylose lysine deoxycholate agar, deoxycholate citrate agar, its modified version deoxycholate lactose sucrose agar, eosin methylene blue agar, and tergitol-7 agar. Typical differential media are Hektoen enteric agar, MacConkey agar, and triple sugar iron agar slant. Chromogenic media have been developed, such as chromogenic Shigella plating medium (CSPM), which contains a proprietary mix of carbohydrates, selected pH indicators, and chromogens. Identification of *Shigella* spp. in CSPM is easy, since they produce white to clear colonies, while bacterial competitors produce colored colonies. Recovery of *Shigella* spp. from food in this medium is similar to that reported for MacConkey and Salmonella–Shigella agars; however, CSPM needs further evaluation with different shigellae serotypes. A single-tube screening test has also been developed for *Salmonella* and *Shigella.* This method, based on a four-layered semisolid medium, has 100% sensitivity (56 *Shigella* isolates tested) and 95% specificity (56 non-*Shigella* isolates tested).

After detection/isolation in culture media, the presumptive isolates must be further characterized by molecular tests, even if a differential medium had been used. The reason for the deeper characterization is that *Shigella* spp. are difficult to identify based solely on the abovementioned media. In addition, from a medical point of view, it is very important to determine which shigellae serotype is isolated.

Primary biochemical characterization of *Shigella* spp. involves four distinctive properties of these bacteria: (swarming) motility, production of H_2S, production of gas from glucose, and fermentation of lactose. These tests, which are carried out on agar media, are negative for most *Shigella* serovars. At this point, it must be mentioned that *Sh. sonnei* ferments lactose very slowly, and that *Sh. flexneri* 6, *Sh. boydii* 13 and 14, and *Sh. dysenteriae* 3 produce gas from glucose. Further biochemical characterization is also desirable though, once again, no specific tests for *Shigella* spp. are available. Test strips for bacterial identification, such as API20E® or similar tests, are very popular in diagnostic laboratories. These systems have two major drawbacks: they need expert interpretation and are time consuming. These concerns are overcome, at least in part, with automated systems such as Vitek®. The EPS (enteric pathogens) card of this system has been evaluated for enteric pathogens. The card gave a sensitivity of 99.5% for enteric pathogens, including several shiegellae serovars, and a specificity of 90.1% for nonpathogens. An automated system for the enumeration (based on the most-probable-number technique) and confirmation of enterobacteria, Tempo® EB (enterobacteria), has also been released; use of this system must be considered when fast results are required. Similar methods are becoming available in the market. More recently, a simple, fast, and inexpensive method specifically developed for *Shigella* spp. has been reported. It is a colorimetric method based on the detection of apyrase, a periplasmic enzyme necessary for intracellular spread of pathogen. The assay shows 96% sensitivity (over 23 isolates of *Shigella* and EIEC) and 80% specificity (over 34 isolates tested). Though the assay has been successfully applied on stools, it requires further validation and domains of application.

Immunological identification of *Shigella* spp. is based on surface antigens, such as LPS. This molecule is composed of three different regions: the lipid A, which anchors the LPS to the outer bacterial membrane, the core oligosaccharide, and the O-antigen. The latter, a polymer of repeating saccharide units, is strain specific, with all strains having the same O-antigen belonging to the same serotype. Serotype acknowledgment depends on various authors of different studies, but less than 46 seem to be acceptable. *Shigella boydii* can be subdivided in 20 serotypes, *Sh. dysenteriae* in 15, *Sh. flexneri* in 6, and *Sh. sonnei* in only 1 serotype. Interestingly, most of the *Sh. flexneri* serotypes share the same O-antigen basic structure. Different commercial kits for serotyping are available. Most of them use polyclonal sera raised in rabbit against reference strains, and slide/latex/tube agglutination, enzyme immunoassay, or immunomagnetic platforms for detection. The main drawback of serotyping is that sera can fail in detecting particular serotypes. In Bangladesh, for instance, 3% of isolates from patients with diarrhea have the typical biochemical properties of shigellae but they fail to be detected with the currently available sera. These are known as *Shigella*-like organisms, one of which has had a high prevalence over several years, and has been classified by molecular methods as a novel serovar of *Sh. dysenteriae*. Likewise, 180 isolates classified as *Shigella*-like organisms in France between 2000 and 2004 were recently identified by molecular methods as *Sh. boydii*. Several commercial kits for serotyping have been evaluated, and only one gave a performance lower than the conservative standard of 90% of accuracy.

Genetic identification is based on genotyping, that is, determining the identity of a strain based on its genetic material using a biological assay. The most popular and widely used method is the polymerase chain reaction (PCR), which consists of specific amplification of a small portion of the genetic material of an organism, such as bacteria, in a complex sample, such as food. Dozens of publications a year deal with PCR identification of *Shigella* spp. in food, as many as the genetic targets to be amplified, among them the loci *ial*, *virA*, or *ipaH*. A plethora of PCR-based assays are also popular, though their use in food is limited. Noteworthy is fingerprinting, based on the generation by PCR of a specific DNA pattern that serves to identify microorganisms. Restriction fragment length polymorphism (RFLP-PCR), amplified fragment length polymorphism (AFLP-PCR), enterobacterial repetitive intergenic consensus (ERIC-PCR), and repetitive extragenic palindromic sequence-based PCR (rep-PCR) are also notable. Recently, an automated system based on rep-PCR, called DIVERSILAB®, has been commercialized. This system allows rapid and specific detection of *Shigella* spp., though it has been applied in epidemiology only.

Before ending this section, identification methods based on a cell's ome, the units that define a cellular constituent or function, should be mentioned. Collectively these methods are called 'omics'. The most popular are transcriptomic, such as DNA (microarrays) chips; proteomic, such as mass spectrometry; and genomic, such as DNA sequencing. DNA sequencing is becoming very popular, since a few devices for fast, reliable, and cheap whole-genome sequencing have been developed in the last 5 years. Based on this high-throughput technology, new methods for identification are becoming available. An example is multiple loci sequence typing (MLST), an identification method halfway between genomics and genotyping. Conceived as a universal, portable, and definitive method, it consists in raising indexes of variation in multiple housekeeping genes of a particular organism, such as *Neisseria meningitidis*, for which the method was originally developed. A similar method, called variable-number tandem-repeat (VNTR) analysis (MLVA) has been applied to *Shigella* spp. A panel of 15 VNTRs has been released to detect *Shigella* spp., though the main drawback is that *E. coli* is also detected. More work in this area is needed to release a panel specific enough to detect only shigellae.

Staphylococcus aureus – Molecular

T J Foster, Trinity College, Dublin, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

The genus *Staphylococcus* comprises more than 20 species, of which *S. aureus* is the most pathogenic. *Staphylococcus aureus* is a commensal of humans and being colonized with *S. aureus* is a risk factor for infection. *Staphylococcus aureus* can cause minor skin infections (abscesses, boils) but occasionally it can gain access to the bloodstream where it can cause serious invasive infections such as endocarditis, septic arthritis, and osteomyelitis. *Staphylococcus aureus* can also secrete potent enterotoxins that cause food poisoning if ingested. *Staphylococcus aureus* can colonize the udder of cattle from where it can infect the mammary gland epithelia causing mastitis. A lactating dairy cow with mastitis will excrete bacteria into milk. Bacterial cells will be killed by pasteurization but enterotoxins are heat resistant and if they are secreted into milk prior to heat treatment they will survive.

Molecular Typing Methods

A variety of molecular typing methods have been applied for studying collections of *S. aureus*. Most effort has gone into analysis of human clinical isolates, notably MRSA (methicillin-resistant *S. aureus*) strains. Some methods (pulsed field gel electrophoresis, random amplified polymorphic DNA) are highly discriminatory and are best applied to analysis of local outbreaks. Other methods are less discriminatory and are suited for studying the population as a whole. Multilocus sequence typing (MLST) has the advantage that it does not suffer from lack of reproducibility inherent in other methods. Segments of seven housekeeping genes are sequenced. Each unique gene sequence is given a numeric code (a bar code) and the unique combination given a sequence type (ST) number. A strain with a single nucleotide polymorphism in any of the seven genes is denoted a single locus variant. A collection of single locus variants are analyzed to form a clone with an ancestral ST in the center. The clone can be expanded to include double locus variants. A detailed analysis of human strains has been performed. Much less data are available for animal strains.

Population Structure

The population of *S. aureus* is described as being clonal. This means that discrete clones of the organism have emerged as a result of genetic divergence due to spontaneous mutations, with relatively minor contributions from gene transfer by recombination. Phylogenetic analysis by several methods agrees that the population is divided into two major groups. It is also evident that the carriage of *S. aureus* by domesticated animals (ruminants, rabbits) and chickens is the result of transmission from humans followed by a period of adaptation to the new host. The most widespread bovine clone diverged from ancestral human-associated clones by acquiring mutations, some of which have resulted in gene decay. Several genes important for human infection are no longer functional due to acquisition of mutations that result in truncation of the protein. Allelic variation occurs in genes encoding proteins involved in colonization, toxins, iron metabolism, and regulation, suggesting adaptation to the nonhuman host.

Superimposed upon the basic clonal population is the occasional emergence and rapid dissemination of new clones. This is exemplified by the recent emergence and spread of the virulent community-associated MRSA (CA-MRSA) strain of the USA300 PFGE type and the ST398 MRSA strain associated with intensively reared pigs.

Colonization: Bacterial and Host Factors

Staphylococcus aureus colonizes the moist squamous epithelium of the anterior nares of humans. This is regarded as the primary site of colonization. The presence of the bacterium on the skin is usually a consequence of nasal carriage. Nevertheless, temporary residence on the skin is a prerequisite for transmission from host to host. It is conceivable that the ability to adhere to keratinized epithelium is also important in colonization of the ruminant.

Recently, advances have been made in our understanding of bacterial and host factors that contribute to bacterial survival on the moist squamous epithelium of the nares and on skin of humans. *Staphylococcus aureus* permanently colonizes about 20% of the population and intermittently colonizes another 60%, whereas 20% of individuals are never colonized. This strongly suggests that host factors determine whether an individual is colonized or not. Individuals admitted to hospital who were permanently colonized developed bacteremia at a slightly higher rate (1.2%) than those who were not colonized (0.4%). Conversely, infected carriers had a lower mortality rate (8%) than infected noncarriers (32%). Carriers had higher levels of antibodies to certain virulence factors, which might have offered some protection when they acquired a bloodstream infection.

The ability to adhere to squamous cells *in vitro* is regarded as a correlate of proficiency in colonization of cornified epithelial tissue. Adherence is a multifactorial process involving teichoic acids and up to five different surface proteins, the best characterized of which are clumping factor B (ClfB) and iron-regulated surface determinant A (IsdA). Mutants defective in these proteins adhered poorly to isolated human squamous cells and colonized less effectively the nares of rodents, and in the case of ClfB, humans. The ligands recognized by these proteins are cytokeratin 10 and loricrin, which are major protein components of the corneocyte envelope. Polymorphisms in the glucocorticoid receptor gene contribute to the effectiveness of host immune responses and seem to determine in part the carriage status of the host. This indicates that colonization of the nares is controlled by host factors expressed in the nasal mucosal secretions. The ability to survive on skin is promoted by the ability of the bacteria to resist the bactericidal effects of skin lipids in sebum, the acidic pH, and cationic antimicrobial peptides.

Virulence Factors

Staphylococcus aureus expresses a diverse array of secreted and surface-associated proteins that promote virulence in experimental rodent models of infection and most likely do so in humans as well. Due to the unique environment of the mammary gland, it is likely that some of these factors are not relevant to the ruminant infection. Indeed several important factors in human strains are not expressed by a widespread bovine mastitis-causing strain of multilocus ST 151. The function of virulence factors can be categorized as (1) adherence to host cells or extracellular matrix proteins, (2) evasion of innate and induced immune responses, and (3) toxins that cause localized or systemic damage. Some factors are multifunctional and contribute to more than one category.

Adhesins

Staphylococcus aureus can elaborate on its cell surface up to 20 different proteins (Figure 1), some of which have been shown to bind to components of the extracellular matrix (fibrinogen, fibronectin, collagen, elastin) and thereby support bacterial adhesion to host tissue. At least four proteins (ClfA, ClfB, and fibronectin binding proteins A and B) bind to soluble fibrinogen and promote adhesion to immobilized fibrinogen and fibrin. However, each is multifunctional and can interact with other host proteins. ClfA, the dominant fibrinogen binding protein expressed by bacteria in stationary phase, also binds to and activates complement factor I. ClfB is expressed in exponential phase and binds to fibrinogen and to cytokeratin 10, the latter interaction being important in nasal colonization. Apart from binding to fibronectin, the eponymous fibronectin binding proteins A and B also bind to fibrinogen and elastin.

Protein A (Spa) is best known for its ability to bind to immunoglobulin (Ig)G at the Fc region, thereby inhibiting opsonophagocytosis. However, Spa is a multifunctional protein: it can also bind to (1) IgM and activate a subset of B cells, thereby exhibiting superantigen activity; (2) von Willebrand factor, contributing to thrombus formation and endocarditis; and (3) tumor necrosis factor receptor-1 on airway epithelial cells, thereby triggering inflammatory reactions that contribute to the pathogenesis of staphylococcal pneumonia.

When the genomes of *S. aureus* strains were sequenced, a number of novel putative surface proteins were identified. The serine aspartate repeat protein (SdrC, SdrD, and SasG) proteins have been shown to promote adhesion to desquamated epithelial cells and may contribute to nasal colonization. However, the ligand(s) involved are not known. Expression of SasG also promotes biofilm formation. The Isd proteins are expressed only in iron-limited conditions. They allow the acquisition of iron from hemoglobin. The IsdA protein also has important roles in promoting resistance to bactericidal lipids on skin, resistance to the bactericidal host protein lactoferrin (this could be important for bovine strains), and adhesion to desquamated epithelial cells. The IsdH protein also contributes to resistance to phagocytosis by promoting accelerated degradation of C3b by an as yet unidentified mechanism.

The fibronectin binding proteins are required for bacteria to become internalized by host cells that are not professional phagocytes. This is triggered by fibronectin acting as a bridge between bacteria and the $\alpha 5\beta 1$ integrin located on the surface of epithelial and endothelial cells. The ability of bacteria to invade mammary gland epithelial cells promoted by this mechanism could be important in the pathogenesis of mastitis.

Evasins

Evasion of innate immune responses of the host is crucial to the success of *S. aureus* as a commensal and pathogen. In humans, this centers around compromising the function

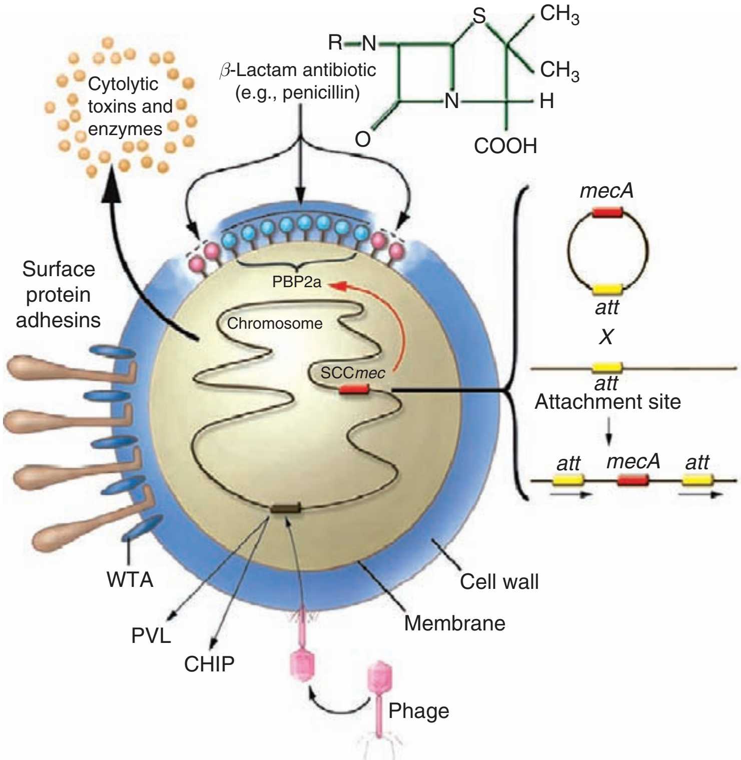

Figure 1 Schematic diagram illustrating how *Staphylococcus aureus* acquires resistance to methicillin and its ability to express different virulence factors. The bacterium expresses surface protein adhesins and wall teichoic acid (WTA), and also secretes many toxins and enzymes by activation of chromosomal genes. Adhesins and WTA have been implicated in nasal and skin colonization. Resistance to methicillin is acquired by insertion of a horizontally transferred DNA element called SCC*mec*. Five different SCC*mec* elements can integrate at the same site in the chromosome by a Campbell-type mechanism involving site-specific recombination. The *mecA* gene encodes a novel *β*-lactam-insensitive penicillin binding protein, PBP2a, which continues to synthesize new cell wall peptidoglycan even when the normal penicillin binding proteins are inhibited. Some virulence factors such as Panton and Valentine leucocidin (PVL) and the chemotaxis inhibitory protein, CHIP, are encoded by genes located on lysogenic bacteriophages. Reproduced from Foster TJ (2004) The *Staphylococcus aureus* 'superbug'. *Journal of Clinical Investigation* 114: 1693–1696.

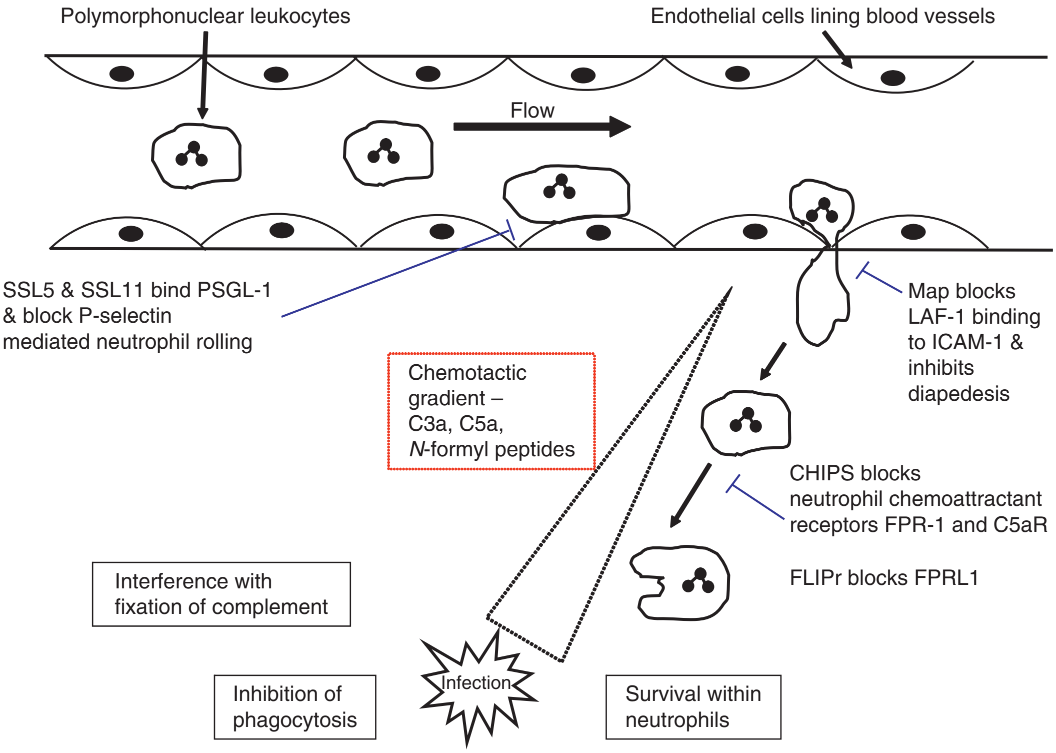
of neutrophils, the first line of defense against invasion by *Staphylococcus*. Several small secreted proteins interfere with the migration of neutrophils from the blood vessels to the site of infection (**Figure 2**). The staphylococcal superantigen-like proteins SSL5 and SSL12 inhibit binding of neutrophils to inflamed endothelial cells in small blood vessels by blocking P-selectin glycoprotein ligand-1 (PSGL-1) on neutrophils from binding to P-selectin on endothelial cells. The extracellular adherence protein (Eap) (also called Map (MHC class II analog protein)) inhibits extravasation of neutrophils (diapedesis) by blocking leukocyte function-associated antigen LAF-1 from binding to intercellular adhesion molecule-1 (ICAM-1) on endothelial cells. The chemotaxis inhibitory protein, CHIPS, inhibits neutrophil migration toward the focus of infection by blocking receptors for chemoattractants *N*-formyl peptide and complement C5a peptide.

Opsonophagocytosis of bacterial cells is important for efficient uptake and killing by neutrophils. Several secreted proteins prevent the efficient deposition of the complement opsonin C3b. The *Staphylococcus* complement inhibitor (SCIN) and the extracellular fibrinogen binding protein Efb (and the related protein relative Ecb) block complement C3b and C5a convertases.

Surface proteins contribute to reducing the efficiency of phagocytosis by enhancing the degradation of C3b. ClfA binds to and activates the complement regulator factor I, which results in enhanced degradation of the C3b opsonin. IsdH also promotes accelerated degradation of C3b. The capture of host plasminogen on the cell surface and its activation by staphylokinase destroys cell-bound IgG and C3b opsonins. Protein A binds to IgG by the Fc region, which then cannot engage in complement fixation or promote phagocytosis. Coating of the bacterial cells by plasma proteins (e.g., fibrinogen binding to clumping factor) and the presence of a polysaccharide capsule also contribute to reduced opsonophagocytosis.

If *S. aureus* is successfully engulfed by functional neutrophils or macrophages, bacteria can evade killing mechanisms in the phagosome. Expression of enzymes



Polymorphonuclear leukocytes

that modify cell surface teichoic acids and cytoplasmic membrane phosphatidyl glycerol by the addition of D-alanine and L-lysine, respectively, reduces the negative charge of the cell surface and reduces susceptibility to cationic peptides. Staphylokinase binds to and neutralizes antibacterial peptides. Cell wall peptidoglycan is modified to render it impervious to the bacteriolytic enzyme lysozyme. *Staphylococcus aureus* expresses catalase and superoxide dismutase, which counteract the reactive oxygen intermediates of the phagosome oxidative burst.

Toxins

Staphylococcus aureus expresses several membrane-damaging cytolytic toxins (α-, β-, γ-, and δ-toxins and several leucocidins) that cause damage to the membranes of host cells leading ultimately to lysis (**Figure 1**). At subinhibitory concentrations, damage to the integrity of the cells is manifested by expression of proinflammatory cytokines. The α-toxin is the archetypal β-barrel pore-forming toxin. It is composed of a heptamer, which assembles from monomers bound to the host cell membrane. The process of assembly results in a conformational change that creates the transmembrane β-barrel pore. The two-component γ-toxin and leucocidins (including the Panton and Valentine leucocidin (PVL)) form similar β-barrels composed of two subunits forming hexamers or heptamers. The PVL is particularly associated with the recently emerged CA-MRSA clones. The δ-toxin is a small cationic peptide with detergent-like properties. The β-toxin is a sphingomyelinase, which lyses cells with membranes that are rich in the lipid sphingomyelin. *Staphylococcus aureus* also expresses a number of small peptides with detergent-like properties called phenol-soluble modulins, which have potent cytolytic activity. Some toxins target a variety of host cells including erythrocytes, where the release of hemoglobin can provide a source of iron in the iron-restricted environment of the host. The leucocidins have a high affinity for neutrophils and thus compromise innate immune responses.

Secreted enzymes and stoichiometric activators also contribute to tissue damage and disease pathogenesis. *Staphylococcus aureus* expresses proteases, lipases, a nuclease, and a hyaluronidase. Staphylokinase binds to plasminogen in 1:1 stoichiometry and activates the latent activity of the host plasma protease plasmin, which degrades thrombin. Coagulase binds to and activates prothrombin, which conversely causes fibrinogen to form fibrin clots.

All strains of *S. aureus* express at least one of the major enterotoxins A–I (SEA–SEI), which are also potent superantigens. They also have the capacity to express several of the many newly described superantigen-like proteins. The enterotoxins have the ability to trigger emesis at low concentrations, but their importance to the pathogenesis of *S. aureus* infections lies in their ability to trigger T-cell activation. Toxic shock syndrome toxin-1 is another potent superantigen produced by both human and bovine strains of *S. aureus*. Superantigens trigger unregulated proliferation of T-helper cells by facilitating the binding of MHC class II molecules of antigen-presenting cells to T-cell receptors in a non-antigen-specific manner. This triggers a large proportion (2–20%) of T cells to become activated and to proliferate. This disrupts the normal immune response. Also, when high levels of toxins are expressed systemically, the massive release of cytokines causes toxic shock. In the rodent house musk shrew emesis model, enterotoxins induce 5-hydroxytryptamine (HT) release in the intestine, rather than in the brain, which is recognized by 5-HT(3) receptors on vagal afferent neurons and is essential for enterotoxin-stimulated emesis.

Bacteriophages

Any isolate of *S. aureus* will be lysogenic for one or more bacteriophages. The phages can contribute to the biology of the host bacterium in several ways. Upon induction of the lysogen, the phage capsid can incorporate fragments of chromosomal DNA or plasmids and introduce them by transduction into a new host. The pathogenicity island *S. aureus* pathogenicity island-1 (SAPI-1) that encodes toxic shock syndrome (TSST-1) in human strains is transduced at very high frequency by certain phages. Excision of the integrated element is actually stimulated by phage replication. A similar process might occur with a related pathogenicity island (PI) expressed by bovine strains. Some bacteriophages have incorporated genes that contribute to the virulence of the host. The genes are expressed when the phage integrates into the chromosome. CA-MRSA strains are commonly lysogenized with a phage that carries the genes encoding PVL (**Figure 1**). This could contribute to the enhanced virulence of CA-MRSA strains. About 60% of human *S. aureus* strains are lysogenized with a phage that carries an immune evasion gene cluster comprising genes encoding CHIPS, SCIN, staphylokinase (SAK), and SEA, or combinations thereof. The site of integration of the phage is within the coding sequence for the β-toxin, explaining why the majority of human strains do not express the toxin. In contrast, many bovine strains are β-hemolytic because carriage of this type of phage is less common. This could reflect an important role for β-toxin in promoting mastitis or the fact that the phage-encoded immune evasion proteins are specific for humans.

Biofilm

The formation of biofilm was first described in infections associated with indwelling medical devices caused by *S. epidermidis*, and later by *S. aureus*. However, it is now thought that the ability to form biofilm is important during *S. aureus* tissue infection. *In vitro* studies identified several stages in establishing a biofilm: (1) primary attachment; (2) cell–cell association; and (3) detachment and dispersal. Bacteria can bind to naked plastic or metal or to biomaterial that has been conditioned by host plasma proteins *in vivo*. The accumulation phase was originally thought to be due to the secretion of a polysaccharide intercellular adhesin PIA, but it is now recognized that cell surface proteins can also cause aggregation. Cells in a biofilm are in a semidormant state, which renders them much more resistant to antibiotics than planktonic cells. Furthermore, the physical structure of the biofilm prevents the immune system from functioning properly to eradicate the bacteria.

Small Colony Variants

Staphylococcus aureus is now regarded as a facultative intracellular pathogen, whereas previously it was thought to be exclusively extracellular. A subpopulation of *S. aureus* cells called small colony variants (SCVs) have an enhanced ability to enter into and survive within mammalian cells that are not normally phagocytic. SCVs are naturally occurring mutants defective in the biosynthesis of menadione, hemin, or thymidine. This results in reduced tricarboxylic acid metabolism. Phenotypically, SCV bacteria form colonies that are 10-fold smaller than normal colonies and which are nonpigmented and nonhemolytic. The fibronectin binding proteins that promote uptake into mammalian cells are expressed by SCV cells at higher levels than in wild-type bacteria. Once inside the host cell, the SCV can persist because it does not cause cell lysis or trigger apoptosis and the infected cells do not react by synthesizing proinflammatory molecules. Clinically, SCVs are associated with relapsing persistent infections such as osteomyelitis, some foreign body infections, and lung infections in cystic fibrosis patients. SCVs have not been associated with chronic mastitis in cattle, but this might be due to difficulties in the identification of the variants in the laboratory and their instability.

Antibiotic Resistance

The ability to treat *S. aureus* infections has been profoundly compromised by the development of resistance. Shortly after the introduction of penicillin in the late

1940s, penicillin-resistant bacteria emerged due to acquisition of the ability to express a β-lactamase that destroyed the antibiotic. The subsequent introduction of methicillin, a β-lactamase-resistant penicillin, was quickly followed by occurrence of methicillin resistance. This was due to acquisition of the *mecA* gene, which encodes a β-lactam-insensitive penicillin binding protein called PBP2a or PBP2′, which takes over cell wall biosynthesis in the presence of antibiotic (**Figure 1**). Methicillin resistance is now widespread in hospital strains and, very recently, highly virulent CA-MRSA strains have emerged and spread in the community at large. It should be emphasized that *mecA* confers resistance to all classes of β-lactam antibiotics including potent broad-spectrum cephalosporins, cephamycins, and monobactams.

In addition, *S. aureus* has developed resistance to all of the antibiotics that are used to treat staphylococcal infections (tetracycline, macrolides, aminoglycosides, quinolones). Wherever these antibiotics have been used to treat bovine mastitis, resistance has also been reported.

New antibiotics that are specifically targeted at MRSA have been licensed (Synercid, Zyvox, Cubicin) or are in development (a dehydrofolate reductase inhibitor called iclaprim, a fatty acid biosynthesis inhibitor called platensimycin, and a peptide deformylase inhibitor).

The rapid development of resistance is facilitated by horizontal transfer of resistance genes on mobile genetic elements or by mutation. In the case of methicillin resistance, the staphylococcal cassette chromosome (SCC) element can excise from the chromosome of the strain in which it is resident by site-specific recombination (**Figure 1**). It circularizes and can be transmitted to another strain by transduction or transformation. It then integrates into the chromosome at a specific site promoted by the element-encoded integrases. This process resembles the behavior of lysogenic bacteriophages. There are five major classes of SCC*mec* element that have transferred into many different strains to form distinct clones of MRSA. There is recent evidence of a specific MRSA type (ST398) infecting intensively reared farm animals, notably pigs. ST398 can be isolated from farm workers and human infections caused by this strain have been reported.

The majority of horizontally acquired antibiotic resistance is encoded by genes that are located on conventional plasmids and/or transposons. Resistance is caused by plasmid-encoded enzymes that modify the antibiotic binding site in the ribosome (macrolide lincosamide and streptogramin B resistance), by modification of the drug (aminoglycoside and chloramphenicol resistance), by specific drug efflux (tetracycline), or by displacement of the drug from its target (tetracycline). Resistance to fluoroquinolones occurs by stepwise acquisition of mutations that reduce the affinity of two topoisomerase enzymes, which are the inhibitory drug targets, and also by overexpression of the multidrug resistance efflux pump NorA, which reduces the intracellular drug concentration.

Vaccination

Recently, there have been several reports of the development and testing of subunit vaccines to combat *S. aureus* infections in humans. A polysaccharide vaccine comprising the two major serotypes of capsular polysaccharide 5 and 8 has progressed furthest but has shown limited success in human clinical trials. Successful vaccination of laboratory animals with recombinant surface protein antigens (e.g., ClfA and IsdB) has been reported recently. A combination of four of the best performing antigens (IsdA, IsdB, SdrD, SdrE) provided superior protection than each component alone. Vaccination to combat bovine mastitis using bacterins has achieved limited success in trials but has not been developed commercially. The poor performance is likely to be due to the nature of the immunogen, the method of administration, but particularly the difficulty of mounting an effective immune response in the lactating mammary gland.

Introduction

Enterotoxin-producing staphylococci, in particular *Staphylococcus aureus*, are probably the leading cause of foodborne illness throughout the world. The pathogenicity of *St. aureus* has been recognized for many years since this species causes mastitis and skin diseases in mammals or leads to foodborne intoxication. Milk and milk products can become contaminated if good hygiene practice (including mastitis control) is not exercised on farms and the milk is inadequately pasteurized or not heat-treated. After contamination with enterotoxigenic staphylococci food poisoning may happen when abundant growth and enterotoxin formation is encouraged during production and storage.

Staphylococcus aureus is classified in the family Micrococcaceae. The genus *Staphylococcus* is distinguishable from the morphologically similar members of the genus *Micrococcus* by biochemical methods such as the ability of growing anaerobically and demonstrating a fermentative metabolism. The two genera differ also in their DNA base, cell wall and enzyme composition.

The genus *Staphylococcus* has been divided into at least 27 species and seven subspecies. The major characteristics of the species *St. aureus* are coagulase and thermonuclease (TNase) production, but other coagulase- and TNase-positive species, such as *St. intermedius* and various strains of *St. hyicus*, are also described. Both species have been reported to produce enterotoxins at low levels.

Characteristics

Morphology and Culture

Staphylococcus aureus are Gram-positive, catalase-positive bacteria that do not produce endospores. They are 0.5–1.5 μm in diameter and divide in more than one plane to form irregular, three-dimensional clusters of cells. Colonies are smooth, raised, glistening and circular, and may reach a size of 4–6 mm in diameter on nonselective media. Colony pigmentation is influenced by growth conditions and varies from grey or grey–white with a yellowish tint, through yellow–orange to orange. In broth, growth changes from a uniform turbidity to a fine, easily suspended deposit.

Biochemistry and Factors influencing Growth

Nutritional requirements are moderate; organic nitrogen sources and group B vitamins are required for growth. *Staphylococcus aureus* is facultatively anaerobic, but grows best under aerobic conditions. Acid is produced aerobically and anaerobically from glucose, lactose, maltose and mannitol; under anaerobic conditions acid is produced from many other carbohydrates. Major end products of glucose metabolism are acetate and CO_2 (aerobic) and lactate (anaerobic). Catalase is produced by cells growing aerobically. *Staphylococcus aureus* is able to grow between 7 and 48 °C (optimum: 37 °C) and at pH values between 4 and 10 (optimum pH 6–7). *Staphylococcus aureus* tolerates lower a_w values than other bacteria (a_w minimum: 0.83–0.86). The microorganisms grow well at up to 10% NaCl and relatively slowly at 15%. Enterotoxins are produced during all phases of growth, but growth is possible at a wider range of environmental conditions than enterotoxin production. Most strains hydrolyse native animal proteins (e.g. caseins, gelatine, fibrin). Proteases, lipases and esterases are produced. Various lipids, Tweens and phospholipoproteins are hydrolysed with the release of fatty acids. Nearly all strains produce one or a combination of several haemolysins (α, β, δ and γ); β-haemolysin predominates in strains of animal origin. Some strains produce lecithinase.

Serology and Lysotyping

Due to the complex nature of the antigens, serotyping is not used often. However, together with phage typing, where the sensitivity to the lytic action of selected bacteriophages is tested, it is a useful tool in identifying the strain origin in epidemiological studies.

Resistance to Antibiotics

Antibiotic susceptibility and resistance are of eminent importance for all *St. aureus* induced illnesses. In

connection with hospitalization, a widespread resistance against many antibiotics is reported. Concerning *St. aureus* causing mastitis in the udder of lactating cows, antibiotic resistance and susceptibility is most significant. Intramammary infusion of penicillin, which is successful in the treatment of streptococcal mastitis, is often ineffective against *St. aureus*. Staphylococcal mastitis has reached major importance today, due to the emergence of penicillin-resistant strains (**Table 1**). Data on the antibiotic resistance of *St. aureus* as a mastitic pathogen are gathered periodically from various countries by the International Dairy Federation.

Source

Infected Udder

Staphylococcus aureus is found on the skin, teats and mucous membranes of mammals. The infected mammary gland of cows and other animals used for milk production is the most important reservoir. From here the organisms spread to the udder skin, hands of milking personnel, udder cloth and bedding material, whereby transfer of the pathogens during milking is most important. When the udder is infected, *St. aureus* is excreted in the milk with high fluctuations in counts ranging from zero to 10^8 cfu ml^{-1}, but a level of 10^4 cfu ml^{-1} is usual. A characteristic of staphylococcal mastitis is its irregular shedding pattern that complicates diagnosis. Some cows never shed the organisms from the udder or do so infrequently; others shed the staphylococci intermittently at short intervals; and still others show a persistent shedding state, extended over several lactation periods. The frequency of the occurrence of *St. aureus* in milk is also related to age of the cow.

In contrast to reports on the frequency of enterotoxin producers in human strains, the findings with animal strains are very diverse and often apparently contradictory, depending on the source of strains, and the methods involved. The incidence of enterotoxigenic *St. aureus* from animal sources is generally lower than from strains in humans and may vary between 5% and 30%, with enterotoxin C predominating; the incidence seems to be higher in strains isolated from mastitic milk. In goats' milk, more than 30% isolates were enterotoxigenic.

Human Sources

Staphylococcus aureus is frequently found on the skin, nose, pharynx, axilla, umbilicus, perineum, gastrointestinal tract and urogenital tract of humans; the major reservoirs are the nails, skin and hair. The nose appears to be the principal site for multiplication. In various surveys, the incidence of human carriers ranged from 4% to 60%. The frequency of enterotoxigenic strains isolated from humans is high, varying between 40% and 60%; enterotoxin A (SEA) producers are most common. The organisms find their way into the food by hands (infected wounds, skin lesions) or by coughing and sneezing. In general, human contamination is the most important factor in staphylococcal food poisoning, because skin lesions are very common and often ignored by food handlers.

Environmental Sources

Originating from humans and animals, *St. aureus* is widespread in nature. The organisms have been isolated sporadically from soil, sand, marine and fresh water, sewage, plant surfaces and products, feeds, poultry and dairy products, and on the surfaces, dust, and air of inhabited areas. While the opportunities for environmental contamination of milk and dairy products are limited, some processes are still vulnerable, e.g. milk powder production.

Isolation and Identification

Numerous methods to isolate and identify staphylococci have appeared in the literature and are standardized by international and national organizations, e.g. International Organization for Standardization (ISO), Comité Européen de Normalisation (CEN), International Dairy Federation (IDF) and Association of Official Analytical Chemists (AOAC). For the bacteriological examination in mastitis control, nonselective media are used in most cases, where *St. aureus* is identified by its typical appearance on blood agar, Gram reaction and coagulase activity. For enumeration in foods, Baird–Parker agar (BPA) is recommended because of its high productivity, especially if foods containing stressed cells are analysed. However, the medium is not completely selective and reduction of tellurite and egg yolk reaction are poor diagnostic tools since competing microorganisms are also able to reduce tellurite and less than a half of the strains isolated from milk and dairy products yield a positive egg yolk reaction. Consequently, all black to grey colony types, irrespective of egg yolk reaction, must be examined for coagulase production. This lack of selectivity may lead to unreliable results in foods in which *St. aureus* is only a minor part of the total flora able to form colonies on the medium. Therefore ISO suggested rabbit plasma fibrinogen agar (RPFA) as an alternative. This medium allows the detection of coagulase directly on the plate due to the formation of fibrin haloes around the colonies, so that further confirmatory tests are not necessary. Plasma media with constant plasma quality are commercially available. For detection of low numbers ($<100\,g^{-1}$), enrichment procedures are used followed by streaking a loopful of the incubated media onto BPA or RPFA. Recommended enrichment media are tryptic soya broth containing 10% NaCl and 1% sodium pyruvate, Giolitti–Cantoni broth supplemented with 1% Tween 80 and liquid Baird–Parker medium. The two latter media are incubated anaerobically to enhance selectivity.

Identification of suspect colonies is done by the tube coagulase test using rabbit plasma EDTA. The production of thermonuclease may be used for screening purposes. As an alternative to the tube coagulase test, commercially available latex agglutination tests based on clumping factor and protein A detection are in use.

Detection of enterotoxins is of great importance in assessing a health hazard of a certain food. They are identified by their reactions with specific antibodies. To date, rapid and very sensitive methods for detecting the enterotoxins A–E based on sandwich enzyme-linked immunosorbent assay (ELISA) procedures are commercially available in test kit form which allows detection of 0.1–1 $ng\,g^{-1}$ of food. Compared to immunodiffusion assays, ELISA procedures are much more sensitive, but less specific and may give false positive results. For this reason, positive results, especially weakly positives, should be considered presumptive and confirmed by other tests. Reversed passive latex agglutination (RPLA) kits are also commercially available, but are less sensitive than ELISA and nonspecific agglutination is also possible. Due to their high specificity, immunodiffusion assays are still important for detecting strains of enterotoxigenic staphylococci. Recently, the polymerase chain reaction (PCR) has been introduced as a simple, highly sensitive and specific technique for the detection of enterotoxigenic strains.

Pathogenicity

Staphylococcus aureus and Infection

Staphylococcus aureus is able to cause acute infections in humans, which may be localized, e.g. pustular, or spread, e.g. septicaemia. These infections are mediated by a wide range of agressins and exotoxins that are chromosomal or plasmid mediated. Diseases due to specific protein toxins are known, e.g. toxic shock syndrome. In animals, *St. aureus* may cause pustular inflammations of the skin and other organs, of which mastitis is most important. Inflammation of the skin and tissues, especially the mammary gland, is treated by application of antibiotics, taking into account the antibiotic susceptibility and resistance properties of the pathogens involved.

Staphylococcus aureus and Intoxication

Food is implicated in staphylococcal disease in the case of enterotoxicosis. The agents responsible for staphylococcal food poisoning are a series of toxins described as enterotoxins because of their effects on the intestinal tract. They are labelled enterotoxins A (SEA), B (SEB), C1 (SEC1), C2 (SEC2), C3 (SEC3), D (SED) and E (SEE). Recently, the enterotoxins G, H and I were isolated and characterized, but only limited data about their characteristics exist to date.

Staphylococcal enterotoxins are single-chain, low molecular weight (26 000–29 000 Da), heat-stable proteins produced by many strains of *St. aureus*, but other coagulase-positive and even coagulase-negative staphylococci are also able to produce enterotoxins. Most food poisoning outbreaks involve enterotoxins A and D. Production of enterotoxins is strain-specific, but one strain may produce more than one toxin. The production of enterotoxins B and C is controlled by plasmids and occurs mainly at the end of the stationary phase whereas production of enterotoxins A, D and E is under chromosomal control and occurs throughout the logarithmic growth phase. Depending on temperature, pH, water activity, atmospheric conditions and the presence of other microorganisms, they can be produced in food when enterotoxigenic staphylococci are able to proliferate up to a level of at least 10^6 cfu g^{-1}. In most food poisoning outbreaks, counts of 10^8 cfu g^{-1} food and more, and enterotoxin concentrations of 1–5 μg g^{-1} food were detected. However, in sensitive individuals, 0.1–1 μg enterotoxin is sufficient to produce illness. Enterotoxins are resistant to proteolytic enzymes such as pepsin and trypsin; this makes it possible for them to pass through the digestive tract to the site of action.

The common symptoms of staphylococcal enterotoxicosis are nausea, retching, vomiting, abdominal cramps and diarrhoea and they usually develop within 1–6 h after ingestion of the enterotoxin- containing food. In severe cases, headache, muscular cramps, fever and drop of blood pressure may be observed. Deaths of children and elderly people have also been recorded, but they are rare. Recovery takes a few hours to approximately one day, so that a doctor is seldom consulted and consequently most cases are never reported. Effective treatment is not possible, primarily due to the short duration of the disease. In cases where excessive vomiting and diarrhoea occur, administration of fluids may be necessary to restore the salt balance.

Incidence in Milk and Dairy Products

Quarter Samples

Staphylococcus aureus is the most common pathogen causing both clinical and subclinical mastitis, not only in cows but also in ewes and goats. The organism is responsible for approximately 30% to 40% of all mastitis cases. The occurrence of *St. aureus* in quarter milk samples varies from 5% to 22%. In foremilk from subclinical cases, *St. aureus* counts vary from 30 to 380 000 cfu ml^{-1}, and in quarter milk from 210 to 78 000 cfu ml^{-1}.

Bulk Milk

The principal source of contamination of raw milk is the infected udder. For this reason, *St. aureus* is regularly found in bulk milk. However, the counts are related to the mastitis situation of the herd and may range from less than 10 to several thousands per ml milk with occasional counts of 10^5 ml^{-1}. In the EU, criteria for the *St. aureus* content in raw cows' milk intended for consumption without heating ($n=5$, $c=2$, $m=100$ ml^{-1}, $M=500$ ml^{-1}) and for the production of raw milk products ($n=5$, $c=2$, $m=500$ ml^{-1}, $M=2000$ ml^{-1}) have been established. In the criteria cited above, $n=$ number of samples analysed; $c=$ maximum allowable number of defective sample units; $m=$ the value of the characteristic separating good quality from marginal quality; $M=$ the value of the characteristic separating marginal quality from bad quality ($m<M$).

These standards can only be met when effective mastitis control programmes are incorporated on farms and the milk is stored at low temperatures before consumption and manufacture according to the cooling temperatures given in the EU Milk Hygiene Directive 92/46.

Dairy Products

Liquid products

In liquid milk, the organisms are eliminated by pasteurization. Nevertheless, if recontamination occurs or contaminated additives are added after pasteurization, pasteurized milk is an excellent medium for growth and enterotoxin production due to its optimal nutritional status, water activity, pH value, redox potential and the lack of competing flora. In general, fluid milk is less often involved in food poisoning outbreaks than dried milk or cheese.

Dried products

The technology of milk powder production includes several heating procedures, i.e. pasteurization, evaporation and the drying process itself. If contamination occurs, growth and enterotoxin formation during the production process is possible; during the storage of dried milk the organisms surviving the drying process slowly die. Poisoning may happen directly when the milk powder contains enterotoxin and indirectly when contaminating enterotoxigenic staphylococci are able to grow after reconstitution of the powder.

Fermented milk products

Fermented milk products may be considered as safe because the raw milk is heated at high temperatures. If recontamination occurs during manufacture the organisms are rapidly inactivated by amensalism and antagonism of the starters used. Actively growing lactic acid bacteria (LAB) inhibit the growth of staphylococci and also kill them off to some extent. If the fermented product itself is contaminated, the contaminants are not able to multiply due the acidic environment even when cooling is unsatisfactory.

Cheese

During cheese manufacture, the staphylococci in milk are physically concentrated approximately 10-fold in the curd. Therefore the *St. aureus* content in the young cheese is directly dependent on the *St. aureus* counts in milk. Further, the organisms are able to proliferate during the first 24 h (in the vat and during pressing/moulding) until the acids produced by the starters inhibit further growth. If abundant growth of enterotoxigenic strains is possible at this stage of production, enterotoxins will be formed. The magnitude of multiplication is strongly dependent on the amount, the activity and the type of the starters used. Growth and enterotoxin production is inhibited primarily due to the low pH and the formation of lactic acid, but during Gouda cheesemaking, inhibition was observed before the pH had dropped below 6.0 and it was concluded that the onset of inhibition of *St. aureus* may be due to the decrease in redox potential and the formation of antimicrobial compounds excreted by LAB. An increase of 1.5 to 3 log during the first 24 h of cheesemaking may be expected under normal conditions, but, in cheeses with suboptimal acidification, increases up to 5 log have been observed. Low acidification is caused by insufficient starter development due to inhibition of LAB by antibiotic residues in milk or by bacteriophage infection, but the acidification rate is also lowered when inadequate inocula were used or the starters are inactivated due to prolonged storage. In the production of Cheddar cheese, inhibition of LAB is also caused by addition of salt to the curd. A special case is the production of cooked hard cheeses made from raw milk (Emmental cheese, Gruyère type cheeses, extra hard cheeses), where the curd is cooked at temperatures between 50 and 57 °C. Due to these high cooking temperatures, the high temperatures on the press and the acidification with active thermophilic starters, *St. aureus* is usually inactivated during the first day of manufacture.

Although there tend to be large differences between cheese varieties, *St. aureus* counts decrease during ripening and storage of cheese manufactured with starters of normal activity. However, when acidification is suboptimal, the decline in numbers may not be apparent and less than 1 log cycle. In general, the higher the ripening temperature the higher is the decline in numbers, although the amount of salt present in the cheese may influence this. If enterotoxins were produced during manufacture, they may persist over years in the cheese.

Apart from the acidification rate at the beginning of manufacture, the *St. aureus* content of cheese is primarily dependent on the cheese variety (technology), the kind of milk used for manufacture (raw milk/heat treated milk) and the possibilities of contamination during the manufacturing process (open/closed system). In contrast to cheeses made from pasteurized milk, where *St. aureus* is usually not detected or present in low numbers, raw milk cheeses are a potential danger, unless contamination of milk is low and acidification is optimal. Therefore, the EU established criteria for cheeses made from raw milk ($n = 5$, $c = 2$, $m = 1000\,\mathrm{g}^{-1}$, $M = 10\,000\,\mathrm{g}^{-1}$), irrespective of the origin of the milk (cow, sheep, goat). If the maximum level M is exceeded, the cheese has to be tested for enterotoxins and also the enterotoxigenicity of the isolated coagulase-positive strains must be determined.

Control

General Hygiene

Contamination with *St. aureus* can be effectively controlled by good manufacturing practice (GMP). In recent years, the dairy industry was forced by international and national authorities to introduce the principles of Hazard Analysis Critical Control Point (HACCP) systems according to the EU Milk Hygiene Directive 92/46. This directive provides guidelines for the hygienic design and maintenance of buildings, services and equipment, and also for personal hygiene. Regular training of persons handling food is of eminent importance in preventing human contamination. Further, cleaning and disinfection schedules are necessary for eliminating staphylococci from surfaces. In the production of raw milk cheeses, it must be guaranteed that milk from mastitic cows is not used. This can be achieved by effective mastitis control programmes on farms including the culling of chronic *St. aureus* cows.

Cooling of milk

Since *St. aureus* fails to multiply at temperatures below 7 °C, cooling is the most effective means of preventing growth and enterotoxin production. When cheese is produced from raw milk, the milk has to be cooled immediately after production and extended storage must be avoided. In general, raw milk must be processed as soon as possible unless the milk is heat treated. Also preripening in the vat must be as short as possible to prevent undesired growth.

Heating of Milk

Pasteurization of milk (72 °C for 15 s) is effective in the elimination of *St. aureus*. However, even after applying this temperature/time combination, 0.38% of the staphylococci may survive, but no survivors were detected at 72 °C for 35 s. In cheesemaking thermization of milk (57–68 °C for at least 15 s) is also applied. The temperature/time combinations at these subpasteurization conditions do not guarantee elimination of *St. aureus* in every case. Thermal resistance is primarily dependent on the strain, the physiological state of the organisms and the medium. Decimal reduction times may vary between 0.43 and 8 min at 60 °C. Unlike the producer organism, staphylococcal enterotoxins are remarkably heat resistant, showing D-values of 3–8 min at 121 °C.

Interactions with other Microorganisms

Since *St. aureus* is a poor competitor, its growth is inhibited by common spoilage organisms. *Bacillus cereus*, *Proteus* *vulgaris*, *Escherichia coli*, *Enterobacter aerogenes* and *Achromobacter* spp. inhibit staphylococci by production of antibiotic substances, while *Serratia marcescens* and *Pseudomonas* spp. appeared to inhibit *St. aureus* by out-competing it for amino acids. In foods with reduced a_w (0.95 or less and salt concentrations of 5.5% and higher), growth of competing flora will be suppressed, whereas *St. aureus* is able to proliferate under these conditions. In such foods, a hazard can only be minimized by preventing contamination and storage at low temperatures.

In the production of fermented milk products, the strong antagonistic activity of LAB is most important. *Staphylococcus aureus* is inhibited by LAB due to low pH and redox potential, and the formation of acids (especially lactic acid) and antibiotic substances. In the manufacture of raw milk cheeses, sufficient acidification, especially in the early stages of cheesemaking, must be achieved by the use of a sufficient amount of an active starter. Measurement of cheese pH two hours after moulding gives information about the acidification rate.

Conclusions

The growing interest concerning the group of 'new emerging pathogens' (e.g. *Listeria monocytogenes*, *Campylobacter* spp., enterohaemorrhagic *E. coli*) has overshadowed the interest in *St. aureus*. Nevertheless, *St. aureus* remains one of the most important foodborne pathogens, therefore the knowledge of specific characteristics of this species, such as pathogenicity, and of its incidence in milk and dairy products is essential for finding effective ways to control this microorganism in food hygiene and food technology.

Yersinia enterocolitica

M D Barton, University of South Australia, Adelaide, SA, Australia

© 2011 Elsevier Ltd. All rights reserved.

Characteristics

Taxonomy

The genus *Yersinia* contains 15 species but only 3 are pathogenic to humans. *Yersinia pestis* is the cause of plague, *Y. pseudotuberculosis* is associated with intestinal infections and mesenteric lymphadenitis, and *Y. enterocolitica* is associated with foodborne intestinal infections. There are a number of species closely related to *Y. enterocolitica*, which were previously called 'atypical *Y. enterocolitica*' or '*Y. enterocolitica*-like organisms', but which have now been identified as separate species including *Y. intermedia*, *Y. kristenseniae*, *Y. frederikseniae*, *Y. mollaretii*, *Y. bercovieri*, *Y. aldovae*, and *Y. rohdei*. These species are widely distributed in the environment and can be isolated from food and water, and from human and animal feces, but there is no evidence linking them with human or animal disease.

Biotypes and Serotypes

Yersinia enterocolitica is a heterogeneous species that can be divided into a number of groups based on biochemical activity (biotypes) and lipopolysaccharide O-antigens (serotype). Six biotypes are described (**Table 1**). The strains associated with human disease are most commonly found in biotypes 1B, 2, 3, and 4. Biotype 1A strains were traditionally regarded as environmental but now there is evidence that some strains can cause human disease, and biotype 5 has been isolated only from animals and the environment.

At least 60 different serotypes are recognized, with O-antigens shared between *Y. enterocolitica* and its close relatives. Heat-labile flagella H antigens have been described but are not used in typing. There are strong associations between particular biotypes and serotypes (**Table 2**) and between bioserotypes, pathogenicity, and geographic distribution. Bioserotype 4, O:3 is the most common human pathogen and is now found worldwide. In northern Europe bioserotypes 2, O:9; 2, O:5,27; and 3, O:5,27 have also been important. However, since 2004 there has been a surge in O:8 cases in northern Europe. Biotype 1B strains (bioserotypes 1B, O:8; 1B, O:13a,13b; 1B, O:20; 1B, O:21), called North American strains, are more pathogenic than the European strains. Information on geographic distribution of bio/serotypes is given in **Table 2**.

Laboratory Identification

Morphology and Appearance in Cultures

Yersinia enterocolitica is a small Gram-negative rod. It is actively motile at 22–25 °C but not motile at 37 °C. It produces circular, smooth, low, convex colonies of 1–2 mm diameter with an entire or slightly crenulated edge after incubation at 37 °C for 24 h. On MacConkey agar, 1.5–2 mm translucent, pale non-lactose fermenting colonies are seen. Some environmental strains do ferment lactose and thus produce bright pink colonies on MacConkey agar. On cefsulodin–irgasan–novobiocin (CIN) agar *Y. enterocolitica* produces highly characteristic 1.5 mm diameter colonies with a dark pink center and a translucent border (bull's-eye) colonies.

Identification

The optimum temperature for growth of *Y. enterocolitica* is 28 °C, and if identification tests are incubated at 37 °C confusing results can be obtained. Commonly used identification tests are listed in **Table 3**. Identification kits such as API 20E (bioMérieux SA, France) kit system can be used but should be incubated at 30 °C. However, biochemical tests are not particularly reliable as non-pathogenic species can be misidentified as *Y. enterocolitica.*

Increasingly, molecular methods such as 16S rRNA sequencing are used for definitive identification. Molecular typing based on DNA–DNA hybridization and 16S rRNA sequencing can distinguish between biotype 1B (North American pathogenic mouse lethal strains) and the European strains. In addition, PCR for virulence genes such as the plasmid-encoded *vir*F and *yad*A, and the chromosomally encoded *ail*, *inv*, *yst*, and *rfb* genes can be used to distinguish *Y. enterocolitica* from its environmental relatives.

Physiological Properties

Yersinia enterocolitica is capable of growth at temperatures ranging from below 0 to 44 °C, although its optimum temperature range is 22–28 °C. It tolerates a pH range from 4.6 to 9.0 but prefers slightly alkaline conditions. The *D* values of *Y. enterocolitica* are approximately 2 min at 55 °C, 0.5 min at 60 °C, and 2 s at 65 °C. The *D* value for *Y. enterocolitica* in milk is 0.24–0.96 min at 62.8 °C.

Serotyping and Biotyping

Serotyping and biotyping are useful indicators of the potential pathogenicity of isolates of *Y. enterocolitica.* Antisera to only a few serotypes (O:3, O:8, O:1,2, O:9, and O:5,27) are available commercially.

Phage Typing

Phage typing is carried out in a few specialized laboratories, and thus is not commonly used. Geographic distribution of phage types of bioserotype 4,O:3 is recognized, as is the association of particular phage types of this bioserotype with the development of postinfection sequelae. Phage typing has largely been replaced by molecular typing.

Molecular Typing

A number of molecular methods have been applied to the identification of *Y. enterocolitica* and differentiating

Table 4 Molecular identification and typing of *Yersinia enterocolitica*

Method	*Typability of strains*	*Reproducibility*	*Discriminatory power*	*Comment*
REAC	All	Poor	Moderate	Some serotype-specific patterns; useful for subtyping O:8 strains
Ribotyping	All	Good	Good	Differentiates species; useful for subtyping O:3 strains
16S–23S IGS typing	All	Good	Potentially useful	Only two studies – potential for subtyping
RAPD	All	Moderate	Moderate	Useful in epidemiological studies
PFGE	All	Good	Good	Best method to date for subtyping
MLST	All	Good	Good	Only one study to date – good inter- and intraspecies differentiation
AFLP	All	Good	Good	Only one study – strong alignment with biotype
16S DNA sequencing	All	Good	Good	Species identification – differentiation of pathogenic strains

16S–23S IGS, 16S–23S intergenic spacer typing; AFLP, amplified fragment length polymorphism; MLST, multilocus sequence typing; PFGE, pulsed-field gel electrophoresis; RAPD, randomly amplified polymorphic DNA; REAC, restriction endonuclease analysis of chromosome.

pathogenic from nonpathogenic strains (**Table 4**). Unfortunately, the high similarity between strains and the predominance of particular genotypes within bioserotypes limit the value of these methods.

Pathogenicity

Virulence determinants of *Y. enterocolitica* are found both on the chromosome and on a 70-kb virulence plasmid. In addition, the North American biotype 1B strains carry a chromosomal pathogenicity island associated with increased virulence for mice and humans.

Chromosomal virulence genes include *yst*, which encodes Yst, a heat-stable enterotoxin; *inv*, which encodes invasin, a surface protein important in the translocation of *Y. enterocolitica* across the intestinal epithelium and in the colonization of Peyer's patches in the mouse model of infection; and *ail* (found only in pathogenic strains), which encodes a membrane-associated protein that promotes attachment of the organism to eukaryotic cells, has a support role as a secondary invasion factor, and confers resistance to the action of serum complement. Numerous other chromosomal genes contribute to virulence, including a urease gene complex – pathogenic strains of *Y. enterocolitica* produce urease, which may facilitate survival of the organism in acidic environments such as the stomach.

The pYV plasmid of *Y. enterocolitica* encodes the Yop (*Yersinia* outer proteins) operon, which is an integrated virulence apparatus. Mouse studies have shown that strains lacking Yop are readily phagocytosed by macrophages and are unable to cause disease. The Yop operon is made up of at least 14 proteins, the majority of which have been shown to be essential for virulence. Another virulence gene carried on the pYV plasmid is *yad*A, which encodes YadA, an outer membrane protein expressed only at 37 °C and which is responsible for adhesion to intestinal epithelium, serum resistance, and resistance to killing by phagocytic cells.

Highly pathogenic biotype 1B strains carry a high-pathogenicity island (HPI), which is an iron uptake system that facilitates the growth of these strains under iron-depleted conditions at 37 °C.

Until recently, biotype 1A strains were regarded as nonpathogenic. They do not carry the pYV plasmid, but are occasionally isolated from humans with gastrointestinal diseases. Serotypes O:5, O:10, and O:6,30 have to date been associated with outbreaks of clinical disease.

The infectious dose of *Y. enterocolitica* is unknown but is estimated to be around 10^6–10^7 organisms.

Pathogenesis

After ingestion, pathogenic *Y. enterocolitica* pass through the intestinal tract to the ileum, where they bind to the M cells in Peyer's patches. This attachment is facilitated by YadA. The organisms penetrate the intestinal mucosa through M cells and colonize the Peyer's patches from where they can spread to the mesenteric lymph nodes through lymphatic vessels. This phase is facilitated by Yops. In rare cases *Y. enterocolitica* can spread through the bloodstream to other sites such as liver and spleen. YadA and Ail contribute to resistance to killing by serum complement.

Clinical Disease

Yersinia enterocolitica is an enteric pathogen, which in susceptible people can cause extraintestinal disease.

Enterocolitis is the most common manifestation and is seen principally in young children. Older children and adolescents may develop mesenteric lymphadenitis (mimicking appendicitis). Some cases are subclinical, and in the clinical cases the onset of clinical signs usually occurs within 24–48 h of ingestion of the organism. The illness usually lasts 1–3 days, with diarrhea seen in most cases plus fever, headache, and vomiting in many cases. Involvement of mesenteric lymph nodes leads to severe abdominal pain. The minimum infective dose for humans is not known, and the duration of excretion of the organism ranges from 2 weeks to more than 2 months.

Yersinia enterocolitica infection is normally self-limiting but long-term sequelae such as reactive arthritis, erythema nodosum, uveitis, glomerulonephritis, and myocarditis have been reported. Reactive arthritis is associated with the human leukocyte antigen HLA-B27 and certain strains of bioserotype 4, O:3 more common in Nordic countries. Patients with underlying iron metabolism disorders such as siderosis, thalassemia, or hemochromatosis are more susceptible to bacteremia and extraintestinal infections, and transfusion-related septicemia has been reported in patients receiving blood transfusions from asymptomatic blood donors.

Epidemiology and Ecology

Most cases of *Y. enterocolitica* infection are reported from the temperate areas of the world, for example, Scandinavia, northern Europe, and New Zealand. It is widely distributed in the environment and can be isolated from soil and water, and the intestinal tract of many vertebrates and invertebrates. The organism has minimal nutrient requirements at low temperatures and can remain metabolically active at very low temperatures. Most environmental strains belong to the nonpathogenic serotypes, but pathogenic serotypes O:8, O:9, and O:5,27 have been isolated from healthy pigs.

The pattern of distribution of serotypes has changed over the years. Originally, serotype O:3 was rare in the United States in comparison with serotype O:8, but in the late 1980s serotype O:3 overtook O:8 and is now the most common serotype worldwide. However, serotype O:8 causes more serious infections.

Sources of Infection

Infection with *Y. enterocolitica* has been linked most clearly to the handling and consumption of raw and undercooked pork, with the same serotypes (principally O:3, O:9, and O:5,27) and genotypes isolated from pigs and affected humans. *Yersinia enterocolitica* has often been isolated from foods, including animal products (beef, lamb, poultry, as well as pork), milk, shellfish, and crustaceans. However, most of the isolates belong to nonpathogenic serotypes.

Most infections with *Y. enterocolitica* occur sporadically, where the source of infection is hard to determine. A prospective case–control study in Norway suggested a strong linkage with consumption of raw or rare meat and untreated water. Vegetables and fresh herbs have also been incriminated.

Outbreaks of *Y. enterocolitica* have been reported in a number of countries including the United States, Canada, Japan, Finland, and Czechoslovakia. Incriminated sources include raw and pasteurized milk, chocolate milk, tofu, bean sprouts, and spring and stream water. In many of the outbreaks no source could be identified. Serotypes reported include O:3 (11 of 20 outbreaks); O:8; O:9; O:5,27; and O:13a, 13b. Person-to-person spread in family clusters and direct transmission from animals have been suspected.

Occurrence of *Yersinia enterocolitica* in Milk and Dairy Products

A small number of outbreaks associated with milk and dairy products have been reported from a number of countries (**Table 5**). No outbreaks have been reported in the literature since 2000. Some serotypes usually regarded as nonpathogenic are alleged to have been the cause of some of these outbreaks. Definitive proof, one way or the other, is difficult to obtain when nonpathogenic environmental strains of *Y. enterocolitica* are so widely distributed in the environment generally and in milk products specifically, as indicated in **Table 6**. In general, the microbiological evidence linking even the pathogenic serotypes with the outbreaks is not strong, and the causative linkage is based on epidemiological criteria from investigations such as case–control studies or analysis of food consumption histories. It is interesting to note that many of the outbreaks are associated with pasteurized milk, although *Y. enterocolitica* is quite heat-sensitive and readily destroyed by pasteurization at concentrations up to 10^5 organisms ml^{-1}. If the milk product is at fault, there must have been postpasteurization contamination. In several of the outbreaks there appears to have been the possibility of postprocessing contamination from pig-related contacts. *Yersinia enterocolitica* grows well in raw milk but there are few outbreaks linked to this source. The role of milk and dairy products in sporadic cases of *Y. enterocolitica* infection is not well studied.

There are a number of reports of isolation of *Y. enterocolitica* from raw and pasteurized milk, as indicated in **Table 5**, and some reports of isolation from milk products such as ice cream and yogurt. Most of

Table 5 Outbreaks of *Yersinia enterocolitica* infection associated epidemiologically with milk and dairy products

Product	*Number of human infections*	*Bioserovar*	*Number of isolates from product*	*Country (year)*

[a] Biotype 1A serotypes previously regarded as nonpathogenic.
?, no information provided.

Table 6 Isolation of *Yersinia enterocolitica* from milk and dairy products

	Serotype	*Countries*
Pathogenic	O:21; O:5,27; O:9	Canada, France, USA, Ireland, UK, Brazil, Bulgaria, Iran
Biotype 1A strains some of which may be pathogenic	O:4,32; O:4,33; O:5; O:6,30; O:6,60; O:7,8; O:14; O:15; O:18; O:34; O:41,42; O:46	Canada, Australia, France, USA, Italy, UK, Ireland, Brazil

the serotypes reported are those regarded as nonpathogenic, and there appear to be no reports of isolation of O:8 or O:3 or O:9 from raw milk, although there are a number of reports of isolation of O:5,27 (which includes both pathogenic and nonpathogenic strains). Many studies unfortunately do not report the serotypes isolated, and some do not differentiate between *Y. enterocolitica* and *Y. enterocolitica*-like species.

There are no reports of detection of *Y. enterocolitica* in ripened hard cheeses and only occasional reports of isolation of the organism from soft cheeses made from raw milk. However, experimental studies have shown that pathogenic serotypes can grow on outer and exposed surfaces of cheese such as Brie at 4, 8, and 20 °C, and in Cottage cheese. In most cases where serotyping is reported, the isolates from milk and milk products belong to the nonpathogenic serotypes of biotype 1A (e.g., serovars O:5; O:6,30; and O:7,8) or environmental stains in other biotypes. A number of studies where samples are spiked with microorganisms have reported that *Y. enterocolitica* does not survive as well as other enteric bacteria in fermented milk products such as yogurt.

Yersinia enterocolitica (serotypes not specified) have been isolated from dairy plant environmental samples and equipment in dairy factories.

Isolation and Detection of *Yersinia enterocolitica* in Food and Environmental Samples

The following are the factors that must be considered in approaching the isolation of *Y. enterocolitica* from food or environmental samples: first, the organism may be present in low numbers, so enrichment is required; second, the presence of the organism could be masked by the presence of large numbers of other bacteria, so a selective step is essential; third, nonpathogenic *Y. enterocolitica* and *Y. enterocolitica*-like species are likely to be present, so differentiation of pathogenic from nonpathogenic organisms is required. As a result, in recent years a combination of selective enrichment and molecular methods has been developed.

Conventional isolation procedures involve an enrichment procedure followed by plating onto selective media and confirmation of the identity of colonies that have typical colonial morphology. There is no single method of enrichment that will guarantee isolation of all pathogenic *Y. enterocolitica* serotypes, so the use of more than one approach is often recommended.

Enrichment approaches include

1. *Cold enrichment at 4 °C*: This approach takes advantage of the fact that *Y. enterocolitica* multiplies at 4 °C. Simple cold enrichment in phosphate-buffered saline

(PBS) or tryptone soy broth (TSB) or PBS supplemented with 1% sorbitol and 0.15% bile salts for up to 3 weeks can be used. The method is quite sensitive as *Y. enterocolitica* multiplies under these conditions while nonpsychrotrophic contaminating organisms die out. However, the method is too slow for routine use.

A modification of cold enrichment is to treat the enrichment broth with KOH, as *Y. enterocolitica* is quite tolerant of alkaline conditions. This is reported to be less effective than other enrichment methods.

2. *Single-step enrichment in various selective broths*: Selective broths used include modified Rappaport's medium (MRM) incubated at 22–25 °C for 2–4 days, irgasan–ticarcillin–potassium chlorate (ITC) medium incubated at 24 °C for 2–3 days, and modified selenite medium. Bioserotype 4, O:3 appears to grow better in MRM and ITC than do other bioserotypes (2, O:9; 2, O:5,27; and IB, O:8). Bile–oxalate–sorbose medium has been reported as suitable for serotype O:8.

3. *Two-step enrichment*: This method involves preenrichment in a nonselective medium such as PBS or TSB at temperatures between 4 and 25 °C for 24 h or longer, followed by inoculation into a selective broth such as MRM. This is reported to allow more sensitive strains of *Y. enterocolitica* to multiply in the nonselective medium so that a larger inoculum is exposed to the selective medium. A different strategy involving the use of Luria–Bertani–bile salts broth incubated for 24 h at 12 °C before the addition of irgasin and a further incubation for 48 h at 12 °C has been reported to be particularly successful in the isolation of serotypes O:8, O:5, O:27, and O:3 from spiked samples and in the isolation of bioserotype 4, O:3 from pig samples.

4. *Selective isolation media*: *Yersinia enterocolitica* grows readily on a range of media used for the isolation of other enteric organisms such as MacConkey agar, desoxycholate citrate agar, and salmonella–shigella agar. However organisms may be overlooked on such media, particularly if present in low numbers. CIN medium was developed specifically for the isolation of *Y. enterocolitica* and has the additional advantage that the organism produces the characteristic bull's-eye colonies on this medium. CIN is considered the most effective medium for the isolation of *Y. enterocolitica*.

A method for direct detection of virulence plasmid-carrying strains of *Y. enterocolitica* has been described, which involves subculture of Luria–Bertani–irgasan broths onto low-calcium Congo red brain heart infusion agar. Colonies of virulent (plasmid-bearing) *Y. enterocolitica* produce pinpoint red colonies on this medium.

Molecular Detection Methods

The traditional cultural methods for the detection of *Y. enterocolitica* have limitations, especially when attempting to detect the organism in food or environmental samples. It is clear that detection of *Y. enterocolitica* in such samples can be improved by the use of polymerase chain reaction (PCR) techniques. Target genes that have been used for PCR include *ail*, *yad*A, and *yst*. Generally speaking, chromosomally located target genes are preferred because the plasmid is unstable and easily lost during subculturing in the laboratory. Single, multiplex, and nested PCR methods have been reported, and, more recently, real-time PCR methods have been described. These have the advantage of greater specificity and require less time to complete than conventional PCR. However, there are some limitations and problems associated with the use of PCR. These include the presence of inhibitory substances in the sample, the inability to differentiate between live and dead organisms, and the low number of organisms in the sample. These problems can be overcome to some extent by using an enrichment step and applying the PCR to the incubated enrichment broth.

Prevention and Control

Pasteurization of milk and milk products is a key control measure. However, care has to be taken to ensure that postpasteurization contamination does not occur as *Y. enterocolitica* can survive and multiply in milk and on the surface of cheeses at refrigeration temperatures. Nonheat methods of treatment such as high-pressure cold pasteurization and pulsed electric field treatments may have a role to play, but their efficacy in killing *Y. enterocolitica* has not been evaluated. While in the past there may have been concerns about milk as a major source of *Y. enterocolitica* infections, it is now clear that most infections are directly or indirectly associated with pigs and pig products.

Process and Plant Design

R P Singh, University of California, Davis, CA, USA

Introduction

The design of a dairy plant and its associated processes is often an open-ended problem with many possible solutions. Each design solution may have a unique impact on production capacity, process control, safety, environment, and economics. In conducting an engineering design project, several requirements relating to the following aspects must be met:

1. Product (raw materials and quality of the end product)
2. Process (plant capacity, equipment, controls, and cleaning)
3. Economics (cost of production)
4. Legal considerations (regulations relevant to process, equipment, and safety).

Although it is common to seek a compromise between these requirements for a specific application, careful consideration of these characteristics is essential to develop an optimal design. This requires an extensive literature search, knowledge of the food and its material properties, and a description of the equipment, including process flow diagrams. Numerous reference books are available for designing dairy processes and plants (see 'Further Reading'). Research journals such as *Australian Journal of Dairy Technology, Dairy Science & Technology, International Dairy Journal, Journal of Dairy Research,* and *Journal of Dairy Science*, patents, and technical literature available from manufacturers through the World Wide Web are also potential sources of information.

Process Flow Sheet

The design process begins with the preparation of a detailed flow sheet, which should clearly indicate the major plant equipment and the flow of product, utilities, and waste materials. Although a simple flow sheet is merely a sequence of processing equipment, it is often necessary to develop a detailed flow sheet with information such as the type of processing equipment, pipes, utility requirements, flow rates, and required instrumentation. It is not uncommon to develop separate flow sheets with more specific information for special purposes, such as for detailing all the control instrumentation. A 3D flow sheet is also generally used for a better visualization of the plant and equipment. A clean-in-place system should be included in the flow sheet for process equipment and pipelines. Each of these items must be labeled clearly. **Figure 1** shows the diagram of a multiproduct dairy plant and illustrates a simple flow sheet for a market milk process. This flow sheet may differ depending on different regulatory and marketing requirements. Although pasteurizing whole milk is a simple process line, complexities arise when manufacturing several types of milk products, such as whole milk, milk standardized to various fat contents, and creams with different fat levels.

After the flow sheet is completed, the next two steps include conducting mass and energy balances. A mass balance must be comprehensive enough to include all materials flowing through the plant and their composition. The energy balance is conducted to determine the energy requirements of all the operations identified on the flow sheet. After the mass and energy balances have been determined, the next step is to design each unit. At this stage, a preliminary economic appraisal should be conducted based on the data acquired for the mass/energy balances.

Equipment Selection

Selection of process equipment requires careful attention to equipment sizing, cost, efficiency, and ease of maintenance. A major emphasis is often placed on the capital as

well as operating costs, as these costs influence the profitability of the operation. In food and dairy processing, the ease of cleaning is an important consideration in selecting equipment.

Equipment Common to All Dairies

Tanks

Tanks of various sizes are essential in dairy processing. Sizes ranging from 100 to 100 000 l are commonly used. Typically, tanks serve two major functions: storage and processing.

Storage tanks (silo tanks) constructed of stainless steel range in size from 25 000 to 150 000 l. These storage tanks are often placed outdoors when indoor space is limited. The number and size of silo tanks used are determined by the quantity of milk processed per day and the number of different products manufactured. Furthermore, the frequency of processing days per week, as well as the number of processing hours per day, will determine the size or number of storage tanks. The size of silo tanks in the delivery area is determined by the expected schedule of raw milk delivery to the plant. If the plant is to be operated continuously, then a 7 h supply of raw material should be available. If milk is to be held for more than 8 h in a tank, then refrigerated or insulated tanks are required. In the process line, buffer tanks are used to hold milk for short durations. A general rule of thumb is to have a buffer capacity of a maximum of 1.5 h of normal operation.

Heat exchangers

Control of temperature is an essential feature of modern dairy plants. Processing steps require either heating or cooling, processes that are carried out using heat exchangers. For heating purposes, hot water or low-pressure steam is used; however, milk itself is used as a heating medium in a regenerative process. For cooling purposes, chilled water or glycol is used; again, milk is used as a cooling medium in a regenerative process. The three most common types of heat exchangers used in the dairy industry are the plate, tubular, and scraped-surface heat exchangers. Plate heat exchangers are best suited for the treatment of milk, the predominant product in the dairy industry. Heat exchanger design and performance are influenced by product flow rate, temperature and time requirements, cleanability issues, and the properties of the product undergoing heat treatment. Most texts on food engineering address the principles of heat transfer.

Pumps

Transport of liquids from one location to another in a dairy processing plant requires energy, which is provided by pumps. For handling milk and dairy products, the construction material used for pumps is typically stainless steel, food grade rubber, or plastic. The pump design should permit easy cleaning-in-place (CIP). The most common types of pumps used in milk and dairy processing include centrifugal, liquid-ring, and positive displacement pumps. Centrifugal pumps are well-suited for low-viscosity liquids, such as milk. When a liquid contains some amount of air, then liquid-ring pumps are suitable. These pumps are also used for CIP return solutions, which invariably contain air. For higher-viscosity products and those exhibiting non-Newtonian characteristics, such as cream, cultured milk products, and curds, positive displacement pumps are used. Piston pumps are used for metering purposes. A homogenizer is a type of piston pump that is used to break large fat globules into smaller ones (*see* **Homogenization of Milk**: Principles and Mechanism of Homogenization, Effects and Assessment of Efficiency: Valve Homogenizers).

Pipes, fittings, and valves

Pipes are ubiquitous in a dairy plant; they are used for transporting low- and high-viscosity liquids and gases. Pipes convey not only dairy products but also all the utilities (steam, water, compressed gases) from one processing apparatus to another. The material of construction and design used for pipes depend on the product being conveyed. In designing pipelines for dairies, the important issues of concern include construction material, size, and contact surface, particularly around welded joints.

In dimensioning the pipelines, careful attention should be given to the selection of flow rates and velocities. Flow rates in fluid-handling systems are typically in the range of 100–30 000 l h^{-1}, with velocity being limited by the product characteristics. For example, the velocity of raw milk should not be greater than 1.5 m s^{-1} to avoid damage to the fat globules. For skim milk and buttermilk, the velocity is normally around 2 m s^{-1}. However, because cream has a high viscosity, its velocity would be less than 0.5 m s^{-1}. Utilities are pumped at much higher velocities: steam at around 30 m s^{-1} and water at 5 m s^{-1}.

A variety of fittings are used in the pipelines, such as elbows, tee connections, and connectors. These fittings match the diameter of pipelines and other process equipment. To control the direction and magnitude of flow, a variety of valves are used. Some examples are seating valve, check valve, air blow valve, and regulating valve.

Stirring devices

Stirring devices are used for equalizing temperature and/or concentration in a vessel. The design of stirrers depends on the viscosity of the product. For low-viscosity products (viscosity <1 Pa s), such as whole milk or whey, paddle, curved blade, propeller, or turbine impeller stirrers are used. For medium- to high-viscosity products (viscosity ≈0.5–5 Pa s), such as condensed milk, yogurt, or cream, cross rod, gate, or blade paddle stirrers are used. For high-viscosity products (viscosity >100 Pa s), such as quark or processed cheese, anchor, finger, or helical ribbon stirrers are used.

Centrifuges

Separating components in a liquid stream is an important process in dairy processing. For purposes of clarification centrifuges are used. Typical centrifuges used in the industry can separate particles of 4–5 μm diameter.

Homogenizers

In full-fat milk, the formation of a cream layer occurs during storage due, *inter alia*, to the large diameter of fat globules. However, if the size of these globules is reduced, creaming is minimized. Homogenizers are used for this process. The degree to which the products should be homogenized depends upon the expected storage time of milk.

Because the fat phase in milk must be in liquid state for homogenization to be effective, milk must be heated to a temperature in the range of 55–80 °C. A homogenization pressure in the range of 10–25 MPa is selected, depending on the product characteristics. Homogenization of cream with a fat content >12% is difficult owing to the lack of casein to stabilize the newly formed emulsion surface. For adequate levels of homogenization, 0.2 g of casein per gram of fat is necessary. Conventional homogenizers are triple-piston high-pressure pumps.

In milk processing, the homogenizer is located after the first regenerative section of a pasteurizer. In the production process of UHT milk, the homogenizer is located in the upstream section when an indirect heat exchanger is used, but on the downstream side when direct heat exchangers are used. When located on the downstream side, the homogenizer must maintain aseptic conditions, requiring special piston seals, packings, and aseptic dampers.

Special Equipment

Table 1 lists some of the special items of equipment required for dairy processing operations.

Materials

Construction materials that have direct contact with the product must be nontoxic and inert to foods. For hygienic reasons, surfaces that come in contact with dairy materials must be well-ground and polished, or cold-rolled. On the other hand, materials that do not make contact with foods, such as pipelines for utilities, must be corrosion-proof and remain stable. The surfaces of materials used for the construction of manufacturing process equipment must be well-ground and treated with lacquer or undergo a similar procedure.

Standards

Specifications for all equipment must be written down carefully. A number of standards are available for writing specifications, such as 3-A Sanitary Standards, 3-A Accepted Practices, International Dairy Federation Documents, and US Department of Agriculture publications. The US Department of Agriculture provides criteria, guidelines, and principles for the sanitary design and fabrication of dairy processing equipment, as well as a list of equipment that are rated as acceptable for use in dairy plants.

Process Control

Because processing equipment must have the capacity for trouble-free operation under variable conditions, control equipment is used to maintain desired liquid levels, flow rates, pressures, concentrations, pH levels, and temperatures. The control systems must be simple, rugged, and robust. Careful attention should be paid to maintenance requirements.

The level of automation in process control is determined by the type of processing equipment and its interaction with the instrumentation used for automation. The selection of instrumentation depends on how it will interact with the operator and with procedures that manage the information obtained from it, such as how errors will be corrected.

Typically, the automation systems use programmable logic controllers. These systems must be flexible, easy to expand, and reliable. These systems should include electronic solutions, with software for diagnostic tests. More recently, simulations have become an attractive part of the software.

Utilities

Dairy operations require a number of utilities such as electricity, steam, hot water, chilled water, compressed air, and refrigeration. Water consumption for a typical dairy plant is 1000–5000 l per 1000 l of milk. Water is transported in stainless-steel pipes with a diameter larger than 6.35 cm or in smaller galvanized-steel pipes. The pipeline system includes valves for shutoff and routing purposes, and pressure gauges. Often, dairy plants rely on their own water supply instead of using municipal water (*see* **Utilities and Effluent Treatment**: Water Supply).

For most heating applications, steam (140–150 °C) is the most commonly used heating medium in the dairy industry. Pipelines convey steam to the locations where it is required. Hot water systems are also used, but heated water must be kept under pressure to avoid boiling,

Table 1 Special equipment required in dairy processing

Product	*Common steps for the process*	*Basic equipment required*	*Comments*
Butter	Milk reception Preheating and pasteurization of skim milk Fat separation Cream pasteurization Vacuum deaeration Culture preparation Cream ripening Temperature treatment Churning Buttermilk collection Packaging	Plate heat exchanger Centrifuge Continuous buttermaking machine Packaging system	Capacities of continuous butter-making machines ≈200–5000 kg h $^{-1}$ butter from sour cream; 200–10 000 kg h $^{-1}$ butter from sweet cream.
Cheese[a]	Preparation of cheese milk Heat treatment Standardization Preripening process Protein coagulation Curd preparation and treatment Molding Pressing Salting Ripening Packaging	Cheese vat with tools for cheese manufacture Pressing and molding vat Brining system Ripening storeroom	Traditional and partially mechanized processes. Equipment is designed specifically for the type(s) of cheese to be manufactured. Nearly all operations are done manually. Completely mechanized processes. Capacities: 50–100 000 l day^{-1}; completely mechanized processes are economical with higher level of automation.
Ice cream	Preheating Formulation mixing Pasteurization/homogenization/cooling Aging Freezing Filling/extrusion/molding Hardening Cold storage	Mixing and processing tank Homogenizer Plate heat exchanger Aging tank Continuous freezer Filler	Rapid freezing process is used for the formation of small ice crystals. In a plant with a small capacity, dry ingredients are generally weighed and supplied to the mix tanks manually. Large-scale producers use automatic batching systems. In large production plants, a continuous flow is maintained using mix tanks with a volume corresponding to the hourly capacity of the pasteurizer.

Long-life products	Cleaning Fat content standardization Preheating and stabilization Cooling UHT[b] Homogenization Heat treatment Cooling Storage Filling	Balance tank Plate heat exchanger Nonaseptic homogenizer Aseptic tank Aseptic filling	To improve the texture and physical stability of certain products like cream, an aseptic downstream homogenizer is used.
Milk powder	Milk pretreatment Concentration Homogenization Drying Packaging	Milk concentrate tank Spray-dryer or drum dryer Cyclone Packaging system	Spray-dryers are used to manufacture milk products from concentrates. Drum drying. Typical specific steam consumption is 1.3–1.6 kg per kg of evaporated water, and 4.3–5.0 kg per kg of powder.
Yogurt	Pretreatment of milk: Standardization of levels of fat and dry matter Heat treatment Homogenization Stirred type yogurt:[c] Incubation Cooling Flavoring Filling Cold storage	Balance tank Plate heat exchanger Evaporator Homogenizer Incubation tanks Plate cooler Buffer tanks Packaging system	Yogurt is a thixotropic non-Newtonian fluid. Its viscosity decreases during processing. A proper optimization of the process is necessary to allow the viscocity to be fully regenerated and syneresis minimized.

[a] Cheese of various types is produced in several stages. Each type of cheese has its specific production formula. Some basic stages are shown here.

[b] UHT is the most common treatment for preserving liquid food products.

[c] Yogurt is typically classified as follows: set type (incubated and cooled in the package); stirred type (incubated in tanks and cooled before being packed); drinking type (similar to stirred type, but the coagulum is ‘broken down’ to a liquid before being packed); frozen type (incubated in tanks and frozen like ice cream); concentrated (incubated in tanks, concentrated, and cooled before being packed).

because most processing operations require water at around 100 °C. Typical steam consumption is around 185–200 kg of steam per 1000 l of raw milk.

Refrigeration systems are vital in dairy processing. At elevated and ambient temperatures (*see* **Utilities and Effluent Treatment**: Refrigeration), products are prone to microbial and enzymatic degradation. Therefore, rapid cooling to a safe temperature is often a necessity. Generally, the operating cost of the refrigeration system is important in the global cost estimation.

For automatic control purposes, especially in damp environments, pneumatically controlled automatic systems are preferred. These control systems require compressed air free from impurities. Compressed air is also used in some processing operations, such as agitation in storage tanks and emptying product from pipelines (*see* **Utilities and Effluent Treatment**: Compressed Air).

For an electric power demand of 300 kW, dairies take low-voltage supplies of 220–440 V. Many dairies rely on local generation of electricity in the event of power failures or sometimes for continuous operations (*see* **Utilities and Effluent Treatment**: Electricity). The typical electric power requirement for a dairy is 15–18 kW per 1000 l of processed raw milk.

Plant Layout

A plant layout includes the arrangements of processing, storage, and handling areas, as shown in **Figure 2**. The layout is developed after the process flow diagrams are completed, and the information is useful in determining construction and manufacturing costs. Several factors influence the plant layout, including the type and quantity of products to be manufactured, process and product controls, utilities, building specifications and code requirements, and waste handling and disposal.

Equipment should be arranged in such a manner as to minimize capital and operating costs. The actual location of process equipment must permit adequate space for cleaning and maintenance. Similarly, adequate aisle space must be provided for workers in conformity with any building codes. Future plant expansion should be considered.

Sanitary Design

In designing any food processing plant, emphasis on proper cleaning and disinfection of equipment and work space is paramount. Disinfection is carried out using chemicals mixed in water: about 1.7 kg of alkali and 0.6 kg of acid are required for each tonne of processed milk. Furthermore, steam is used for high-temperature sterilization. For optimum use of chemical agents, the nature of dirt, the surface characteristics, water quality, and the effectiveness of cleaning and disinfection agents must be clearly understood. According to the terminology used in cleaning, physical cleanliness is removal of all visible dirt from the surfaces; chemical cleanliness is removal of microscopic residues that can be detected by taste or smell; bacteriological cleanliness is obtained by disinfection; and sterile cleanliness is destruction of all microorganisms. In dairy cleaning operations, chemical and bacteriological cleanliness are achieved using chemical agents.

Cleaning-in-Place Systems

Modern dairy processing plants use CIP systems, which involve circulation of rinsing water and detergent

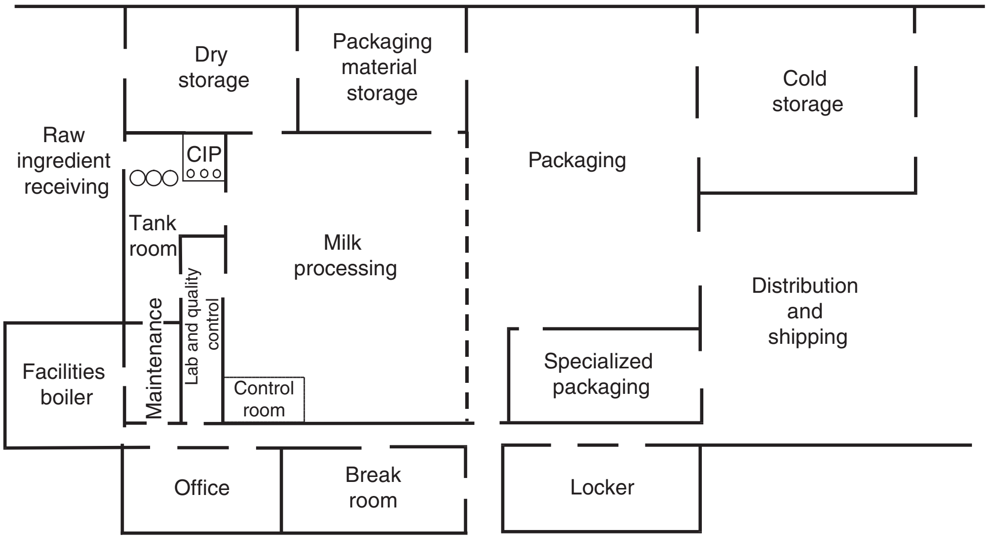

Figure 2 Dairy processing plant layout. Adapted from Hui YH (1993) *Dairy Science and Technology Handbook*. New York: VCH.

solutions through tanks, pipes, and other process equipment. Because the entire processing system is interconnected, there is no need to dismantle equipment for cleaning. An automated cleaning system requires that all surfaces be accessible to the detergent solution. If the detergent cannot get to any area, such as to the dead ends in a pipe, then the system fails. The installation of pipes and equipment must be done in a manner that promotes easy drainage of cleaning solutions. All components of the equipment that come into contact with chemical detergents must be able to withstand them. Depending on whether heated surfaces are involved in cleaning, a typical dairy CIP program would operate as follows.

A CIP program for a pasteurizer involves rinsing with warm water for about 10 min, circulation of an alkaline detergent solution (0.5–1.5%) for about 30 min at 75 °C, followed by rinsing out the alkaline detergent with warm water for about 5 min. Then nitric acid solution (0.5–1.5%) is circulated for about 20 min at 70 °C, followed by postrinsing with cold water and gradual cooling with cold water for about 8 min. With pipes and tanks, which may be considered as 'cold components', the process involves rinsing with warm water for 3 min, circulation of 0.5–1.5% alkaline detergent at 75 °C for about 10 min, and again rinsing with warm water for about 10 min. Disinfection with hot water at 90–95 °C for 5 min is carried out, which is then followed by gradual cooling with cold tap water for about 10 min.

After the process equipment is cleaned, it is sanitized to destroy residual yeasts, molds, bacteria, and bacterial spores. The surfaces must be thoroughly cleaned before sanitizing. Common chemicals used for sanitizing include chlorine compounds, iodophors, quaternary ammonium compounds, and acid-anionic surfactants.

Design Strategy and Optimization

In process design, optimization to minimize costs and maximize profitability plays a major role. A number of mathematical procedures are widely available to optimize manufacturing processes. These procedures have the following common elements: design variables, equality and nonequality constraints, feasible solutions, and objective function.

Process optimization is increasingly being used in the dairy industry. Typically, the optimization problem is to determine values of independent variables that result in an optimal value of a dependent variable. Commercially available software has made modeling and simulation more user-friendly. These models require reliable information on the physical and thermodynamic properties of foods, preferably in the form of computerized databases.

Cost data are also crucial in plant design. Typical data for processing plants manufacturing dairy products are shown in **Table 2**; this is for indicative purposes only, as differential inflation since 1987 will have changed the relative figures significantly.

Safety and Hazard Evaluation

In designing plants and processes, the safety of the operating personnel and people living in the vicinity of the plant is of major concern. A safe design involves appropriate steps to protect the life and health of the working population. In the United States, the Occupational Safety and Health Administration (OSHA) promulgates regulations regarding worker safety and health. In Europe, information can be found from EU agencies and national bodies.

Environmental Constraints

Since the 1970s, environmental protection has become a primary issue in many industrialized countries. This has resulted in the development of stricter environmental regulations and their enforcement. Dairy processing plants generate large volumes of organic waste, which must be properly discharged and treated. Treatment facilities for waste materials must be designed and constructed in collaboration with local agencies.

A large quantity of wastewater in a dairy plant contains milk components, particularly the water used for cleaning equipment and pipelines. Typically, 2 l of water is used for every liter of milk handled. Wastewater from employee washrooms, toilets, etc. amounts to 75 l day^{-1} per employee. A certain amount of wastewater results from cooling water used for cooling milk. Dairy wastewater is high in organic matter and hence must be diluted by a factor of 150 to 200 (*see* **Utilities and Effluent Treatment**: Design and Operation of Dairy Effluent Treatment Plants). As this would be extremely wasteful, dairies use treatment facilities, using either mechanical or biological means. The use of acids and alkaline detergents for cleaning equipment and pipelines results in the pH of wastewater ranging between 2 and 12. Typically, wastewater with a pH higher than 10 or lower than 6 must not be discharged into the sewage system. Effluents from the cleaning systems are usually collected and the pH carefully monitored and adjusted if necessary.

Another component of the dairy wastewater is whey. Recently, manufacturing processes have been developed to convert whey into economically attractive by-products such as whey and lactose powders. A variety of separation processes, such as ultrafiltration, reverse osmosis, and electrophoresis, in addition to enzymatic hydrolysis, are used for manufacturing whey products (*see* **Whey Processing**: Utilization and Products).

Table 2 Cost data referred to fixed capital and annual operating costs in US dollars

			Fixed capital cost (US$)			*Annual operating cost (US$ yr^{-1})*			
Plant	*Capacity ($\times 10^9$ g yr^{-1})*	*Operationg time (h yr^{-1})*	*Equipment*	*Mechanical and electrical*	*Civil*	*Materials*	*Utilities*	*Labor*	*Supplementary*
Mozzarella cheese plant	1875	3000	340 750	65 850	435 000	1 700 000	51 600	86 000	10 000
Ice cream plant	4000	2000	1 330 000	650 000	535 000	1 074 860	143 500	271 000	31 000

Yogurt plant	25 000	3125	3 236 600	878 000	713 000	11 750 000	465 375	246 000	111 700

Bartholomai A (1987) *Food Factories: Processes, Equipment, Costs*. New York: VCH Publishers.

It has become increasingly important for dairy plants to be certified by the ISO13000 series of norms that deal with environmental protection.

Computer-Aided Design

Several commercial computer-aided design packages are used in the chemical industry for simulation and design of processes. These simulators are valuable tools for flow sheeting, determining mass and energy balances, sizing the equipment, and analyzing performance. Although the majority of these packages are more suitable for the general chemical industry, some efforts have been made during the last decades to develop materials useful for the dairy and food industry.

Introduction

Hygienic design of processing equipment is a particular requirement for the dairy industry that in general does not apply to the bulk chemical area. The primary intention is to prevent the contamination of product materials during processing. Hygienic design is based on a combination of mechanical, process, and microbiological requirements. Two particular aspects of hygienic design are selection of appropriate materials of construction for equipment and specification of an acceptable surface finish for those materials. Hygienic equipment must be constructed of a durable material that will not compromise the purity of the product, is completely drainable, and has smooth surface finish. If equipment is of poor hygienic design, it will be difficult to clean and difficult to free from microorganisms, which may then survive and multiply in product residues in crevices. It should be noted that hygiene regulations for equipment handling dry product (such as powders) are more relaxed as dry products do not support the growth of microorganisms to the same extent as wet products.

There are a number of professional bodies that issue regulations concerning hygienic design. In the United States, the 3-A Sanitary Standards, Inc. (3-A SSI), is a nonprofit association representing equipment manufacturers, processors, regulatory sanitarians, and other public health professionals. This group has established a comprehensive inventory of 3-A Sanitary Standards and 3-A Accepted Practices now known around the world for dairy and food processing equipment and systems. The American Society of Mechanical Engineers (ASME) Bio-Processing Equipment (BPE) Code came into being in the United States in 1998, although it is primarily aimed at the biopharma and biotech sectors rather than the dairy sector. In Europe, the closest equivalent code is the EHEDG Regulations. The European Hygienic Equipment Design Group (EHEDG) is composed of representatives from research institutes, process equipment manufacturers, the food and biopharma industry, and legislative bodies. The objective is to provide specialist advice on hygienic and aseptic design. The EHEDG and both the 3-A and ASME BPE provide suggestions and recommendations but their standards are not mandatory.

Construction Materials

At the outset, it must be understood that when discussing the choice of acceptable materials and required surface finish for dairy plant and equipment, the focus is on product holding and processing equipment. In other words, it is equipment that has a product contact surface that is being examined (i.e., the insides of pipes and vessels). For equipment that does not come into direct contact with the dairy product, such as the pumps and pipes for service fluids (steam, water, and air), the conditions determining acceptable materials and surface finish are far less stringent. Likewise, the nonproduct-contact part of dairy processing equipment (such as legs and support features) is not subject to the same scrutiny.

In the dairy sector, conditions are in general less exacting than in the chemical industries. Processing temperatures (usually within the range −40 to 140°C) and usual operating pressure ranges (0–10 bar) are limited, and pH does not deviate widely from neutral (a pH of 2 or 3 being a minimum). However, dairy processing operations are unique in that the needs for sanitary design and operation are stringent. In all cases, product contact surfaces must withstand the aggressiveness of the product and processing (temperature, pH, flow velocity, roughness) and must meet special needs of resistance to wear and abrasion and corrosion resistance. The material of construction must also withstand the often greater aggressiveness of the chemicals used for cleaning and sanitation. As a general classification, most dairy products are slightly acidic, and detergents (especially caustic detergents) are alkaline. Sometimes though acids, including hydrochloric and nitric, are used for removing scale from dairy processing equipment and this must be taken into account in material selection. Regulations require that process equipment should be made from a durable, impermeable, and corrosion-resistant material to avoid the contamination of the product and be of such construction as to enable the equipment to be kept clean and disinfected. In Europe, the European Union issues regulations to the member states to this effect. Toxic substances, likely to endanger health (if consumed with the product) or taint the product, must not be used in the construction of equipment if contact with edible material can occur. Some materials are slightly soluble, nontoxic, and do not adversely affect the product. Tin and aluminum are in this category. Other materials are toxic and cannot be used for dairy contact surfaces such as lead (solder), zinc (present in galvanized steel), and iron compounds (mild steel). In principle, dairy processing equipment can be built from a wide variety of metals, ceramics, or polymers. However, as stainless steel (particularly the grades 304L and 316L) is so prevalent, it merits the majority of the subsequent discussion.

Stainless Steel

Introduction

Stainless steel is defined as an alloy of chromium and steel. It has the characteristic of greatly enhanced corrosion resistance over conventional lower alloy and carbon steels. This corrosion resistance derives from the addition of at least 12% chromium, although the most widely used grades contain about 18% of this element. Chromium on its own oxides quickly and produces a stable passive oxide film on exposed surfaces. This property also occurs when chromium is in a solid solution in iron becoming very marked as the amount exceeds 12% in low carbon steels. This corrosion-resistant film protects the underlying metal. This film can be up to 5 nm thick and contains varying amounts of Cr_2O_3. In an oxidizing media, any defect in the film that arises through abrasion is quickly repaired (i.e., the film is self-healing). However, it must always be remembered that no stainless steel is completely corrosion proof; oxygen is required to maintain passivity.

In terms of chemical composition, stainless steel contains the basic elements of steel (iron and carbon) plus chromium. Almost all stainless steels (with the exception of some martensitic steels) have low carbon contents, generally below 0.15%. The main reason is that under certain conditions (e.g., in the heat-affected zone of a weld), carbon can preferentially combine with chromium to form chromium-rich carbon deposits at grain boundaries. This depletes the prevailing chromium levels in this region of the material and makes corrosion possible. Chromium itself is the defining element of stainless steel. It is present in amounts from 12% (a minimum) to 30%, and the most widely used grades contain chromium in contents between 17 and 25%. There are two other elements that can be found in stainless steel, though not all grades of stainless steel contain them. Nickel is added to produce austenitic grades of stainless steel. These steels usually contain 9% nickel and have improved corrosion resistance especially against acids. Stainless steels with 18% chromium and 8% nickel are commonplace ('18/8 steels'). Finally, molybdenum can be added to improve further corrosion resistance in especially aggressive environments such as acids. It is added in amounts of 2% to the 18/8 steels.

Types and Classification

There are four main types of stainless steel microstructure: ferrite, austenite, martensite, and duplex. These are distinguished from each other by their chemical composition and consequent mechanical and corrosion-resistance properties. Furthermore, within each of these main groups, there is a huge variety of grades depending upon the number and amount of minor alloying elements present and the heat treatment that is carried out. Austenitic steels have excellent toughness (impact resistance) at low temperatures and they are the most readily weldable of the different stainless steel types, which is a very important consideration for a processing plant. One drawback is that the high nickel and chromium content make these alloys expensive.

Ferritic stainless steels are cheaper than the austenitic steels and have very good corrosion resistance. Their ductility and toughness is not comparable with that of the austenitic steels. Martensitic stainless steels can have carbon contents ranging from 0.1 to 1%. They have less corrosion resistance than the other steels. The high carbon content makes them very hard, and they are suitable for applications where wear and abrasion resistance is essential. Duplex stainless steels are a newer type of stainless steel with high-strength features. In this stainless steel, the internal structure is an equal mix of face-centered and body-centered crystal structures (austenitic and ferritic). Duplex stainless steels have better toughness than ferritic grades and much higher yield strengths than the austenitics.

Most of the above stainless steels are also available as L grades (e.g., 316L). The L designation means the carbon content in the steel is at a particularly low level, usually below 0.03%. This is to diminish further the possibility of chromium carbides being formed at grain boundaries and reducing the protection offered by chromium to the steel.

Corrosion

The very name 'stainless steel' can be misleading; stainless steels are protected by a passive oxide film, and defeat of this film is possible by certain corrosion mechanisms. There are many possible corrosion mechanisms: pitting corrosion, crevice corrosion, stress corrosion cracking, sulfide stress corrosion cracking, intergranular corrosion, galvanic corrosion, contact corrosion, microbial corrosion, and so forth. Stainless steel should be used for corrosion resistance where oxidizing conditions exist. This is to enable the oxide film to regenerate itself constantly. Furthermore, stainless steel is susceptible to corrosion caused by chlorine. Thus, corrosion of stainless steel is especially serious if accompanied by an absence of oxygen or presence of halogens or both. In such a situation, alternative materials of construction such as Hastelloy^{TM} or titanium should be specified.

Exposure to free chlorine in water droplets (e.g., sea air), brines, or cleaning fluids (hypochlorite bleaches) can cause pitting corrosion in stainless steel depending on factors such as concentration and temperature of the fluid. It is estimated that up to 90% of corrosion failures of stainless steel in the process industries are due to exposure to chloride-containing fluids. It should be mentioned here that chloride attack can lead to the formation of microscopic channels that cannot be detected by dye-penetration testing (only by radiographic methods), yet are significant as channels for bacterial ingress, for example in heat exchangers and water-jackets. Most cleaning solutions may only contain 20 ppm chlorine. However, if they are applied to the steel surface (in a pipe or vessel) and then allowed to dry off rather than being flushed away, the chlorine concentration can rise 10-fold. As a rule of thumb, stainless steel type 304 is liable to corrode when chlorine concentration rises above 200 ppm and type 316 when chlorine concentration is greater than 1000 ppm. The main problem with chlorine-containing cleaning agents is not the cleaning itself; it is not rinsing thoroughly with ordinary water so that chloride levels are allowed to rise to dangerous levels.

To maintain the corrosion resistance of stainless steel, a clean, dry surface must be exposed to oxygen (air) so that the passive layer is continually maintained. Poor plant and equipment design or layout can promote corrosion of stainless steel by preventing equipment walls coming in contact with air. When corrosion does occur, remedial action is possible by passivation of stainless steel. Passivation of stainless steel is carried out when the beginnings of rusting are first seen (say inside a liquid holding vessel or pipe network). First, the rust debris contaminant must be removed by rinsing with a 10% nitric acid solution. This is vital because if the rust debris is not removed, corrosion will recommence. Then air is allowed into the pipe and left for a few days (i.e., the pipe is taken out of commission and left idle). The oxygen in the air will regenerate the chromium oxide inert layer and restore corrosion resistance to the pipe.

Dairy Plant

In summary, stainless steel is the material most widely used for contact surfaces in dairy processing equipment. This metal offers resistance to corrosion, mechanical strength, hardness, and ease of fabrication (weldable). The preferred grades for general process fluid heating, storage, and distribution are AISI type 304 (Deutsches Institut für Normung (DIN) 1.4301) and 316 (DIN 1.4401). Type 316 is more expensive but offers greater corrosion resistance due to the inclusion of molybdenum. AISI 304 is nearly always used externally, or for the outer vessel jacket, as it is needed only for protecting the machine from the atmosphere, water, and any spilled liquids. For parts in contact with product, either type can be used though 316 is necessary for acidic products. In very acidic conditions, where the pH falls to 1, type 317 austenitic stainless steel is specified as it has a greater molybdenum content of 4%. For dry solid foods such as dairy powders, wear resistance is also needed in addition to corrosion resistance. The ferritic structural stainless steels offer good flow characteristics for hoppers, chutes, and conveyor lines. High loads on mechanical components or very abrasive conditions may result in the selection of the strong, hard martensitic stainless steels; for example type 410 and 420. These steels can find an application in knives and cutters and mixers and extruders. If chlorides are present, even type 316 is not suitable to prevent localized corrosion (where the oxide film is damaged), and materials such as AL-6XN (a molybdenum-containing super austenitic stainless steel) or titanium may be required. Alternatively in this situation, AISI 410 (DIN 1.4006) or AISI 329 (DIN 1.4406) can be employed.

Other Metals

In the rare cases where very extreme corrosion conditions are present, nickel alloys or titanium can be employed. Inconel 600 is a high-nickel alloy (three-quarters nickel) and offers excellent resistance across a broad range of corrosive conditions. It is unsurpassed in caustic conditions. It maintains high strength at elevated temperatures. Its main drawback is the high cost. Hastelloy C276 is a nickel–chromium–molybdenum alloy that has the broadest general resistance to corrosion compared with many other common alloys. It has good resistance to wet chlorine and strong oxidizers and can combat aggressive corrosion conditions that are combined with high temperature and high pressures.

Titanium, although very expensive, is sometimes used where extremely high corrosion resistance is required (e.g., to hold liquids containing chlorine ions). It is also used where a brine solution would attack stainless steel. Titanium is an excellent metal for use with oxidizing agents such as nitric acid and mixtures of nitric and hydrochloric acids. It also has good resistance to chloride ions. Inert to nitric acid, it gives acceptable corrosion rates of less than 0.05 mm yr^{-1} to sulfuric and hydrochloric acids but is attacked by concentrated sulfuric and hydrochloric acids (more than 1.25 mm yr^{-1}). Commercially pure titanium is available in several grades. Grade 2 is suitable for welding. Grade 4 contains traces of iron, has higher strength, but is not suitable for welding.

Aluminum and its alloys have the advantages of being light, easily fabricated, and of reasonably low cost. However, it is so susceptible to corrosion that it is probably safe only for special applications where it can be guaranteed not to encounter alkaline detergents used in cleaning in place (CIP) systems. The low mechanical strength of aluminum can be improved by alloying. Though slightly soluble in many foods, aluminum is not toxic. It may be used in food plants, but as the metal is attacked by both acids and alkalis, great care must be exercised. Aluminum is also attacked by nitric acid, which is a commonly used cleaning agent. As aluminum salts are colorless, tasteless, and claimed to be nontoxic, and the metal is cheap, light, easily cleaned, and has high thermal conductivity, use in food manufacture should be extensive. However, it can impart taints or off-tastes to certain foods. Milk 'churns' (cans) are made out of aluminum as its low weight compared with stainless steel is an advantage in handling these containers.

Copper and its alloys such as brass (copper–zinc), bronze (copper–tin), and Monel (copper–nickel) should not be used for dairy equipment. Copper alloys do offer ease of fabrication (very advantageous for pipe networks) and display durability in air and water. Alloying is necessary to overcome the lack of strength in pure copper. Copper and its alloys can oxidize food oils and fats and cause flavor and off-taste problems (even at concentration levels as low as 0.1 mg kg^{-1}) especially in food processing at higher temperatures (above 80 °C). It should be specifically avoided when handling high-fat foods. Copper is used where its excellent electrical and thermal conductivities are advantageous (e.g., electric conductors and cooling fins). It is also used in nonpotable water distribution circuits such as boiler feed water.

Finally, the undesirability of using galvanized steel, for example for motor covers or framework, should be emphasized as this is rapidly corroded by the typical alkaline detergents used in food premises.

Plastics and Rubbers

Plastic materials offer certain advantages (being cheap, easy to fabricate, and having low weight and good corrosion resistance) but suffer from low mechanical strength and poor temperature and fatigue resistance. Polymers such as polypropylene, Teflon, silicone, ethylene propylene diene monomer (EPDM), and so forth, can be used. In dairy processing equipment, they must be abrasion resistant and free from constituents that can migrate into foodstuffs especially if they are being used as seals in pipes and process vessels. Food-grade polymers must always be specified. Factors such as reactions with detergents and stability at sterilization temperatures must also be considered (so most polymers are appropriate only for lower temperatures). The relatively strong and heat-stable plastics (such as nylon and Teflon) are used in storage vessels, pipework, and pumps. Seals made from elastomeric materials are a common example of the use of plastic and rubbers in dairy processing equipment. Two issues are absorption of materials from the process liquid into the elastomer, which can produce swelling of it and extraction of components from the elastomer seal into the process liquid, which can cause contamination. The perfluoroelastomers behave well with regard to both these issues.

Surface Finish

Irrespective of the material chosen, the presence of pits, crevices, and any other surface defects on product contact surfaces are not allowable. These defects can act as harborage sites, trapping and protecting microorganisms from sterilization. Thus, product contact surfaces must be polished (usually by grinding and buffing) to ensure a low surface roughness. Generally speaking, the higher the degree of surface finish, the more cleanable is the surface. All manufactured surfaces will consist of a series of peaks and valleys, varying in both height and spacing. The main measurement parameter of this texture is designated R_a and is the arithmetic average value of the departure of the profile above and below an imaginary centerline throughout the sampling length. Surface quality is generally specified by this surface roughness number, R_a. Food product contact surfaces should have a surface finish of a maximum 0.8 μm R_a. Measurements of contamination levels on a surface after a cleaning regime indicate that the lower the R_a value, the smaller is the contamination level. There are four finishing techniques to reduce surface roughness:

1. Mechanical polishing: Aluminum oxide grit is glued to flat felt disks that are rotated at high speed while being traversed over the surface.
2. Abrasive blasting: The surface to be treated is blasted with high-speed glass beads.
3. Electropolishing: This process involves the electrochemical removal of a surface layer of material. It is the opposite of electroplating. The surface to be treated is dipped into a tank of electrolyte and connected to the positive pole of a current supply. Because peaks of the surface are removed preferentially, a leveling of the surface occurs.
4. Chemical finishing: Chemicals (pickling acids) are applied by brush and left on the surface for a few hours and then rinsed off.

Table 1 indicates the roughness level that can be achieved with each method.

Table 1 Surface treatments of stainless steel and the resulting surface roughness (R_a)

Treatment	*Grit number*	R_a (μm)
Cold rolling		0.2–0.5
Hot rolling		>4
Glass bead blasting		1
Pickling		0.5–1
Electropolishing		
Mechanical polishing	60	<3.5
	120	<1.1
	240	<0.5
	500	<0.2

The issue of acceptable surface roughness is particularly important for welds in equipment. The primary purpose of a weld is to provide a permanent joint of sufficient mechanical strength to meet all requirements. However, the weld must also satisfy hygienic requirements. Any excessively rough weld surface promotes adhesion of soil material and is difficult to clean. For a weld to be hygienic, it must have a smooth inner weld bead surface free of crevices, cracks, or pits that would harbor bacteria. Such welds permit sterilization of the equipment to be carried out satisfactorily. A typical series of finishes is the following:

- As-welded: flux chipped out and weld wire-brushed,
- Rough ground: welds are ground with coarse grit,
- Fine scurf: the ground weld scurfed with carborundum grit,
- Bright polished: polishing with/without aid of greases,
- Chemically pickled: application of pickling acids to remove weld scale.

Stainless steel, available as hot rolled plate, normally has a surface finish of greater than 5 μm R_a. High-quality Tungsten Inert Gas (TIG) welds will leave a finish of between 3 and 8 μm R_a. Thus, polishing is necessary to bring the roughness down to 0.8 μm R_a or less. A grit size of 150 is usually sufficient to give the required surface finish of 0.8 μm R_a.

Principles of Calculation

Ideal Flow

Conservation of mechanical energy

The basic principle used to describe the flow of liquids in any type of installation is that the total mechanical energy of an element of the fluid at a given position, *A*, should be maintained while it flows, so that when it reaches another position, *B*, there may have been conversion of one form of energy to another, but the total should be the same. This analysis is applied at isothermal conditions, so that only mechanical energy needs to be considered (non-isothermal flow will not be addressed).

Three forms of energy are involved: pressure, potential energy and kinetic energy. The mathematical expression that translates this principle of conservation of mechanical energy is known as Bernoulli's equation (the differential form is Euler's equation), and for isothermal ideal flow of incompressible fluids (liquids), it can be written as:

$$\frac{P_a}{\rho \cdot g} + h_a + \frac{v_a^2}{2g} = \frac{P_b}{\rho \cdot g} + h_b + \frac{v_b^2}{2g} \qquad (1)$$

where P is pressure, h the height (vertical distance from the ground to the central axis of the pipe), v the average velocity and the subscripts a and b designate the values at locations A and B, respectively. ρ is the specific gravity of the liquid and g the acceleration due to gravity (9.8 ms^{-2}). The left-hand side is the sum of energy terms at location *A*, and the right-hand side at location *B*. This equation is written so that all terms have units of length (e.g. m), and are known as 'heads': the first term is the pressure head, the second is the potential head and the third is the kinetic head. **Figure 1** sketches a generic situation where all heads have changed from location *A* to *B*, in an example where the potential and kinetic heads have increased at the expense of the pressure head.

Conservation of momentum

In addition to Bernoulli's equation, it can also be stated that there should be a conservation of momentum. For steady flow, this principle reduces to a mathematical expression which simply states that the flow rate must be constant throughout the installation, otherwise there would be an accumulation of liquid. For incompressible fluids, the volumetric flow rate (Q) is used, which is equal to the average velocity of the fluid times the cross-sectional area of the pipe (A), and this leads to the so-called continuity equation:

$$v_a \cdot A_a = v_b \cdot A_b \qquad (2)$$

General design principles

Substituting eqn [2] in eqn [1] and with some basic manipulation, the expression that relates flow rate to the pressure difference between two locations (which is designated ΔP) is obtained:

$$\frac{\Delta P}{\rho \cdot g} = \Delta h + \frac{Q^2}{2g}\left(\frac{1}{A_a^2}\right) - \frac{1}{A_b^2} \qquad (3)$$

where $\Delta P = P_a - P_b$; $\Delta h = h_b - h_a$. It should be noted that, by definition, $Q = V_a \cdot A_a$ (or $Q = V_b \cdot A_b$) and that for cylindrical pipes (circular cross-section area), $A = (\pi \cdot D^2)/4$, D being the diameter of the pipe.

Equation [3] allows calculation of the pressure difference that must exist to ensure a given flow rate, or by reversing it, to calculate the flow rate that a given pressure difference will imply.

Nonideal Flow

Head losses

The analysis above implies that the fluid behaves ideally, i.e. there is no dissipation of mechanical energy. However, this is rarely true and fluids exhibit a resistance to flow which depends on their rheological properties. The concept of viscosity is familiar – a viscous fluid shows greater resistance to flow. Fluids are not rigidly structured materials and flow implies a continuous movement of molecules in relation to one another. Either through viscous shear energy dissipation or by molecular collisions, there is inevitably a loss of mechanical energy, dissipated in the form of heat. It is assumed that this is not so significant that the situation will cease to be isothermal – it is considered that the heat dissipated is transferred easily and lost to the outside and causes no significant rise in temperature. However, while flowing from *A* to *B*, part of the mechanical energy is lost. Equation [1] is therefore incorrect, and a term ($F_{A \rightarrow B}$) must be inserted to account for all head losses:

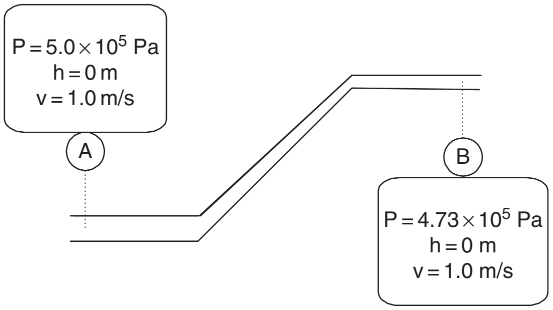

Figure 1 Conservation of mechanical energy in an ideal system.

$$\frac{P_a}{\rho \cdot g} + h_a + \frac{v_a^2}{2g} = \frac{P_b}{\rho \cdot g} + h_b + \frac{v_b^2}{2g} + F_{A-B} \qquad (4)$$

Hence, the problem can be solved in the same way as if the fluid was ideal, with a minor correction to eqn [3]:

$$\frac{\Delta P}{\rho \cdot g} = F_{A-B} + \Delta h + \frac{Q^2}{2g}\left(\frac{1}{A_a^2}\right) - \frac{1}{A_b^2} \qquad (5)$$

To deal with this new factor, it is necessary to know more about fluids and their flow behavior.

Viscosity and flow regimes

Reynolds performed a simple experiment to visualize how fluid molecules move in the flow of liquids. He injected a dye at a given point in a transparent tube section and noted how the color dispersed in the flow (**Figure 2**). He found that, for low flow rates, a smooth straight line developed. At different distances from the pipe wall, the velocity of this line was different. He concluded that, at low flow rates, the molecules move in layers and there is no collision between them, but there is friction between adjacent layers, as they move at different velocities (maximum at the centre of the tube, and approaching zero near the walls). He designated this situation as laminar flow.

However, when the flow rate is increased, a critical point is reached where turbulence starts to develop and the dye moves unpredictably along the tube. In this case, it is evident that there will be collisions between the molecules and the flow is turbulent. **Figure 2** shows how a single drop of dye solution might move along the tube – different drops will move along different paths, as turbulent patterns are unstable (time-dependent).

Figure 3 helps to visualize two layers of molecules moving adjacent to each other and at different velocities. Newton's law states that the shear stress (the force per unit cross-sectional area exerted tangentially to the layers, which is responsible for the velocity difference) should be proportional to the shear rate (the variation of the velocity per unit length), and that proportionality is the viscosity. Hence:

$$\sigma = \mu \frac{\mathrm{d}y}{\mathrm{d}y} \qquad (6)$$

where σ is the shear stress, μ the viscosity, $\mathrm{d}v/\mathrm{d}y$ the shear rate, v the velocity and y the height.

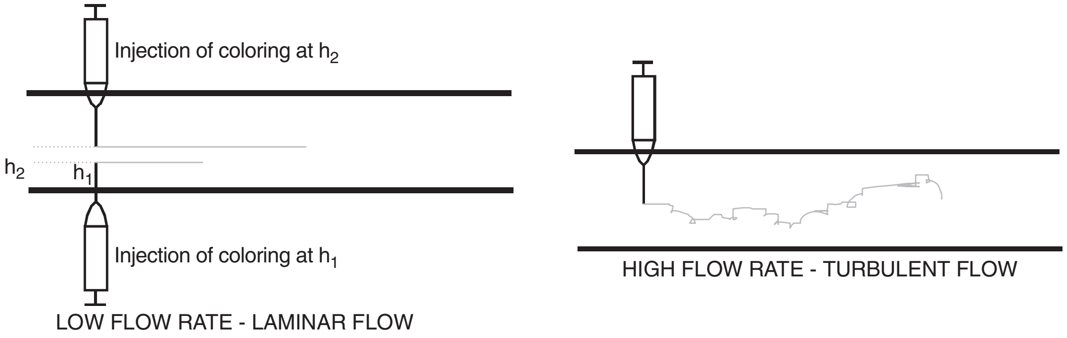
However, not all fluids obey this law, and those that do not are termed non-Newtonian. Water and milk are Newtonian fluids, while most viscous liquids are non-Newtonian.

It makes sense to think that the head losses due to viscous shear energy dissipation in laminar flow, where there are no collisions, should be proportional to the viscosity. This result has been verified empirically and later derived theoretically. The so-called Hagen–Poiseuille equation can be written as:

$$F = \frac{32 \cdot L \cdot v}{\rho \cdot g \cdot D^2}\mu \qquad (7)$$

where L is the length of pipe (distance from A to B) and v is the average velocity (it should be noted that the velocity of a specific layer varies with the distance from the wall), which is given simply by dividing the flow rate by the cross-sectional area.

On the other hand, when there is fully turbulent flow, with collisions between molecules causing the loss of so much energy that the effect of viscosity is irrelevant, the head losses should be proportional to the kinetic head. The so-called Darcy–Weisbach equation is applied in this case, stating that:



Injection of coloring at h2

Figure 3 Concept of viscosity as friction between adjacent layers of fluid moving at different velocities.

$$F = f \frac{L}{D}\frac{v^2}{2g} \tag{8}$$

where *f* is a friction factor that depends on the roughness of the pipe.

It has been found that the critical point when laminar flow ceases and eqn [7] is no longer valid occurs for all systems when the so-called Reynolds number reaches a value of 2000. The Reynolds number (*Re*) is the ratio between kinetic and viscous forces, and its application is based on the principle of dynamic similarity. It is:

$$Re = \frac{\rho \cdot v \cdot D}{\mu} \tag{9}$$

Note from eqns [7], [8] and [9] that it can be concluded that the Darcy–Weisbach equation can be used in laminar flow, provided *f* is considered as a value which varies with the Reynolds number, with $f = 64/Re$.

However, once laminar flow ceases, fully turbulent flow is not immediately established, where viscosity is irrelevant and eqn [8] applies. Between *Re* 2000 and 4000 there is an instability regime, where the flow can switch from laminar to turbulent, and above that there is a gradual change to fully turbulent flow as *Re* increases. This is well visualized by plotting the *f* value of the Darcy–Weisbach equation as a function of the Reynolds number, in what is known as the Moody diagram (**Figure 4**). In laminar flow, there is a straight line in a log-log graph ($f = 64/Re$). In fully developed turbulent flow, *f* is constant, and in between there are the instability and the transition regimes. The point at which fully turbulent flow is reached and *f* is constant depends on the roughness of the pipe wall. For very smooth tubes, which is the case of stainless steel pipes used in the hygienic design of food-processing installations, fully turbulent flow is not actually reached in regions of practical interest of *Re*. In transition flow, the Colebrook–White empirical equation can be used to estimate *f*:

$$\frac{1}{\sqrt{f}} = -2 \cdot \log\left(\frac{k}{3.7D} + \frac{2.51}{\mathrm{Re.}\sqrt{f}}\right) \tag{10}$$

where *k* is the roughness factor of the pipe (for perfectly smooth tubes, $k = 0$) and log is the decimal logarithmic.

Viscus shear energy dissipation

The effect of viscous shear energy dissipation and of collisions between molecules during flow due to turbulence are calculated using eqn [8], with *f* being given by eqn [10]. However, as this is an implicit equation for *f*, many people prefer to read the result graphically from Moody's diagram; a simple version is given in **Figure 4**.

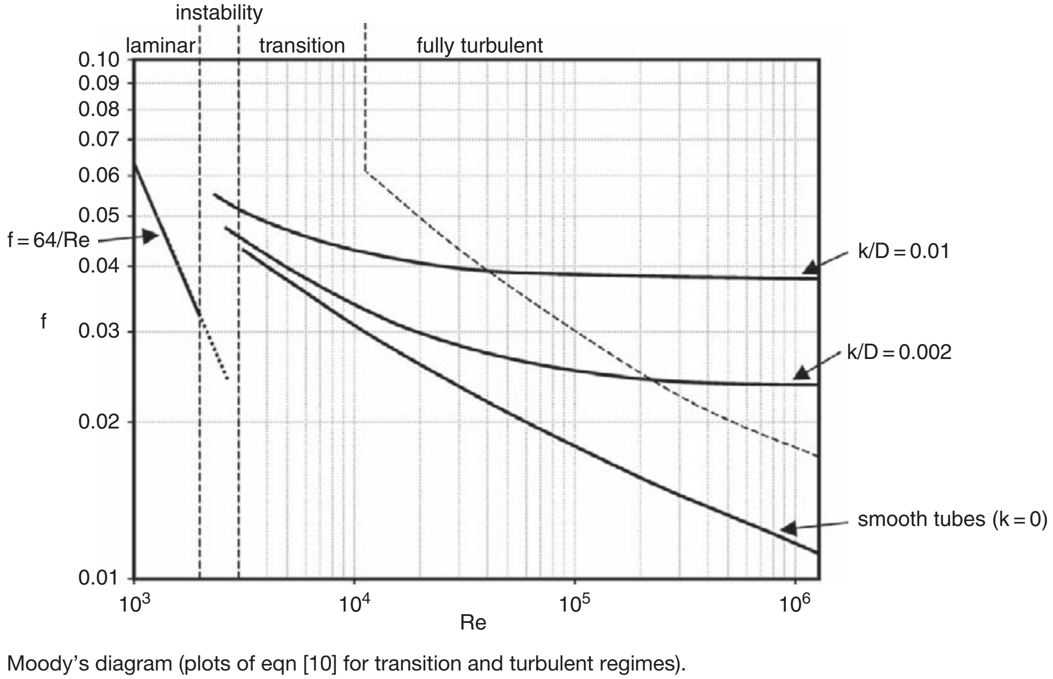

Figure 4 Moody's diagram (plots of eqn [10] for transition and turbulent regimes).

Localized head losses

It is evident that any geometric variation in the installation, such as bends, junctions and expansions, will cause collisions between molecules and the pipe walls, and between molecules themselves, resulting in turbulence. Whether the flow regime is laminar or turbulent prior to these geometric effects, there are kinetic losses due to collisions, and hence it is reasonable to assume that these head losses should be proportional to the kinetic head. The simple expression used is similar to eqn [8], but there is no need to individualize the length and diameter of these elements, and a simpler expression can be used:

$$F = K\frac{v^2}{2g} \tag{11}$$

where *K*, the so-called 'number of velocity head losses', must be estimated depending on the constriction. Various tables and graphs to estimate *K* for the various relevant elements that may exist in an installation can be found in the literature, such as bends (where *K* depends on the curvature), expansions and contractions (where *K* depends on whether the expansion/contraction is sudden or gradual and on the diameter before and after the element), junctions and flow dividers (where *K* depends on the type of junction), and valves (where *K* depends on the type of valve). Except at low Reynolds numbers in some cases, *K* is usually independent of *Re*, just like *f* in fully turbulent flow.

Calculation of head losses in an installation

When calculating the head losses in an installation, eqn [5] is applied and $F_{A\rightarrow B}$ estimated as the sum of all individual head losses: in each straight section of the pipes there is viscous shear energy dissipation given by eqn [8], and in each element that can cause localized head losses, eqn [11] is used with the corresponding *K*-value.

Net Positive Suction Head

Cavitation

When point *B* is located above point *A*, and with the added effect of head losses contributing to pressure decrease, Bernoulli's equation indicates that it is eventually possible to reach a pressure low enough to be at the boiling point of the liquid. This would result in the release of gas bubbles. From Bernoulli's equation, the points to check will be those with smaller cross-sectional area (higher velocity) and located higher in the installation. Gas bubbles are difficult to move, and this could result in severe loss of pumping efficiency. Moreover, the impact of gas bubbles collapsing against a surface moving at high speed is very destructive for centrifugal pumps (cavitation). Hence, the situation where point *B* is the entrance of a pump is of particular concern (**Figure 5**).

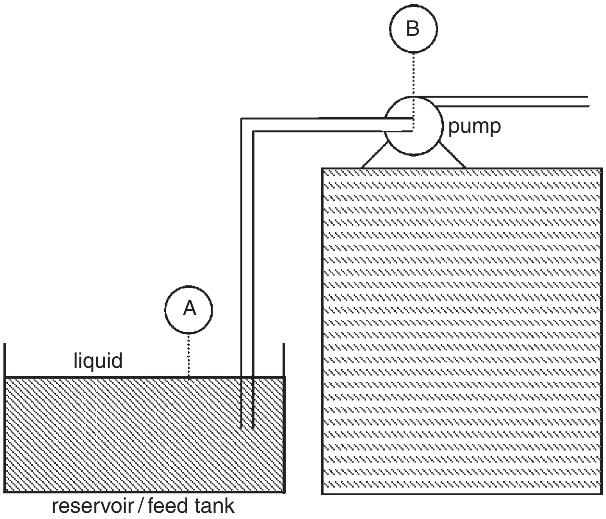

Figure 5 Pump in suction mode from lower reservoir.

Available Net Positive Suction Head

The net positive suction head (NPSH) in a given point is defined as the pressure head above the vapor pressure head, that is:

$$\mathrm{NPSH} = \frac{P}{\rho\cdot g} - \frac{P_V}{\rho\cdot g} \tag{12}$$

where *P* is the pressure of the liquid at that point and P_v is the vapor pressure (pressure at which the liquid is boiling for the system temperature – for instance, the vapor pressure of water at 100 °C is 1 atm, at 20 °C it is 0.025 atm).

The NPSH available ($\mathrm{NPSH_a}$) is the value of the NPSH at the entrance of the pump. It can be calculated by determining the pressure at point *B* from eqn [3], knowing the pressure at point *A*, and estimating all relevant head losses using the appropriate eqns [8] and [11]. Mathematically:

$$\mathrm{NPSH_a} = \frac{P_a}{\rho\cdot g} - \Delta h - F_{A\rightarrow B} - \frac{Q^2}{2g}\left(\frac{1}{A_b^2} - \frac{1}{A_a^2}\right) - \frac{P_V}{\rho\cdot g} \tag{13}$$

It is noted that if the cross-flow areas at *A* and *B* are the same, the kinetic flow rate term is zero.

Required Net Positive Suction Head

In principle, there would be no cavitation if $\mathrm{NPSH_a}$ is greater than zero. However, in every pump there will be head losses until the fluid starts to build up pressure – there are possibly geometric constrictions at the entrance, collisions with pump parts, etc. Usually, pump manufacturers will provide this information in terms of an NPSH required (NPSH_r), from bench scale tests. Basically, these are the head losses that occur at the pump entrance, until the liquid builds up pressure. Thus, the NPSH_r of the pump (or pumps being analyzed) must be checked to ensure that $\text{NPSH}_a > \text{NPSH}_r$. A safety margin of about 0.7–1 m is normally recommended.

It is noted that the NPSH_r, like all head losses, is obviously a function of the flow rate, and pump manuals usually provide the NPSH_r in the form of a graph, as a function of the flow rate or of the Reynolds number.

Pumping Efficiency and Power Requirements

Calculation of Pumping Requirements

Generically, a pump will be located somewhere between the entrance of an installation (piping line, piece of equipment) and the exit, and must promote a given flow rate. Applying Bernoulli's equation between the exit of the pump and the exit of the installation gives the pressure head that must exist at the pump exit to ensure the flow rate specified:

$$H_e = \frac{P_g}{\rho\cdot g} = \frac{P_{out}}{\rho\cdot g} + \Delta h + F_{e\rightarrow \text{out}} + \frac{Q^2}{2g}\left(\frac{1}{A^2_{\text{out}}} - \frac{1}{A^2_e}\right) \qquad (14)$$

where H_e is the pressure head at the exit of the pump, and the subscripts *e* and *out* indicate values at the exit of the pump and at the end of the installation, respectively. $F_{e\rightarrow \text{out}}$ is the total head loss from the pump onward.

Similarly, the pressure head at the pump inlet can be calculated by applying Bernoulli's equation between the entrance of the installation and the pump:

$$H_i = \frac{P_i}{\rho\cdot g} - \frac{P_{in}}{\rho\cdot g} - \Delta h - F_{\text{in}\rightarrow i} - \frac{Q^2}{2g}\left(\frac{1}{A^2_{\text{in}}} - \frac{1}{A^2_i}\right) \qquad (15)$$

Power, Energy and Calculation of Pumping Costs

Assuming the usual case of no variation in the potential and kinetic heads at the inlet and outlet of the pump (same cross-flow area and level height), the power provided by the pump to the liquid (W, energy per unit time) to ensure the flow rate, Q, is that required to raise the pressure head from H_i to H_e:

$$W = \rho\cdot g\cdot Q\cdot(H_e - H_i) \qquad (16)$$

To calculate the pumping energy costs, it must be noted that not all power used by the pump from the mains electrical supply will be delivered to the fluid, as there are various energy losses. The pump efficiency (η) is the ratio between the power delivered to the fluid (W) and that spent from the mains (W_{used}):

$$v = \frac{W}{W\text{used}} \qquad (17)$$

The pump efficiency depends on the type of pump and on the conditions of operation. Generally, there is an optimum efficiency for a given flow rate – operating above or below implies that the pump is under- or overdimensioned for the job, and the consequence is that the pumping efficiency is lower. Hence, engineers must select the pump dimensions according to the specific job, targeting the region of operation of the pump where η is maximum, as otherwise W_{used}, and hence pumping costs, are higher than they could be with an appropriate pump. They may also find that using more than one pump in parallel lines may be more efficient than a single, larger pump. Optimum efficiencies for centrifugal pumps are of the order of 80–90%. This subject is discussed in more detail elsewhere (*see* **Plant and Equipment**: Flow Equipment: Pumps).

Pressure Drop in Valves

In a certain way, valves are the opposite of pumps. They are the elements that cause a loss of pressure head. From eqn [14], as a valve increases, the head losses, Q, decrease. The head loss caused by a valve is generally described by eqn [11]. The value of K will depend on the type of valve and percentage opening, and is given by manufacturers (otherwise, estimates can be found in the literature for generic valves). Valves and pumps work together: pumps must have some overcapacity and have a valve next to it (the discharge valve) to control the pressure to the desired level. Otherwise, the flow would be subjected to fluctuations due to variations in atmospheric pressure and temperature. Discharge valves and surge valves may also be needed for start-up and/or shutdown procedures.

Care should be taken to ensure that the pressure head at the exit of the valve when it is in the lowest opening position (higher K) does not go below the vapor pressure, which can be checked with Bernoulli's equation, in a similar manner to NPSH_a calculations.

Introduction

Pumps are small pieces of equipment that promote the circulation of liquids between and through pieces of equipment. When selecting a pump, the main factors to consider are:

1. The viscosity of the fluid, and whether it is a clear fluid or contains solid particles in suspension.
2. The sensitivity of the fluid quality characteristics to shearing and viscous shear energy dissipation.
3. The pumping requirements (pressure, flow rate).
4. The hygienic requirements of the process (which are high for dairy products).
5. The cost of the pump and of its maintenance.

The main issues are to ensure that:

1. The mechanical action of the pump affects the fluid characteristics to the least extent possible.
2. The pump is operating close to its optimum point.
3. There is no cavitation (the pressure of the fluid cannot go below its vapor pressure anywhere in the pump).
4. The mechanical wear of the elements of the pump (moving parts, seals) is not extensive to the point of causing significant loss of pumping efficiency (a preventive maintenance program would be quite adequate for pumps).

General Classification

Pumps force liquids to flow in one of two ways, which gives rise to the major division between pumps: (1) centrifugal, (2) positive displacement.

Centrifugal pumps have a rotor that rotates at very high speed (thousands of rotations per minute) and accelerates the fluid. As the fluid leaves the rotor, it is suddenly forced to slow down, pressing against the fluid which is already there. By looking at Bernoulli's equation, it is evident that the sudden substantial loss of kinetic energy must correspond to a sudden increase in pressure (see eqn [4] in article **Plant and Equipment**: Flow Equipment: Principles of Pump and Piping Calculations). Those that provide particularly accurate flow rates are also called metering pumps. A centrifugal pump does not ensure either a specific flow rate or a specific pressure: both will depend on the piping system after the pump (level differences, head losses, etc.)

There is a wide variety of positive displacement pumps, but in general it can be said that they capture a small amount of fluid, cause it to compress in some way, and then deliver the compressed fluid at the outlet. As they deliver a fixed amount of fluid at specific regular intervals, these pumps generally assure a given flow rate, and pressure will be dictated by the piping system and can be estimated by applying Bernoulli's equation.

Centrifugal pumps will obviously cause a substantial amount of kinetic losses due to collisions of molecules with the rotating elements and walls, and between themselves. This can generate a substantial amount of heating and affect thermally sensitive fluids. In addition, the high shearing may also affect molecular networking. Therefore, fluids with delicate macromolecular structures (for instance, a milk coagulum) should not be run through centrifugal pumps. It also follows that very viscous fluids are not suitable, as heat generation would be substantial, and slip is also potentially high (which implies a low pumping efficiency). As a rule of thumb, centrifugal pumps are not generally recommended for fluids with 10 times the viscosity of water or higher. They are obviously not suitable for liquids containing solid particles either. Due to the high velocity of the moving elements, cavitation is a major problem, as it can wear the rotor blades quite extensively and very rapidly (the collapse of a gas bubble when impinging on a moving surface at high speed causes roughly the same type of destruction as the collision with a hard solid particle). In positive displacement pumps, the generation of gas bubbles affects mostly the pumping efficiency, and not so much the actual pump.

On the other hand, centrifugal pumps will deliver a steady flow rate. Positive displacement pumps are more prone to pulses and fluctuations in the flow rate, as the cycle capture–compress–deliver repeats itself. It can also be expected that centrifugal pumps will generally have lower pumping costs, as acceleration of a low-viscosity fluid is easy, and pressure is then generated by the fluid slowing down the energy costs are basically those of accelerating the fluid. Positive displacement pumps must supply the totality of pressure by direct mechanical means, and this can be expected to require generally higher energy levels. However, these are not general rules, as there are very different types of positive displacement pumps.

In general, it can also be said that the action of positive displacement pumps can be reversed (inlet and outlet may be swapped), which is totally impossible in centrifugal pumps.

Not all pumps will be reviewed in this article, only the more common types.

Centrifugal Pumps

General Design and Principles of Operation

Figure 1 shows a centrifugal pump, in front and side view. The fluid enters perpendicular to the axis of rotation of the rotor and will leave tangentially in relation to the rotor blades. As the fluid disperses from the center due to the action of the centrifugal force toward the walls of the rotor casing, it travels in the radial direction through the channel between the blades. It is also accelerated tangentially to the velocity of rotation of the blades. These are constructed in such a way that the distance between blades increases with the radius – therefore, this channel widens as the fluid moves toward the wall. As the continuity equation shows (see eqn [2] in article **Plant and Equipment**: Flow Equipment: Principles of Pump and Piping Calculations), the fluid pressure will therefore increase as its kinetic energy decreases, while moving radially between the blades. The fluid then joins the layer moving around the wall toward the exit, pushed by the centrifugal force, which obviously moves slower than the blades, and so the pressure increases again. This layer, close to the casing wall, may also have an increasing flow area as a result of an eccentricity of the axis of the rotor in relation to the center of the casing – again, the reason for this design is to cause a gradual slow-down and respective pressure increase. This eccentricity, and whether it exists or not, depends on the pump design. At the outlet, another slow-down will occur, as the fluid starts moving at the velocity corresponding to the flow rate through the piping system, and pressure reaches a maximum. The conversion of kinetic energy to pressure is therefore gradual, and it stands to reason that the more gradual it is, the higher the efficiency – a very sudden slow-down implies many collisions between molecules, hence loss of mechanical energy, dissipated in the form of heat. Some pumps have a static ring between the moving rotor and the casing (usually, with channels having the opposite obliquity to the rotor blades), which provides a further gradual step of conversion from kinetic energy to pressure. **Figure 2** illustrates this description schematically.

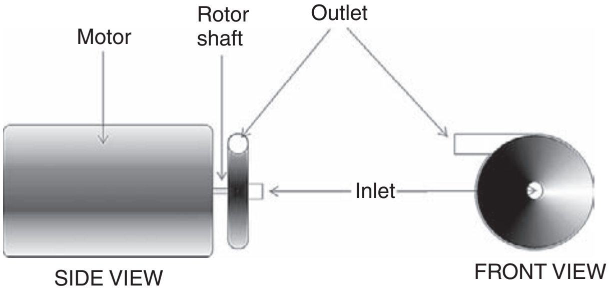

Figure 1 Front and side view of a centrifugal pump.

Hygienic Requirements

The most obvious hygienic requirement for a centrifugal pump is that it should be easy to disassemble, so that every part can be thoroughly cleaned easily. The blades should be rounded to avoid crevices, and therefore hygienic pumps generally have a lower number of blades (see **Figure 2**).

The pump motor releases much heat, as one would expect from a drive that generates velocities of the order of thousands of rotations per minute. Therefore, the motor casing of normal pumps is corrugated (the higher specific area promotes heat loss). However, this is not satisfactory for hygienic food processing, and food-grade pumps must have a smooth, stainless steel casing. This implies a pump that is built specifically for that, as other means of removing the heat generated by the motor must be improved; if a normal corrugated pump is covered by a smooth casing, it will run the risk of overheating.

Operating Points and Pumping Efficiency

Depending on the piping system to which the pump outlet is connected and on the rotor design and speed, a centrifugal pump will be able to deliver various flow

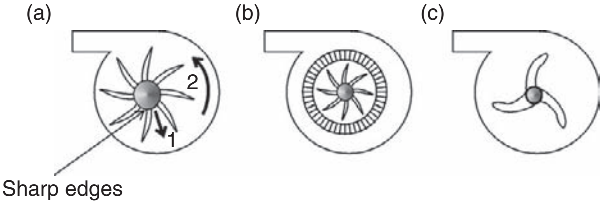

Figure 2 Rotors of centrifugal pumps. (A) Typical rotor without hygienic design considerations. Note path 1, where the fluid moves toward the wall pushed by the centrifugal force along a channel with increasing cross flow area, thereby increasing pressure; and path 2, where the fluid moves rotationally toward the axis, pushed by the centrifugal force, through a channel of increasing cross flow area due to the eccentricity of the rotor in relation to the casing; (B) rotor encased in a fixed channel distributor; (C) hygienically designed rotor, with smooth edges.

rates at various pressures. The pump characteristic curve indicates all possible operating points of a given pump. **Figure 3** shows a typical example. Pump manufacturers usually supply these graphs.

Pumping efficiency is not the same along these curves; it is normally maximum around the top right-hand corner and decreases as one approaches the limits of the curve. Therefore, a pump should ideally operate close to the flow rate and pressure combination that gives the maximum efficiency (at the expense of unnecessarily spending more power from the electrical mains to deliver the same amount of energy to the fluid). Lines of constant efficiency are usually drawn on these graphs (see **Figure 3**).

Checking the operating point of a pump in a given piping system is straightforward. Using Bernoulli's equation, the characteristic curve for the piping system can be constructed by calculating the pressure head at the outlet of a pump for various flow rates. An operating point for a given pump in a given piping system is the intersection of the two characteristic curves (pump and piping system). **Figure 3** shows a sketch of a situation where the maximum efficiency is achieved with the intermediate pump configuration, that actually delivers a slightly lower flow rate at a lower pressure than the configuration that gives the maximum flow rate. It should be noted that the characteristic curves of piping systems can be easily modified by operating valves, as they will increase head losses if partially closed. In the example of **Figure 3**, closing a flow rate control valve would increase head losses and the characteristic curve would be steeper. It would be possible to bring the piping system curve close to the maximum efficiency of the pump only if it would be possible to decrease the head losses.

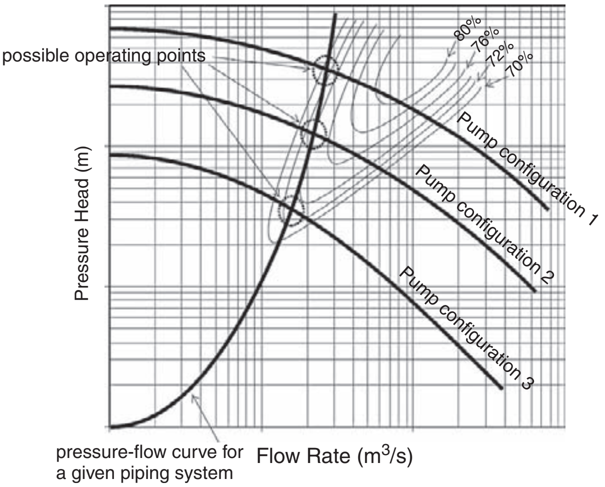

Figure 3 Typical characteristic curves for a pump in three possible configurations (different rotor design and/or speed), efficiencies and operating points.

Selection of Centrifugal Pumps

In order to select a centrifugal pump, one must know:

1. The net positive suction head (NPSH) available at the inlet of the pump (*see* **Plant and Equipment**: Flow Equipment: Principles of Pump and Piping Calculations).
2. The characteristics of the system (cross flow areas, level differences, total length of the piping system, localized head losses).

Item (1) is needed only for a verification: the NPSH available must be higher than the NPSH required by the pump chosen, in order to ensure that the vapor pressure is not reached inside the pump, which would cause cavitation and severe wear.

Item (2) is needed so as to apply Bernoulli's equation and determine the characteristic curve of the piping system, from where the operating point and efficiency of the pump can be calculated. The pump, and its operating variables, are chosen that give the maximum efficiency.

Manufacturers may provide graphs that indicate which of their makes/models are generally more suitable depending on pressure head and flow rate required. This helps to narrow choice to pumps that are designed for the type of demand in question. **Figure 4** shows a typical example.

Positive Displacement Pumps

Piston Pumps

General design and principles of operation

A typical piston pump, which operates according to a very straightforward principle, is shown in **Figure 5**. Fluid is admitted to a chamber through the inlet valve, as the piston moves back and sucks the fluid in. The

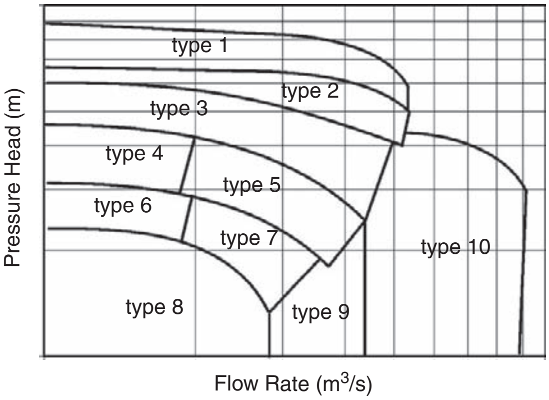

Figure 4 Typical chart for selection of the type of centrifugal pump better adapted to a given demand.

valve closes when the piston reaches its back position and then starts moving forward, compressing the fluid trapped in the chamber. When the specified pressure is reached (for incompressible fluids, this is obviously almost instantaneous), the outlet valve opens and the fluid is discharged, as the piston expels it while moving forward. When the piston reaches its forward position, the outlet valve closes, the inlet valve opens and the cycle begins again.

A piston pump will therefore deliver a flow rate equal to the volume of the chamber times the number of cycles per unit time. However, it is delivered only when the outlet valve is open, and nothing is delivered during the admission part of the cycle. In order to avoid a pulse in the flow, it is normal to use two chambers with the piston of each moving asynchronously, so that when one delivers the other admits and vice versa. Obviously, this can be neatly done by a dual chamber pump, with chambers placed back to back, so that the piston is actually the same. **Figure 6** sketches this design.

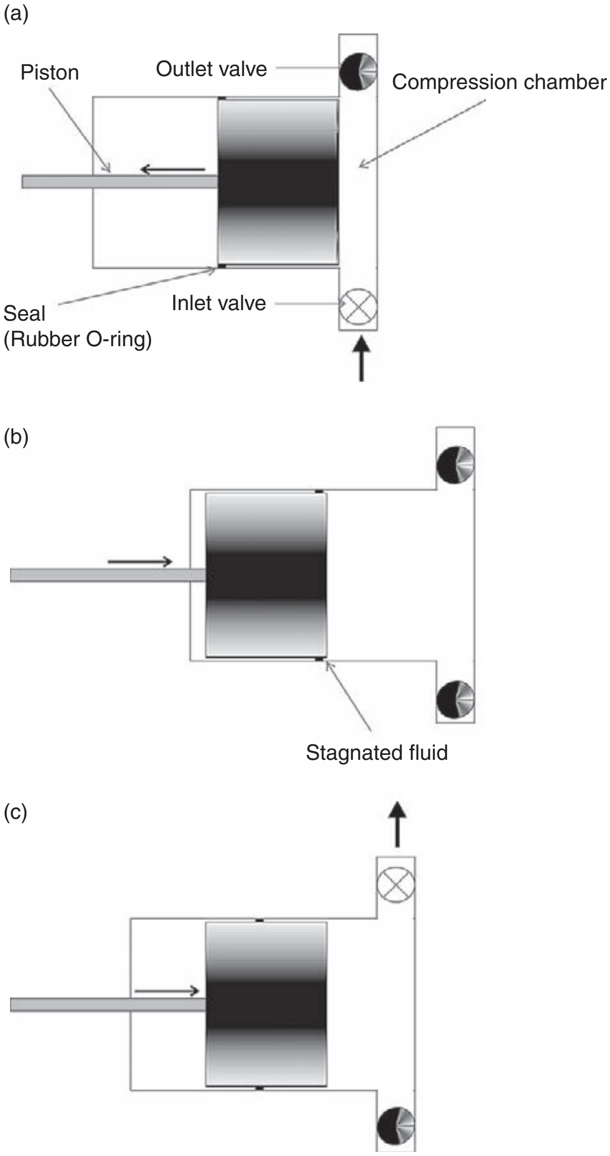

Figure 5 Piston pump. (A) Commencement of the admission stage of the cycle; (B) commencement of the compression stage; (C) during the delivery stage. White circles represent open valves and gray cones indicate closed valves.

Hygienic requirements: diaphragm pumps

Piston pumps are not very hygienic because fluid can be trapped in the space between the cylinder side and the chamber wall, at the back (see **Figure 5**). Diaphragm pumps were built to solve this problem. The piston is not in direct contact with the fluid, but pushes a rubber diaphragm, which fits totally in the chamber geometry. There are pumps commercially available that use compressed air to move the diaphragm.

Figure 7 sketches an example of a single-chamber diaphragm pump. For hygienic design, it would be ideal that the pump expels the totality of the fluid in order to avoid stagnated or dead volumes – the design in **Figure 7** shows an example which is particularly poor in this respect.

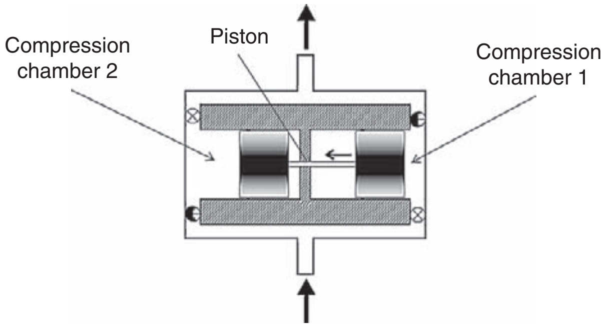

Figure 6 Twin-chamber piston pump. Chamber 1 is sucking fluid from the bottom and chamber 2 is delivering compressed fluid to the top. White circles represent open valves and gray cones indicate closed valves.

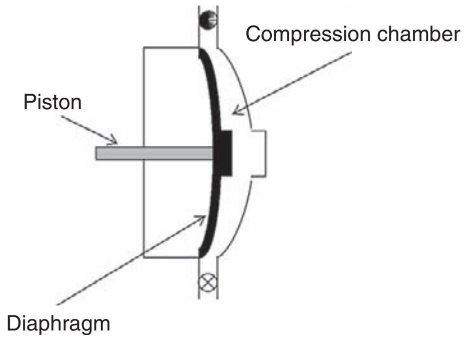

Figure 7 Diaphragm pump.

Rotary (Gear) Pumps

General design and principles of operation

Rotary pumps are also known as gear pumps. They have two rotors and dented wheels moving in such a way that the dents of one wheel fit snugly inside the other. Thus, the fluid is forced toward the outside wall and must move around. The fluid will be trapped inside chambers formed by two dents and the outside casing and is then forced out at the other side. **Figure 8** shows this principle of operation. Rotating speeds are about 100 times lower than those of centrifugal pumps.

These pumps are therefore more similar to centrifugal than to piston pumps in the sense that they assure a given flow rate rather than a given pressure: the flow rate is simply given by the volume between each pair of dents and the speed at which this volume is transferred to the other side. Pressure is then given by Bernoulli's equation, as once the flow rate is fixed, the piping system after the pump defines the pressure. Furthermore, while some compression occurs when the fluid is trapped inside the dents, most results from delivering the fluid to the other side and compressing it against the fluid which is already there, a similar situation to that in centrifugal pumps. However, this characteristic makes them the best metering pumps, with the flow rate being quite well controlled, as it is simply proportional to the rotating speed.

Hygienic requirements: lobular pumps

Rotary pumps such as that shown in **Figure 8** are not hygienic because the dents have sharp edges. Thus, lobular pumps have been developed, with well-rounded lobes, such as those shown in **Figure 9**. The sealing between the counterrotating rotors is obviously less good than in rotary pumps, as the rounded geometry implies fewer dents and therefore fewer points of contact for sealing at the center. A higher leakage flow between the high-pressure and low-pressure regions through the center is likely, compared to rotary pumps with more dents and more sealing points.

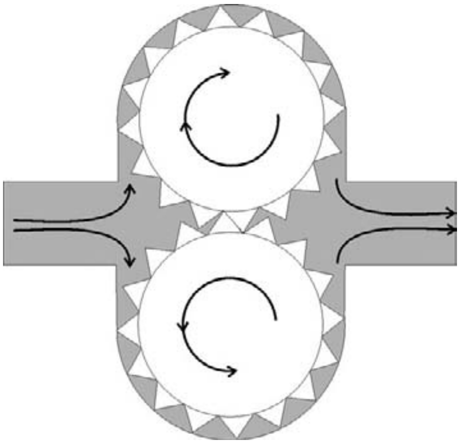

Figure 8 Rotary pump.

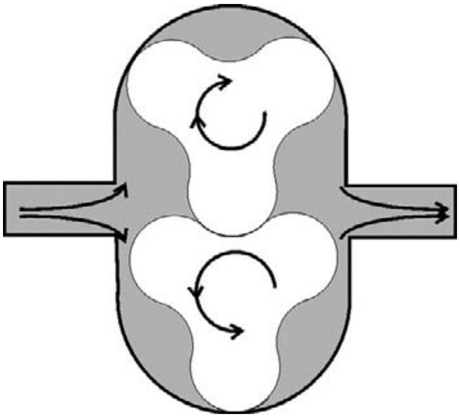

Figure 9 Lobular pump with three lobes per rotor.

Single-Rotor (Impeller) Pumps

Single-rotor pumps are also known as impeller pumps. They seem similar to rotary pumps, having only one rotor. However, their operation is quite different, as they can provide mechanical compression of the fluid in a much better way than rotary or lobular pumps. The blades are either made of rubber so that they can bend against the casing, or are made of metal, but have a spring at the base, so they can be pushed inward while moving against the casing. **Figure 10** shows both cases.

As the rotor moves, fluid is trapped between two blades. To improve compression, the casing may have a different curvature from the rotor axis, so that the space between them decreases. Therefore, the volume between two blades decreases while the rotor revolves, causing a compression (for relatively incompressible fluids, such as water and milk, this is not so important, while for viscous viscoelastic materials it would be helpful). On reaching the other side, the compressed fluid is expelled. In some pumps with rubber blades, the volume between blades is always the same, and the only compression results from the blades snapping at the inlet and squeezing at the outlet (see **Figure 10**).

Some fluid will certainly remain and proceed to a second turn – potentially, there could be a problem of stagnant fluid. The blades must therefore be designed in a way that helps the expulsion at the outlet, which is better achieved with rubber blades.

Progressing Cavity Pumps

Also known as monopumps, they have a curious design, with a rotating axis that looks like a twisted worm. It is not really a

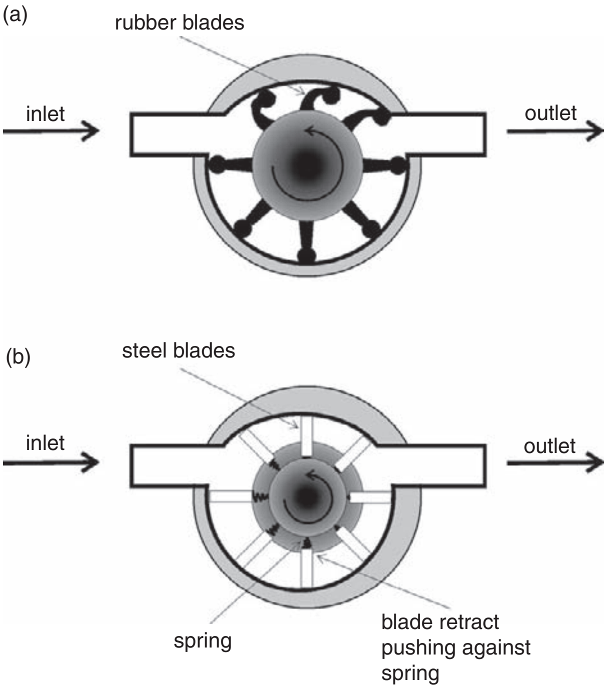

Figure 10 Single-rotor pumps. (A) Pump with rubber blades and no compression in the chambers between blades and outside casing wall; (B) pump with steel blades and with compression caused by decreasing volume between blades.

screw, it is more like a twisted bar which rotates against a rubber casing (the stator), that adapts to the movement of the rotor. The rubber casing has a grooved path of a different shape from the rotor curvature, so that at a given position there is a perfect match between grooves of the rubber casing and curved rotor, while a space exists between each two matching points (for instance, the rotor is a single helix and the casing is a double helix). As the rotor revolves, the points of contact appear to move forward. Hence, the fluid is trapped in a chamber formed by the rubber casing grooves and rotor, sealed at the matching points. The curvature of the rotor (and grooves) may show a decreasing amplitude, so as to reduce volume and hence cause compression (particularly helpful for viscoelastic materials). **Figure 11** shows this type of pump.

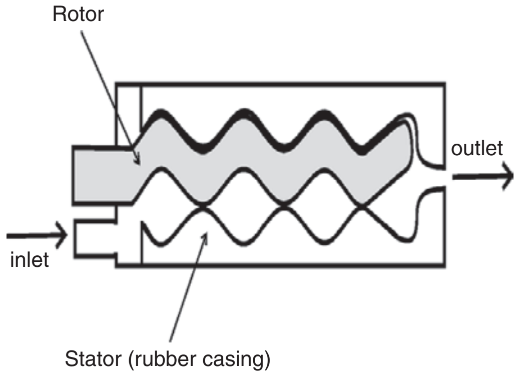

Figure 11 Progressing cavity pump.

These pumps have a good hygienic design, as all fluid is expelled, there is no need for valves, and there are only rounded edges and surfaces.

Peristaltic Pumps

Peristaltic pumps require a rubber tube through which the fluid flows. A wheel with rollers moves on top of the rubber tube, so that as the rollers move they squeeze the tube. This gentle squeeze causes a compression and therefore the fluid is trapped between two points of roller compression, forced to move forward and delivered at the outlet. Just like rotary pumps, peristaltic pumps basically deliver a fixed flow rate and most of the compression results from forcing the movement of the fluid. Hence, pressure will depend on the piping system, and it is the flow rate that is fixed by the pump operating characteristics. They can therefore provide good metering (flow rate accuracy and control). **Figure 12** shows this design.

These are obviously the most hygienic pumps of all, as there is no contact between pump parts and fluids. They are also the best for solid particles, as particles are not squeezed. The main limitation is that tubes must be relatively small, as it is not viable to compress very large tubes. Flow rate is therefore more limited than in other pumps. Pumping efficiency is also limited if very large pressures are required. In general, commercial peristaltic pumps can be found for flow rates up to 10 $m^3 h^{-1}$ and pressures up to 1.6 MPa.

Summary of Pump Selection Criteria

Table 1 provides an overview of the main selection criteria for pumps. In general practice, centrifugal pumps are used unless the fluid is too viscous, contains solid particles, or is too strongly affected by the high shearing and/or internal energy generation.

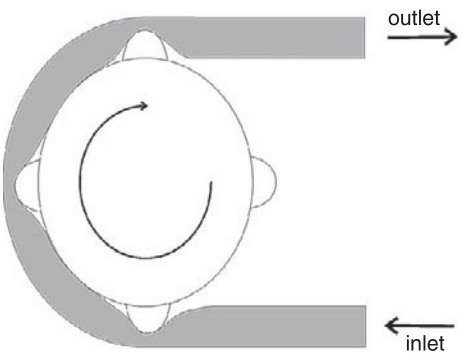

Figure 12 Peristaltic pump.

Table 1 Selection criteria for types of pumps

Type of pump	*Good for*	*Not good for*
Centrifugal	Low-viscosity fluids Clean fluids Steady flow rate	Viscous fluids Fluids containing solid particles Fluids sensitive to heat Fluids sensitive to shearing
Piston/diaphragm	Viscous fluids Clean fluids High pressures Precise pressure control	Fluids containing solid particles
Rotary/lobular	Viscous fluids Clean fluids Fluids sensitive to shearing Precise flow rate control	Fluids containing solid particles
Single-rotor	Viscous fluids Fluids with solid particles Fluids sensitive to shearing	High pressures
Mono	Viscous fluids Fluids sensitive to shearing	High pressures Fluids containing solid particles
Peristaltic	Viscous fluids Fluids with solid particles Fluids sensitive to shearing Flow rate control	High pressures High flow rates

This article is a revision of the previous edition article by K. Cronin and D. MacCarthy, Volume 2, pp 1093–1099, © 2002, Elsevier Ltd.

Introduction

Valves are devices for controlling the flow of fluids (liquids and gases), and in some cases granular or powdered materials. This article primarily discusses the valves used in product liquid lines in a dairy processing plant although many of the comments are equally applicable to the valves used for service fluids such as steam, refrigerant, compressed air, and process water, which will also be present in a dairy.

Broadly speaking, valves can be classified by their function as being either

1. on–off valves or
2. flow regulation valves.

On–off valves, which include shutoff, isolation, and changeover valves, have distinct positions, fully open or closed. These valves are used to stop flow or isolate part of a process. Their function is to minimize resistance to flow when fully open and to provide tight shutoff characteristics when fully closed.

Regulating valves, on the other hand, have a flow passage, the area of which can be changed gradually. Such valves are used to control flow rates and pressures at various points in the system. Flow control valves can be continuously adjusted from fully open to fully closed in order to govern the flow rate. Pressure control valves determine pressure downstream of the valve, that is, maintain it at some set value irrespective of the flow rate through the valve.

Valve Construction Principles

While a wide range of valves are used in industry, there are only a limited number of basic geometries by which an opening in a pipe can be opened or closed. Almost all valves can be classified as belonging to one of three fundamental designs or their variants. These are

- globe valve (**Figure 1**),
- butterfly valve (**Figure 2**), and
- gate valve (**Figure 3**).

The globe valve (also referred to as a seat valve) consists of a rigid valve body, weir, plug, and spindle. In the closed position, the plug rests on the valve seat in the weir. Linear upward motion of the spindle will raise the plug off the seat and open the valve. This is the most popular type of valve for dairy products.

The butterfly valve consists of a flat disc (equal in cross-sectional area to the bore of the pipe), a valve spindle, and an elastomeric or plastic seal ring. It operates on the principle of rotational rather than linear motion. In the closed position, the disc is face-on to the flow area and seals against the seal ring. Turning the spindle rotates the disc through a quarter turn (90°) and moves it to a side-on orientation with respect to the pipe bore, and thus allowing flow. This valve has low pressure drop characteristics.

The gate valve (sometimes known as the slide valve) like the globe valve operates on the principle of linear motion of a spindle. A flat disc is attached to the spindle, and in the closed position, it is fully extended and blocks the flow area of the pipe. Linear upward motion of the spindle will retract the gate into the valve body and permit fluid flow. This type of valve is not found in product lines in the dairy industry as it is unhygienic, although it is used for service fluids.

Valve Flow Design

Valve flow design applies the principles of fluid mechanics to determine the flow rate and pressure drop through the valve. Other issues that are of concern include valve flow characteristic and avoidance of water hammer.

Pressure Drop

All valves cause losses of head (i.e., pressure) in the system due to friction effects. In general, the smaller and more intricate the passage through which the fluid has to pass, the greater the pressure loss. Considering the flow of a

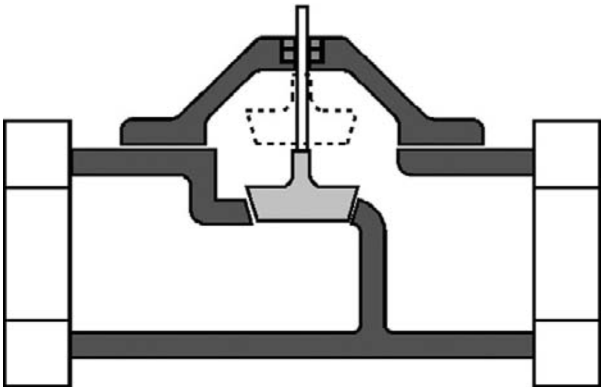

Figure 1 Globe valve.

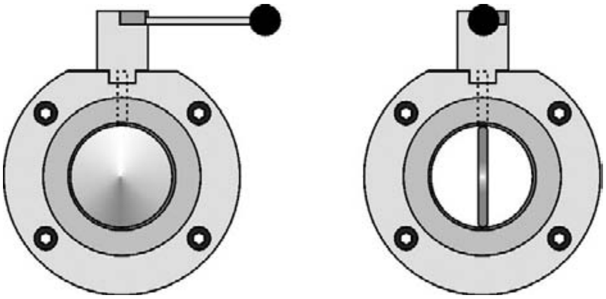

Figure 2 Butterfly valve.

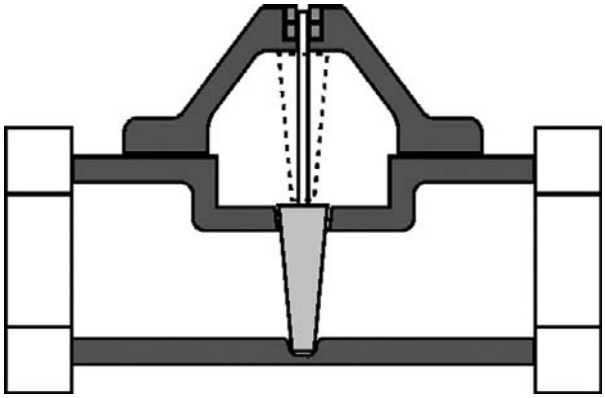

Figure 3 Gate valve.

turbulent and incompressible liquid (liquid milk for example), the pressure loss through a valve will be proportional to the square of the mean liquid velocity:

$$\Delta P = k\frac{\rho u^2}{2}$$

where ΔP is the pressure loss through the valve (Pa), ρ the density of the liquid (kg m^{-3}), u the mean fluid velocity (m s^{-1}), and k the friction factor (dimensionless).

Note that the mean fluid velocity refers to velocity through the adjacent piping (if piping of various diameters is used, this is taken to mean the velocity through the smallest diameter piping).

Using the continuity equation, the pressure drop can also be expressed in terms of the volumetric flow rate through the valve:

$$\Delta P = \frac{8k\rho Q^2}{\pi^2 D^2}$$

where Q is the volumetric flow rate (m^3 s^{-1}) and D the valve bore diameter (m).

Values of the friction factor k of the valve depend on the exact shape of the flow passage and are generally found from experiments. In some cases, the pressure loss through a valve is expressed in terms of an equivalent length of unobstructed straight piping in which an equal pressure loss would occur:

$$\Delta P = \frac{4fL_{\text{eq}}\rho u^2}{2D}$$

where f is the friction factor (dimensionless).

In the above equation, f, u, and D relate to the values associated with the adjacent straight piping and f is the Fanning friction factor, which is equivalent to 16 times the inverse of the Reynolds number in the pipeline where the pipeline flow is laminar. (In the US texts, the Darcy friction factor, which is 4 times larger than the Fanning friction factor, is often substituted for the $4f$ term in the above equation.)

Rather than this equivalent length being given as an absolute measurement in meters, it is more conventional to express it as an integer number, n, times the diameter:

$$L_{\text{eq}} = nD$$

Table 1 gives approximate values of the friction factor and equivalent lengths for a fully open globe valve and gate valve. It must be stressed that these figures are only rough estimates and many unstated assumptions (such as Reynolds number of flow, valve bore diameter, and pipe roughness) underlie them.

Valve Characteristic

An important design feature of modulating valves is the valve characteristic. This is the relation between the stem (spindle) position of the valve and the flow through the valve at a constant pressure drop. The valve characteristic determines how a control valve regulates the flow. Two

Table 1 Friction losses through valves

	k	*L/D*
Globe valve (wide open)	10	340
Gate valve (wide open)	0.2	13

characteristics must be evaluated for valve selection: the inherent and installed characteristics. The inherent flow characteristic is the relationship between valve stroke and the resulting fluid flow through the valve for the valve on its own. The installed flow characteristic is the actual relationship between valve stroke and flow when the valve is an element in a particular flow system. Hence the installed flow characteristic incorporates the inherent flow characteristic of the valve itself together with the flow characteristics of the whole line, that is, it depends upon the ratio of the pressure drop through the valve to the total pressure drop across the line and valve.

The inherent flow characteristic is the theoretical performance of the valve and is generally either linear or equal percentage. For a valve with a linear characteristic, the flow rate is linearly proportional to spindle position. For a valve with an equal-percentage characteristic, equal increments of spindle movement produce equal percentage changes in flow for a given pressure drop. An equal percentage valve may be combined with a centrifugal pump to provide a linear system. For the control system designer, the aim is to select a valve whose inherent flow characteristic gives an installed flow characteristic that makes the flow controllable over the whole range of valve movement, that is, stem position.

Water Hammer

Sudden closure of a valve can produce the phenomenon of water hammer in the pipe system. The name is a misnomer; this problem can occur with all liquids. Water hammer occurs when the abrupt deceleration of a liquid in a pipeline, caused by closing a valve too quickly, produces transient pressure shock waves in the liquid. These shock waves in turn can lead to appreciable and damaging levels of pipe vibration. Equipment such as process vessels and heat exchangers connected to the pipe may also be exposed to this vibration. Water hammer must be avoided in the design and selection of the pipe and valve system. Valves should be installed so that valve spring force and fluid pressure force act in opposite directions. Analysis of the phenomenon has been done in greater detail but fundamentally it involves imposing a minimum time limit on the duration of valve closure to avoid decelerating the liquid too rapidly.

Valve Hygienic Design

In a dairy, of all the pipe fittings in the product line, valves are probably the most technically complex. For hygiene reasons, all wetted metal parts of the valve are made of stainless steel. These are surfaces that intentionally or unintentionally (e.g., by splashing) come in contact with the product. Two main grades are used, AISI 304 and AISI 316. The valve body and all the fittings (actuator spindle, springs, flanges, bolts, operating levers, and wheels) will generally be made from 316 stainless steel.

Valve seals can be made from a variety of synthetic food grade rubbers; among the most common types are silicone rubber, butyl rubber, nitrile rubber, and EPDM (ethylene propylene diene monomer). The actual choice of rubber is determined by the demand of the particular application of the seal such as required mechanical properties (particularly compression set), temperature regime, and exposure to steam and cleaning/sterilizing agents.

Apart from functional performance, the most significant criterion in the selection of valves for milk processing plants is that they must be of a sanitary design and cleanable. Sanitary valves are designed according to the American 3A standards or other relevant hygienic design codes such as EHEDG (European Hygienic Equipment Design Group), Swedish, and German DIN standards.

Valves should be self-draining, free of dead spaces, and readily cleanable. They should protect the product from contamination, prevent product leakage, and not allow the ingress of microorganisms. For improved standards of hygiene and cleanability, valves should be connected to pipelines by butt-welding or by sanitary unions. Product contact surfaces should have a surface finish of 0.8 μm R_a or better, and be free of any pits, folds, or crevices.

A consequence of hygienic design considerations is that globe valves and butterfly valves are the most prevalent type of valves used in the dairy industry.

Valve Actuation

The choice is between manual, pneumatic, hydraulic, or electric drives to control valve position.

In general, manually operated valves are now found only in the smaller dairy plants. Automated valves have replaced them in large modern facilities although they are still used occasionally.

Pneumatic actuation is generally the first choice in the dairy industry with either a diaphragm or a piston actuator. Spent air can be discharged directly to atmosphere and there are no sparking risks. Because air pressures are generally low (in the region of 7 bar), there are upper limits on the forces that air systems can develop and there is no necessity to resort to impracticably large actuators. However, as valve opening/closing forces in dairy product lines are seldom of large magnitude compared to valve forces found in bulk chemical processing, this limitation is not of great significance.

If high valve opening/closing forces need to be generated, hydraulic actuation of the valve is suitable because of the very high oil pressures that can be generated. However, due to the possibility of contamination of the product with the oil, hydraulic actuation is very rare in the dairy industry. It can be found in applications where there is no possibility of contact with the product.

Electric solenoid actuation is not prevalent in the industry due to the fire/explosion risk from electric sparking. Also the damp conditions that can prevail in dairies can lead to problems with electrical connectors. They can be used, however, to control the pneumatic actuation circuits that in turn operate the main process and clean-in-place (CIP) valves.

Irrespective of the actuation mechanism chosen, valves can be arranged to be normally open or normally closed according to safe practice. Two arrangements are common:

- air closing/spring opening (a normally open valve, NO) and
- spring closing/air opening (a normally closed valve, NC).

Air opening/air closing arrangements are occasionally used.

In a system with pneumatic actuation, the usual configuration is that air under pressure is used to move the valve from its default (safe) state to the active state. If the pressurized air is removed, a compressed spring will automatically return the valve to the default state. Hence, occurrences such as electricity failure leading to a loss of compressed air need not have unwanted consequences. As an example, valves on outflow lines from silos or storage tanks will usually have the configuration of air to open and spring to close. This diminishes the possibility of loss of the product due to valve system failure.

Valves in Dairy Processing

The functions of valves in the dairy processing industry are summarized in **Table 2**.

The different types of valves used in dairy processing are described below.

Table 2 Dairy valve functions

	Valve type	*Function*
1	Product shutoff	Stop and start the flow of the product
2	Product changeover	Divert flow to another pipeline
3	Product separation	Separate two fluids, for example, product and detergent
4	Flow regulation	Adjust the pressure or rate of flow of the product
5	One-way flow	Ensure that the product flows in one direction only
6	Pressure relief	Control the maximum pressure of a fluid
7	Vacuum relief	Admit air to a vessel if vacuum exceeds a preset value
8	Constant pressure	Maintain the process liquid at a constant preset pressure

Globe Valve

The globe valve (also called seat valve or poppet valve) is operated by the movement of a valve stem, which raises or lowers a plug on to a valve seat. It can be used as a shutoff valve (**Figure 4**) or as a changeover or divert valve (**Figure 5**). When used as a shutoff valve in piping systems, it should close against the flow to reduce the possibility of water hammer. If used as a tank outlet valve, it should be installed so that static liquid pressure helps to keep the valve closed. Depending on system requirements, this valve is available with up to five ports.

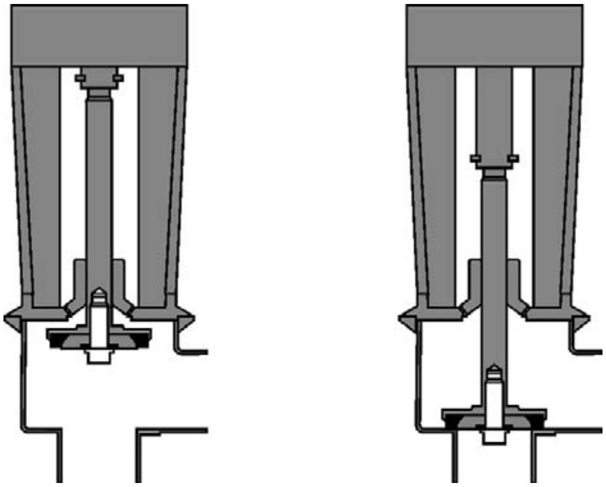

Figure 4 Seat valve – shutoff.

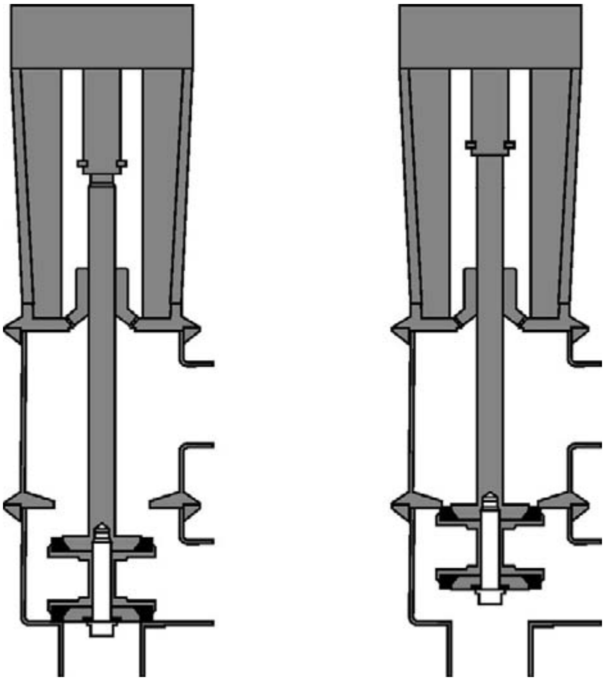

Figure 5 Seat valve – changeover.

Butterfly Valve

The butterfly valve (**Figure 6**) is designed primarily as a shutoff valve, but is sometimes used for flow regulation. When fully open, pressure drop is small, which makes the valve suitable for products that require delicate handling with minimum turbulence. It is also suitable for viscous products. The butterfly valve is available in manual or automated formats.

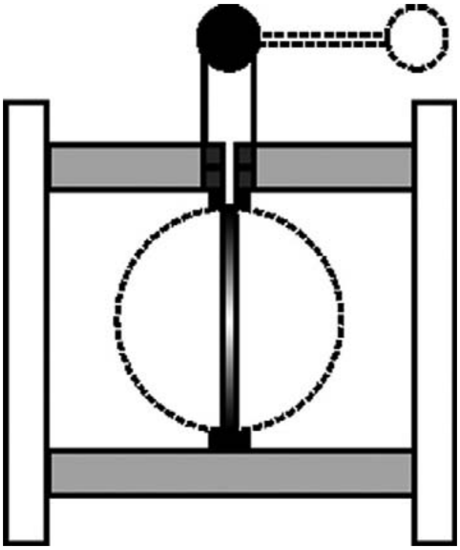

Figure 6 Butterfly valve.

Double-Seat Valve

Situations arise in the dairy industry in which two pipelines must be connected to allow the product to flow from one pipeline to the other, or separated to prevent mixing of two fluids such as product and detergent, and to ensure product integrity by directing any leaks to drain. This function can be achieved by use of three butterfly valves, three on–off globe valves, or one on–off and one changeover valve. It can also be achieved using one double-seat valve (**Figure 7**), which has two separate seals, one for each pipeline. Between the seals is a chamber, which is connected to atmosphere. Provision is made for in-place cleaning of this leakage chamber. To reduce the risk of a valve seat being lifted by surges in liquid pressure, this valve is available with a hydraulically balanced plug.

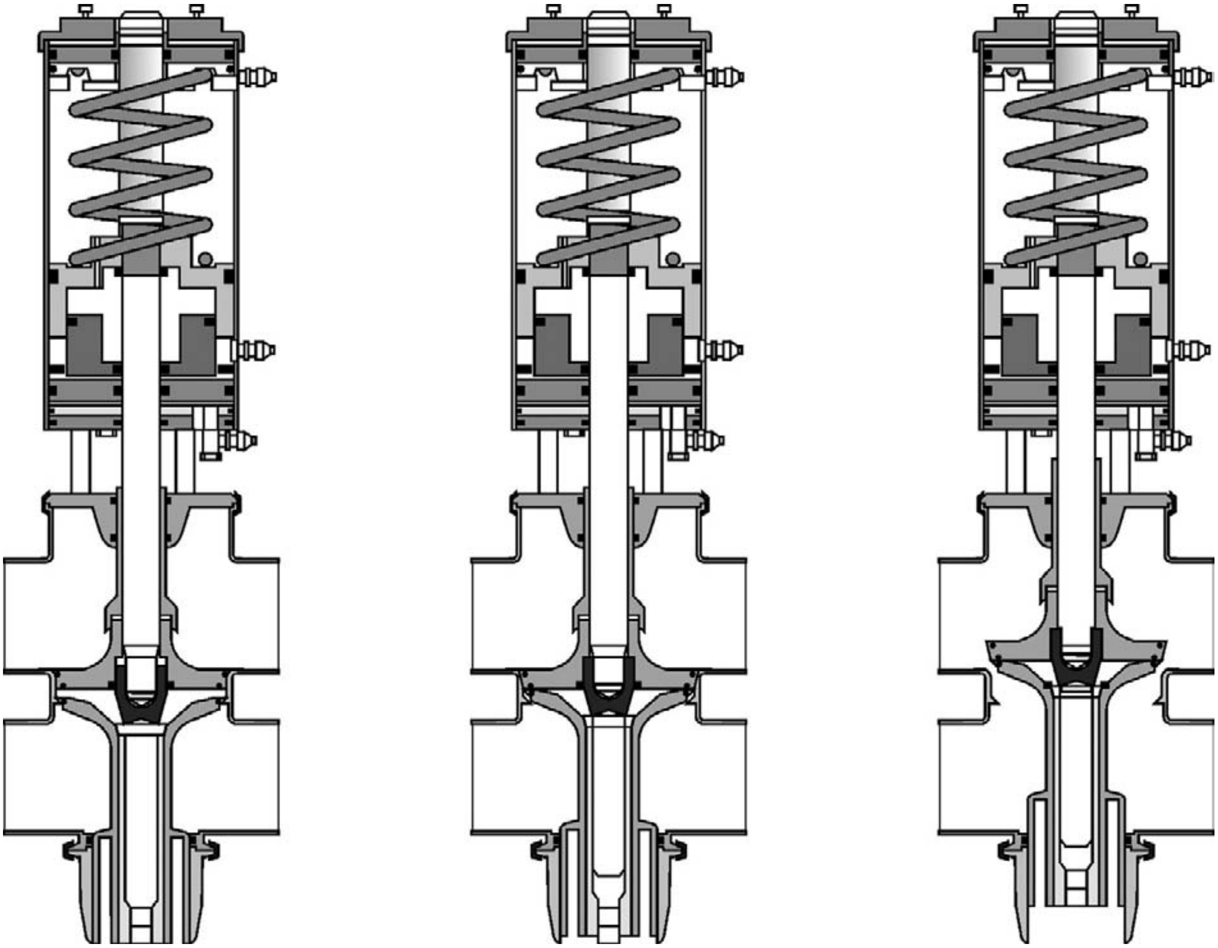

Figure 7 Double-seat valve.

Constant-Pressure Valve

In the constant-pressure valve (**Figure 8**), compressed air acting on a diaphragm modulates the flow in the system, in response to changes in product pressure. By this means, product pressure can be maintained constant, for example, for supply to an item of processing equipment.

Modulating Valve

The modulating valve (**Figure 9**), which is conceptually similar to the globe valve, is used to vary product flow rate. It operates by varying the position of the valve in the orifice in the flow weir and flow rate is reduced as the plug is lowered toward the valve seat. It may be operated in conjunction with a flow sensor, which detects product flow rate, and a controller, which adjusts the valve setting to the required flow rate.

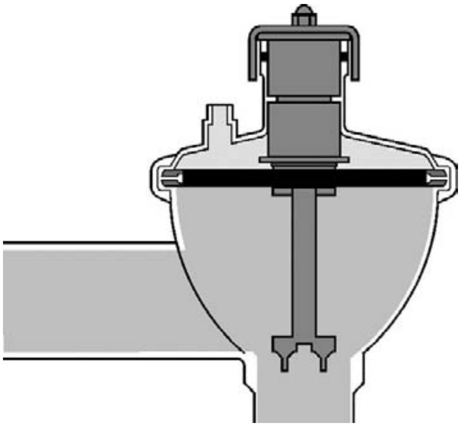

Figure 8 Constant-pressure valve.

One-Way Valve

The one-way valve or check valve (**Figure 10**) uses a spring-loaded seal to allow flow in one direction and to stop flow in the reverse direction. Fluid flow in the desired direction uses the momentum of the fluid to keep the valve open. If the direction of flow is erroneously reversed, the valve closes under the influence of the fluid and the spring, to prevent backflow.

Safety Valves

Pressure/vacuum relief valves (two possible configurations of a safety valve are shown in **Figure 11**) are used to ensure safe operation by limiting the maximum pressure/vacuum that can develop in a system. Pressure can be controlled by air pressure or by preset compression of a helical spring. Applications include the use of a pressure relief valve downstream of a positive displacement pump, to avoid damage in the event of a flow shutoff downstream. Since many safety valves are not air actuated, it is difficult to open them for CIP cleaning.

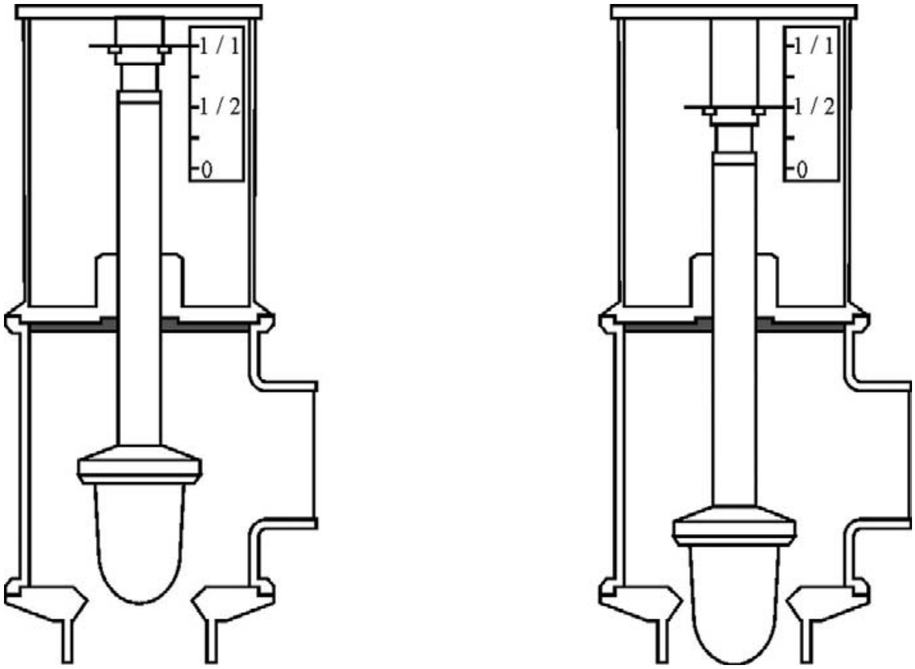

Figure 9 Modulating valve.

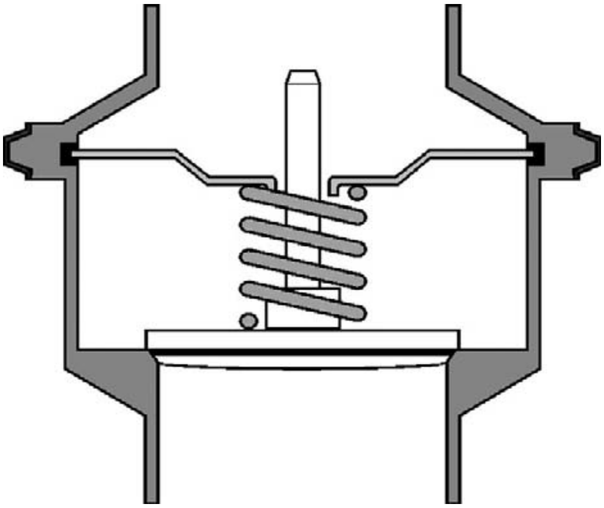

Figure 10 Check valve.

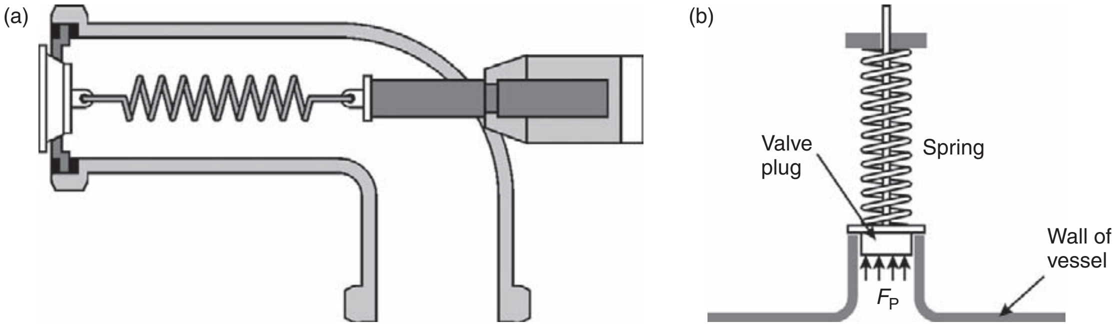

Figure 11 Safety valve.

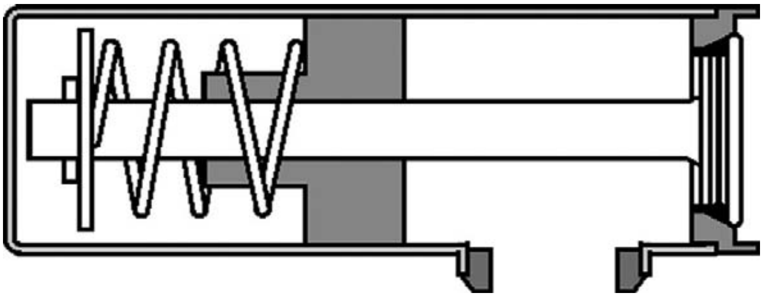

Figure 12 Air blow valve.

Air Blow Valve

Before in-place cleaning commences, the product is cleared from pipelines by use of compressed air introduced via an air blow valve (**Figure 12**).

Other valves used in the dairy industry include flow splitters, mixing valves, sampling valves, and plug cocks (for manual operation only).

Agitators in Milk Processing Plants

K Cronin and J J Fitzpatrick, University College Cork, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

This article is a revision of the previous edition article by D. A. MacCarthy, J. S. Fitzpatrick and K. Cronin, Volume 1, pp 1–6, © 2002, Elsevier Ltd.

Introduction

There are many reasons for the agitation of milk and milk products, including

1. to maintain product uniformity,
2. to promote heat transfer, and
3. to disperse and dissolve solids in water.

However, excess agitation is to be avoided, as it can cause product damage by disrupting the fat globule membrane and exposing the fat to the lipase enzyme. Overagitation can also cause the formation of butter granules.

This article describes the types of agitators that are commonly used in the dairy industry. The mechanical and hygienic design of such systems is outlined. The issues involved in the selection and sizing of a particular agitation system are presented. Heat transfer in agitated vessels is explained, and finally an overview of the applications of agitation in milk processing is presented.

Types of Agitators

Several types of agitators are used in dairy processing and these can be broadly classified based on the viscosity of the product.

Propeller Agitators

The three-bladed marine impeller (**Figure 1(a)**) is a high-speed impeller (400–1750 rpm) with a small impeller-to-tank diameter ratio (0.2–0.3). It is used for agitating low-viscosity liquids (usually <1 Pa s) whereby the momentum generated by the impeller is easily transferred throughout the liquid. It produces an axial flow pattern (**Figure 1(b)**), which gives reasonable mixing and good suspension of particles.

Turbine Agitators

These impellers have an impeller-to-tank diameter ratio in the range of 0.2–0.5, and can be operated at high speeds if required. They are used for agitating low-viscosity liquids (usually <1 Pa s); however, they have also been applied for agitating liquids with viscosities as high as 50 Pa s. The basic turbine is a flat-blade design, and one of the most common turbines is the flat-blade impeller with six blades mounted on a disc (**Figure 2**), which is often used in fermentations. Turbine impellers can induce strong radial flows in addition to axial flows, which impart a much greater mixing capability than imparted by propeller agitators. Pitch-bladed turbines have blades set at an angle less than 90° from the horizontal (**Figure 3**) and are used in the dairy industry, for example, in lactose crystallization and yogurt manufacture. The smaller the angle, the milder the agitation, as less shear forces are exerted on the liquid and on any particle or droplet within the liquid.

Paddle Agitators

The basic paddle agitator resembles the basic turbine agitator except that it has a larger impeller-to-tank diameter ratio (>0.5 to <1) and rotates at low speeds, typically 10–150 rpm. Paddle agitators are used in the dairy industry for agitating medium-viscosity liquids (0.5–10 Pa s). Increasing the viscosity will more rapidly dampen the momentum transfer through the liquid, and thus greater contact between the impeller and the liquid is required, which results in larger-diameter impellers with greater contact area. There are many variants of the basic paddle, as illustrated in **Figure 4**, which give greater contact area. Some of these, such as the gate anchor agitator, can be used with high-viscosity liquids up to around 100 Pa s.

High-Shear Agitators

High-shear mixers are used for breaking up particles such as in powder reconstitution or emulsion droplet formation. Rotor–stator agitators (**Figure 5**) are commonly used, in which the product is drawn into a high-speed rotor, with a typical speed of 3000 rpm, positioned in a closely machined stator, in which the solids are subject to milling and intensive hydraulic shear. This may be done batchwise in a mixing vessel, or in-line for continuous blending. Powder-mixing systems are commercially available, incorporating powder hopper, venturi feeder, and in-line mixer.

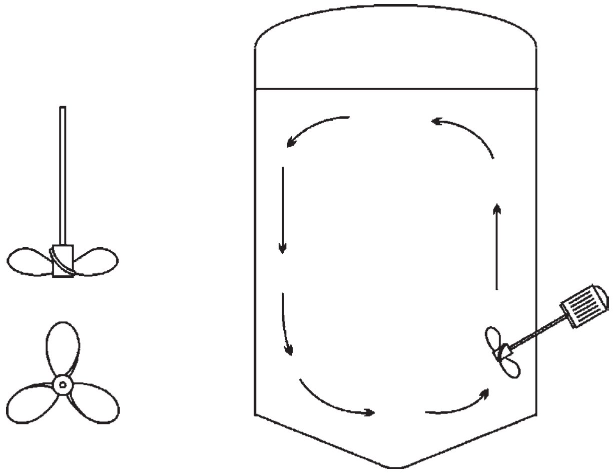

Figure 1 Three-bladed marine propeller showing typical flow pattern for side entry.

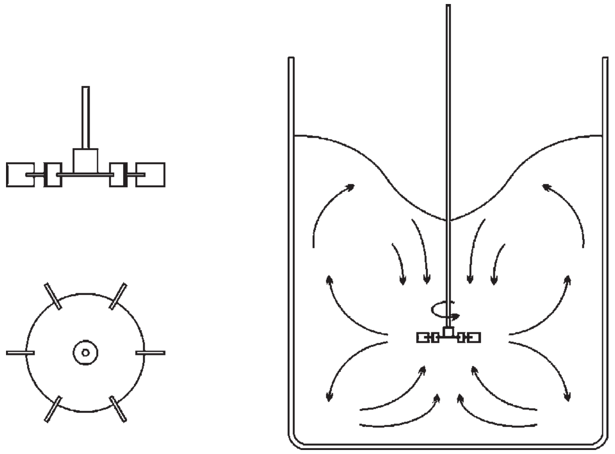

Figure 2 Six-bladed disc turbine impeller showing typical flow pattern for center axial entry.

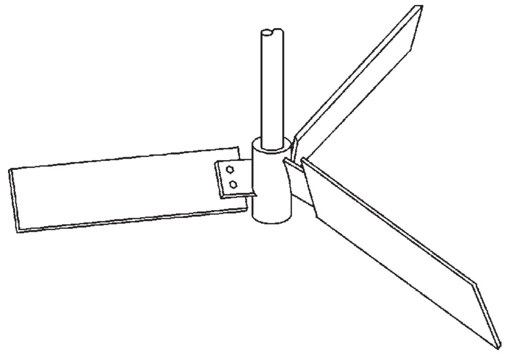

Figure 3 Pitched three-bladed impeller.

High-Viscosity Agitators

Helical and ribbon-type agitators are used for agitating very high-viscosity liquids (up to 1000 Pa s).

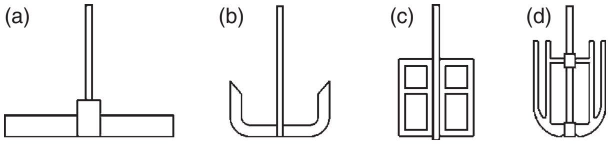

Figure 4 Paddle impellers: (a) basic paddle, (b) anchor, (c) gate, (d) anchor gate.

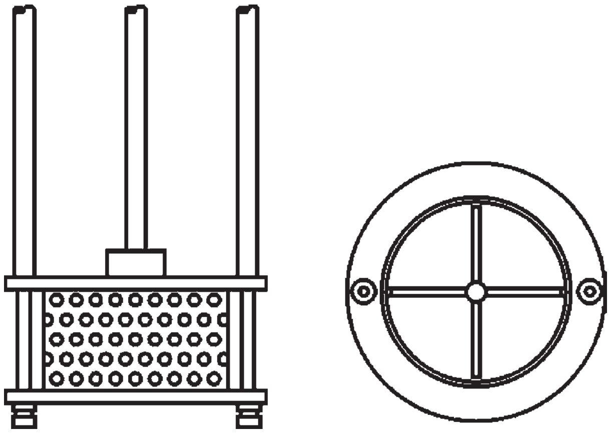

Figure 5 High-shear rotor–stator impeller.

Air Agitation

Milk in large storage tanks may be agitated by supplying compressed air near the base of the tank. The air bubbles rise, expand, and set up circulation currents in the milk. The air supply is regulated using a level detector, which matches the flow rate of air to the quantity of milk in the tank.

Mechanical Design

The agitation system consists of an electric motor transmitting power through a mechanical drive system. The drive system consists of a power transfer unit (gearbox or belt drive), shaft and impeller, bearings, and seals. **Figure 6** illustrates schematically the basic system configuration.

Electric Motor and Gearbox/Belt Drive

Electric motors rotate at an angular velocity (nominally 1500 or 3000 rpm) that is too high for the agitator impeller. Thus, a power transfer unit that allows a reduction in rotational velocity will be needed in the system, as in many cases impeller angular velocity will be less than 100 rpm. In the special case where a power transfer unit is not required, the system is referred to as direct drive. Two of the most common types of power transfer units are the gearbox and the belt drive. Gearboxes have the advantage of high torque transmission capability, high dimensional accuracy, and low friction losses, and they

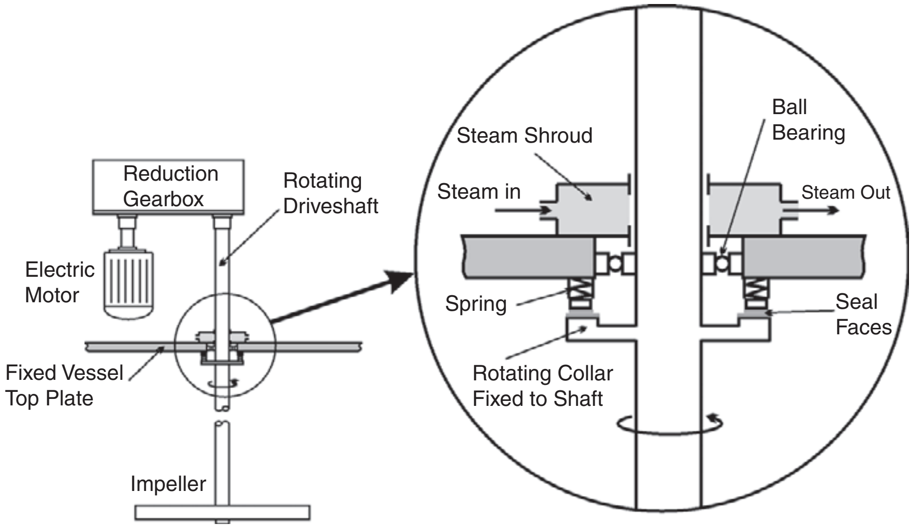

Figure 6 Drive system for top-mounted agitator.

predominate in this application. In many cases, the electric motor and gearbox will be supplied as a single unit. Belt drives are a flexible power transfer unit with the features of quiet running and good vibration damping properties. They are limited by (relatively low) operating temperatures and speeds and are less common in dairy agitation systems.

Drive Shaft

The drive shaft transmits mechanical power from the electric motor to the impeller. In tall tanks, it may be necessary to fit more than one impeller at different levels on the stirring shaft in order to obtain the required effect. The number of impellers required is approximately equal to the ratio of tank height to tank diameter. It will be necessary to support this shaft with bearings in order to minimize friction, wear, noise, deflection, and vibration. Bearings can be classified as journal (plain) bearings and rolling bearings, and it is the latter that are generally employed.

A variety of arrangements are possible to introduce the impeller shaft into the process vessel. The shaft can enter the vessel from the top (top mounted), from the bottom, or from the side. The shaft can be parallel, perpendicular, or inclined to the longitudinal axis of the vessel. Top-mounted vertical agitator drives are most common with the shaft either coaxial or eccentric (off-center) with respect to the vessel axis. Bottom or side entry may be advantageous if more space is needed on top for entry ports and manifolds, or if headspace is limited. The shaft can run the full length of the vessel and be supported by bearings at either end (top and bottom), or can terminate at the impeller and be supported by a bearing at the point of entry into the vessel.

Sealing

Satisfactory sealing of the rotating agitator shaft is essential to hygienic operation and yet difficult to achieve. As an example, in top-mounted systems, the dripping of lubricant oil from the gearbox into the tank contents is not acceptable even if a food-grade lubricant oil is specified. Any sealing arrangement must be able to resist the sterilizing temperatures applied. The most common type of dynamic seal is the axially loaded face seal (mechanical seal). Note that O rings should generally be avoided in food contact equipment.

A mechanical seal consists of a pair of rings: one stationary and one rotating with the shaft. They are spring-loaded together, and dynamic sealing takes place between the flat annular surfaces. Mechanical seals can be carbon rings (graphite) rubbing on carbon rings, or silicon carbide on silicon carbide. Silicon carbide is a ceramic material, is harder, and thus gives a longer seal life. For long-life and low-wear seals, tungsten carbide can be chosen. High-temperature, low-friction plastics such as Teflon (PTFE) are also employed. Mechanical seals with silicon carbide/carbon running surfaces are inert under normally encountered operating conditions and are considered safe in food processing. Steam barriers may also be employed to further guarantee containment.

Hygienic Design

Hygienic design of the agitator system involves consideration of issues such as materials of construction, cleanability, and surface finish. As food contact surfaces, which must remain inert, impervious, and durable, the shaft and impeller will in all likelihood be built from stainless steel. There are many grades of stainless steel but the austenitic grades AISI 304 and AISI 316 are the most common in dairy applications (*see* **Plant and Equipment**: Materials and Finishes for Plant and Equipment). Cleaning and sterilizing agents (caustic and chlorite bleaches) will generally be more dangerous to the steel than the product itself. It is for this reason that grade 316 may be preferred with its higher resistance to corrosion attack from chloride ions. This also highlights the need for careful water rinsing in the cleaning cycle to ensure that the concentration of chloride ions does not reach dangerous levels in inaccessible places such as any machine crevices.

The surface finish of the agitator affects the ability to clean, sanitize, and sterilize the shaft and impeller. Surface finish can be quantitatively measured by the value of the arithmetic mean roughness, Ra, number. Generally, such dairy product contact surfaces should have an Ra of less than 0.8 μm and such a finish is obtainable by mechanical- and electropolishing.

Agitator Selection and Sizing

Viscosity

Liquid viscosity is the resistance to flow of the liquid. Low-viscosity liquids show little resistance to flow and thus liquid momentum is easily transferred throughout the liquid and low power is required to agitate the liquid. On the other hand, high-viscosity liquids have a high resistance to flow, whereby viscous forces dampen liquid momentum transfer, and require higher power to agitate the liquid. In addition, many dairy liquids are non-Newtonian, and are mainly pseudoplastic, where viscosity decreases with increasing shear rates. This results in higher viscosities in regions of the liquid more remote from the impeller, which may lead to poor mixing in those regions. Some typical values for the viscosity of dairy liquids are presented in **Table 1** at specified temperatures, as viscosity is usually a strong function of temperature.

Agitator Selection

Selection of agitator type is determined by the viscosity of the liquid and the agitation job to be performed, whether it is mixing, heat transfer, particle dispersion, oxygen transfer, or a combination of these. Each agitator type has a range of viscosities where it performs best and an agitation duty that it is best suited to, as mentioned above. Equipment suppliers and process design companies have the experience and practical knowledge for selecting an appropriate agitator to perform a specified job.

Agitator Dimensions and Speed

Once an agitator type is selected, it then has to be sized in terms of its dimensions. This will depend on the size of the tank and the volume of the product to be processed. For a given impeller type, there are standard geometrical configurations for the impeller and tank, which give guidance to sizing the impeller. For most agitation applications with the exception of heat transfer, there is no well-developed mathematical analysis supported with property data that can be used for evaluating the effect of impeller speed and diameter on agitation performance. In these cases, it is necessary to evaluate on a small/pilot scale how impeller speed and diameter affect agitation performance and then scale up these results. Impeller tip speed is usually constrained in dairy processing because of its effect on product quality.

Agitator Power Requirement

There are many power curve correlations available in the literature for estimating the power requirement for specific impeller–tank configurations, and these are usually presented in the form of power number or function versus Reynolds number, as illustrated in **Figure 7**. Once the impeller speed and diameter, liquid density, and viscosity are known, then the Reynolds number can be calculated. The power number can be read from the power curve for the specific impeller–tank configuration, and the power requirement can be calculated from the power number or function. Separate curves are required for baffled and unbaffled systems due to possible vortex formation in unbaffled systems. As a general guide, the typical mixing power consumption varies from 0.2 kW m^{-3} for

Table 1 Typical viscosities of dairy liquids

Liquid	*Temperature (°C)*	*Viscosity (Pa s)*
Low viscosity		
Water	20	1×10^{-3}
Whole milk	20	2×10^{-3}
Skim-milk concentrate (33% solids)	25	13×10^{-3}
Medium viscosity		
Yogurt	10	1–4
Milk concentrate (48% solids)	20	1
Whey concentrate (65% solids)	10	5

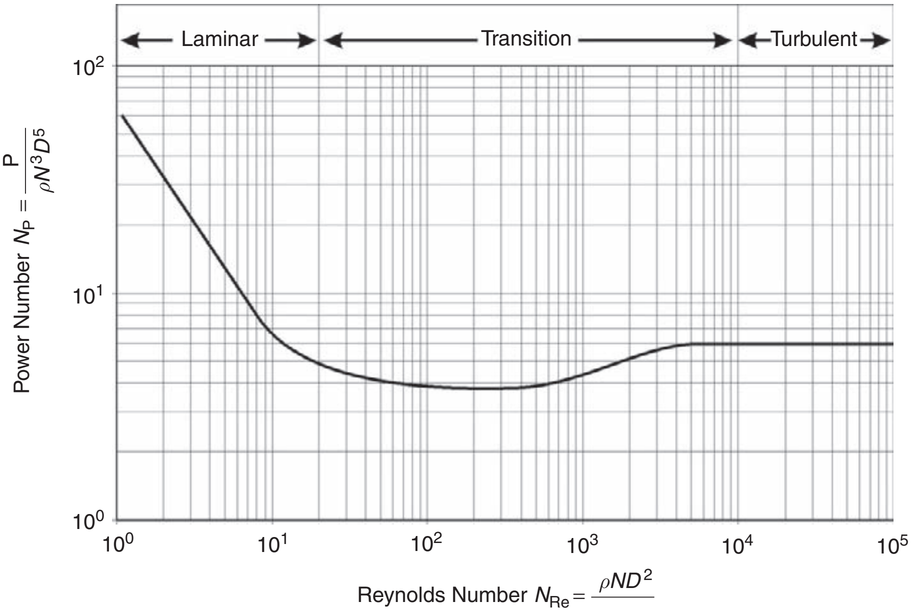

Figure 7 Power curve correlation for estimating agitator power requirement.

low-viscosity liquids up to 4 kW m^{-3} for blending materials that have the consistency of pastes and dough.

Vortexing

Tangential flow in the direction of rotation of the impeller can lead to vortex formation when agitating low-viscosity liquids by centrally mounted impellers in unbaffled tanks. Vortexing due to increasing rotational speed may lead to air entrainment by exposing the impeller to air. This can also produce large oscillating forces acting on the impeller shaft. Vortexing can be prevented by mounting the impeller off-center or using a horizontal side-entering impeller. There are cases where vortexing is advantageous, for example, powder reconstitution. When powder is added to the surface of water, the vortex can greatly improve powder sinkability by centrifugally spinning the powder into the water, and this becomes even more important as the solids content of the reconstituted mixture increases.

Heat Transfer in Agitated Vessels

Heat transfer coefficients for the heating or cooling of a liquid in a jacketed vessel may be calculated using the correlation

$$\mathrm{Nu} = a\mathrm{Re}^b\mathrm{Pr}^c\left(\frac{\mu}{\mu_\mathrm{W}}\right)^d$$

where

$\mathrm{Nu} = hD_\mathrm{T}/k$
$\mathrm{Re} = D_\mathrm{A}^2 N\rho/\mu$
$\mathrm{Pr} = C_p\mu/k$
h = heat transfer coefficient (product) (W m^{-2} K^{-1})
k = thermal conductivity (W m^{-1} K^{-1})
D_T = tank diameter (m)
D_A = agitator diameter (m)
N = rotational speed (s^{-1})
ρ = density (kg m^{-3})
C_p = specific heat (J kg^{-1} K^{-1})
μ = viscosity (Pa s)
μ_W = viscosity at wall temperature (Pa s)

Values of *a*, *b*, *c*, and *d* depend on system geometry. Heat transfer in a jacketed vessel may sometimes be problematic when dealing with medium- and high-viscosity liquids because of low heat transfer rates and formation of deposits on the tank wall. This is overcome by using paddles with small clearances between the impeller and the tank wall so that the blade surfaces sweep the wall of the tank, clearing away any deposits and preventing a stagnant layer at the wall surface.

Applications

On Farm

Following milking, milk is stored in refrigerated tanks pending milk collection and delivery to the dairy. Agitation is required for two purposes: to improve heat transfer while the milk is being cooled, and to avoid fat separation and facilitate milk sampling for analysis and payment. The typical agitation system used on farm is a paddle agitator, with an approximately 100 W motor geared down to about 30 rpm. The agitator will operate continuously during cooling and intermittently (e.g., 30 s/15 min) during storage.

Milk Intake

When milk is received at the dairy, it is stored as raw or pasteurized milk. Agitation is required at this stage to maintain uniform composition for downstream processing and inventory control. Typical agitation systems include (1) top-entry agitator with more than one pitched-blade impeller, (2) side-entry agitator, marine propeller, angled down from the horizontal, and (3) air agitation, which is less commonly used because incorporation of air in milk can lead to problems in heat exchangers and centrifuges. In modern installations, provision is made to inactivate the agitator if the product surface reaches the height of the agitator.

Cream Storage

Agitation of cream should be gentler than agitation of milk because of the greater possibility of product damage. The typical agitator used is the pitched-blade or paddle impeller, at a speed of 30–60 rpm.

Milk and Whey Concentrates

Milk concentrates are produced by evaporation for dehydration, or by the addition of solids for yogurt or ice cream manufacture. These products can be effectively agitated using a marine propeller or pitched-blade agitators at 200–400 rpm.

Powder Dispersion

The dispersion of powders in water is required for the manufacture of many dairy products such as ice cream, yogurt, dairy spreads, and dairy desserts. Complete dispersion of the solids in the aqueous phase is required, with no residual lumps and without air incorporation. Particular difficulty is encountered in dispersing stabilizers, for example, guar gum and locust bean gum, and emulsifiers, for example, mono/diglycerides. This is usually achieved using high-shear mixers.

Yogurt

Yogurt is characterized by a high solids content (about 20%) and a medium to high viscosity depending on whether the yogurt is stirred or set. Gentle agitation is required to avoid damage to product texture. This can be achieved by using a top-mounted agitator with large paddles and speeds of 20–60 rpm.

Processed Cheese

Processed cheese manufacture is characterized by high viscosity, dispersal of solids, and high heating rates. Agitation is achieved by anchor-type scraped-surface agitators, at speeds of approximately 100 rpm.

Introduction

Since ancient times it is known that milk tends to separate into cream and skim milk. In static systems this was just a matter of time. During the nineteenth century centrifugal separation was developed for milk skimming before it was introduced to other technologies.

Milk separators enabled a very quick skimming of the milk. The first machines were manually driven with a crank handle and mainly used on farms. For increasing the efficiency the original spiral channels were replaced by conical disks. The development of industrial dairies demanded higher capacities, and the machines were equipped with electric motors. Another important step forward was the introduction of self-discharging bowls in the 1970s, which enabled automatic cleaning or cleaning in place (CIP).

The Basics of Centrifugal Separation

Centrifugal seperation can be applied on two-phase systems composed of either solid particles dispersed in a liquid or liquid droplets emulsified in another liquid. The individual particles or droplets form a discontinuous phase in the continuous liquid phase. If the density of the particle or droplet is higher than that of the liquid, it will sink down (sedimentation), otherwise it will float up (creaming), as depicted in **Figure 1**.

The velocity of separation is described by Stokes' law:

$$V_\mathrm{s} = \frac{d^2 \cdot \Delta\rho \cdot g}{18 \cdot \eta}$$

where V_s is the velocity of sedimentation, d the diameter of particle or droplet, $\Delta\rho$ the difference of densities, g the acceleration due to gravity, and η the viscosity of the continuous phase.

This equation shows that the velocity of sedimentation is

- proportional to the difference of densities
- proportional to the square of the size of the particle or droplet
- inversely proportional to the viscosity of the continuous phase
- proportional to the acceleration due to gravity

Another important figure is the separating distance. In a slim and tall vat a particle or droplet has to travel a longer distance and needs more time to separate than in a wide flat pan of the same volume.

Density and particle or droplet size are product parameters that generally have to be taken as constant values. However, other parameters can be influenced to optimize the process.

- Usually increasing temperature reduces the viscosity and thus increases the sedimentation speed. Therefore, dairy separators are integrated in a pasteurizing process mostly at temperatures of 50–60 °C.
- Centrifugal acceleration in a separator is determined by the bowl diameter and the rotational speed. It can be 8000 times higher than the acceleration due to gravity.
- Separating distance can be minimized by the geometrical design of the flow path. In modern separators the space between the disks has been reduced to 0.3–0.6 mm.

The increase of the separation effect in a centrifuge is described by the acceleration factor ξ. This figure indicates the centrifugal acceleration as a multiple of the gravitational acceleration.

$$\xi = \frac{\omega^2 \cdot r}{g}$$

where ξ is the acceleration factor, ω the angular speed ($\omega = 2 \cdot \pi \cdot n \ \mathrm{rad\,min^{-1}} = \frac{2 \cdot \pi \cdot n}{60} \ \mathrm{rad\,s^{-1}}$, where n is the bowl speed in rpm), r the radius, and g the acceleration due to gravity (9.806 65 m s^{-2}).

As the acceleration factor is proportional to the radius of the centrifuge, the centrifugal acceleration is not constant but increases outwardly and decreases inwardly, as sketched in **Figure 2**.

In a static system the gravitational acceleration forces the heavy phase (i.e., solids) downward and the light phase (i.e., cream) upward. In a rotating centrifuge the heavy phase moves outward, and the light phase inward.

Separation in the Disk Stack

The feed flow is distributed to the rising channels and then split into a large number of parallel flows in between the conical disks. From here the liquid splits into

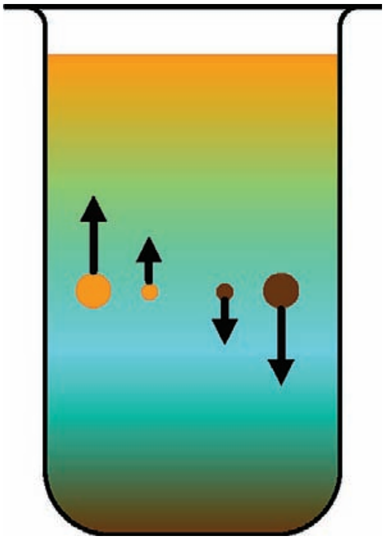

Figure 1 Creaming and sedimentation.

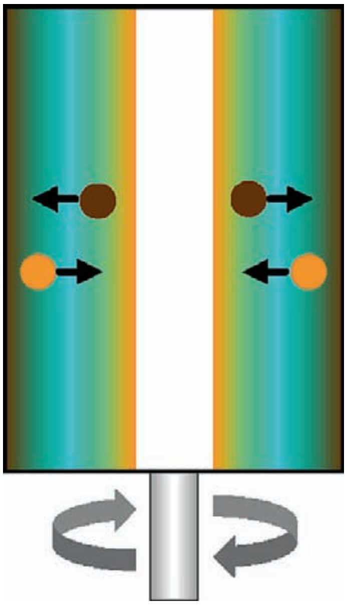

Figure 2 Centrifugation.

the light phase that flows inward and the heavy phase that flows outward.

A light fat droplet carried over to the heavy phase will move inward from the main stream until it hits the surface of the disk below. Here the wall speed of the heavy phase flow is close to zero, and the buoyant force is able to move the droplet inward against the main flow until it merges with the light phase. In the light phase the inverse process separates heavy particles and carries them back outward to the heavy phase, as depicted in **Figure 3**. **Figure 4** shows a typical disk stack.

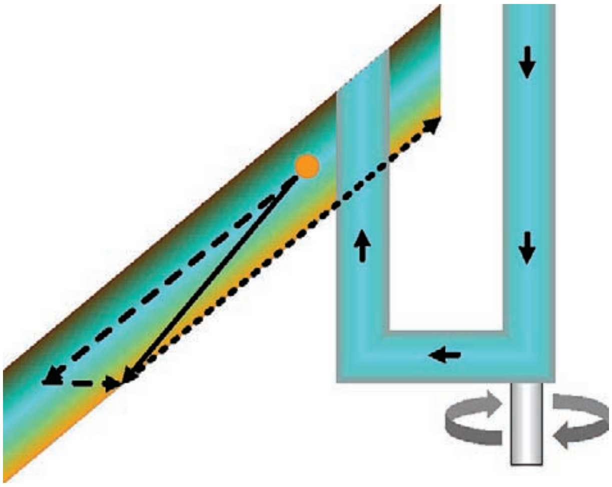

Figure 3 Separation in disk stack.

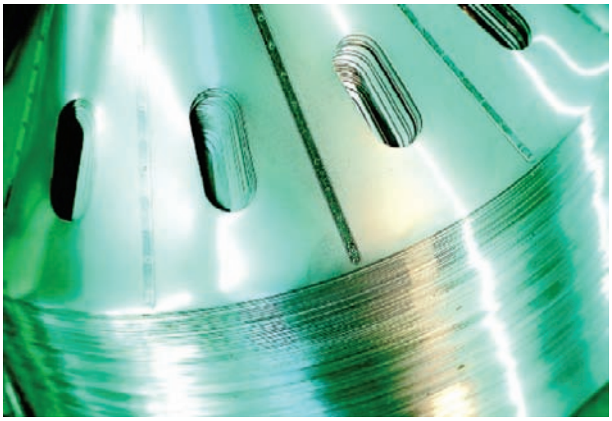

Figure 4 Separator disk stack.

Design Features

Separators

The most common type of centrifuge in dairy installations is the separator, which is a vertical centrifuge with a stack of conical disks. The size of the flow channels between the disks is defined by spacers welded onto the disks.

Phases

There are two main types of separators. Two-phase separators (**Figure 5**) provide a solid–liquid separation (clarification), whereas three-phase separators (**Figure 6**) deal mainly with liquid–liquid separation (skimming). As dairy products always contain a certain amount of solids, such as raw milk impurities or coagulated proteins, in skimming separators there is also a third phase of heavy solids.

With regard to the bowl components, the significant difference between two- and three-phase separators is the separating disk. In three-phase separators the heavy liquid

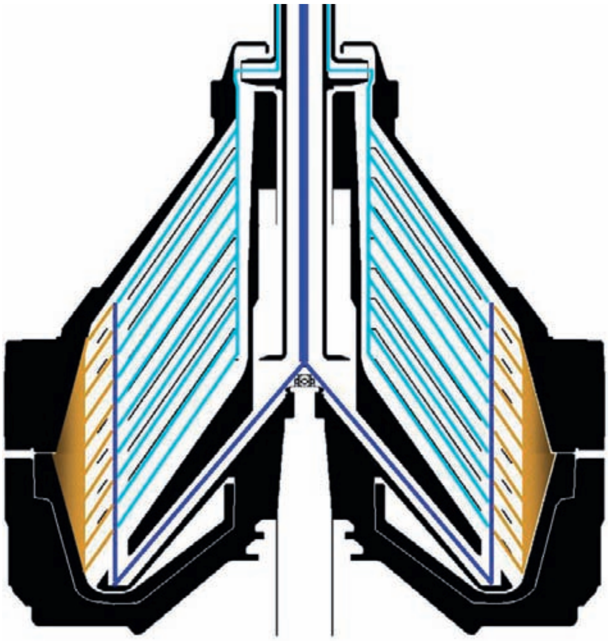

Figure 5 Two-phase bowl (clarification).

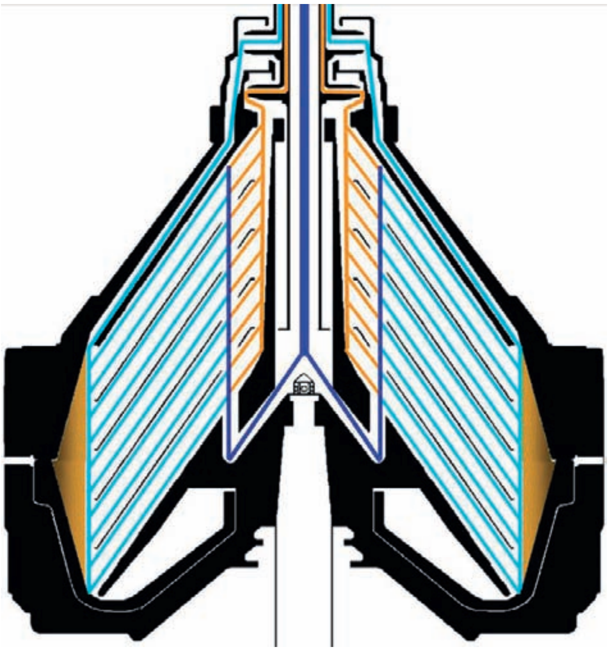

Figure 6 Three-phase bowl (skimming).

phase moves outward in the disk stack. It is redirected and flows inward on top of the separating disk to get to the discharge near the center of the bowl.

Sealing

Basically, there are two different types of sealing for the feed and discharge connections. Closed bowls use mechanical seals (hermetic sealing), whereas 'open' bowls are equipped with hydraulic sealings (hydrohermetic sealing). In terms of air intake there are no significant differences between the two types.

On open bowls the feed and the discharge are usually connected from the top. Due to the additional space requirement of the mechanical seals, the product supply to a closed bowl is preferably connected from below via a hollow spindle.

On hermetic separators the mechanical seals are fragile components, and they are prone to wear and tear.

An open-bowl separator generates the discharge pressures from the separator drive. On a closed-bowl separator the discharge pressure is largely created by the feed pump, so the machine drive can be smaller, but a bigger feed pump is required.

Discharge

In the original and the most simple design the liquid phases horizontally overflow from the bowl into collecting channels in the hood. The disadvantages of an open-discharge system are the generation of foam and the need for collecting vats for the discharged liquids. Nowadays, only very small separators feature this type of discharge.

Centripetal pumps are fixed devices that use the rotary speed of the liquids to create pressure and forward flow in a closed-discharge system. This system avoids foaming and air intake, and it enables the integration of the separator in a closed-pipe system.

The equivalent counterpart to a fixed centripetal pump in open bowls is a rotating impeller on a closed bowl.

For some applications, a continuous discharge of major quantities of solids is required, for example, for the production of fresh cheese. Nozzle bowls are equipped with a collar of calibrated nozzles on the circumference of the bowl. To avoid an accumulation of solids between the nozzles, the inside of the bowl has a special shape with conical pockets directing the sedimented solids to the nozzles.

Rising channels

In all cases the product is fed into a distributor that distributes it underneath the disk stack to a number of rising channels. The position (radius) of the rising channels determines the relation between the flow paths of the light and the heavy phases.

Channel positions close to the center result in long flow paths for the heavy phase and short flow paths for the light phase. Therefore, there is an improved removal of the light phase from the heavy phase, whereas the removal of the heavy phase from the light phase is less efficient. This is the typical configuration for skimming separators where the efficiency is defined by the residual fat content in the skimmed milk.

On the other hand, a clarifier needs long flow paths for the light phase to remove as much of the (heavy) solids as possible from the (light) liquid. Therefore, the rising channels are positioned further to the outside of the disk stack.

In some cases it is favorable to have no rising channels and the product rises completely outside of the disk stack.

Drive

The development of the drive system has proceeded from gear drive (**Figure 7**) via flat belt drive (**Figure 8**) to direct drive (**Figure 9**). With fewer changes of direction, the mechanical efficiency factor increases and the noise level reduces. The number of serviceable parts is reduced significantly as well.

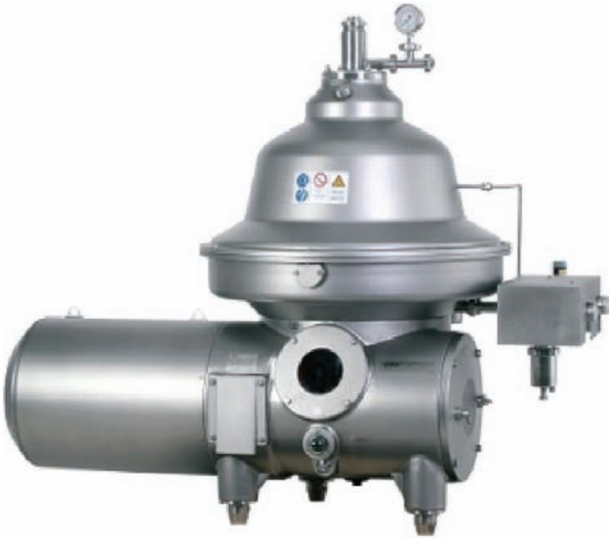

Figure 7 Gear drive separator.

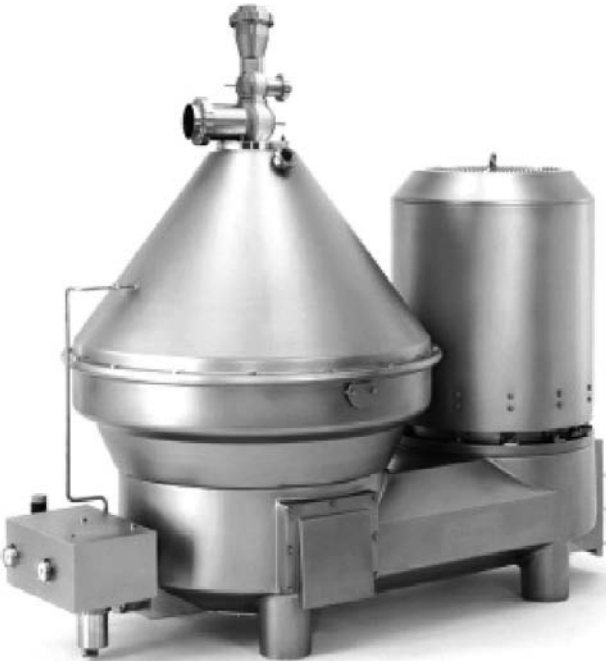

Figure 8 Belt drive separator.

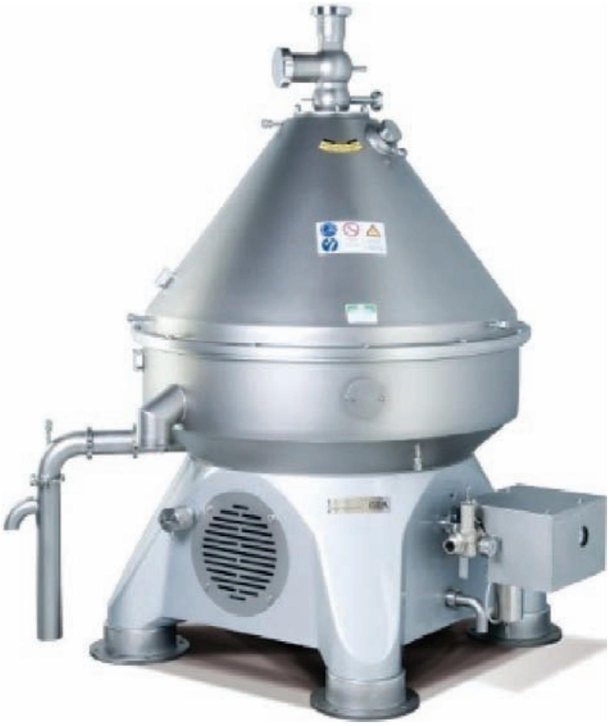

Figure 9 Direct drive separator.

A limiting factor for the rotary speed is the tensile strength of the bowl material. The admissible bowl speed depends on the bowl diameter and varies within a range of ~4800 rpm (>Ø 800 mm) to 11 000 rpm (<Ø 300 mm).

Hydraulic system

Until the 1970s all separators had solid wall bowls. They could be operated until the solids holding space was filled up with sediments. After production, they had to be completely dismantled and cleaned manually (‘takedown machines’).

One of the most important steps in the development of separators was the introduction of self-discharging bowls. A hydraulic system closes and opens the solids holding space at the bowl perimeter. During production this is used to perform regular discharges of the solids sediment. This enables long production runs without being limited by the solids load.

Furthermore, these machines are suitable for automatic cleaning or CIP. Discharges during the recirculation of cleaning solutions remove sedimented solids from the bowl, and at the same time the sudden high velocities in the disk stack effect a mechanical cleaning. Besides the cleaning of the machine itself, the integration of a separator in a CIP loop also provides for cleaning of the CIP solutions.

The discharged quantity can be controlled to achieve partial discharges during production and total discharges during CIP. A partial discharge ejects a quantity equivalent to approximately the volume of the solids holding space. This can be done without any interruption of the process.

A total discharge, however, ejects the complete contents of the bowl. The loss of rotating fluid means a loss of kinetic energy and slowing down of the rotary speed. In order to limit the drop of speed, the feed flow has to be closed during total discharges and has to be kept closed during a recovery time after the discharge.

Decanters

Unlike separators, decanters have a horizontal axis of rotation (**Figure 10**). The continuous discharge of sedimented solids is performed by a scroll rotating at a differential speed in relation to the bowl.

Generally, decanters are used for the removal of higher solid loads or to achieve a higher dry matter content in the discharged solids. In the dairy industry decanters are used only for a limited range of special applications.

Phases

Similar to separators, horizontal centrifuges are available for two-phase or three-phase separations. In dairy applications only two-phase decanters are used.

Discharge

The liquid discharge can be executed as an open discharge (**Figure 11**) or as a closed discharge with a centripetal pump (**Figure 12**). Depending on the further use of the liquid phase, both versions are used in dairies.

GEA
Westfalia Separator

Figure 10 Decanter.

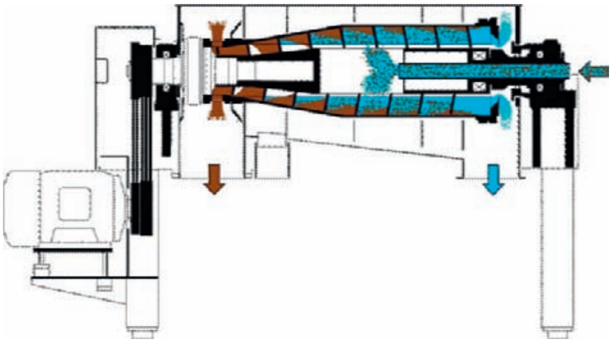

Figure 11 Decanter with open discharge.

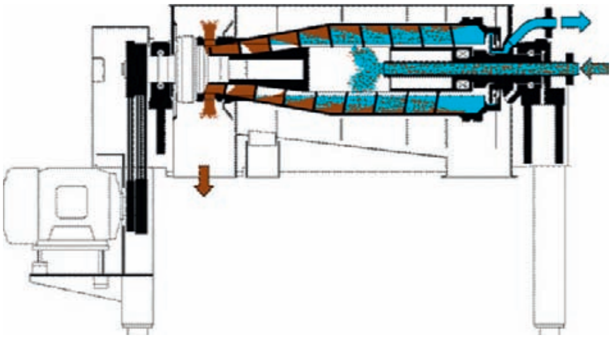

Figure 12 Decanter with centripetal pump.

Drive

A wide range of drive systems is available for decanters. The main classification is into fixed differential speed (selected by exchangeable pulleys, as shown in **Figure 13**) and variable differential speed (**Figure 14**).

The selection of the drive system is determined mainly by the solids load. If the quantity or quality of the solids is variable, the machine has to cope with it by a variable differential speed.

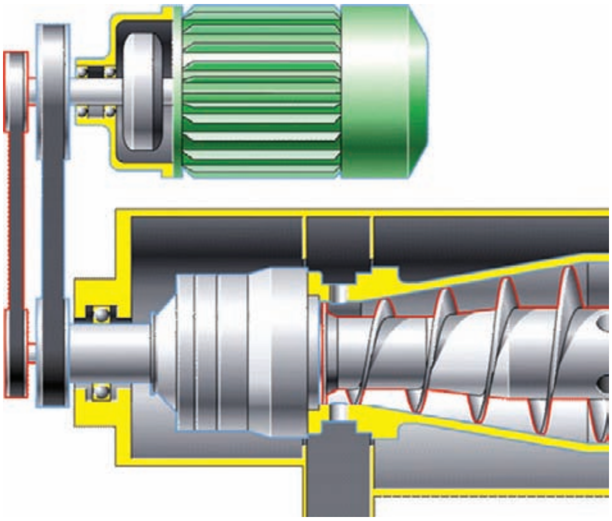

Figure 13 Decanter drive for fixed differential speed.

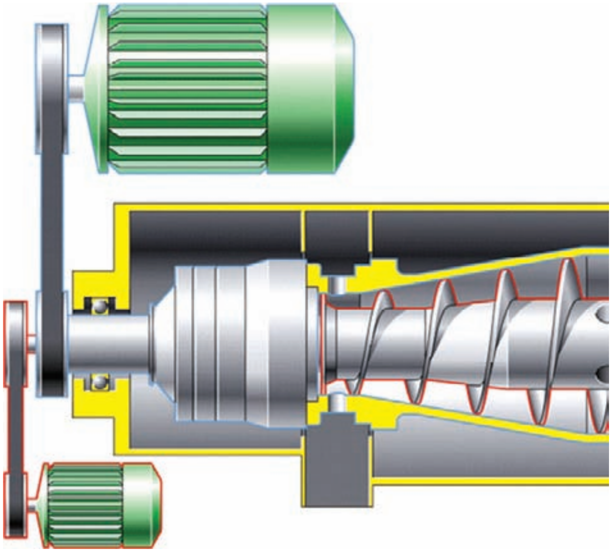

Figure 14 Decanter drive for variable differential speed.

Centrifuges for Dairy Applications

Skimming

Hot milk skimming

Milk skimming is still the most common and most important application for separators today. Worldwide, dairy legislation stipulates pasteurization of raw milk, and in all pasteurizers an important unit is the separator, which is integrated into the process at a temperature of 50–60 °C.

There are three modes of operation in milk skimming: full skimming (production of skimmed milk and cream), standardizing (production of standardized milk and cream), and back blending (production of whole milk). In all these modes, apart from skimming, the separator also cleans the milk from solid dirt.

According to the mass balance, the cream fat content is controlled by adjusting the cream flow rate:

$$\dot{V}_c = \dot{V}_r \cdot \frac{F_r - F_s}{F_c - F_s}$$

where $\dot{V}_c$ is the cream flow rate, $\dot{V}_r$ the raw milk feed flow rate, F_r the raw milk fat content, F_s the skim milk fat content, and F_c the cream fat content.

In the standardizing mode there is no requirement for a high skimming efficiency, so the skimming separator can be operated at a higher capacity than that is possible in the full-skimming mode.

Cold milk skimming

In some cases it is desirable to do the skimming at cold temperatures of 4–15 °C. Here, thermal changes are avoided and no heating energy is required at that stage of the process.

The skimming efficiency achieved is less than that achievable with hot milk skimming, and the milk fat is more crystalline than at hot temperatures. Therefore, the thickness of the flow paths has to be considerably larger. Also viscosities of the cream and skimmed milk are higher.

To increase efficiency and/or capacity, the temperature can be gently increased to ~20 °C.

Whey skimming

Compared to milk (4%), the fat content of whey (0.4%) is much lower. Whey originates mostly from cheesemaking, which is a batch operation; so the operating conditions cannot be kept constant as in a milk pasteurizing line.

Cheese whey always contains a certain amount of cheese fines. As a third phase, these particles tend to obstruct the separation process and can cause fouling of the disk surface. For a good skimming efficiency, a proper preclarification is indispensable. Best results are obtained with a clarifying separator rather than by screening.

Standardizing

Many dairy processes require standardized milk with a specified fat content. The blending of skimmed milk and cream can be done batchwise or continuously, applying different levels of automation.

For tank standardizing, the pasteurizer toggles between whole-milk and skimmed-milk production and both qualities are mixed in the right proportion in the pasteurized milk tank. This method is applied in manually operated plants.

Continuous standardizing is possible by splitting the cream flow and blending a part of the cream with the skimmed milk. Systems of different automation levels, from manual to fully automatic, are available.

Volumetric standardizing systems imply a constant raw milk fat content; they should be recalibrated after a raw milk tank change.

Modern high-end systems like the GEA Westfalia Separator ®standomat continuously measure the fat content of the cream, so that they can compensate for variations in the raw milk composition. The control unit can be equipped with additional features like a continuous density/protein measurement for fat in dry matter or fat/protein standardizing, or proportional dosing of extra cream or other additives.

The size of the cream discharge determines a maximum cream flow rate, which corresponds to a minimum cream fat content. The production of low-fat cream is possible with a cream dilution feature in the standardizing unit. **Figure 15** shows a typical standardizing unit.

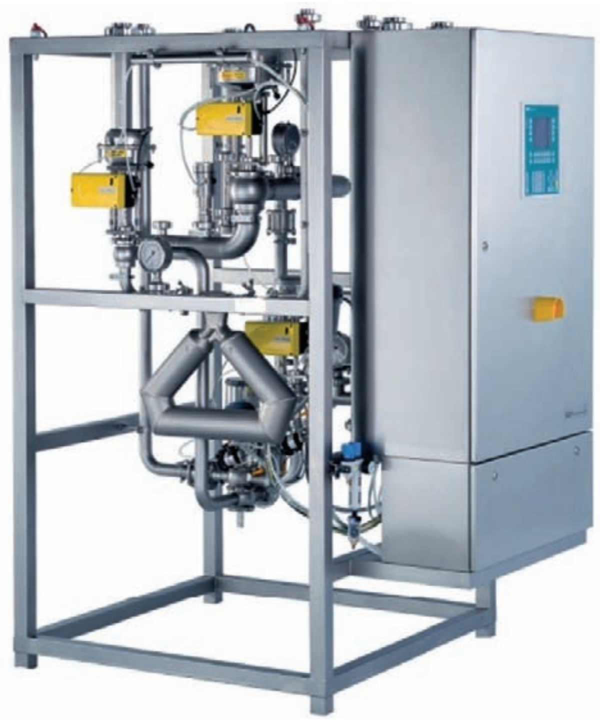

Figure 15 Standardizing unit.

Butter oil

For the production of butter oil or anhydrous milk fat (AMF) skimming-type separators are used in different ways.

- Cream concentration: The cream fat content is increased from 40 to ~80%.
- Oil concentration: After a phase inversion from oil-in-water to water-in-oil in a high-pressure homogenizer, the fat content can be further increased to over 99%.
- Oil polishing: Addition of water enables the elimination of concomitant substances.
- Serum skimming: This is the recovery of the remaining fat in the heavy phases discharged from the abovementioned stages.

Clarification

In the dairy industry clarifiers are mostly used for the cleaning of raw milk at an early stage of processing or for the clarification of whey before a whey skimming separator. Recovered cheese fines can be further dewheyed in a decanter and then be used for the production of processed cheese.

Bacteria Removal

Spore-forming bacteria include *Bacillus* (aerobic) and *Clostridium* (anaerobic) species. The spores of these species are dormant bodies that carry all the genetic material as is found in the vegetative form, but do not have an active metabolism. They are much more resistant against heat, dryness, and other negative ambient conditions than the vegetative form, so they act as a mean of survival during hard times. When the environmental conditions turn favorable, spores germinate to vegetative *Bacillus* or *Clostridium* cells.

The concentration of spores in milk varies with the conditions of feeding and milking. Wherever the cows are fed with silage in the winter season, there is an important peak in spore count during that time. Owing to the heat resistance of the spores, this imposes specific limitations on the quality of pasteurized milk. On the other hand, spores have a higher dry matter content and a higher density than vegetative cells, so they are easier to remove by centrifugal separation.

Removal of bacteria from liquid milk or from cheese milk is usually done in a pasteurizing line immediately before or immediately after the skimming separator. Besides the spores, vegetative bacterial cells and somatic cells from the cow's udder are also removed.

There are two different separation principles that can be applied. Most manufacturers use special clarifying separators to accumulate spores and heavy cells in the solids holding space before they are ejected from the bowl at regular intervals.

In contrast to this, GEA Westfalia Separator uses a skimming-type bowl where a small quantity of the heavy phase enriched with respect to bacteria is recirculated to the product feed. This heavy-phase flow acts as a carrier to promote the deposition of the spores and bacteria to the solids holding space and increases efficiency.

Fresh Cheese Production

Fresh cheese

Pasteurized cheese milk (skimmed or up to 3% fat) is coagulated by fermentation with or without the addition of rennet. Heating steps before and after coagulation serve to bond the whey proteins to the casein and to increase the yield of coagulated protein.

The coagulated protein is separated at 30–50 °C as heavy phase and continuously discharged via the nozzles on the perimeter of the bowl (**Figure 16**).

The discharged product quantity is a constant value; therefore, the dry matter of the product is controlled according to the mass balance by adjusting the feed flow.

Figure 17 shows a schematic diagram of a fresh cheese bowl.

Double-cream fresh cheese

Enriched cheese milk of 8–12% fat content is pasteurized and homogenized before it is coagulated by fermentation. The pretreatment aggregates the protein with the fat, so

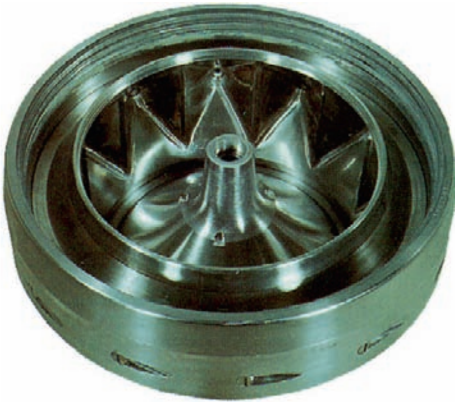

Figure 16 Inside shape of a nozzle bowl.

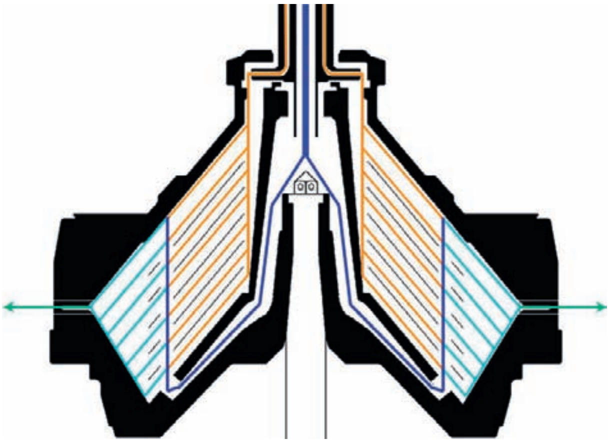

Figure 17 Bowl of fresh cheese separator.

the coagulate constitutes a lighter phase when compared to whey.

The separation is performed at ~80 °C in a specially designed skimming separator that can handle the high viscosity of the cheese.

The fat-in-dry matter content is determined by the properties of the cheese milk. The dry matter is controlled during separation by adjusting the discharged whey flow.

A schematic of a typical double-cream fresh cheese bowl is shown in **Figure 18**.

Decanter

Decanters are used in some dairy applications where high dry matter content of the solids phase is required:

- concentration of recovered cheese fines
- production of lactose
- production of casein
- production of high dry matter fresh cheese

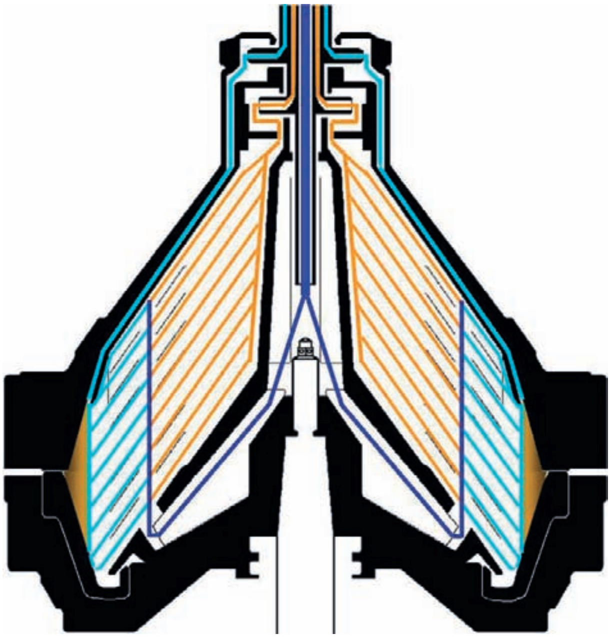

Figure 18 Bowl of double-cream fresh cheese separator.

Process Conditions

Satisfactory results are achieved with proper process conditions.

- The discharge pressure determines the (vertical) product level in the bowl. The adjustment of pressure to an appropriate value is fundamental for the functioning of a separator.
- The process control has to provide constant conditions with regard to temperatures, flow rates, and pressures.
- Any shearing during the pretreatment of the product tends to reduce the size of fragile particles or droplets and can reduce separation efficiency.
- An increased air content in the milk, owing to, for example, an inappropriate design of the balance tank, can change the flow pattern in the disk stack and reduce efficiency. However, a certain amount of released air has to be accepted if air-saturated milk is heated from storage temperature to separation temperature.

Centrifuges and Separators: Applications in the Dairy Industry

O J McCarthy, Massey University, Palmerston North, New Zealand

Introduction

Centrifugal separation is the mechanical fractionation of a fluid mixture of two or more immiscible phases of differing densities by the imposition of a centrifugal acceleration field. Density differences of not less than 3% are required for effective fractionation at respectable throughputs.

In the context of the dairy industry, the term centrifugal separation comprises centrifugation and cyclone separation. Centrifugation means separation in centrifuges with power-driven rotating bowls (rotating-boundary machines). Cyclone separation means separation in cyclone separators, in which the mixture to be fractionated, but no part of the machine, rotates; cyclones are stationary-boundary machines. In both cases, it is the rotation of the mixture that generates the centrifugal acceleration field required for fractionation.

In dairy processing, the following types of mixtures can successfully be separated centrifugally:

- Liquid–liquid (e.g., cream and skim milk)
- Liquid–solids (e.g., whey and casein curd)
- Gas–liquid (e.g., water vapor and heat concentrated milk)
- Gas–solids (e.g., dryer outlet air and milk powder)
- Liquid–liquid–solids (e.g., cream, skim milk, and suspended insoluble matter)

Rotation causes separation because, on a per unit volume basis, the higher the density of a component the greater is the centripetal (center-seeking) force that would have to be applied to prevent radial movement away from the axis of rotation. This is a consequence of Newton's first law of motion.

Centrifugal (center-fleeing) force, unlike centripetal force, is a fictitious force when, as is commonly the case, the Earth, rather than the rotating entity, is taken as the inertial frame of reference. However, it is a real force if the rotating entity itself (e.g., a centrifuge bowl) is taken as the inertial frame of reference. In a given case, centripetal force and centrifugal force are numerically equal, but opposite in sign. Centrifugal force is a concept useful in the analysis of a rotating system.

Consider the combined separation and clarification of whole milk in a centrifuge. In this context, whole milk can be considered to comprise milk plasma as a continuous phase and milk fat globules and insoluble particles (impurities) as dispersed phases. The centripetal force required to keep the whole of the centrifuge bowl contents rotating is supplied by the bowl wall. However, no centripetal force acts on the individual insoluble particles or fat globules, because these are free to move in the plasma. The insoluble particles, being denser than the milk plasma, accelerate towards the bowl wall, while the fat globules, being less dense than the milk plasma, are displaced (and decelerate) towards the bowl axis.

The following expression for the speed of movement of a dispersed particle (or globule) at a given radius can be derived by taking the rotating centrifuge bowl as the inertial frame of reference and then equating the centrifugal force to the sum of the two opposing forces – the buoyancy force (caused by the displacement by the particle of a volume of plasma equal to the particle's volume) and the drag force (caused by the movement of the particle through the plasma):

$$v = \frac{d^2 \Delta\rho \left(\frac{\pi N}{30}\right)^2 R}{18\mu} \qquad [1]$$

where v is the (radial) separating velocity (m s^{-1}), d the particle diameter (m), $\Delta\rho$ the density difference between the particle or fat globule and the continuous phase (plasma) (kg m^{-3}), N the bowl rotational speed (rpm), R the radial distance from the axis of rotation (m), and μ the viscosity of the continuous phase (plasma) (Pa s).

The net centrifugal force (centrifugal force minus buoyancy force) can be positive or negative, depending on whether the particle is denser or less dense than the continuous phase, but is independent of velocity. The drag force, on the other hand, is directly proportional to velocity (Stoke's law). Thus, the greater the density difference $\Delta\rho$ (eqn [1]), the greater the net centrifugal force and the higher the velocity at which this force comes into balance with the drag force. It is this phenomenon that makes centrifugal separation possible; phases differing in density, because they move radially at different velocities in the centrifugal acceleration field, inevitably become separated as the feed mixture flows through the centrifuge or cyclone separator.

$\Delta\rho$ and thus v are positive for the insoluble particles in milk (positive net centrifugal force), but negative for fat globules (negative net centrifugal force). The sign of velocity indicates the direction of radial movement during separation. As eqn [1] shows, the separating velocity, in either radial direction, increases with distance, *R*, from the bowl axis.

The dairy separation operations listed above could be achieved using gravitational sedimentation or filtration or both; eqn [1] applies to gravitational separation when the centrifugal acceleration term $\left(\frac{\pi N}{30}\right)^2 R$ is replaced by the gravitational acceleration, *g*. However, the rotational speed of a centrifuge bowl (which is limited only by the bowl's ability to withstand the centrifugal stress of its contents and its own mass) can be high enough to make centrifugal acceleration thousands of times greater than *g*, resulting in rapid separation.

Centrifugal separation is thus far superior to gravitational separation in terms of effectiveness and throughput, and is also superior in terms of controllability, hygienic operation, compactness, and ease of integration into continuous processing systems. In the case of centrifugation, these advantages outweigh the high capital cost and high power consumption of centrifuges.

Even though raw milk is routinely in-line filtered to remove impurities with large particle sizes, filtration is generally unsuitable for more demanding solids–liquid separation duties in the dairy industry owing to low efficiency, low throughput, hygiene risks, and other disadvantages. Filtration is, however, effective for solids–gas separation, and is used, for example, for recovering powder particles from dryer outlet air.

The main types of centrifugal separators used in the dairy industry are the disk bowl centrifuge, the decanter centrifuge, the scroll-screen centrifuge, and the cyclone separator. Applications of each of these are discussed in turn, with particular emphasis on separating conditions, significant features of machine design, separation control, and separating efficiency.

Applications of Disk Bowl Centrifuges

Whole Milk Separation

The classical, and still the most important and commonest, application of the disk bowl separator is the separation of whole milk into cream and skim milk. This operation is an early stage in the manufacture of most dairy products.

The development of the modern dairy industry began with the introduction of the centrifugal separator, first on individual farms and later at centralized creameries to which farmers brought their milk. Its use enabled the efficient concentration of milk fat, then considered the only milk component of significant value, into the cream stream while minimizing fat loss to the skim milk. The replacement of gravitational separation by centrifugal separation resulted in enormous increases in throughput and efficiency. The first hand-driven disk bowl separators began to be used on farms in 1893.

The capacity of the modern milk separator is around $60\,000\,\mathrm{l\,h^{-1}}$ for warm separation (52–55 °C) and $50\,000\,\mathrm{l\,h^{-1}}$ for cold separation (4–10 °C). Fine control of cream fat content is achieved by manual or automatic adjustment of the pressure balance across the separator's rotating bowl. Usually, the back pressure at the skim milk outlet is kept constant automatically, and cream fat content is controlled by manipulating the back pressure at the cream outlet either manually or automatically. Cream fat content can be adjusted to any desired value up to about 50% without compromising separating efficiency.

Separating efficiency, usually called skimming efficiency, is defined either as the percentage of the fat in the whole milk that is separated into the cream stream, or simply as the skim milk fat content. The former definition can be expressed as follows:

$$E = \left(1 - \frac{f_\mathrm{s}}{f_\mathrm{w}}\right) \times 100\% \qquad [2]$$

where E is the skimming efficiency, f_s the skim milk fat content (% w/w), and f_w the whole milk fat content (% w/w).

Equation [2] is derived from a fat mass balance across the separator that incorporates a pragmatic simplification based on the fact that the skim milk fat content is very much lower than that of the whole milk.

Separators designed for warm separation, and separators designed for cold separation operating at 20 °C, have efficiencies of about 99% (skim milk fat content = 0.05% w/w). In cold separation, efficiency drops with temperature to about 50% (skim milk fat content = 2% w/w) at 5 °C if the cold milk separator is operated at its full nominal throughput. The efficiency can be increased to about 94% or more by reducing throughput by half to increase the residence time of the milk in the bowl. This increase compensates for lower fat globule separating velocities, which are a consequence of $\Delta\rho$ decreasing and μ increasing with decreasing temperature (eqn [1]). It is not possible even in warm separation to recover fat globules of less than about 1 μm in diameter because of their very low separating velocities.

Separators designed for warm separation can be used for cold separation at temperatures as low as 20–25 °C, without an excessive drop in efficiency, provided creams of no more than 15% fat are required.

The bowls of dedicated cold milk separators are designed to cope with the very much higher cream viscosity, while avoiding churning of the cream and maximizing skimming efficiency. Cold separation, though not as efficient as warm separation, is useful in some circumstances, and is being more widely applied. Its advantages include better control of the product's microbiological quality, improved cream quality (e.g., improved whippability), improved quality of unpasteurized milk cheese, and greater flexibility in the processing of chilled milk on receipt from farms. Separators that can be used for either warm or cold separation are now available, allowing further improvements in flexibility.

Separating temperatures above 55 °C give negligible improvements in efficiency. Temperatures above 60 °C result in a loss of efficiency owing to the deposition of denatured whey protein on to the separator's disks (which disrupts the smooth two-way flow pattern in the interdisk spaces) and a drastic reduction in the tendency of fat globules to agglomerate; agglomeration is a useful tendency given the d^2 term in eqn [1], and should be preserved.

Skimming efficiency is adversely affected by a number of factors besides temperature. As fat globule separating velocity is directly proportional to the square of globule diameter (eqn [1]), pipelines should be designed to avoid damage to fat globules and fat globule agglomerates, and flow rates should be controlled by variable speed drives on pumps rather than by pump throttling. The natural decrease in fat globule size that occurs during lactation, and therefore during the dairy season in countries such as New Zealand and Ireland, can be compensated for by gradually decreasing separator throughput over time.

Whole milk to be separated should be deaerated, both to avoid fat globule damage and to avoid loss of efficiency caused directly by the presence of air in the separator itself. Air, being very much less dense than either skim milk or cream, is displaced rapidly to the inner edge of the disk stack, obstructing the flow of cream and in effect throttling the cream outlet. This causes an increase in the fat content and thus in the viscosity of the cream, increasing the throttling effect further. This vicious circle results in excessive fat loss to the skim milk.

Milk should ideally be separated when it is fresh, as prolonged storage results in changes in the fat globule membrane that increase fat globule density. This results in a decrease in $\Delta\rho$ (eqn [1]), in turn decreasing fat globule separating velocity and thus skimming efficiency.

Modern milk separators, which also act as clarifiers (see below) if the whole milk has not been purposely clarified prior to separation, are self-desludging. Sludge, comprising leukocytes, somatic cells, microbial cells and spores, blood and dirt particles, and some milk solids (mostly protein) are ejected at preset intervals. At least one separator manufacturer has introduced a separator bowl modification that almost eliminates loss of milk protein to the sludge. This increases protein yield and reduces sludge production, and reduces water usage by allowing longer intervals between desludges.

Equation [1] shows that separator bowl rotational speed, N, has a large influence on separating velocity, and thus on skimming efficiency; separators should be run at the bowl speed recommended by the manufacturer.

Protein streams or concentrated skim milk should not be blended with whole milk prior to separation as this results in an increase in milk plasma viscosity, and thus a reduction in skimming efficiency (eqn [1]). However, badly separated skim milk with an excessive fat content can be blended with the whole milk. This results in an improved overall fat recovery from the blend owing to agglomeration of smaller fat globules.

Partial Homogenization of Milk

So-called partial homogenization, mainly applied to retail milk, involves temporarily separating whole milk into skim milk and cream, homogenizing the cream, and then remixing the homogenized cream with the skim milk. Only the cream passes through the homogenizer, significantly reducing the homogenizer's power consumption, which is directly proportional to volumetric throughput; this is the purpose of the process. As stabilization of the homogenized cream emulsion depends on the presence of at least 0.2 g casein g^{-1} fat, the cream fat content should not exceed 12%. The economics of partial homogenization depend upon the cost of power, and the capital and operating costs of the centrifugal separator and homogenizer.

Milk and Cream Standardization

Milk and cream often require standardization of their fat and/or solids-not-fat (SNF) contents for retail sale or, in the case of milk, prior to the manufacture of products such as whole milk powder and cheese. In small-scale dairy processing, standardization can be carried out batchwise by blending whole milk with either cream or skim milk in appropriate proportions. In large-scale operations, so-called direct standardization is used.

The first step in direct standardization is centrifugal separation of the whole milk into skim milk and cream. A typical basic system works as follows: The back pressure at the skim milk outlet of the separator is kept constant automatically. The back pressure at the cream outlet is controlled automatically, using continuous in-line temperature-compensated sensing of cream density (inversely related to fat content) and cream flow rate, to give a fat-standardized cream. Part of the cream flow and the skim milk flow are remixed (by means of automatic flow rate ratio control using in-line measurements of cream and skim milk flow rates) in proportions that result in a reblended whole milk of the desired standardized fat content. Surplus cream leaves the system as fat-standardized cream. A variation of this system is one in which the fat contents of the standardized cream and the remixed standardized whole milk are controlled solely on the basis of in-line measurements of density. The accuracy of these systems is unaffected by variations in the flow rate, fat content, or temperature of the whole milk.

The capability of simple systems can be extended in a number of ways:

- In-line measurement of skim milk density allows fluctuations in the SNF content of the feed milk, which cause density fluctuations unrelated to fat content, to be automatically compensated for. It also allows the fat to SNF ratios of both milk and cream, as well as milk and cream fat contents, to be standardized.
- Separator size can be reduced by causing part of the feed whole milk flow to bypass the separator, and to be blended in-line with the remixed standardized cream and skim milk from the separator.
- Part of the skim milk flow from the separator can be made to bypass the skim milk–standardized cream remixing point and rejoin the remixed stream downstream of the homogenizer in the remix line, thus allowing partial homogenization as well as standardization.
- High-fat standardized milk can be produced by taking off part of the skim milk flow upstream of the cream–skim milk remixing point. Alternatively, cream from a separate source can be remixed with the skim milk along with standardized cream from the separator.
- Other additive streams, such as concentrated skim milk and whey permeate, can be added to the skim milk from the separator along with the standardized cream, depending on standardization requirements.

As skimming efficiency is of less importance in standardization than it is in separation *per se*, higher separator throughputs can be used in direct standardization systems.

Milk Clarification

Self-desludging disk bowl clarifiers are used to remove solid impurities, especially leukocytes and bacterial cells and spores, from (usually raw) whole milk. *Listeria* cells enveloped by leukocytes, and therefore heat resistant, are removed by clarification, while those not so enveloped are easily killed by subsequent pasteurization.

The clarifying efficiency of clarifiers is some 150% higher than that of separators, owing to the greater path length and thus longer residence time of the milk in the disk stack. Clarifiers operate at higher throughputs than separators do, and at low (<8 °C) or high temperatures (50–60 °C). Lower temperatures result in less loss of milk protein, while higher temperatures result in a greater reduction in total microbial count and allow complete removal of hair and other fibers, which are common contaminants of milk. The optimum temperature range is 50–55 °C. As a clarifier has only one outlet, and flow in the bowl is from the outside of the disk stack to the inside, no fat globule separation takes place. The sludge can amount to 0.05–0.1% of the milk volume, and contains 14–16% dry matter comprising nitrogen (6–8%), fat (0.25–0.35%), lactose (~4.7%), and nonmilk substances (1.5–3%).

Bacterial Clarification of Milk

When a substantial reduction of the bacterial contamination of milk is required, but without the use of severe heat treatment, purposely designed high rotational speed clarifiers (called ‘bactofuges’ by one separator manufacturer) are used for bacterial clarification prior to pasteurization.

Bacterial clarification of standardized cheese milk is carried out mainly to remove spores of a number of (anaerobic) *Clostridium* species, especially *Clostridium tyrobutyricum*, which otherwise cause late fermentation-induced gas production (late blowing) in semihard cheese. Their removal enables the use of spore-inhibiting substances such as nitrate to be greatly reduced or eliminated. The numbers of wild lactobacilli are also lowered, resulting in less competition for starter cultures in the manufacture of raw milk cheese. Clarification at 65 °C removes 98–99% of anaerobic spores and 95% of aerobic spores (e.g., those of *Bacillus cereus*). Clarification at 50 °C removes 90–92% of lactobacilli.

Bacterial clarification of cheese milk is particularly useful in Europe where cows are fed silage during winter; the spore content of milk is directly related to the extent of silage feeding and to the spore content of the silage.

Bacterial clarification of consumer milk prior to pasteurization can result in a useful extension, of 3–5 days, in pasteurized milk’s shelf life. It has become more important in regions such as northern Europe where consumers are purchasing pasteurized milk less frequently (but expect it to remain of high quality even after some days of storage) and distribution lines have become longer owing to increasing centralization of milk-processing facilities. Clarification at 50 °C reduces the total bacterial count by 86%. The removal of *B. cereus* spores is of particular significance in this application, as these spores survive pasteurization. The best results are achieved if the milk to be clarified is first separated into cream of 43% fat (to ensure a large density difference between cream and spores) and skim milk. Only the skim milk, which contains virtually all of the spores originally present in the feed milk, is clarified, before being standardized by cream remixing.

Bacterial clarification can also be applied to milk and whey for the purpose of improving the bacteriological quality of low-heat milk powders and whey protein concentrate powders, respectively; to milk to be made into fresh cheese to remove ascospores of the molds

Byssochlamys nivea and *Byssochlamys fulva*; and to skim milk destined for casein manufacture.

Two-stage bacterial clarification, using two machines in series, must be employed if one stage is inadequate.

The design of bacterial clarifiers varies. The simplest machines separate the milk into a clarified milk stream and either a bacteria-rich milk stream or a sludge stream. In a somewhat more complex design, the milk is separated into a clarified milk stream, a bacteria-rich milk stream, and a sludge stream. In the case of cheese milk, the sludge, the bacteria-rich stream, or both can be UHT sterilized and recombined with the clarified milk. This reduces or obviates loss of milk solids. In another design, used where the total quantity of bacteria-rich material removed from the milk must be minimized, a flow of partially clarified milk (3–5% of the feed flow rate) is continuously recycled from the outer part of the bowl to the bowl feed. This changes flow conditions in the bowl in a way that increases the efficiency of separation of the smallest bacteria, and reduces the amount of sludge produced. Sludge is the only stream removed from the milk in this design.

Cream Processing

The main products made from milk fat are butter and anhydrous milk fat (AMF). Centrifugal separation of whole milk to concentrate the fat in cream is the first significant processing step in each case.

Butter making

Butter can be made in four ways:

- traditional batch churning of 25–35% fat cream produced by a single separation step
- Fritz continuous churning of 40–41% fat cream, also produced by a single separation step
- continuous phase inversion of 75–82% fat cream. Milk is first separated to give 40% fat cream, which is then itself separated in a cream concentrator (a specialized disk bowl separator) to give cream of the required high fat content
- blending fresh AMF made using the direct-from-cream process (see below) with cream and salt, or with water, milk solids, and salt. The separation steps required in making AMF are described in the following section

Anhydrous milk fat manufacture

AMF can be made from cream or butter. The direct-from-cream process involves the following main separation operations using disk bowl separators: separation of whole milk to give 40% fat cream, concentration of this cream to $\geq$75% fat, concentration of the butteroil phase after phase inversion of the concentrated cream, and polishing of the butteroil phase after in-line wash water addition and perhaps neutralization of free fatty acids. Fat recovery is carried out by centrifugal separation of the heavy phase (secondary skim milk/buttermilk) from the cream concentrator. The heavy phase from the butteroil concentrator can be either recycled to the cream concentrator or centrifugally separated to yield β-serum (a phospholipid-rich heavy phase) and a light fat-containing phase (that is recycled).

In the manufacture of AMF from sweet cream butter, the melted butter is centrifugally concentrated and then polished in disk bowl separators prior to dehydration. If cultured butter is used, it may be necessary to separate the melted butter in a three-phase decanter centrifuge (see below) because of the butter's high solids content (which is mainly due to the generation of biomass during cream culturing). The decanter separates the melted butter into butteroil, buttermilk, and solids.

Buttermilk separation

Buttermilk has a fat content of 0.5–2.5%, which economically justifies separation to recover fat. As cream for buttermaking is pasteurized at temperatures high enough to denature whey proteins, it may be necessary to centrifugally clarify buttermilk prior to separation to avoid rapid fouling of the separator's disks. For separating cultured cream buttermilk, the feed rate to the separator should be about 50% of that for milk separation in the same machine, with frequent desludging if prior clarification has not been carried out. Separation is carried out at 40–45 °C for sweet buttermilk and at 35 °C for cultured cream buttermilk to avoid excessive protein precipitation. The cream produced contains about 25% fat.

Fresh Cheese

The large-scale production of fresh soft cheeses is made possible by the use of specialized disk bowl machines for separating curd and whey after coagulation. In the case of nonfat or low-fat cheeses made from fresh and recombined whole and skim milks, and buttermilk, the whey is discharged via a centripetal pump (paring disk), while the denser curd is discharged continuously via nozzles at the periphery of the bowl. In the case of double cream cheese, the whey and the less dense curd are both discharged via centripetal pumps.

Whey Processing

Cheese whey contain curd fines and fat, which can be removed by centrifugal clarification and separation. Such removal is essential where the whey is to be used as an ingredient of, for example, clear drink products, and where it is to be used as a feedstock for the manufacture of whey protein concentrate, whey powder, or lactose.

As the fines tend to block the disk spaces of a separator, it is necessary to clarify the whey prior to separation.

(One separator manufacturer used to offer a specialized clarifier separator whose disk stack had a lower preclarifying section and an upper separating section.)

Casein whey and casein wash water contain casein fines, which can be recovered with disk bowl clarifiers and recycled, thus increasing the casein yield.

Cheese fines recovered as sludge from whey clarifiers and separators can be put through a casein solubilization process. Undissolved denatured casein particles and other impurities are removed from the solution by centrifugal clarification.

It can be economically viable to separate whey with a fat content higher than about 0.045% during heat concentration. This is typically done between evaporator stages 2 and 3. Difficulties can be encountered owing to the precipitation of whey protein and adventitious homogenization of fat globules.

The dephospholipidation of whey, carried out in the production of whey protein concentrates with very low fat contents, involves treating the whey to cause the lipoproteins to flocculate and then removing the flocculates as sludge by means of centrifugal clarification. The clarifier used has a high rotational speed and nozzle discharge of the sludge, giving a simultaneous bacterial clarification effect. Dephospholipidation improves the performance of ultrafiltration plants and, as a significant proportion of the calcium phosphate in the whey is also separated, allows longer evaporator running times.

The fat content of whey protein concentrates made from whey that was itself separated can be reduced by 20–30% by centrifugal separation under optimal conditions. Separator throughput must be about half that of the machine when separating milk, because of the higher viscosity of retentate.

Whey can be purposely bacterially clarified, after the initial clarification to remove fines, to reduce the growth of bacteria in ultrafiltration plants, and to enable the production of whey powder suitable for use in baby food. Self-desludging nozzle discharge clarifiers are required in this case.

In the basic lactalbumin process, whey is first centrifugally clarified. It is then treated to cause denaturation and precipitation of whey proteins, which are centrifugally recovered as sludge from a second clarifier. This sludge is mixed with water, and the washed protein solids are recovered as sludge (lactalbumin) from a third clarifier. The dry solids content of the lactalbumin is increased from about 16 to 34–35% in a decanter centrifuge (see below) prior to drying.

Calcium phosphate is separated from whey permeate to avoid problems caused by precipitated calcium phosphate in evaporator plants and to minimize the salt content of products made from the permeate. Adjustment of pH to 6.6 and suitable heat treatment cause the formation of calcium phosphate flocculates, which can be separated as sludge using a self-desludging centrifugal clarifier. The sludge from cultured whey that is not pH adjusted is extremely compact and can be continuously discharged from the clarifier via nozzles.

Nozzle discharge disk bowl clarifiers are used to separate yeast from fermented serum in the production of ethanol from whey.

Other Applications of the Disk Bowl Separator

The use of centrifugal clarifiers to remove cheese solids from brine in the manufacture of brined cheese can sometimes be justified economically. Frequent cleaning in place is required because of the deposition of crystalline fat on the separator's disks at the low brine temperature, and the parts of the machine coming into contact with brine must be made of corrosion-resistant materials.

Applications of Decanter Centrifuges

Centrifugal decanters (also called conveyor bowl centrifuges) are used in solids–liquid separation duties where the solids concentration in the feed and the particle size of the solids are too high to allow the use of disk bowl separators, and where a high dry matter content is required in the separated solids phase. The principal dairy industry applications of the decanter occur in casein and lactose manufacture. These and other applications are described briefly below. The use of decanters in lactalbumin manufacture and in the manufacture of AMF from sour-cream butter has been mentioned above.

Casein

Decanters are commonly used to dewhey casein curd, the curd–whey mixture being first put through a dewheying screen to reduce the hydraulic load on the machine. After washing, the curd can be dewatered using decanters. In this operation, the aim is to obtain as dry a curd as possible prior to drying.

The scroll-screen (also called the worm-screen) centrifuge is used as an alternative to the decanter for dewatering. It consists of a perforated bowl of truncated-cone shape with an internal corotating helical-flight screw (like that in the decanter). The mixture to be separated is fed to the inside of the narrow end of the bowl, and the solids are conveyed to the wide end during separation. As it approaches the wide end, the layer of solids becomes looser owing to the increasing diameter, and efficient further washing can be achieved by means of water sprays.

Lactose

Decanters are used to separate crystals of so-called edible lactose from the crystal–mother liquor mixture resulting from the crystallization of whey or whey permeate. Two-stage decantation is used in which wash water is added to the solids phase from the first decanter. In the manufacture of refined lactose from edible lactose, decanters are used to recover the lactose after recrystallization.

Concentration of Cheese Fines

The fines in the sludge from disk bowl cheese whey clarifiers and separators can be concentrated to 30–50% dry matter by decanting the sludge after dilution to 8–12% dry matter with water and whey. The liquid phase is discharged by means of a centripetal pump.

Effluent

The sludge from the flotation and sedimentation steps in the treatment of dairy wastewaters can be concentrated in decanters before disposal, reducing disposal costs.

Decanter Operating Variables

Decanter operating variables are the radial location of the liquid discharge (which determines the thickness or depth of the layer of the separating mixture that rotates with the bowl), the rotational speed of the bowl, the differential speed (the difference between the rotational speeds of the bowl and the screw conveyor), and the feed rate. Liquid discharge at a larger radius gives a dryer solids phase, but increases fines losses, while discharge at a smaller radius has the opposite effects. Thus, in casein dewatering, for example, there must be a trade-off between the dryness of the curd and fines losses to the wash water, although, as mentioned previously, fines can be recovered from wash water (and whey) by means of disk bowl clarifiers.

The rotational speed of the bowl must be higher for smaller solids phase particles and/or for a smaller density difference between the particles and the liquid phase.

Differential speed must be matched to the rate at which solids are fed to the bowl, to avoid a solids buildup inside the bowl.

Feed rate must be matched to the bowl speed, a higher feed rate requiring a higher bowl speed to maintain separating efficiency. The lowest possible bowl speed should be used, to minimize machine wear and power consumption.

Cyclone Separators

Cyclone separators (used for solids–gas, solids–liquid, and gas–liquid separation tasks), in contrast to centrifuges, are mechanically simple; relatively cheap to purchase, install, and run; are compact compared with noncentrifugal (gravity) separators; and require little maintenance.

Cyclone separators are used in the dairy industry for

- gas–solids separation, mainly for separating product fines from the air leaving spray dryers and fluidized bed dryers, both to increase yield and to minimize air pollution. This is the commonest application of cyclones.
- gas–liquid separation, mainly for the in-line deaeration of milk (essential for maintaining the efficiency of downstream centrifugal separators), and for separating the concentrate leaving an effect of a multiple-effect evaporator from the water vapor (steam) evaporated from the product in the effect. In the latter application, clean separation prevents bubbles of steam being retained in the concentrate (ultimately diluting the concentrate when they condense on cooling) and carryover of concentrate into the steam side of the next effect, or into the condenser.
- solids–liquid separation, one application of which is separating solids from waste streams. Solids–liquid cyclone separators are called hydrocyclones.

Cyclone design is shown in **Figure 1**. The principles of design and operation can be understood by considering fines recovery from dryer air.

The cyclone is a vertical body with a cylindrical upper part and a conical lower part. The solids–air mixture enters tangentially at the top of the cylinder. The linear motion of the mixture is converted to rotational motion by the flow of the air around the curved wall of the cyclone; the cyclone wall provides the centripetal force required to make the air rotate.

As soon as the air starts rotating, the fines particles, which are free to move relative to the air, move toward the wall, as there is no centripetal force being applied to them to keep them in orbits about the cyclone's axis. When they hit the wall, they are separated from the air, and slide to the bottom of the cyclone under the influence of gravity. They are removed via a rotary valve.

The centrifugal effect is thus produced by the shape of the cyclone itself, the way the mixture to be separated enters the cyclone, and the velocity of the mixture (which is generated by a fan in the case of dryer air, or by a pump, or by a pressure difference).

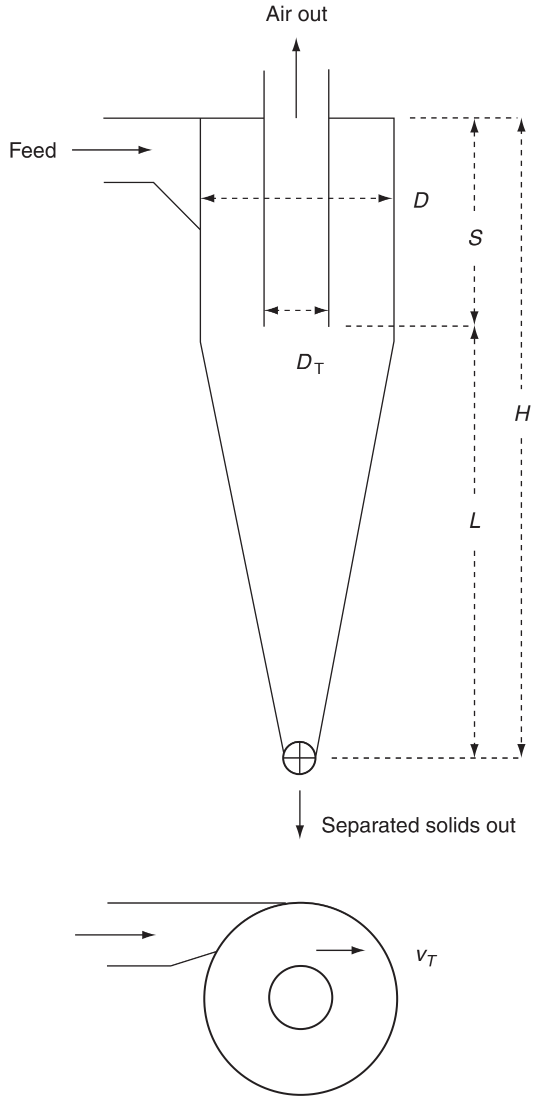

Figure 1 Elevation and plan views of a cyclone separator for recovering solids from an airstream.

Separation of the particles in the way described above is not instantaneous; a sufficiently long residence time is attained by the way the air flows through the cyclone. The air moves in a spiral path down the cylindrical part and then the conical part of the cyclone, then flows inward toward the cyclone's axis, and finally upward into a coaxial tube by which it leaves at the top of the cyclone.

Separating Efficiency

The solids (e.g., milk powder particles) in the solids–air mixture entering a cyclone invariably exhibit a particle size distribution; particle size ranges from very small to relatively large. Separating efficiency can be expressed in terms of the diameter of the limit particle, the smallest particle that can successfully be separated. A simplified analysis of the flow pattern inside the separator, which incorporates eqn [1], leads to the following expression for the limit diameter:

$$d_{\mathrm{L}} = \sqrt{\frac{18\,\eta\,Q}{v_{\mathrm{T}}^{2}(\rho_{\mathrm{particle}} - \rho_{\mathrm{air}})2\pi L}} \qquad [3]$$

where d_{L} is the limit diameter (m), η the viscosity of the continuous phase (Pa s), Q the volumetric feed rate ($\mathrm{m}^3\,\mathrm{s}^{-1}$), v_{T} the maximum tangential velocity of the particle ($\mathrm{m\,s}^{-1}$), ρ_{particle} the density of the particle ($\mathrm{kg\,m}^{-3}$), and ρ_{air} the density of the continuous phase ($\mathrm{kg\,m}^{-3}$).

The maximum tangential velocity occurs at the radial position $D_{\mathrm{T}}/2$ (**Figure 1**).

Equation [3] shows that it is possible to separate even very small particles in a cyclone if the entry velocity, v_{T}, is high; if the cyclone is long (tall); and if it is possible to distribute the flow of feed over a number of smaller cyclones rather than a big one (because d_{L} is directly related to volumetric flow rate, Q). Though the value of the recovered solids (e.g., milk powder fines) has to be balanced against the capital and operating costs of a battery of cyclones, air pollution control may be an overriding factor.

In practice, it is often found that the exhaust air contains a small percentage of particles with diameters larger than the limit diameter. The reason for this is probably that small particles impinge on larger ones and push them into the exhaust air.

On the other hand, a considerable proportion – often more than 50% – of particles with diameters lower than the limit value are successfully separated in the cyclone. These are particles that have reached the vicinity of the wall shortly after entering the cyclone. From there they are carried down and out by a secondary stream of air produced by frictional forces at the wall.

The following geometrical relationships (see **Figure 1**) have favorable effects on cyclone efficiency:

$$\frac{D}{D_{\mathrm{T}}} = 2 \text{ to } 25;\ \frac{H}{D_{\mathrm{T}}} = 7 \text{ to } 8;\ \frac{S}{D_{\mathrm{T}}} = 0.8 \text{ to } 1.3$$

As a general rule, the diameter of the exhaust pipe (D_{T}) should be as small as possible, and the entry velocity of the feed mixture as high as possible.

The separating efficiency of cyclones falls off dramatically in solids–air separation for particles below about 10 µm in diameter. For this reason, cyclone exhaust streams may need to be bag filtered to ensure that the emission standards aimed at protecting the environment are not exceeded. Cyclones may be entirely replaced by bag filters in milk powder manufacture.

Conclusion

It is clear from the foregoing that the modern dairy industry could not exist without centrifugal separation. Indeed, as intimated in the introduction, it could never have become established. Arguably, centrifugal separation is the most important unit operation in dairy processing, and the disk bowl centrifuge the single most important item of processing equipment.

Centrifuge manufacturers, who are extremely competitive, are continuously improving the performance of their already highly sophisticated machines, by clever design and control innovations. They also put much effort into designing and improving dairy processes in which their machines can be used. It does not seem that the limits of this advanced separation technology, and its application in the manufacture of dairy products, have yet been reached.

Introduction

One of the most important requirements of modern dairying is to be able to control the temperature of products at every stage in the process. Heating and cooling are therefore very common operations in the dairy.

Heating

Milk is heated by a heating medium such as low-pressure steam (seldom used nowadays) or hot water, so that the temperature of the product rises and that of the water drops correspondingly (*see* **Utilities and Effluent Treatment**: Heat Generation).

Cooling

On arrival at the dairy, the milk is cooled to 5 °C or lower, to limit microbiological growth. After pasteurization, the milk is cooled to about 4 °C using chilled water, brine solution, or an alcohol solution such as propylene glycol.

Regenerative Heating and Cooling

In many processes, a product must first be heated and then cooled. During pasteurization, milk is heated from, perhaps, 4 °C to a pasteurization temperature of 72 °C, held at that temperature for 15 s, and then chilled again to 4 °C. The heat of the pasteurized milk is utilized to warm the cold milk. The process takes place in a heat exchanger and is called regenerative heat exchange or, more commonly, heat recovery. As much as 94–95% of the heat content of the pasteurized milk can be recycled.

Heat Transfer

Theory

Heat can be transferred in three ways: conduction, convection, and radiation.

1. Conduction means transfer of thermal energy through solid bodies or through layers of liquid at rest (without physical flow or mixing in the direction of heat transfer).
2. Convection occurs when fluids (gases or liquids) being heated or cooled develop internal mixing currents, either by the temperature-density effect itself (natural convection) or by mechanical agitation or turbulent flow (forced convection).
3. Radiation is the emission of heat from a body that has accumulated thermal energy. The thermal energy is converted to radiant energy, emitted from the body, and absorbed by other bodies, which it strikes. Almost all substances emit radiant energy.

Principles

Heat transfer in dairies occurs by convection and conduction. Two principles are used: direct and indirect heating.

Direct heating

Direct heating means that the heating medium is mixed with the product. This technique is used

- to heat water (steam is injected directly into the water and transfers heat to the water);
- to heat products such as curd in the manufacture of certain types of cheese (by mixing hot water with the curd); and
- to sterilize milk or milk products by steam injection or infusion of the product into steam.

The direct method of heat transfer is efficient for rapid heating. It offers certain advantages, especially in the production of long-life, ultraheat-treated (UHT) milk, where heating is followed by rapid flash-cooling. It does, however, involve mixing of the product with the heating medium, which necessitates certain steps in the subsequent process. It also makes strict demands on the quality of the steam. Direct heating is forbidden by law in some countries on the grounds that it introduces foreign matter into the product.

Indirect heating

Indirect heat transfer is therefore the most commonly used method in dairies. In this method, heat is transferred from the heating medium through a partition into the

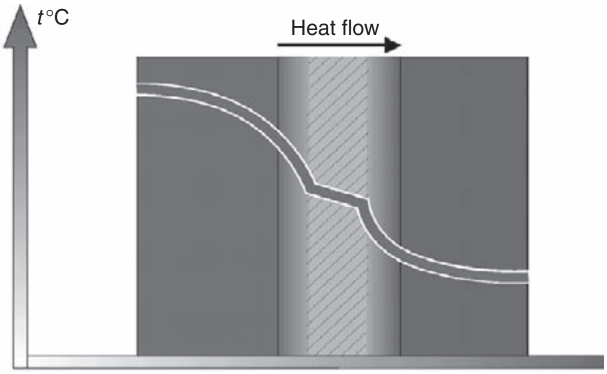

Figure 1 Heat transfer from a heating medium to a cold product on the other side of the partition. Courtesy of Tetra Pak.

product (**Figure 1**). In a plate heat exchanger, the plate is the partition. The velocity of the liquids is reduced by friction to almost zero at the boundary layer in contact with the partition. The velocity increases progressively and is the highest at the center of the channel. The temperature of the hot water is the highest in the middle of the channel. The closer the water is to the partition, the more it is cooled by the cold milk on the other side. Heat is transferred, by convection and conduction, to the boundary layer. Transfer from the boundary layer through the wall to the boundary layer on the other side is almost entirely by conduction, while further transfer to the milk in the central zone of the channel is accomplished by both conduction and convection.

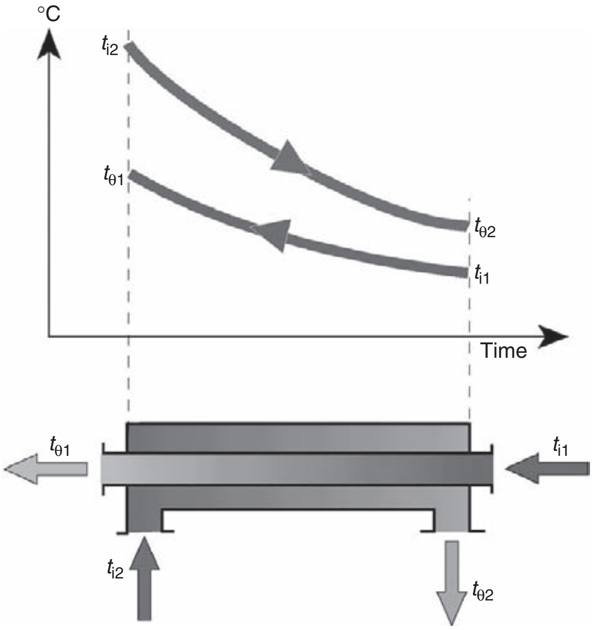

Figure 2 Temperature profiles for heat transfer in a heat exchanger with countercurrent flow. Courtesy of Tetra Pak.

The Heat Exchanger

The heat exchanger is used to transfer heat by the indirect method. The temperature profiles of the heating medium and milk in a typical tubular heat exchanger (THE) are shown in **Figure 2**.

Dimensioning Data for the Heat Exchanger

The size and configuration of the heat exchanger depend on many factors. The calculation is intricate and is normally done with the aid of a computer. The factors that must be considered are

- product flow rate
- physical properties of the liquids
- temperature program
- permitted pressure drop
- heat exchanger design
- cleanability requirements
- running time requirement

The formula for calculating the heat transfer area of the heat exchanger is

$$A = \frac{Q \times \rho \times c_p \times \Delta t}{\Delta t_m \times k} \tag{1}$$

where A is the required heat transfer area, Q the product flow rate, ρ the density of the product, c_p the specific heat of the product, Δt the temperature change of the product, Δt_m the logarithmic mean temperature difference (LMTD), and k the overall heat transfer coefficient.

Product flow rate

The flow rate Q is determined by the planned capacity of the dairy. Other factors being constant, the size of the heat exchanger is directly proportional to the flow rate.

Physical properties of the liquids

These include density, ρ, specific heat, c_p, and viscosity, μ. The values depend on product and temperature.

Temperature program

Several aspects of the operating temperature must be considered, including the change of temperatures, the differential temperature between the liquids, and the flow direction of the liquids.

Temperature change

Inlet and outlet temperatures of the product are determined by the preceding and subsequent process stages. The change of product temperature (Δt in the general formula above) can be expressed as (**Figure 2**)

$$\Delta t_1 = t_{o1} - t_{i1} \tag{2}$$

The inlet temperature for the service medium is determined by processing conditions. The temperature of the outgoing service medium can be calculated by an energy balance calculation. For a modern heat exchanger, the energy losses to the surrounding air can be neglected. Thus, the heat lost by the hot liquid is equal to the heat gained by the cold liquid. It can be expressed as

$$\underline{Q_1} \times \rho_1 \times c_{p1} \times \Delta t_1 = \underline{Q_2} \times \rho_2 \times c_{p2} \times \Delta t_2 \qquad (3)$$

Logarithmic mean temperature difference

There must be a difference in temperature between the two media for heat transfer to occur. The differential temperature is the driving force. For sensitive products there are, however, limits to how large a difference can be used. The differential temperature can vary through the heat exchanger. A mean value, LMTD or Δt_m, is used for calculation.

$$\Delta t_m = \frac{(t_{i2} - t_{o1}) - (t_{o2} - t_{i1})}{\ln((t_{i2} - t_{o1})/(t_{o2} - t_{i1}))} \qquad (4)$$

An important factor in determining the mean temperature differential is the direction of flow in the heat exchanger. There are two main options: countercurrent or cocurrent flow.

Countercurrent flow

The temperature difference between the two liquids is best utilized if they flow in opposite directions through the heat exchanger (**Figure 2**). The cold product then meets the cold heating medium at the inlet and a progressively warmer medium as it passes through the heat exchanger. During its passage, the product is gradually heated so that the temperature is always only a few degrees below that of the heating medium at the corresponding point. This type of arrangement is called countercurrent flow.

Cocurrent flow

With the opposite arrangement, that is, cocurrent flow (**Figure 3**), both liquids enter the heat exchanger from the same end and flow in the same direction. In cocurrent flow it is impossible to heat the product to a temperature higher than what would be obtained if the product and the heating medium were mixed. This limitation does not apply in countercurrent flow; the product can be heated to within 2–3 °C of the inlet temperature of the heating medium.

Overall heat transfer coefficient

This factor, *k*, is a measure of the efficiency of the heat transfer. It indicates how much heat passes through 1 m^2 of the partition per 1 °C of differential temperature. In the heat exchanger, *k* should be as high as possible. The heat transfer coefficient depends on the following:

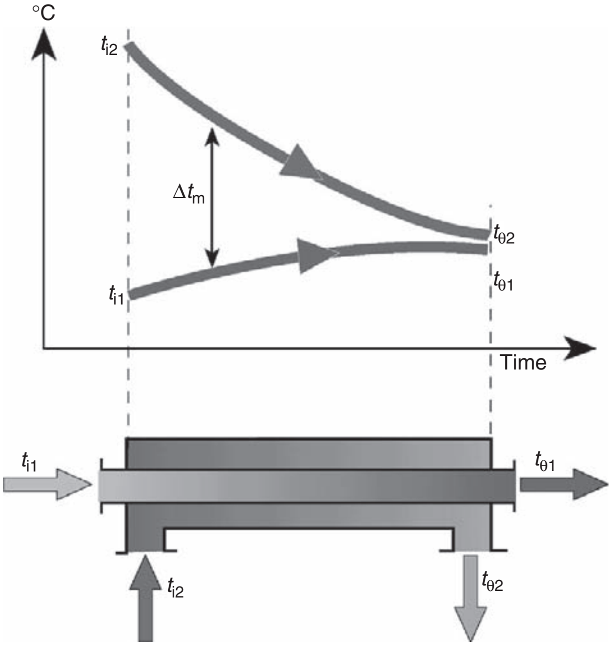

Figure 3 Temperature profiles for heat transfer in a heat exchanger with cocurrent flow. Courtesy of Tetra Pak.

- permitted pressure drops for the liquids
- viscosities of the liquids
- shape and thickness of the partition
- material of the partition
- presence of fouling matter

Permitted pressure drop

To increase the value of *k*, and improve heat transfer, it is possible to reduce the size of the channel through which the product flows. This reduces the distance over which heat must be transferred from the partition to the center of the channel. At the same time, however, the cross-sectional area of flow is reduced.

As a result, the flow velocity through the channel increases, which in turn makes the flow more turbulent and increases the pressure drop.

The greater the allowed pressure drops for the product and service medium, the more heat is transferred and the smaller the heat exchanger needed. Products sensitive to mechanical agitation (e.g., milk fat globules) may, however, be damaged by violent treatment. The product pressure before the heat exchanger must be increased to force the product through the narrower channels. It may then be necessary to install a booster pump. In some countries, installation of a booster pump is specified in legal requirements, basically to secure a higher pressure on the product side and thus prevent leakage of unpasteurized product into the pasteurized product.

Heat exchanger design

Viscosity of media

The viscosity of the product and the service medium are important determinants of the dimensions of the heat exchanger. A liquid with high viscosity develops less turbulence when it flows through the heat exchanger as compared to a product with lower viscosity. This means that a larger heat exchanger is needed, everything else being constant. Special attention must be paid to products with non-Newtonian flow behavior. For these products, the apparent viscosity depends not only on temperature but also on shear rate. A product that seems rather thick in a tank may flow much more readily when it is pumped through pipes or the heat exchanger.

Shape and thickness of the partition

The partition is often corrugated to create a more turbulent flow, which results in better heat transfer (**Figure 4**). The thickness is also important; the thinner the partition, the better the heat transfer. However, this must be balanced against the need for the partition to be strong enough to withstand the pressure of the liquids. Modern design and production techniques allow thinner partitions than were possible only a few years ago.

Material of the partition

For food processing, the normal material is stainless steel, which has fairly good heat transfer characteristics.

Presence of fouling matter

Most dairy products are sensitive to heating, which must therefore be done very carefully to avoid product damage. If the surface is too hot in relation to the product, there is a risk that proteins in the milk will coagulate and be deposited in a thin layer on the partitions. The differential temperature between the heating medium and the product should therefore be as small as possible, normally 2–3 °C above the pasteurization temperature. Heat must be transferred through the deposit, reducing the value of the overall heat transfer coefficient, *k*. The temperature differential between the heating medium and the product will then no longer be sufficient to transfer the same amount of heat

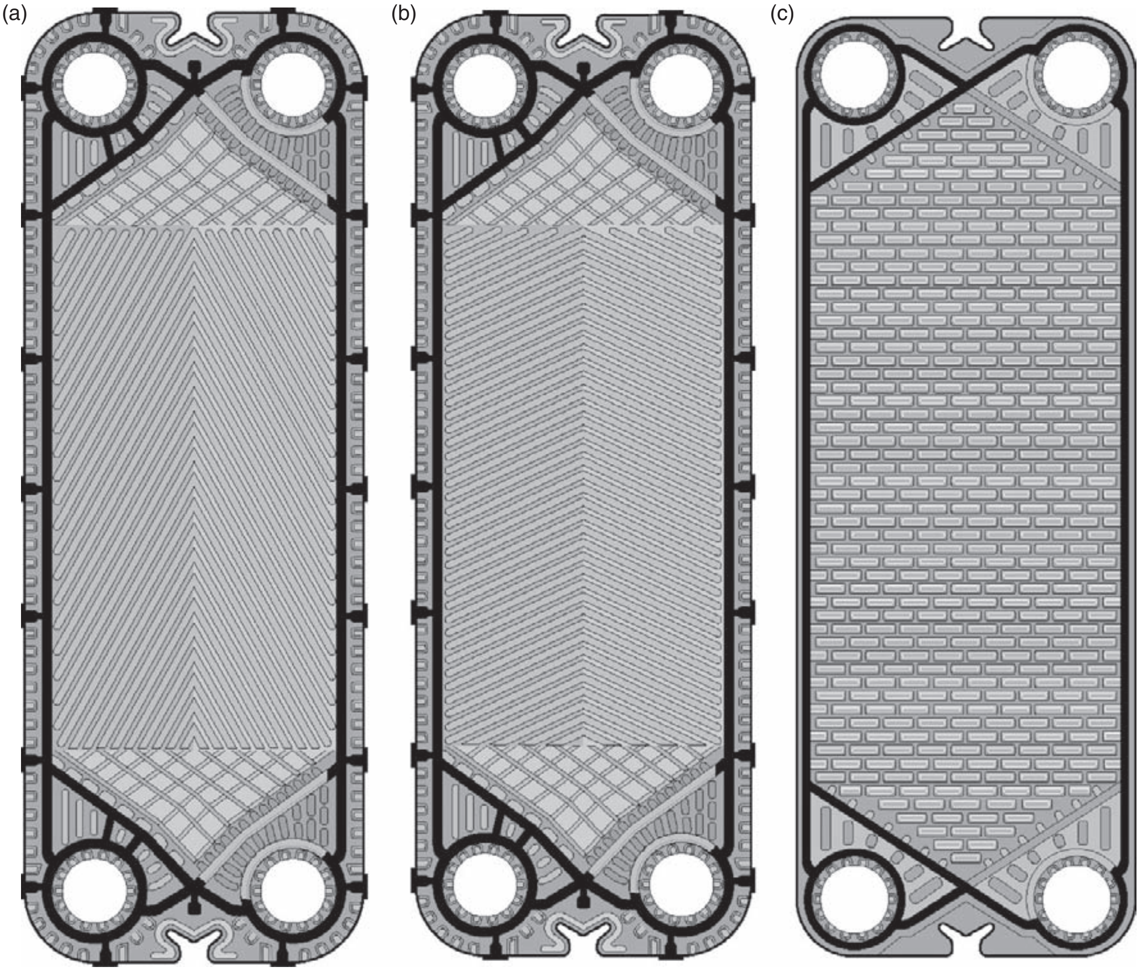

Figure 4 The shape of the partition in a plate heat exchanger may differ depending on the product to be treated and thermal efficiency requirements. (a) and (b) herringbone pattern; (c) washboard pattern. Courtesy of Tetra Pak.

as before, and the product outlet temperature will drop. This can be compensated for by increasing the temperature of the heating medium, but this also raises the temperature of the heat transfer surface so that more protein coagulates on the surface, the thickness of the crust increases, and the value of *k* drops still further.

The value of *k* is also affected by the flow rate through the heat exchanger. Increasing the flow rate makes the flow more turbulent and increases the value of *k*. Throttling the flow reduces the turbulence and hence also reduces the value of *k*. In modern pasteurizers and sterilizers the possibility of variable capacity is often included. In addition, multipurpose plants, that is, plants designed for the processing of various products in combination, are common today. As an example, a modern milk sterilizer for 10 000 l h^{-1} of whole milk may be capable of also processing milk-based vanilla pudding at 5000 l h^{-1}.

In calculating the heat transfer area, the sensitive nature of the product and the process demands must also be considered. Two such factors, not included in the formula, are the requirements for cleanability and running time.

Cleanability requirements

The heat exchanger in a dairy must be cleaned at the end of a production cycle, by circulating detergents. To achieve efficient cleaning, while designing the heat exchanger not only the temperature requirements, but also the cleaning requirements must be kept in mind. If some passages in the heat exchanger are very wide, that is, have several parallel channels, the turbulence during cleaning may not be enough to remove fouling deposits effectively. On the other hand, if some passages are very narrow, that is, have few parallel channels, the turbulence may be so high that the pressure drop will be very large. Such a high pressure drop may reduce the flow velocity of the cleaning solution, thereby reducing its effectiveness. The heat exchanger must therefore be designed for effective cleaning.

Running time requirement

Some fouling always occurs when milk products are heated to a temperature above 65 °C. Hence, the pasteurizer must be stopped periodically for cleaning. The length of the running time is difficult, not to say impossible, to predict, as it is determined by the degree of fouling, which depends on factors such as

- temperature difference between the product and the heating medium
- milk quality
- air content of the product
- pressure conditions in the heating section

It is especially important to keep the air content as low as possible. Excess air in the product will greatly contribute to increased fouling. Under certain conditions, the running time may also be limited by the growth of microorganisms in the downstream part of the regenerative section of the plate heat exchanger. This is, however, rare; when it occurs it is usually related to the pretreatment of the milk.

Hence it is important to allow for cleaning at regular intervals when making production plans for pasteurizers.

Regeneration

Utilizing the heat of a hot liquid, such as pasteurized milk, to preheat cold incoming milk is called regeneration. The cold milk also serves to cool the hot milk, thus economizing on water and energy. Regeneration efficiencies of up to 94–95% can be achieved in efficient modern pasteurization plants.

The percentage of regeneration is calculated as

$$R = \frac{(t_\mathrm{r} - t_\mathrm{i}) \times 100}{(t_\mathrm{p} - t_\mathrm{i})} \tag{5}$$

where R is the regenerative efficiency (%), t_r the milk temperature (°C) after regeneration, t_i the temperature (°C) of raw incoming milk, and t_p the pasteurization temperature (°C).

Holding

Correct heat treatment requires that the milk be held for a specified time at the pasteurization temperature. This is done in an external holding cell, which usually consists of a pipe arranged in a spiral or zigzag pattern and often covered by a metal shroud to protect operators against burns. The length of the pipe and the flow rate are calculated so as to provide the required holding time. Accurate control of the flow rate is essential to achieve the specified holding time. The holding time changes in inverse proportion to the flow rate.

Calculation of holding time

The appropriate tube length can be calculated when the hourly capacity and the inner diameter of the holding tube are known. As the velocity profile in the holding tube is not uniform, some milk molecules will move faster than the average. To ensure that even the fastest molecule is pasteurized sufficiently, an efficiency factor, η, must be used. This factor depends on the design of the holding tube, but is often in the range 0.8–0.9.

The length, L, of the holding cell is calculated as follows:

$$V = \frac{Q \times H}{3600 \times \eta}\ \mathrm{dm}^3 \tag{6}$$

$$L = \frac{V \times 4}{\pi \times d^2 \times 10}\ \mathrm{m} \qquad (7)$$

where Q is the flow rate at pasteurization ($\mathrm{l\,h^{-1}}$), H the holding time (s), L the length (m) of the holding tube, d the inner diameter (dm) of the holding tube, V the volume (l or $\mathrm{dm^3}$) of milk, and η the efficiency factor, dimensionless.

Types of Heat Exchangers

The following three types of heat exchangers are most widely used in the dairy industry:

- plate heat exchangers
- tubular heat exchangers
- scraped-surface heat exchangers

Plate heat exchangers

Most heat treatments of dairy products are carried out in plate heat exchangers. The plate heat exchanger (often abbreviated PHE) consists of a pack of stainless-steel plates clamped in a frame. The frame may contain several separate plate packs – sections – in which different stages of treatment, such as preheating, final heating, and cooling, take place. The heating medium is hot water and the cooling medium cold water, ice water, or propylene glycol, depending on the required product outlet temperature.

The plates are corrugated in a pattern designed for optimum heat transfer. Formerly, the so-called washboard pattern (**Figure 4(c)**) was predominant, but today the herringbone pattern is normally used for all types of plates, also within the dairy industry (**Figures 4(a)** and **4(b)**). The main advantages with the herringbone pattern are increased thermal efficiency and increased mechanical strength, the latter allowing the plates to be made thinner, which reduces the cost and weight of the plate. The increased thermal efficiency reduces the number of plates necessary, which in turn reduces the cost of the unit and also product hold-up volume.

The plate pack is compressed in the frame. Supporting points on the corrugations hold the plates apart so that narrow channels are formed between them. The liquids enter and leave the channels through holes in the corners of the plates. Varying patterns of open and blind holes route the liquids from one channel to the next. Gaskets around the edges of the plates and around the holes form the boundaries of the channels and prevent external leakage and internal mixing. **Figure 5** shows a typical arrangement.

Flow patterns

The arrangement of the plates is such that the product flows through alternate channels in the plate pack. The service (heating or cooling) medium is introduced at the other end of the section and passes through alternate plate channels. Each product channel consequently has service medium channels on both sides. For efficient heat transfer, the channels between the plates should be as narrow as possible, but both flow velocity and pressure drop will be high if a large volume of product must pass through these narrow channels. Neither of these effects is desirable and, to eliminate them, the passage of the product through the heat exchanger may be divided into a number of parallel flows. In **Figure 6**, the product flow is divided into two parallel flows, which change direction 4 times in the section. The channels for the heating medium are divided into four parallel flows, which change direction twice. This combination is written as 4 × 2/2 × 4, that is, the number of passes multiplied by the number of parallel flows for the product over the number of passes multiplied by the number of parallel flows for the service medium. This is called the grouping of the plates.

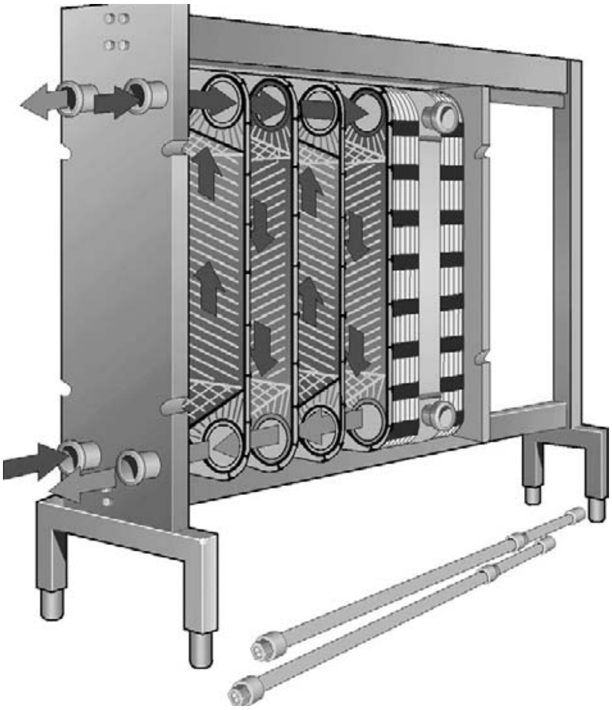

Figure 5 Principles of flow and heat transfer in a plate heat exchanger. Courtesy of Tetra Pak.

Tubular heat exchangers

THEs are today normally used for UHT treatment of dairy products. The THE (**Figure 7**), unlike plate heat exchangers, has no contact points in the product channel and can thus handle products with particles, the maximum particle size depending on the diameter of the tube. The THE can also run longer between cleanings than the plate heat exchanger in UHT treatment. From the standpoint of heat transfer, the THE is less efficient than the plate heat exchanger. THEs

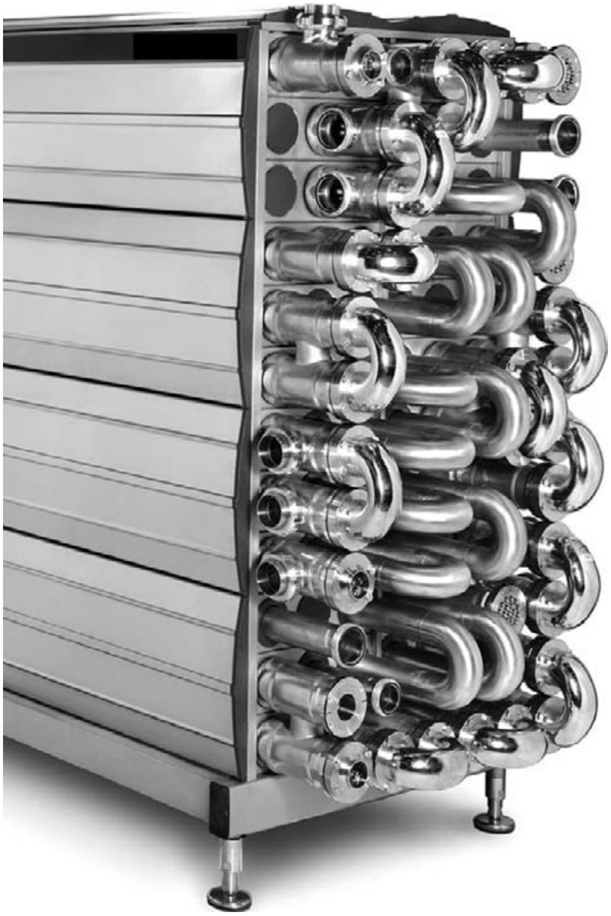

Figure 7 The tubular heat exchanger tubes are assembled in a compact unit. Courtesy of Tetra Pak.

are available in two fundamentally different types: multi/monotube and concentric tube.

Multi/monotubes

The multitube THE operates on the classic shell-and-tube principle, with the product flowing through a group of parallel tubes, and the service medium between and around the tubes. Turbulence for efficient heat transfer is created by helical corrugations on the tubes and shell. The heat transfer surface consists of a bundle of straight corrugated or smooth tubes welded into tube plates at both ends. The tube plates are in turn sealed against the outer shell by a double O-ring construction (floating design). This design allows the product tubes to be taken out of the shell by unscrewing the end bolts, and this makes the unit strippable for inspection. The floating design absorbs thermal expansion, and the product tube bundles in the shell can be changed, allowing different combinations to be used for different applications. The monotube is a version with only one inner tube, which will permit particles with a diameter up to 50 mm to pass. Multi/monotubes are well suited for processes operating at very high pressures and temperatures.

Concentric tubes

The heat transfer surface of a concentric THE consists of straight tubes of different diameters concentrically located on a common axis, connected by headers at both ends. The product flows in the gap between two concentric tubes and the service medium on both sides of these tubes. The floating design as described above for multi/monotubes is also applied to the concentric tubes. In addition, the multi/monotube inserts and the concentric tube inserts are interchangeable for maximum flexibility. The concentric tube is especially suited for processing viscous products, such as dessert puddings. Due to the thin product layer in the annular channel, very efficient heat transfer is achieved. Also, due to the single product channel design, the risk of maldistribution across parallel tubes for viscous products is eliminated.

Scraped-surface heat exchangers

The scraped-surface heat exchanger (**Figure 8**) is designed for heating and cooling viscous, sticky, or lumpy products, and for crystallization of products. The operating pressures on the product side are high, often as much as 4 MPa. All products that can be pumped can therefore be treated. The scraped-surface heat exchanger consists of a cylinder through which the

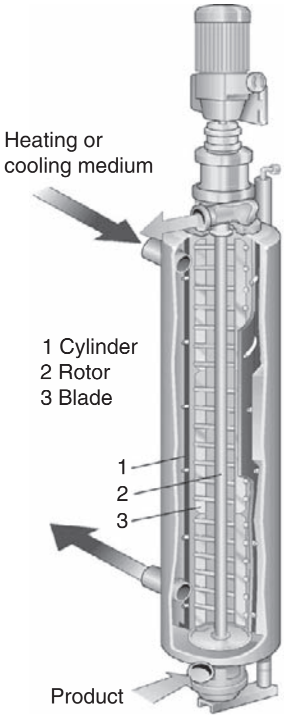

Figure 8 Vertical type of the scraped-surface heat exchanger. Courtesy of Tetra Pak.

product is pumped in countercurrent flow to the service medium in the surrounding jacket. Exchangeable rotors of various diameters, from 50.8 to 127 mm, and varying pin–blade configurations allow adaptation to different applications. Smaller-diameter rotors allow larger particles (up to 25 mm) to pass through the cylinder, while larger-diameter rotors result in shorter residence time and improved thermal performance. The product enters the vertical cylinder through the lower port and continuously flows upward through the cylinder. At process start-up, all the air is completely purged ahead of the product, allowing complete and uniform product coverage of the heating or cooling surface.

The rotating blades continually remove the product from the cylinder wall (**Figure 9**), to ensure uniform heat transfer to the product. In addition, the surface is kept free from deposits. The product exits the cylinder via the upper port. Product flow and rotor speed are varied to suit the properties of the product flowing through the cylinder. At shutdown, thanks to the vertical design, the product can be displaced by water with minimum intermixing, which helps assure product recovery at the end of every run. Following this, complete drainage facilitates cleaning-in-place (CIP) and product changeover. As mentioned above, the rotor and blades are exchangeable, an operation which is possible owing to the automatic hydraulic lift that facilitates raising and lowering of the rotor/blade assembly

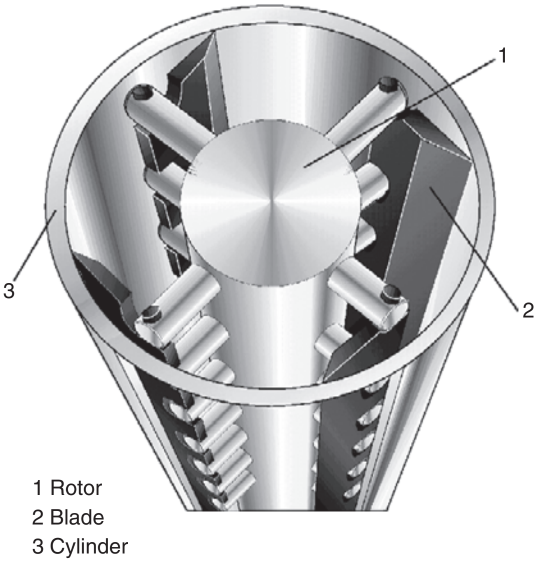

Figure 9 Section through a scraped-surface heat exchanger. Courtesy of Tetra Pak.

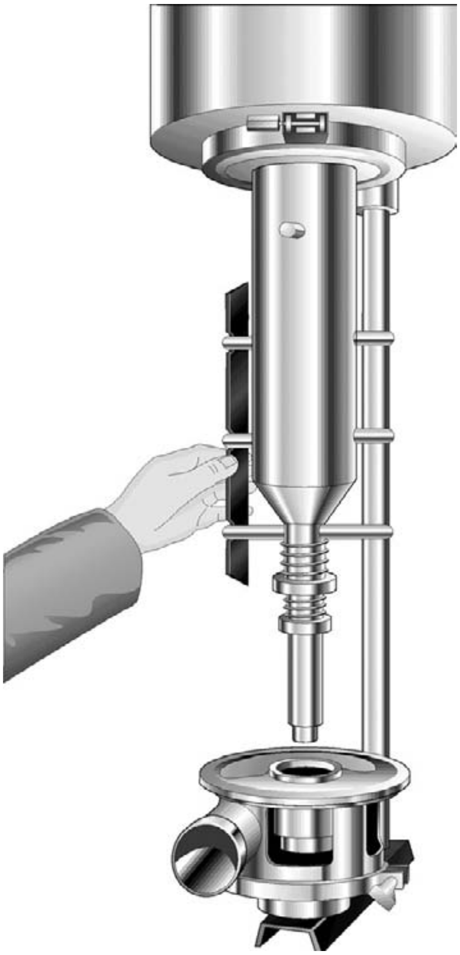

Figure 10 Removal of blades from the rotor assembly in lowered position. Courtesy of Tetra Pak.

(**Figure 10**). The typical products treated in the scraped-surface heat exchanger are ice cream and dairy spread, but fruit preparations, such as yogurt, are also treated. It is also used for fats and oils for crystallization of margarine and shortenings. The scraped-surface heat exchanger is also available in versions designed for aseptic processing. Two or more vertical-type scraped-surface heat exchangers can be linked in series or parallel to give a greater heat transfer surface depending on the processing capacity required.

Introduction and Historical Development

Pasteurization is a heat treatment that inactivates vegetative pathogenic microorganisms so as to render the product safe for consumption if refrigerated, and also prolongs the shelf life of the product. Pasteurized products are not sterile and still harbor low numbers of nonpathogenic psychrotrophic bacteria, which eventually reduce the shelf life. The growth of thermophilic spore-forming bacteria, which survive the relatively mild heat treatment applied, in pasteurized milk is largely controlled by cold storage of the pasteurized milk. Thus, pasteurization is a process that has profound impacts on both the public health implications of milk consumption and the keeping quality of milk and dairy products.

The process is named after the French microbiologist Louis Pasteur, who discovered that wine could be preserved by inactivating bacteria by heating at a temperature below boiling. The principle was soon applied to milk, and the first systems for the commercial pasteurization of milk were introduced in about the last decade of the nineteenth century. Early systems relied on heating milk to about 63–65 °C and holding for about 30 min in batch heating units, followed by rapid cooling to less than 12 °C (i.e., low-temperature–long-time (LTLT) pasteurization). This process is still used by small-scale processors but, since about 1940, such systems have been largely superseded by high-throughput continuous-flow plate heat exchanger (PHE)-based pasteurizers, in which milk is heated to 72–74 °C and held for at least 15 s, in a process called high-temperature–short-time (HTST) pasteurization. This remains the most common design of industrial pasteurizers today, and will be the focus of this article. Public health aspects of pasteurization are discussed in **Liquid Milk Products**: Pasteurization of Liquid Milk Products: Principles, Public Health Aspects.

Heat Treatment Conditions Used for the Pasteurization of Milk

In 1980, the International Dairy Federation defined pasteurization as "a process applied to a product with the object of minimising possible health hazards arising from pathogenic micro-organisms associated with milk by heat treatment which is consistent with minimal chemical, physical and organoleptic changes in the product".

The time–temperature conditions selected for the pasteurization of milk were determined, primarily, from the knowledge of the sensitivity of pathogenic microorganisms in milk to heat and, secondarily, from the consideration of the negative impact of heat treatment on the flavor and perceived 'freshness' of milk. The most heat-resistant vegetative pathogen in milk was identified originally as *Mycobacterium tuberculosis* (*see* **Pathogens in Milk:** *Mycobacterium* spp.), and the conditions for LTLT pasteurization were defined to ensure inactivation of this bacterium. The pathogenic rickettsia, *Coxiella burnetii*, was subsequently recognized as being slightly more heat-resistant, and the need to inactive this species was a key factor in the development of HTST pasteurization conditions (*see* **Pathogens in Milk**: *Coxiella burnetii*). Heat treatments sufficient to thermally inactivate these bacteria kill all less resistant microorganisms, and thus pasteurization should render milk safe for consumption, at least in terms of vegetative bacteria.

In recent years, as a result of better understanding of the diversity of the microflora of raw milk and the thermal inactivation kinetics of various bacterial strains, there has been some discussion on modification of pasteurization conditions. For example, use of an extended holding time during HTST pasteurization (to 25–40 s) or a slightly higher pasteurization temperature has been suggested as being required to ensure inactivation of heat-stable strains of *Listeria monocytogenes*, *Escherichia coli*, and *Campylobacter* species (*see* **Liquid Milk Products**: Pasteurization of Liquid Milk Products: Principles, Public Health Aspects).

Also, in the last 15 years, there has been much debate on the heat sensitivity and public health significance of emerging pathogens in milk, particularly *Mycobacterium avium* subsp. *paratuberculosis* (*see* **Pathogens in Milk:** *Mycobacterium* spp.). This bacterium is the causative agent of Johne's disease, a bowel disease in cattle, and has been linked to a similar syndrome, Crohn's disease, in humans. Early experiments to determine its heat sensitivity were hampered by the immense difficulty in quantifying this bacterium in milk owing to its extremely slow growth rate in culture and its tendency to grow in clumps due to its rough waxy cell wall. Nevertheless, early studies on the thermal inactivation of this bacterium in milk suggested that conventional HTST treatments were not sufficient to ensure complete inactivation of *M. avium* subsp. *paratuberculosis*, leading to an extension of the holding time and/or use of a higher pasteurization temperature in many countries. However, more recent studies have suggested that, under the extremely turbulent flow conditions in a modern milk pasteurizer, protective clumps of this bacterium are disrupted, enhancing its heat sensitivity and permitting inactivation under conventional HTST conditions.

Principle of Operation of an HTST Pasteurizer

As stated above, in modern dairy processing plants, HTST pasteurization in continuous-flow PHEs is practiced almost exclusively, although on farms or small dairy plants, smaller batch units may still be used (*see* **Plant and Equipment**: Heat Exchangers). A typical PHE consists of a vertical stack of many stainless steel plates clamped in a frame. The frame may contain several groups of plates, known as sections, in which different stages of treatment, such as preheating, final heat treatment, and cooling, take place (Figure 1). The heating medium may be steam or hot water, and the cooling medium may be cold water, brine, glycol, or ice water, depending on the desired outlet temperature of the product. The capacity of a milk pasteurizer depends on the size and number of plates, and can be as high as 100 000 l h^{-1}.

The surface of the plates displays a corrugated pattern to increase turbulence in the liquid flowing over them and, thus, efficiency of heat transfer (Figure 2). The stainless steel plates are compressed together in the frame, but supporting points on the corrugations hold the plates apart so that thin, rectangular channels are formed between them. Gaskets (made from natural rubber or, more recently, from synthetic elastomers) around the edges of the plates and holes define the boundaries of the channels and prevent leakage. The liquids flowing in the PHE enter and leave these channels by openings at the corners of the plates, and varying patterns of open and blind openings route the liquid from one channel to the next.

The flow pattern in alternating plates is illustrated in Figure 3. Milk is introduced through a corner opening into a channel between two plates and flows vertically through the channel; it leaves through the opening at the opposite corner, and bypasses the next channel between plates. In parallel, the heating or cooling medium is introduced at the other end of the section and it passes through the alternating interplate channels in the same manner. Thus, milk has heating or cooling medium, in the respective sections, flowing countercurrent, on either side of it, but separated by the intervening plate wall.

For efficient heat transfer, the channels between the plates should be as narrow as possible; however, if a large

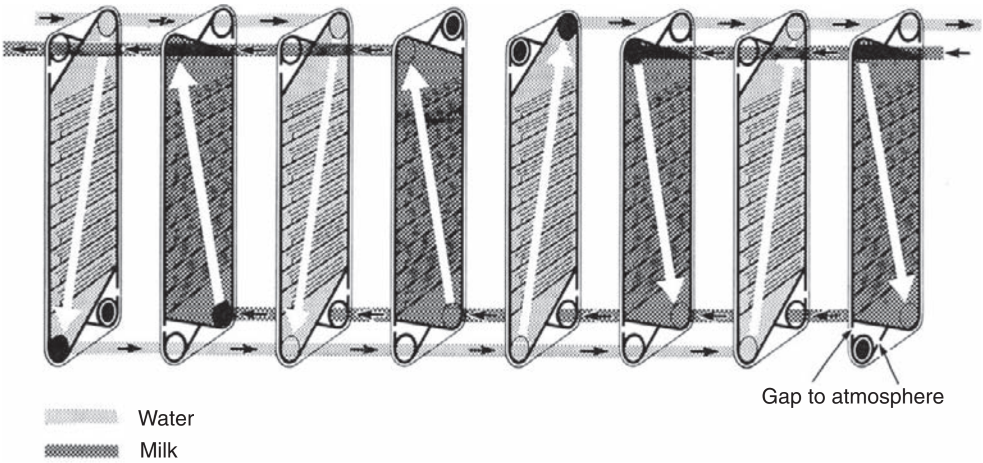

Figure 3 Principles of flow and heat transfer in the heating sections of a pasteurizer. Reproduced with permission from Harrison PC (1983) HTST pasteurising plant. In: Green E (ed.) *Pasteurising Plant Manual*, 3rd edn., pp. 7–36. Huntingdon, UK: Society of Dairy Technology.

volume of product has to pass through these narrow channels, both flow velocity and pressure drop will be high. Neither of these effects is desirable, and to minimize their significance the passage of product through the PHE may be divided into a number of parallel flows. One section of parallel flow is known as a pass, and passes in the PHE change the direction of flow a number of times. Within each section of the pasteurizer, there are many passes, that is, the direction of flow of product or heating/cooling medium is changed several times.

In a pasteurizer, cool raw milk is fed from a silo to a float hopper (balance tank) and pumped at a constant rate to the preheating, or regeneration, section of the pasteurizer, where it is heated to 68–70 °C. In this section, milk is heated by absorbing heat from outgoing pasteurized milk through the plates, with the medium being cooled simultaneously. Similarly, heat from the pasteurized milk is transferred to a cooling medium after reaching the pasteurization temperature. The use of pasteurized milk as a heating medium for incoming cold raw milk results in substantial energy savings, and is called heat regeneration. Raw milk is heated in this manner by pasteurized milk from about 6 °C to about 68–70 °C and the pasteurized milk is cooled to about 10 °C. The temperature of the milk thus preheated must be increased by only about 2–4 °C (depending on the pasteurization temperature set point) using steam or hot water in the final heating section, while in the cooling section the pasteurized milk must be cooled by only about 6 °C (from 10 to 4 °C). With a well-dimensioned regenerative section, it is possible to recover about 94% of the heat from the pasteurized milk.

Regenerative preheating of raw milk is usually divided over 2–3 sections of the PHE; milk between sections is thus at intermediate temperatures between 6 and 70 °C. Milk at around 50–55 °C is at the optimum temperature for treatments such as separation (fat removal and/or standardization; *see* **Plant and Equipment**: Centrifuges and Separators: Applications in the Dairy Industry), clarification (removal of undesirable solids; *see* **Plant and Equipment**: Centrifuges and Separators: Applications in the Dairy Industry), or homogenization (*see* **Homogenization of Milk**: Principles and Mechanism of Homogenization, Effects and Assessment of Efficiency: Valve Homogenizers), as milk fat is in a liquid state. Incorporation of such processing steps into the pasteurization line avoids the need to heat milk separately to carry out these operations, making liquid milk processing more economical and reducing the chances of contamination of the milk. Thus, milk is typically routed out of the pasteurizer between regeneration sections for treatments such as homogenization or standardization, before being returned to the PHE for completion of the pasteurization cycle. Milk may, in theory, exit the regeneration section for such parallel processing while being either heated (raw milk) or cooled (pasteurized milk), but the former option is more common, as it avoids the risk of recontamination of pasteurized milk, which otherwise would have to be avoided by use of aseptic homogenization or separation systems. A complete process line for homogenized market milk is shown in Figure 4.

The heating medium in the final heating section is circulated by a pump from a hot water generator, the temperature of which is maintained at 2–7 °C above the set point by injecting steam via a steam-regulating valve, which is controlled by an automatic temperature controller (*see* **Utilities and Effluent Treatment**: Heat Generation). Both the pasteurization temperature and final milk temperature are generally logged on a chart recorder, which is mounted, along with the flow diversion valve (FDV) (see below) setting control, on a control panel.

Correct pasteurization requires that the milk be held for a specified time at the set pasteurization temperature. This can be achieved either in a specific section of plates within the PHE (holding section) or in an external holding tube. No heating or cooling should take place within the holding section or tube; the milk simply flows through a passage, the length of which is determined from the flow rate of the milk and the required residence (holding) time. The control of residence time may be undertaken with greater confidence in a tube than under the turbulent flow conditions encountered in flow between plates. As a fundamental principle, the minimum residence time of milk in the holding section should always exceed the residence time stipulated for the process. An external holding tube

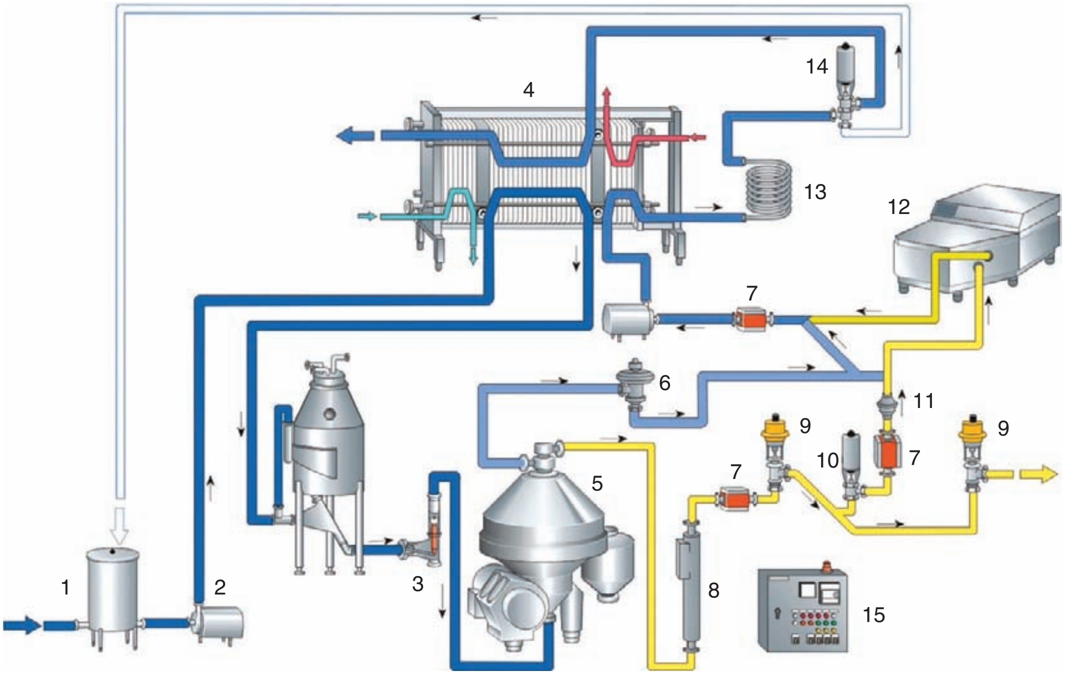

Figure 4 Production line for market milk with homogenization of cream, showing (1) balance tank, (2) feed pump, (3) flow controller, (4) plate heat exchanger, (5) centrifugal separator, (6) constant pressure valve, (7) flow transmitter, (8) density transmitter, (9) regulating valve, (10) shutoff valve, (11) check valve, (12) homogenizer, (13) holding tube, (14) flow diversion valve, and (15) control panel. typically consists of a length of piping arranged in a spiral or zigzag pattern, and should be insulated. Since the residence time in the holding cell is determined primarily by the flow rate, accurate flow regulation is essential, as changes in flow rate will directly and inversely affect holding time.

A resistance thermometer (thermistor) monitors the temperature of milk, generally at the point of exit from the holding section. Less commonly, the thermistor may be located at the start of the holding section. The latter position allows more time for the reaction to drop in temperature, ensuring that no underpasteurized milk can flow downstream for packaging, but does not account for the drop in temperature that can occur in an uninsulated external holding tube. The former position is thus more common, although a drop in temperature in the holding tube may be minimized by insulating the tube or by heating the milk slightly above the set pasteurization temperature in the heating section. However, the latter option implies overheating of milk, with concomitant potential alterations to flavor and properties.

The thermistor (which typically operates over the range of 60–80 °C) controls the action of a flow diversion device (FDD) or flow diversion valve (FDV), which is located downstream from the thermistor, either at the end of the holding section or, less commonly, after the cooling section of the pasteurizer. The plant shown in Figure 1 shows the FDV located in the latter position, while in Figure 4 the more common configuration is displayed. The function of the FDV is to prevent unpasteurized milk from reaching the packaging unit, by returning milk to the balance tank if the temperature determined by the thermistor drops below the target pasteurization temperature (sometimes referred to as the set point). The default, or fail-safe, position of the FDV of the pasteurizer is the closed or divert position, and the valve opens only if and when the temperature exceeds the set point. During operation, if the temperature of the milk, as measured by the thermistor, falls below the set point, a programmable logic controller (PLC) or similar device detects and records the decrease, often sounds an alarm for operators, and deactivates the FDV, causing the valve to close so that milk is diverted to the balance tank. The principle of operation of a pasteurizer's FDV is illustrated in Figure 5.

If the FDV deactivates and milk is returned to the balance tank, either the plant may stop, necessitating emptying, cleaning, and sanitizing before processing is recommenced, or the milk may be recirculated in the regeneration and cooling sections so as to allow restart when the set-point temperature is reached. In cases where the FDV is located at the outlet from the cooling section of the pasteurizer, the heat exchanger must be emptied, cleaned, and sanitized before restarting operation, if milk temperature decreases below the set point.

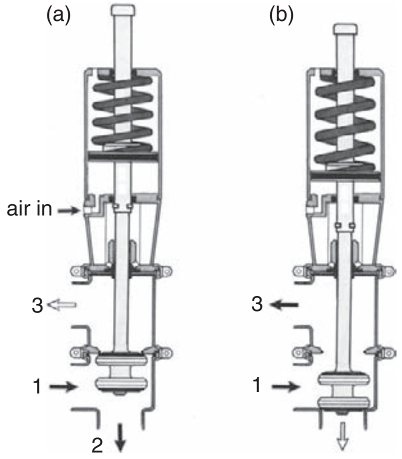

Figure 5 Principle of operation of a flow diversion valve of a high-temperature–short-time pasteurizer. Valves are shown in the (a) open (operating) and (b) divert positions. Indicated are (1) milk inlet from holding section or tube, (2) milk line to regenerative section, and (3) diverted milk line. Reproduced with permission from Tetra Pak A/B, Lund, Sweden.

There is always a possibility of fractures or pinholes occurring in pasteurizer plates, which could lead to recontamination of pasteurized milk. To guard against this possibility, a booster pump may be fitted to the pipeline as it leaves the holding section to increase the milk pressure slightly (by around 0.01–0.02 MPa); should a pinhole then occur, the direction of leakage would be of pasteurized milk into raw milk, thereby precluding postpasteurization contamination. A simpler means of protecting the pasteurized product is to increase the number of passes in the regeneration sections, thereby increasing the back pressure within the pasteurized milk section of the plant.

The chilled milk from the pasteurizer flows either to an intermediate storage tank or directly to a packaging unit. It is extremely important to avoid conditions that could introduce microorganisms into pasteurized milk during processing downstream from the pasteurizer; it has been acknowledged that postpasteurization contamination has in the past significantly influenced the shelf life and public health aspects of pasteurized milk.

The key operating parameters for an HTST pasteurizer are plant capacity, temperature program, regenerative efficiency, and the temperature of the heating and the cooling medium. During operation, the PHE may be controlled in a feedback loop by monitoring the temperature of the milk in the heating section, milk leaving the cooling section, the heating medium, or the cooling medium.

The shelf life of pasteurized milk is dependent on factors such as the microbial quality of the raw milk, the precise processing conditions used, postpasteurization contamination, and refrigeration temperature, but is generally around 10–16 days at 5 °C.

Pasteurization of Other Dairy Products

Similar processing conditions are generally used for the full range of fat-standardized liquid milk products. However, cream, which contains a higher level of fat, must be heated more severely (e.g., 80 °C for 3–5 s), as the fat acts as a thermal insulator, and increases the stability of bacteria (*see* **Cream**: Manufacture; Products). Ice cream and dessert mixes, which contain high levels of fat and sugar, are generally pasteurized at about 80 °C for 25 s. In some countries, milk or cream heated to around 80 °C for a few seconds may be referred to as being 'flash' pasteurized.

Testing and Maintaining Pasteurizers

The requirements for the successful operation of a pasteurization plant are shown in **Table 1**.

Pasteurizers should be checked routinely as follows:

- correct calibration of thermometers must be verified;
- the FDV must be shown to be in correct working order and functioning as intended; and
- heating plates should be inspected regularly for leaks.

It is recommended that basic parameters of pasteurizer operation, such as diversion temperature, recorder accuracy, and flow rate (determined by measuring the time to process a known quantity of milk), should be checked on a daily basis. The exterior of the plant should be inspected daily for leaks of all kinds and for general cleanliness. The FDV should be checked regularly for signs of wear or damage, which could impair its operating efficiency. Cleaning procedures for pasteurizers should be designed to prevent the growth of bacteria as biofilms (*see* **Biofilm Formation**), which have been shown to have the potential to proliferate on plate surfaces, but which can be removed by use of a cleaning cycle that includes exposure of surfaces to extremes of pH, as in cycled acid and caustic washes.

Methods for determining the integrity of PHEs and monitoring the occurrence of pinholes or cracks include differential electrolytic analysis and helium leak detection systems.

Testing for Milk Pasteurization

The efficiency of pasteurization is generally assessed by using an indicator enzyme, alkaline phosphatase, naturally present in raw milk (*see* **Enzymes Indigenous to Milk**: Phosphatases). This enzyme is almost completely inactivated by processing times and temperatures just higher than those required to kill *M. tuberculosis*, that is, under conditions required for pasteurization. There are simple tests to detect the residual activity of this enzyme in milk and, therefore, if milk has been heated sufficiently strongly to inactivate this enzyme, it is assumed to be free of

Table 1 Critical aspects of control of pasteurizer operation

Application of correct heating by the use of
Correct control of temperature of heating medium
Positive control of flow rate through holding tube
Correctly dimensioned holding tube
Flow diversion valve
Prevention of crosscontamination
Positive pressure between raw and pasteurized milk in regenerative section
Correct positioning of flow diversion valve
Routine inspection of seals for leaks
Cleanability
High-grade stainless steel used for fabrication
Welds, joins, and other parts of highest possible standard
All materials compatible with cleaning fluids
Limitation of heat damage
Minimize temperature difference between heating medium and milk
Minimize milk residence time in holding section
Ensure efficient cooling
Economic operation
Ensure efficient regeneration
Use a maximum heating surface-to-volume ratio

Adopted from Varnam AH and Sutherland JP (1994) Liquid milk and liquid milk products. In: *Milk and Milk Products*, pp. 42–102. London: Chapman and Hall.

surviving pathogenic bacteria. For many years, tests for the pasteurization of milk were generally based on the production of a colored product from an uncolored substrate by the enzyme (if active). In modern dairy testing laboratories, automated equipment, such as the Fluorophos™ system, is used to detect and quantify residual phosphatase activity in milk, where a small amount of milk is mixed in a small test tube with a substrate for alkaline phosphatase; if active enzyme is present, it hydrolyzes the substrate, yielding a fluorescent product, which is then measured by the instrument. Incubation, reading, and printing of results take place in a single small, compact unit, with results being produced within 1–3 min.

For cream, lactoperoxidase (an enzyme that is considerably more heat stable than alkaline phosphatase; *see* **Enzymes Indigenous to Milk**: Lactoperoxidase) is used as the indicator enzyme, rather than alkaline phosphatase, due to the requirements for use of a higher temperature in the pasteurization of cream. Lactoperoxidase activity may also be used to test for excessive heating during pasteurization of liquid milk, as HTST-pasteurized milk should be phosphatase-negative, but lactoperoxidase-positive.

Developments in Pasteurization Technology

The shelf life of pasteurized milk may be increased significantly by combining pasteurization with technologies that remove bacterial spores such as *Bacillus cereus*, which would otherwise grow, albeit slowly, during storage and spoil the milk. Approaches to spore removal before heat treatment generally involve either centrifugation (e.g., bactofugation) or microfiltration of skim milk, followed by mixing with strongly heat-treated cream, often followed by aseptic packaging (*see* **Milk Protein Products**: Membrane-Based Fractionation). Such extended shelf life (ESL) products have a considerably longer shelf life than pasteurized milk, but suffer significantly less undesirable nutritional or sensory effects than ultra-high temperature (UHT)-treated products. ESL-type processes may also be referred to as superpasteurization of milk (*see* **Liquid Milk Products**: Liquid Milk Products: Super-Pasteurized Milk (Extended Shelf-Life Milk)).

Evaporators

V Gekas, Cyprus University of Technology, Limassol, Cyprus

K Antelli, Technical University of Crete, Chania, Greece

© 2011 Elsevier Ltd. All rights reserved.

Introduction

An evaporator is a device wherein evaporation occurs, that is, liquid is evaporated from a thin (low-density) feed material in order to produce a denser or thicker product (concentrate). The feed may be a solution, slurry, or suspension of solid materials in a liquid. The heat necessary for the phase change or vaporization is supplied through heat transfer across metallic surfaces by condensing steam. Thus, evaporation as a unit operation involves energy transfer (heat for vaporization and condensation), mass transfer (moisture removal), and fluid flow (feed and vapor flows).

In the dairy industry, evaporation is used for concentration of milk or whey. It is also used as a preliminary step to drying. Milk products intended for milk powder are normally concentrated from an initial solids content of 9–13% to a final concentration of 40–50% total solids before the product is pumped to the dryer.

Evaporation in the dairy industry involves boiling off part of the water from a solution. To do this, heat must be supplied. The products to be evaporated are normally heat-sensitive and can be destroyed by adding heat. To reduce this heat impact, evaporation is done under vacuum, sometimes at a temperature as low as 40 °C. At the same time, the evaporator should be designed for the shortest possible residence time. Most products can be concentrated with good results provided that the evaporator is designed for a low temperature and short holding time.

It requires a large amount of energy to boil off water from a solution. This energy is supplied as steam. To reduce the amount of steam needed, the evaporation station is normally designed as a multiple-effect evaporator. Two or more units operate at progressively lower pressures and thus with progressively lower boiling points. In such an arrangement, the vapor produced in the previous effect can be used as a heating medium in the following effect. The result is that the amount of steam needed is approximately equal to the total amount of water evaporated divided by the number of effects. Evaporators with up to seven effects are now used in the dairy industry.

Alternatively, electricity can be used as the energy source; in this case, an electrically powered compressor or fan is used to recompress the vapor leaving an effect to the pressure needed on the heating side.

Although evaporator plants generally work on the same principle, they differ in the details of their design. The tubes that form the partitions between steam and product can be either horizontal or vertical and the steam can be circulated either inside or outside the tubes. In most cases, the product circulates inside vertical tubes while steam is applied on the outside. The tubes can be replaced by plates, cassettes, or lamellae.

Operation

Processing Factors

The physical and chemical properties of the solution being concentrated and of the vapor being removed have a great effect on the type of evaporator used and on the following characteristics:

1. *Concentration of solutes in the liquid*: Usually, the liquid feed to an evaporator is relatively dilute, so its viscosity is low, similar to that of water, and relatively high heat-transfer coefficients are obtained. As evaporation proceeds, the solution may become very concentrated and quite viscous, causing the heat-transfer coefficient to drop markedly. Adequate circulation and/or turbulence must be present to prevent the coefficient from becoming too low.
2. *Solubility*: As solutions are heated and the concentration of the solutes increases, the solubility limit of the material in solution may be exceeded and crystals may form. This may limit the maximum concentration in solution which can be obtained by evaporation.
3. *Temperature sensitivity of materials*: Many products, especially foods and other biological materials, may be temperature-sensitive and degrade at higher temperatures or after prolonged heating. The amount of degradation is a function of temperature and length of time.
4. *Foaming or frothing*: In some cases, materials composed of caustic solutions, food products such as skim milk, and solutions of fatty acids form foam or froth during boiling. This foam accompanies the vapor phase and entrainment losses occur.

5. *Pressure and temperature*: The boiling point of the solution is related to the pressure of the system. The higher the operating pressure of the evaporator, the higher the temperature at boiling. Also, as the concentration of the dissolved material in solution is increased by evaporation, the boiling point increases. In order to keep the temperature low in heat-sensitive materials, it is often necessary to operate below atmospheric pressure, that is, under vacuum.
6. *Scale deposition and materials of construction*: Some solutions deposit solid materials, called scale or fouling, on the heating surfaces. These could be formed by decomposition products or due to insufficient solvent. The result is that the overall heat-transfer coefficient decreases and the evaporator must eventually be cleaned. The materials used in the construction of the evaporator are important to minimize corrosion.

Evaporator Types

There is no single type of evaporator that is satisfactory for all conditions or all kinds of materials. Heat-transfer properties, energy, and cost factors determine the choice between various types of evaporators for a particular application. Both tubular and plate-type steam-heated heat exchangers have been used. Major manufacturers of evaporators are APV Crepaco, Alfa-Laval, Cook Machinery, Dedert Corp., FMC, GEA Food and Process Systems Corp., Niro Evaporators, Signal Swenson Div., Tito Manzini, and Figi s.p.a.

Circulation evaporators

Horizontal tube natural circulation evaporator

The horizontal tube natural circulation evaporator is shown in **Figure 1**(**a**). The horizontal bundle of heating tubes is similar to the bundle of tubes in a heat exchanger. The steam enters the tubes where it condenses and the condensate leaves at the other end of the tubes. The boiling/liquid solution covers the tubes. The vapor leaves the liquid surface, often goes through some de-entraining device, such as a baffle, to prevent carryover of liquid droplets, and leaves from the top. This type is relatively cheap and is used for nonviscous liquids having a high heat-transfer coefficient and liquids that do not deposit scale. It is unsuitable for viscous liquids because circulation is poor.

Vertical-type natural circulation evaporator

In this type of evaporator, vertical rather than horizontal tubes are used; the liquid is inside the tubes and the steam condenses outside the tubes. Because of boiling and decreases in density, the liquid rises in the tubes by convection, as shown in **Figure 1**(**b**), and flows downward through a large central open space or downcomer. This natural circulation increases the heat-transfer coefficient. This type is often called the short-tube evaporator and is not used for viscous liquids.

Circulation evaporators can be used when a low degree of concentration is required or when small quantities of product are processed. In yogurt production, for example, evaporation is used to concentrate milk 1.1- to 1.25-fold, or from 13 to 14.5% or 16.5% solids content, respectively. This treatment simultaneously deaerates the product and removes off-flavors.

During the circulation evaporation process, the milk, heated to 90 °C, enters the vacuum chamber tangentially at a high velocity and forms a thin, rotating layer on the wall surface, as shown in **Figure 2**. As it swirls around the wall, some of the water is evaporated and the vapor is drawn off to a condenser. Air and other noncondensable gases are extracted from the condenser by a vacuum pump.

The product eventually loses velocity and falls to the inwardly curved bottom, where it is discharged. Part of the product is recirculated by a centrifugal pump to a heat exchanger for temperature adjustment and then to the vacuum chamber for further evaporation.

Long tube vertical-type evaporator

Because the heat transfer coefficient on the steam side is very high compared to that on the evaporating liquid side, high liquid velocities are desirable. In a long tube vertical-type evaporator, shown in **Figure 1**(**c**), the liquid is inside the tubes. The tubes are 3–10 m long and the formation of vapor bubbles inside the tubes causes a pumping action, giving quite high liquid velocities. Generally, the liquid passes through the tubes only once and is not recirculated. The contact time can be quite low in this type of evaporator. In some cases, as when the ratio of feed to evaporation rate is low, natural recirculation of the product through the evaporator is made possible by including a large pipe connection between the outlet concentrate line and the feed line. This is widely used for the production of condensed milk.

Falling film-type evaporator

A variation of the long tube type is the falling film evaporator, wherein the liquid is fed to the top of the tubes and flows down the walls as a thin film. Separation of vapor and liquid usually takes place at the bottom. This type of evaporator is widely used for concentrating heat-sensitive materials because the holdup time is very short (5–10 s or more) and the heat-transfer coefficients are high. It is also the type

most often used in the dairy industry. The heating surface may consist of stainless-steel tubes or plates. The plates are stacked together, forming a pack with the product on one side of the plates and steam on the other.

Forced circulation-type evaporator

The liquid-film heat-transfer coefficient can be increased by pumping to cause forced circulation of the liquid inside the tubes. This could be done in the long tube vertical type shown in **Figure 1(c)** by including a pipe connection with a pump between the outlet concentrate line and the feed line. However, the vertical tubes are usually shorter in a forced circulation type (**Figure 1(d)**) than in the long tube type. In other cases, a separate and external horizontal heat exchanger is used. This type is very useful for viscous liquids.

Agitated film evaporator

In an evaporator, the main resistance to heat transfer is on the liquid side. One way to increase turbulence in this film, and hence the heat-transfer coefficient, is by mechanical agitation. This is done in a modified falling film evaporator with only a single large jacketed tube containing an internal agitator. This type of evaporator is very useful for highly viscous

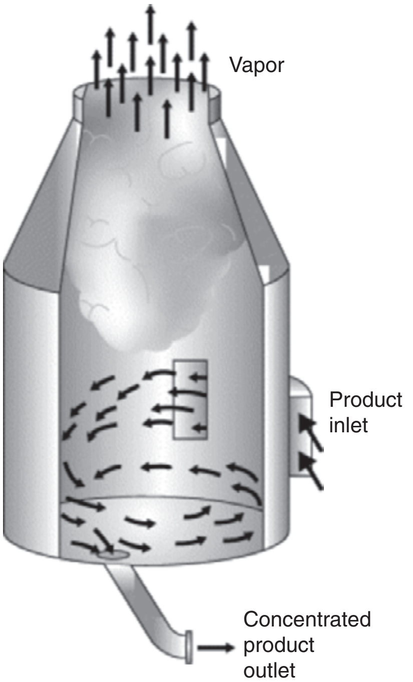

Figure 2 Product flow in a vacuum chamber. Courtesy of Tetra Pak, Sweden.

materials. However, it is expensive and of small capacity.

Modes of Operation of Evaporators

1. *Single-effect evaporators*: A simplified diagram of a single-stage (single-effect) evaporator is given in **Figure 3**. The feed enters at T_f and saturated steam enters the heat-exchange section at T_s. Condensed steam leaves as condensate or drip. Assuming that the solution in the evaporator is perfectly mixed, the concentrated product that exits the evaporator and the solution in the evaporator have the same temperature, which is T_1, because of thermal equilibrium with the boiling solution. The pressure is P_1, which is the vapor pressure of the solution at T_1. Single-effect evaporators are often used when the required capacity of operation is relatively small and/or the cost of steam is relatively cheap compared to the cost of the evaporator. However, for large-capacity operation, using more than one effect will markedly reduce steam costs.

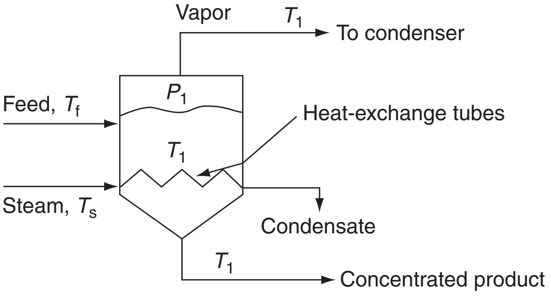

Figure 3 Simplified diagram of a single-effect evaporator.

2. *Forward-feed multiple-effect evaporators*: A single-effect evaporator, shown in **Figure 3**, is not energy-efficient because the latent heat of the vapor leaving is not used but discarded. However, much of this latent heat can be recovered and reused by employing a multiple-effect evaporation system, as shown in **Figure 4**. The first effect operates at a high enough temperature so that the evaporated water serves as the heating medium to the second effect. Here again, the evaporated water can be used as the heating medium to the third effect. Hence, the steam economy, which is kg vapor evaporated per kg steam used, is increased. This also approximately holds for a number of effects over three. However, this increased steam economy of a multiple-effect evaporator is gained at the expense of the original first cost of these evaporators. In forward-feed operation, as shown in **Figure 4**, the fresh feed is added to the first effect and flows to the next in the same direction as the vapor flow. This method of operation is used when the feed is hot or when the final concentrated product might be damaged at a high temperature. The boiling temperature decreases from effect to effect.
3. *Backward-feed multiple-effect evaporators*: In the backward-feed operation, shown in **Figure 5** for a triple-effect evaporator, the fresh feed enters the last and coldest effect and continues until the concentrated product leaves the first effect. This method of reverse feed is advantageous when the fresh feed is cold, because a smaller amount of liquid must be heated to the higher temperature in the second and first effects. However, liquid pumps are used in each effect, because the flow is from low to high pressure. This method is also used when the concentrated product is highly viscous. The high temperatures in the early effects reduce the viscosity and give reasonable heat-transfer coefficients.
4. *Parallel-feed multiple-effect evaporators*: Parallel feed in multiple-effect evaporators involves adding fresh feed and withdrawing concentrated product from each effect. The vapor from each effect is then used to heat the next effect. This method of operation is mainly used when the feed is almost saturated and the product is in the form of solid crystals, as in the evaporation of brine to make salt.

Heat and Material Balances for Evaporators

Single-effect evaporators

A single-effect evaporator is shown in **Figure 6**. The basic equation for solving for its capacity is

$$Q = UA\Delta T \tag{1}$$

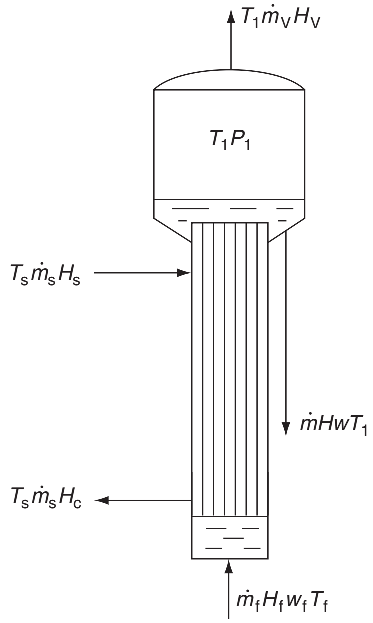
where ΔT is the temperature difference between the condensing steam and the boiling liquid in the evaporator, Q is the heat flow, U the overall heat transfer co-efficient and A the contact surface area. In order to solve this equation, the value of Q must be determined by making a heat and material balance on the evaporator shown in **Figure 6**.

The feed to the evaporator is $\dot{m}_f$, having a solids content of w_f (mass fraction), temperature T_f, and enthalpy H_f. The concentrated liquid, $\dot{m}$, from the evaporator has a solids content of w, temperature T_1, and enthalpy H. The vapor $\dot{m}_v$ is given off as pure solvent having no solids, temperature T_1, and enthalpy H_v. Saturated steam entering is $\dot{m}_s$ and has temperature T_s and enthalpy H_s. The condensed steam leaving, $\dot{m}_s$, is usually assumed to be at T_s, the saturation temperature, with enthalpy H_c.

Total material balance:

$$\dot{m}_f = \dot{m}_v + \dot{m} \tag{2}$$

Material balance for the solute (solids):



$T_1 \dot{m}_V H_V$
$T_1 P_1$
$T_s \dot{m}_s H_s$
$\dot{m} H w T_1$
$T_s \dot{m}_s H_c$
$\dot{m}_f H_f w_f T_f$

Figure 6 Simplified diagram of an evaporator.

$$\dot{m}_f w_f = \dot{m} w \tag{3}$$

Heat balance:

$$\dot{m}_f H_f + \dot{m}_s H_s = \dot{m} H + \dot{m}_v H_v + \dot{m}_s H_c \tag{4}$$

The heat Q transferred in the evaporator is

$$Q = \dot{m}_s(H_s - H_c) \quad (5)$$

Selection of Evaporators

Evaporator systems are major pieces of process equipment and are often purchased on a total responsibility basis. The purchaser's task is to define the process, quality, and mechanical limitations accurately to enable the vendor to engineer economical and suitable systems for the intended duty.

When selecting an evaporator, one should include the following considerations:

1. compare initial capital cost and operating cost
2. check to see that specifications have been met. Some important specification considerations are
   - operation capacity
   - product viscosity, suspended solids, and density
   - temperature–time profile as related to product quality
   - cooling water temperature
   - steam levels and requirements
   - materials of construction
   - condenser type
   - volatile recovery requirements
   - headroom requirements
   - any special requirements
3. Maintenance considerations
   - manual versus automatic control
   - reliability and simplicity of operation
   - sanitation, ease of cleaning, and cleaning cycle
   - safety requirements
4. Guarantees of after-sale services
   - start-up assistance
   - engineering expertise and response to problems
   - personnel training

Economics

Evaporation is one of the high capital cost and energy-intensive unit operations. During the era of low energy costs, the major selection criterion was based on the low initial equipment costs. Energy is by far the major cost factor in evaporator operations. As a result, more energy-efficient designs have gained favor for new installations.

Methods of Energy Savings

Considerable economic benefits can be gained by upgrading existing evaporator systems to reduce energy costs for evaporation. There are three general areas for modifying existing evaporators for energy saving:

1. *Fine-tuning existing evaporator*: These low-investment improvements do not change the basic evaporator layout.
2. *Modifying auxiliary hardware*: These moderate-investment changes normally can be authorized at the plant level.
3. *Major hardware modifications*: These high-investment changes normally require approval at the corporate level.

Thermocompression

The vapor evolved from the product can be compressed and used as a heating medium. This improves the thermal efficiency of the evaporator. A thermocompressor is used for this purpose. A single evaporator with a thermocompressor is as economical as a two-effect unit without one. Using thermocompression together with multiple-effect units optimizes thermal efficiency. The main components of an evaporator with thermal vapor recompression (TVR) are shown in **Figure 7(a)**.

Mechanical Vapor Compression

Unlike a thermocompressor, a mechanical vapor compression system draws all the vapor out of the evaporator and compresses it before returning it to the evaporator. The pressure increase is accomplished by the mechanical energy that drives the compressor. In mechanical vapor compression, the total amount of steam is circulated in the plant. This makes a high degree of heat recovery possible. A three-effect evaporator with mechanical vapor compression can reduce the operating costs by half compared to a seven-effect plant with a thermocompressor. The main components of an evaporator with mechanical vapor recompression (MVR) are shown in **Figure 7(b)**.

Evaporators in the Dairy Industry

Milk

Evaporators are used during the production of evaporated milk or as a step in the production of dairy powders. As shown in **Figure 8**, after preheating, the milk is evaporated under vacuum. It is of utmost importance that the evaporator works under optimal hygienic conditions, regardless of the fact that the product is sterilized afterward.

All modern milk evaporators are multiple-effect plants, and they almost always use either TVR or MVR.

Whey

The whey (typically 6% total solids) is normally evaporated, after pretreatment to remove fat (and/or cheese fines), to between 40 and 60% total solids. The choice of total solids in the final product depends on subsequent processing needs. If the whey concentrate has to be transported, 40% is preferred, to avoid crystallization taking place en route and causing unloading difficulties. Alternatively, when the whey is to be spray-dried (on-site), 60% is better. Both TVR and MVR falling

film equipment can be used in this application as well as others, with the latter configuration usually giving better energy economy.

An advanced case of application is in the production of whey protein concentrate. As shown in **Figure 9**, membrane technology and evaporation are combined for protein recovery and the subsequent concentration of the protein solution.

Introduction

Drying is defined as the unit operation in which volatile liquids are separated from solids by vaporization to yield (nearly) liquid-free products.

A number of different drying processes are in use in the dairy, food, chemical, and pharmaceutical industries, such as

- spray drying,
- fluid bed drying,
- drum drying,
- batch drying in trays,
- freeze drying,
- microwave drying, and
- superheated steam drying.

As the liquid to be removed in the dairy industry is invariably water, only water evaporation into atmospheric air is considered here, although the drying principles involved in the evaporation of nonaqueous, organic solvents into any controlled gaseous atmosphere are the same.

From the point of view of drying economy and the final product quality, the processes of major significance in milk powder manufacture are spray drying, fluid bed drying, and drum drying. Spray drying and fluid bed drying are most often used in combination and drum drying is only of limited use. Only spray drying and fluid bed drying processes will be discussed here.

Spray Drying

The basic principle of spray drying is exposure of a fine dispersion of droplets, created by means of atomization of pre-concentrated milk products, to a hot airstream. The small droplet sizes created, and hence a large total surface area, result in very fast evaporation of water at relatively low temperatures. Hence, heat damage to the product is minimized.

The spray drying process for milk drying comprises essentially five subprocess stages: (1) atomization of the feed, (2) mixing of spray and drying air, (3) evaporation, (4) separation of the product from the drying air, and (5) cooling of the powder. The last two points will be discussed elsewhere (*see* **Plant and Equipment**: Milk Dryers: Dryer Design).

Each of these process stages can be carried out in different ways, depending on the plant design, which in combination with operational conditions and other features, such as integrated and/or external fluid beds and destination of fine powder from powder separators, in turn determine the characteristics and properties of the final powder.

Atomization of the Feed

Atomization of the feed, that is, formation of a spray, is the characteristic feature of spray drying. The purpose of atomization is to create a large number of small-diameter droplets. Assuming a completely homogeneous spray, the total droplet surface area is inversely proportional to the droplet diameter, and the number of particles inversely proportional to the square of the droplet diameter. **Table 1** shows the number of droplets and the total surface area created by homogeneous atomization of 1 l of concentrate to different droplet sizes.

Rotary atomizers and pressure nozzles are in use in the milk powder industry, the former utilizing centrifugal energy and the latter pressure energy in the atomization process. The design of atomization devices is discussed elsewhere (*see* **Plant and Equipment**: Milk Dryers: Dryer Design).

Rotary atomizers (wheel atomization)

In rotary atomizers, the feed is accelerated to the applied peripheral speed of the atomizer wheel, which is typically in the range of 150–170 $\mathrm{m\,s^{-1}}$. The feed is introduced centrally around the atomizer shaft via a liquid distribution device. A number of different liquid distributor designs have been developed over the years, which emphasizes the importance of this component for optimum and trouble-free operation of the atomizer (absence of vibrations and product deposits).

The efficiency of atomization (droplet size) depends on a number of factors:

Table 1 Number of droplets and total surface area created by atomization of 1 l of feed

Mean droplet diameter (μm)	*Number of droplets per liter* ($\times 10^6$)	*Total surface area* (m^2)
500	15.3	12
250	122.2	24
100	1909.9	60
75	4527.1	80
50	15 278.9	120
10	1 909 859.3	600

- higher peripheral speed, vane height, and number of vanes decrease the mean droplet size; and
- higher rate, viscosity, and surface tension of the feed increase the mean droplet size.

The power consumption of a rotary atomizer is directly proportional to the feed rate and to the square of the peripheral speed of the wheel.

The main advantages of rotary atomizers are the following:

- very flexible with respect to feed rate and feed viscosity;
- higher feed solids concentrations can be handled, hence higher product capacity and better economy;
- no fouling or blockage problems;
- high-capacity units available (up to 200 tonnes h^{-1}, although not relevant in the milk powder industry);
- advantageous for abrasive, crystal-containing feeds like precrystallized whey or permeate; and
- different powder properties achievable with different wheel design.

Nozzle atomization

The nozzles used in spray drying are of the centrifugal pressure type, in which pressure energy is converted into kinetic energy of a thin liquid sheet with a partly rotational motion, which causes the spray pattern to be of the 'hollow cone' type.

Pressures in the range of 180–250 bar are used for most dairy products. However, pressures as high as 500–600 bar have been applied occasionally for highly viscous feeds, such as sodium caseinate.

The volumetric flow rate of a nozzle is directly proportional to the square root of the pressure:

$$Q = ANF\sqrt{p} \qquad (1)$$

where Q is the flow rate (m^3 h^{-1}), A the nozzle capacity factor for water, F the 'viscosity factor' (0.9 is used for most milk concentrates), p the nozzle pressure (bar), and N is the number of nozzles.

The effects of operating parameters on the efficiency of nozzle atomization (droplet size) are as follows:

1. higher capacity of nozzles, higher viscosity and surface tension of the feed, and larger orifice diameter (other parameters are constant) will increase the droplet size; and
2. higher pressure and wider spray angle will reduce the droplet size.

The power consumption of the high-pressure pump is directly proportional to the feed rate and nozzle pressure.

The main advantages of nozzle atomization are the following:

1. minimum aeration of the feed during atomization, hence virtually air-free particles and higher particle density. Typical particle densities of whole milk powder with different types of atomization are
   a. straight vane wheel atomization: 1.14 g cm^{-3},
   b. curved vane wheel atomization: 1.18 g cm^{-3},
   c. nozzle atomization: 1.23 g cm^{-3};
2. improved powder flowability;
3. possibility of individual directions of sprays from each nozzle in multinozzle installation, hence improved control of agglomeration; and
4. less fouling of dryers producing 'difficult' products.

The main disadvantages of nozzle atomization are the following:

1. inflexible to variation in throughput, as it affects the nozzle pressure and hence the atomization efficiency;
2. fairly low feed capacity per nozzle, ideally not more than 2000 kg h^{-1} and preferably lower;
3. multinozzle arrangements required for larger plants, resulting in more complicated plant start/stop procedures;
4. fouling with deposited 'milk stone' – particularly at higher feed temperatures – causing a gradual increase in nozzle pressure at a constant throughput; and
5. wear of orifice and swirl chamber/core grooves limiting the lifetime of the components. Depending on the operating conditions and product type, the nozzle insert parts (made of tungsten carbide) should be renewed after 400–800 h of operation.

Mixing of Spray and Drying Air

The air disperser and the atomizing device are the most vital components in a spray dryer. It has been metaphorically claimed that they are 'the lungs and the heart' of a spray dryer. Consequently, the air disperser design has to be in unison with the atomization device and the desired airflow pattern in the drying chamber. Air disperser design and airflow patterns in different types of dryers are discussed elsewhere (*see* **Plant and Equipment**: Milk Dryers: Dryer Design).

In recent years, the development of computerized fluid dynamics (CFD) software and the emergence of required powerful computers have provided a new tool for the study of airflow, temperature profile, and particle paths in spray dryers. Particularly, the newer three-dimensional (3D) CFD software combined with the specific drying characteristics of the product in question has proven to be a very powerful tool in the design of dryers and in troubleshooting. **Figure 1** shows examples of 3D CFD simulations.

Evaporation

Similar to the drying air, the product to be dried (the feed) undergoes dramatic changes in its physical properties during the drying process. Before entering into a more detailed discussion of the actual evaporation process, the definition of certain terms is required.

Properties of air/water vapor mixture

Partial water vapor pressure

Partial water vapor pressure is the pressure the water vapor would exhibit if existing alone in the same volume and at the same temperature. The sum of the partial pressures of all gaseous components is equal to the total pressure of the mixture. The relation between partial pressure, p_w (Pa), absolute humidity, x (kg kg^{-1} water vapor in dry air), and total air pressure, p_{total} (Pa), is

$$p_w = x\frac{p_{\text{total}}}{x + 0.622} \tag{2}$$

Saturated water vapor pressure

Saturated water vapor pressure is the maximum vapor pressure at a given temperature exhibited by air saturated with water vapor. The extended Antoine equation describes the relation between saturated water vapor pressure (Pa) and temperature (°C):

$$P_{\text{sat}} = \exp\Big(72.55 - \frac{7206.7}{T + 273.15} - 7.1385 \times \ln(T + 273.15) + 0.000\,004\,046 \times (T + 273.15)^2\Big) \tag{3}$$

where T is the temperature in °C.

Relative humidity

Relative humidity (RH) is the water vapor content relative to the content at saturation at the same temperature, expressed as %:

$$\text{RH} = \frac{p_w}{p_{\text{sat}}} \times 100 \tag{4}$$

Properties of the humid air can be shown in a humidity chart (or psychrometric chart, Mollier diagram, I-X diagram) (**Figure 2**).

In the diagram, which is valid only for an atmospheric pressure of 1013 hPa, the water vapor content in g kg^{-1} dry air is plotted on the abscissa and the temperature on the ordinate. The parallel, sloped lines are curves of enthalpy in kcal kg^{-1} dry air and finally the curved lines show the RH. By knowing two of the

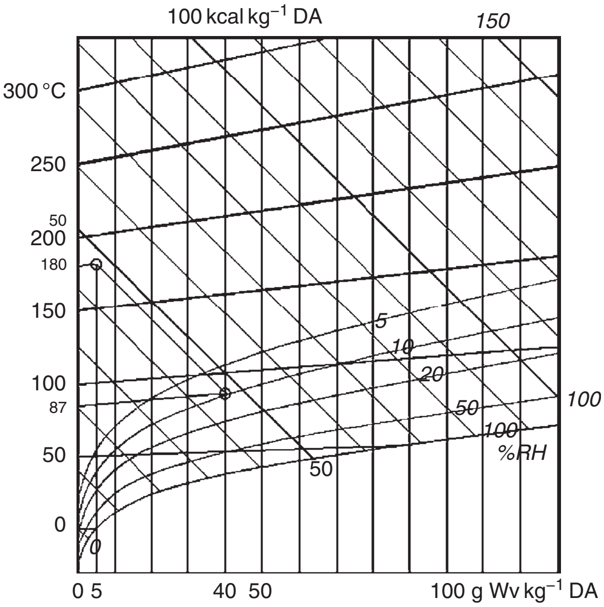

Figure 2 Humidity chart showing a spray drying process. Ambient air with 5 g moisture per kg dry air is heated to 180 °C. It is assumed that adiabatic drying to a relative humidity (RH) of 10% in the exhaust air, which is assumed to give the required final product moisture content, results in an outlet temperature of 87 °C. Wv, water vapor; DA, dry air.

four parameters (for instance, the temperature and RH, which are easily measured), the other two can be found from the diagram.

Common drying terms

The moisture in the feed is present as (1) unbound moisture or (2) bound moisture. The physicochemical properties of the product determine the relation between the two types. Bound moisture is bound to the solids by bonds of different strength. Water of crystallization in α-lactose monohydrate, ionic bonds in minerals and proteins, and hydrogen bonds in proteins and lactose are examples of different bond strengths. Bound water exerts a water vapor pressure lower than that of pure water. A product containing bound water is said to be hygroscopic. In a nonhygroscopic material, all water is unbound.

Equilibrium moisture is the moisture content of the product when it is in equilibrium with the partial water vapor pressure in the surrounding air. Free moisture is the moisture in excess of the equilibrium moisture. A curve showing the relation between moisture content and the RH in the surrounding air at constant temperature is called a sorption isotherm.

Figure 3 shows graphically the relationships between the different terms in an ideal case. In practical spray drying, the equilibrium moisture content is never reached due to variations in temperature and humidity inside the drying chamber and limited residence time.

Properties of the feed

Moisture content and solids content

The moisture content of the feed is most often expressed as % (w/w). The solids content equals 100−moisture content. However, in drying theory, moisture content on dry basis (DB), which is the weight of moisture per unit weight of solids, is often used:

$$\text{moisture content (DB)} = \frac{\text{moisture content (g)}}{\text{solids content (g)}} \tag{5}$$

Water activity (equilibrium relative humidity)

The water activity expresses the moisture content of a product as the RH of the surrounding air with which the product is in equilibrium:

$$a_{\mathrm{w}} = \frac{p_{\mathrm{w}}}{p_{\mathrm{sat}}} \tag{6}$$

Drying

The drying rate and the droplet temperature during drying depend on whether bound or unbound moisture is being evaporated. As long as unbound moisture is available at the droplet surface, the partial water vapor pressure in the interface between particle and air will be near the saturated vapor pressure at the droplet temperature, the drying will proceed at a near-constant rate, and the droplet temperature will be near the wet-bulb temperature. At the critical moisture content, the diffusion of moisture inside the particles is no longer sufficient to maintain saturated conditions on the particle surface. The result is a gradual decrease in vapor pressure and drying rate and a concomitant increase in the droplet temperature. These drying characteristics are shown in **Figure 4**.

It can be seen that the product temperature never reaches the outlet temperature (T-out) from the dryer and that the residual moisture content is higher than the equilibrium moisture content for the reasons mentioned above.

Changes in the state of drying air

The humidity chart is also useful in illustrating the changes that the air undergoes during the spray drying process. **Figure 2** shows an example where the ambient air with an absolute humidity of 5 g kg^{-1} is heated to 180°C. If a change of state of the air during drying takes place without any heat exchange with the surroundings, the enthalpy of the system will not change and hence follow a line parallel to the enthalpy lines, and the change is said to be adiabatic. The drying process shown is assumed to be adiabatic. However, in a real situation in a spray dryer, this is not quite the case. Heat will be added to the system with the warm concentrate ($T \neq 0$°C), but on the other hand, heat is also removed from the system

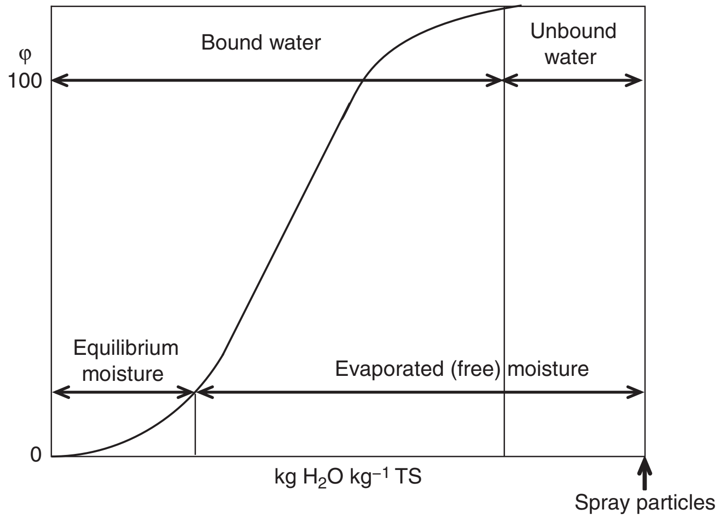

Figure 3 Sorption isotherm and common drying terms.

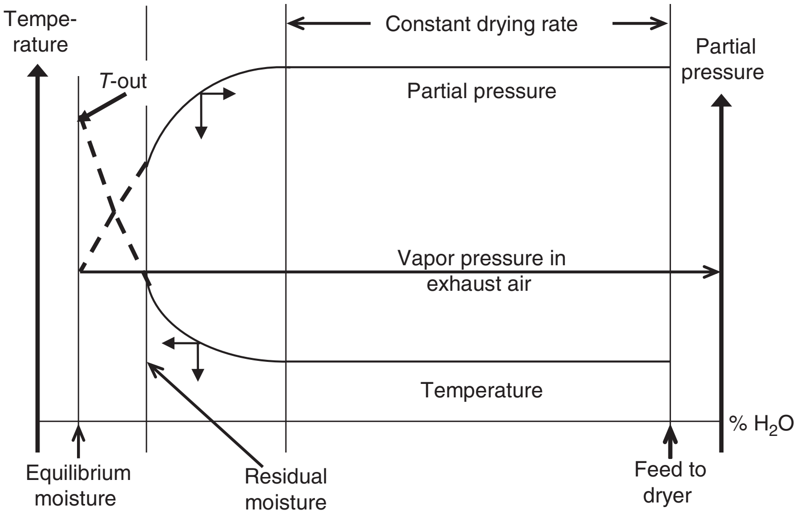

Figure 4 Temperature and vapor pressur vs. moisture content during drying.

by transmission loss and with the warm powder leaving the dryer. It is assumed that an RH in the exhaust air of 10% results in the required powder moisture content, which corresponds to a *T*-out of 87°C.

Any additional airflow to the dryer, such as air disperser and atomizer cooling air or integrated fluid bed air, will also have an effect, but for the situation in a conventional dryer, the adiabatic change as shown in **Figure 2** is a reasonable approximation.

If the drying air rate of a plant is known, the evaporative capacity can be estimated under any given drying conditions (ambient humidity, inlet and outlet temperature). In the example in **Figure 2**, the ambient humidity is 5 g kg^{-1} dry air and the outlet air humidity is 40 g kg^{-1}, that is, the evaporation is 35 g kg^{-1} dry air, which multiplied by the air rate yields the evaporative capacity of the plant. Likewise, the heat input required to increase the temperature from ambient, say 20°C, to the inlet temperature (*T*-in) can be read. The enthalpy of air at 20°C and absolute moisture content of 5 g kg^{-1} dry air is approximately 8 kcal kg^{-1} dry air. After heating to 180°C, the enthalpy is approximately 47 kcal kg^{-1} dry air, that is, a heat input of $47-8=39$ kcal kg^{-1} dry air is required. It can further be calculated that the specific heat consumption is $35/39 \times 1000 \sim 1115$ kcal kg^{-1} water evaporation.

Change of state of droplets

When pure water is dried, the water droplets will reach the wet-bulb temperature in the initial stage of drying. However, the presence of dissolved and/or dispersed solids in the droplets causes the water activity (a_w) of the drying product to decrease as drying proceeds. The driving force in the drying process is the difference between the partial vapor pressure in the droplet/air interface and the partial vapor pressure in the surrounding air or (roughly) between a_w of the product and the RH of the drying air. Any decrease in a_w of the particles or increase in RH of the drying air will reduce the driving force.

The relation between a_w (or equilibrium RH) and moisture content at constant temperature is called a sorption isotherm. As hysteresis effects are quite common, it is important to differentiate between absorption and desorption isotherms in connection with drying. A typical shape of a sorption isotherm is shown in **Figure 3**.

In practice, the minimum outlet temperature from a spray dryer (the highest RH of the outlet air), and the highest capacity and best drying economy without getting excessive deposits, depends mainly on the corresponding a_w. If the particle and gas residence time were infinite, equilibrium between the product and drying air would be reached. However, this is obviously not the case and the outlet air RH must be kept well below the product a_w to achieve the desired powder moisture content and achieve trouble-free dryer operation. In **Figure 2**, it can be seen that the RH at a given absolute humidity is highly dependent on temperature, so the lower RH is achieved by operating at increased outlet temperatures.

The outlet temperature is a very important process parameter, and to cope with smaller changes in other key parameters and still maintain constant product moisture content, the following guideline can be given:

$$\Delta T\text{-out} = \frac{\Delta T\text{-in}}{10} + \Delta\%\text{TS} + \frac{\Delta x\text{-amb}}{2.8} - K\Delta \text{H}_2\text{O} \quad (7)$$

whereΔT-out is the required change in outlet temperature, ΔT-in is the change in inlet temperature, Δ%TS is the change in percent total solids in the concentrate, Δx-amb is the change in ambient humidity in g kg^{-1} dry air, K is a product-dependent factor, which is about 5 for skimmed milk powder and 6 for whole milk powder, and ΔH_2O is the change in powder moisture content. It can be seen that an increase in T-in of 10°C, an increase in %TS of 1%, and an increase in absolute humidity of $2.8\,\text{g kg}^{-1}$ should be compensated for with an increased T-out of 1°C.

Fluid Bed Drying

A fluid bed is basically a box, divided by a perforated air distributor plate into a lower clean air plenum section and an upper product section. Different types of fluid beds are used:

- back-mix or plug-flow fluid beds;
- stationary or vibrated fluid beds; and
- external fluid beds or fluid beds integrated in the drying chamber.

Stationary plug-flow beds are used for products that are easily fluidizable at the inlet conditions of the bed. On the other hand, back-mix beds are used for products that are not directly fluidizable, but may be so when mixed and conditioned with the (partly) dry powder already present in the fluid bed.

Fluid bed design and technology will be discussed elsewhere (*see* **Plant and Equipment**: Milk Dryers: Dryer Design).

Originally, the external, vibrating plug-flow fluid beds were implemented for cooling purposes only, but the advantages of using them for the drying of the last amount of moisture as well were soon realized. When the drying takes place in one stage in the drying chamber, the outlet temperature has to be kept fairly high to maintain the required driving force to achieve the desired final moisture content during the fairly short residence time (10–30 s) in the drying chamber. The residence time in fluid beds is typically in the range of 10–20 min, thus allowing the time-dependent diffusion of moisture to the particle surfaces to take place.

Stickiness and Glass Transition

Powder buildup on drying chamber walls is a well-known phenomenon, caused by certain product properties described with terms such as stickiness or thermoplasticity.

Thermoplasticity is a very descriptive term that implies that the product plasticizes at elevated temperatures. It is well known that increased powder moisture increases the stickiness of the products. The relation between powder moisture and T-out, influenced by other drying parameters as well, is shown in eqn [7]. It shows that increased T-in or %TS – changes that increase the plant capacity – will result in increased powder moisture content and potentially in powder buildup if not compensated for by T-out. Increased ambient air humidity will have the same effect. However, T-out can only be increased within limits, partly for product quality reasons, but also because the powder particles become sticky at a certain T-out due to thermoplastic behavior, even though the moisture content may be quite low. This phenomenon is shown in **Figure 5**. It should be emphasized that the sticking curve is a product property that depends on product composition, whereas the T-out–moisture relation (and hence T-particle–moisture relation)

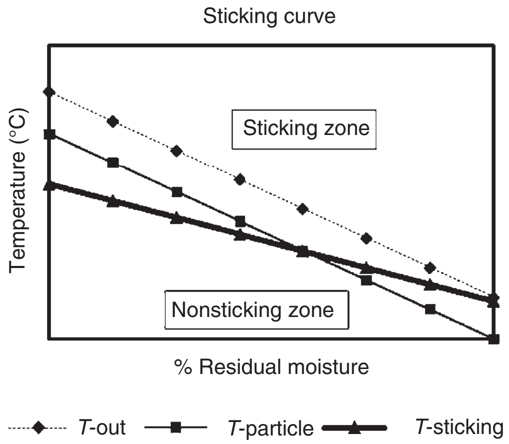

Figure 5 Empirical sticking curve. Relationship between moisture content, outlet air temperature, particle temperature, and the sticking point temperature.

depends on product properties (composition) as well as drying conditions (*T*-in, %TS, etc.).

The sticking curve approach described above is a rather empirical one. The use of the glass transition concept in the last decade has formed a more theoretical basis for understanding the phenomena.

A glass is an amorphous, high-viscous liquid in a non-equilibrium state, exhibiting the mechanical properties of a solid, but with structural characteristics of a liquid, that is, contrary to the crystalline state, a glass is without any ordered molecular arrangement.

Due to the non-equilibrium state, a glass is thermodynamically unstable and can undergo phase transitions. The glass transition in amorphous systems is a reversible change in the physical state from a mechanically solid glass to a viscoelastic, rubbery state, which takes place at the characteristic glass transition temperature, T_g. T_g of a product depends on the product composition and in particular on the presence of plasticizers, of which water is very potent, that is the T_g declines drastically at increased moisture content.

In spray-dried milk powders, the lactose is usually in an amorphous state because the drying took place so fast that there was no time for the molecular ordering required for crystallization of the lactose. Hence milk powders exhibit glass transition. Although the glass transition temperature of a milk powder is not identical to the 'sticking temperature', defined as the temperature at which powder buildup in dryers may occur, there is still a relation between T_g and the sticking temperature. Indications are that the 'sticking' temperature is about 20–25°C above the T_g.

Glass transition is accompanied by measurable physical changes in viscosity, heat capacity, and other properties. The change in heat capacity can be measured by differential scanning calorimetry.

Models describing T_g in binary systems (one component and a plasticizer) are available. The Gordon–Taylor model [8] has been used extensively, being a generalization of the Couchman–Karasz equation [9].

$$T_g = \frac{w_1 T_{g1} + k w_2 T_{g2}}{w_1 + k w_2} \tag{8}$$

$$T_g = \frac{w_1 \Delta C_{p1} T_{g1} + w_2 \Delta C_{p2} T_{g2}}{w_1 + w_2 \Delta C_{p2}} \tag{9}$$

where w_i is the weight fraction of component i, T_{gi} the glass transition temperature of component i, k is the softening constant, and ΔC_{pi} the specific heat change of component i across the glass transition.

Table 2 shows the glass transition temperature of some food components. It can be seen that lower molecular weight carbohydrates exhibit lower T_g (monosaccharides < disaccharides, and the higher the DE (dextrose equivalent) of maltodextrins, the lower the T_g). The high T_g of starch and low-DE maltodextrins explains why these components are good 'carriers' for more difficult components in spray drying. The extremely low T_g of lactic acid also explains the difficulties of drying acid whey.

Although the relation between a_w of milk powders and T_g is essentially sigmoidal, it has been found to be almost linear in the a_w range of 0.2–0.65,

$$T_g = -143.6 a_w + 77.8 \tag{10}$$

Knowledge of the parameters in eqn [7] for a given product and drying process together with knowledge of the corresponding desorption isotherm and the glass transition temperature as a function of a_w can be very helpful in defining optimized but still safe drying conditions.

Table 2 Glass transition temperature of different food components

Component	T_g *(°C)*

Introduction

This article focuses on spray dryers. Although other means of drying are possible, this is by far the most common in the dairy industry.

By definition, spray drying is the transformation of a product from a fluid state into a dried form by spraying the liquid feed into a hot drying medium. The feed can be a solution, a suspension, or a paste, depending on the characteristics of the dairy product to be dried. The dried product is a powder consisting of single particles or agglomerates, all depending on the chemical composition and physical properties of the feed as well as on dryer design and operation.

Drying Principles

A spray dryer operates in the following way:

The feed is pumped from the product feed tank to the atomizing device that is situated in the air disperser at the top of the drying chamber. The drying air is drawn from the atmosphere via a filter by a supply fan and is passed through the air heater to the air disperser. As the atomized droplets meet the hot air, evaporation takes place cooling the air at the same time. After the drying of the atomized feed in the chamber, the majority of the dried product falls to the bottom for further processing. The fines, which are the particles with a small diameter, will remain entrained in the air. Therefore, the air has to pass through powder collectors like cyclones or bag filters. The air passes from the powder collector to the atmosphere via the exhaust fan. The two fractions of powder are collected, for example, in a pneumatic system for conveying and cooling. After separation in a cyclone, the powder is bagged off.

A conventional spray dryer consists of the following main components (**Figure 1**):

1. Drying chamber
2. Hot air system and air distribution
3. Feed system
4. Atomizing device
5. Powder separation system
6. Pneumatic conveying and cooling system
7. Integrated fluid bed
8. Fluid bed after-dryer/cooler

Drying Chamber

Various designs of the drying chamber are available on the market. The most common one is a cylindrical chamber with a cone of 40–60°, enabling the powder to leave the chamber by gravity. The chamber is also found with a flat bottom in which case a scraper or suction device is needed for removing the powder fraction from the chamber. Horizontal box-type drying chambers are also used, and they, too, operate with a forced (i.e., scraper or screw) powder removal system (**Figure 2**).

Generally, it can be concluded that chambers with a cone for gravity discharge of the powder give the best flexibility for adapting various drying processes like integrated fluid beds or belts to the plant and therefore offer the greatest possibility for drying different products. The tendency in modern designs of drying chamber is to avoid any object inside the chamber that can obstruct the air flow.

In the chamber of the TALL FORM™, the emphasis has been put on designing a plant with a laminar air flow and a special air outlet system, where the diameter of the cone is bigger than the diameter of the cylindrical part thus forming a ring duct termed 'bustle'. This minimizes the cyclone fraction by the low velocity of the exhaust air. This chamber is especially suited for infant milk formulae or protein products dried from low-solid content feed.

The drying chamber should always be equipped with inspection doors and overpressure vents to withstand a pressure of 1.6 mbar(g). Other safety equipment such as fire extinguishing equipment in the form of water or steam nozzles is always standard in a modern dryer.

Drying chambers are usually insulated, either with removable air-filled sandwich panels (see **Figure 3**) or with 80–100 mm mineral wool covered with a stainless-steel plate. The advantage of the removable panels is that inspection for cracks in the chamber wall is possible. Furthermore, the risk of having wet insulation material, which can foster bacterial development or cold spots on the chamber wall, is eliminated.

Integrated Static Fluid Bed

In an attempt to improve the drying efficiency, a static fluid bed is integrated in the drying chamber. The secondary drying air, typically 25% of the main drying air, is introduced into a plenum chamber below a perforated plate, through which the drying air is distributed. This type of dryer can be operated in such a way that the primary particles reach a moisture level higher than that obtained by using the VIBRO-FLUIDIZER™.

A specially designed and patented perforated plate, the BUBBLE PLATE™ (see **Figure 4**), provides an air–powder mixture that ensures optimal drying without attrition and powder penetration into the clean-air plenum. Furthermore, the BUBBLE PLATE™ has a more sanitary finish than the other types of perforated plates.

The static fluid bed is available in two configurations:

- Ring-formed fluid bed (compact drying chamber)
- Circular fluid bed (multistage drying (MSD) chamber)

Ring-formed fluid bed (compact drying chamber)

The ring-formed back-mix bed is placed at the bottom of a conventional chamber cone around the exhaust duct placed in the center. The powder is discharged continuously from the static fluid bed by overflowing an adjustable powder weir, thus maintaining a certain level of fluidized powder. When the powder leaves the drying chamber it may be cooled in a pneumatic conveying or VIBRO-FLUIDIZER™ system. The resulting powder will consist of single particles.

For fat-containing products, cooling should be done in a vibrating fluid bed that is also used when agglomerated powders are produced. In this case, the cyclone fraction is returned to the atomizer device for agglomeration (see **Figure 5**).

Circular fluid bed (multistage drying (MSD™) chamber)

To improve the dryer efficiency and the powder properties even further, the multistage dryer MSD™ has been designed (see **Figure 6**).

The dryer operates with three drying stages, each adapted to the moisture content prevailing during the drying process. In the preliminary drying stage, the concentrate is atomized by co-current nozzles or a rotary atomizer placed in the hot-drying air duct. Air enters the dryer vertically through the air disperser, ensuring optimal mixing of the atomized droplets with the drying air. The particles reach a moisture content of 6–15%, depending upon the type of product. The fluid bed is supplied with air at a sufficient velocity and temperature for the second-stage drying. The drying air from the preliminary drying stage and the integrated fluid bed leaves the chamber from the top passing through powder separators.

This type of dryer offers a perfect choice if the aim is to produce an agglomerated product. Owing to the velocity of the primary drying air, a venturi is formed around the atomizing device, thus sucking in secondary air with powder entrained so that agglomeration is facilitated, that is, attrition between the primary spray particles and the fines powder.

When the powder has reached a certain moisture content it is discharged via a rotary valve into a VIBRO-FLUIDIZER™ for the final drying and subsequent cooling.

The powder exhibits a coarse powder structure originating from the natural agglomeration taking place in the chamber.

Hot Air System and Air Distribution

Air Filtration System

Until a few years ago, no special requirements were placed on filtration of the process air for the spray drying process. Today, however, very strict requirements are presented by local authorities to ensure a cleaner

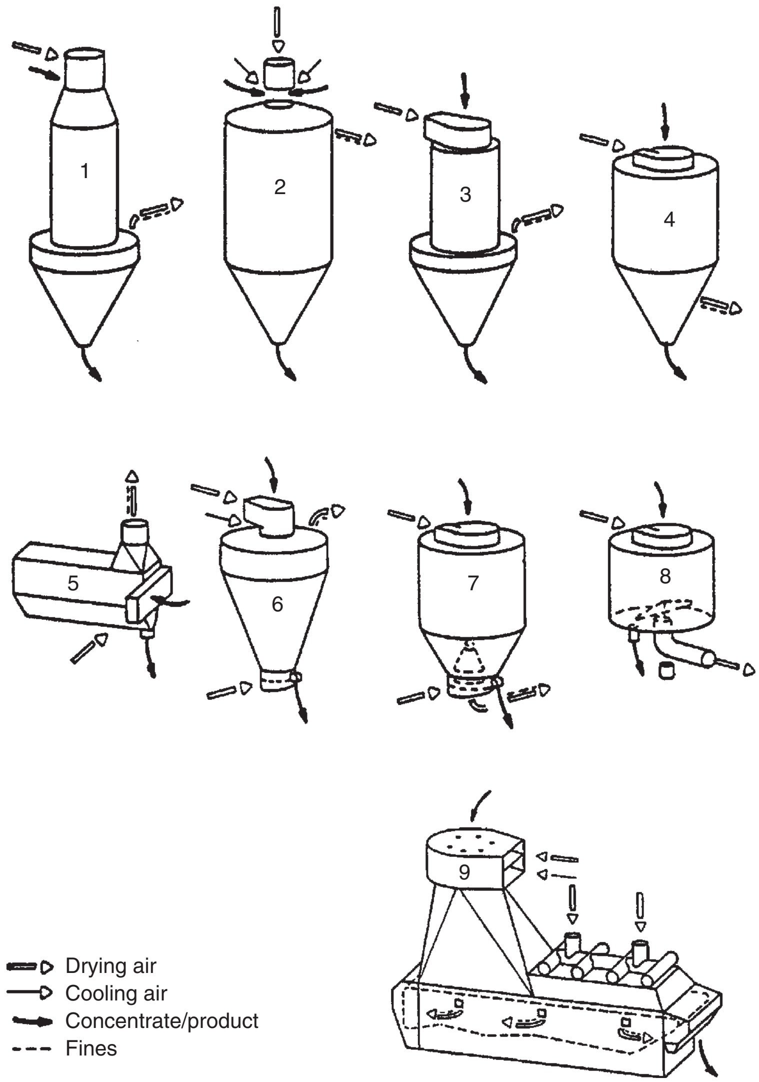

Figure 2 Different types of drying chambers. 1, TALL FORM™ dryer type seen in Japan. It is equipped with a low-velocity air disperser, and, although it is used for milk, it is not very suitable for this product; 2, TALL FORM™ dryer with high-temperature primary drying air. Secondary air is sucked into the drying chamber during the drying operation. The 'mix' air temperature is similar to that of a normal spray dryer; 3, Conventional TALL FORM DRYER™ chamber used predominantly for baby food and protein products; 4, Conventional drying chamber with conical bottom; 5, Box dryer for one-stage drying only – poor economy and normally seen only in the United States; 6, Multistage MSD™ drying chamber with integrated fluid bed; 7, Conventional COMPACT™ drying chamber with integrated fluid bed; 8, Flat-bottom spray drying chamber for one-stage drying only. No longer seen on new installations; 9, FILTERMAT® drying chamber in a special design for very sticky products.

operation and a higher level of food safety. Common for the different standards are as follows:

- The air should be prefiltered and supplied by a separate fan to the fan/filter/heater room, which must be under pressure to avoid the entry of unfiltered air (**Figure 7**). As an alternative to a fan room, complete ducting of all air flows is fully acceptable.
- Filtration degree and filter position depend on the final temperature of the process air as follows:
  - For air to be heated above 120 °C only coarse filtration up to 90% (filter class EU7/F7) is needed. The filter should be placed on the pressure side of the fan.
  - For air to be heated below 120 °C or not heated at all, the filtration must be 95% (filter class EU/F9) or above, and the filter must be placed after the heater/cooler. Some countries and companies have even stricter requirements demanding a filtration of up to 99.995% (filter class EU13-14/ H13-14).

Air Heating System

The drying air can be heated in different ways: indirect (steam/oil/gas/hot oil/electricity) or direct (gas).

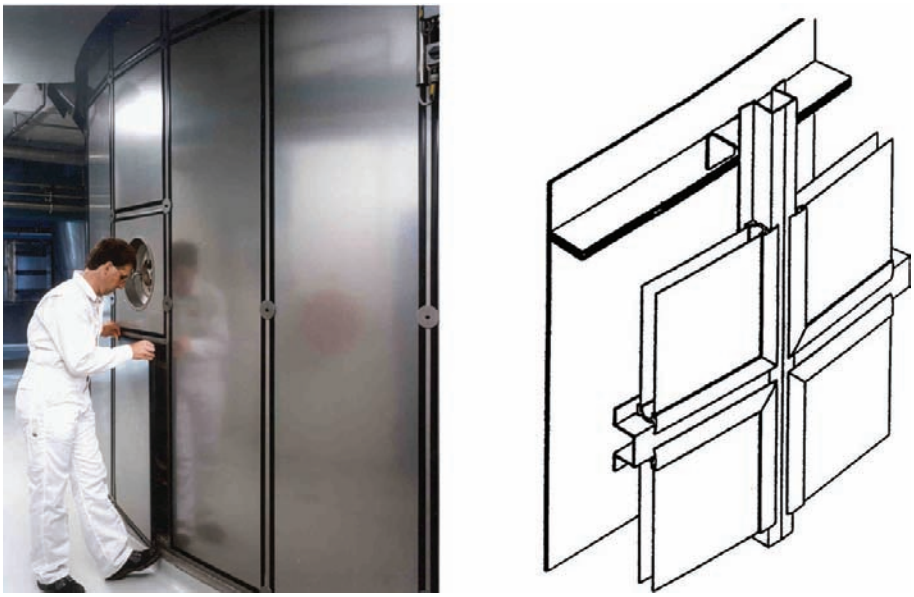

Figure 3 Removable insulation panels for spray drying chambers.

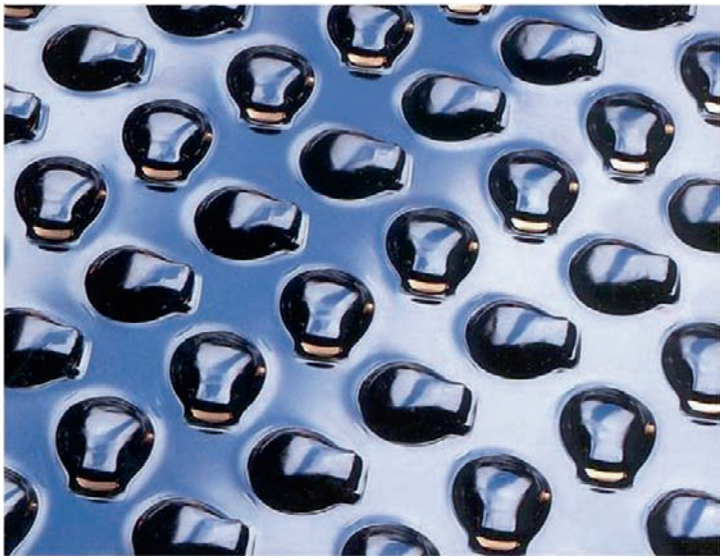

Figure 4 BUBBLE PLATE™.

Indirect heating

A steam heater is a simple radiator. The temperature to be obtained depends on the steam pressure available. The air heater consists of rows of finned tubes housed in an insulated metal case. The heat load is calculated from the quantity and specific heat of the air. The heater size depends on the heat transfer properties of the tubes and fins and is usually about $50\,\mathrm{kcal}\,{}^{\circ}\mathrm{C}^{-1}\,\mathrm{h}^{-1}\,\mathrm{m}^{-3}$ for an air velocity of $5\,\mathrm{m\,s}^{-1}$. To avoid corrosion of the tubes in the air heater, use of stainless-steel tubes is recommended.

In indirect oil and gas heaters, drying air and combustion gases have separate flow passages. The combustion gases pass through galvanized tubes, which act as the heat transfer surface for the drying air. The combustion chamber is made of heat-resistant steel. Heaters of this type will have an efficiency of about 85% in the range of 175–250 °C (see **Figure 8**).

Hot oil liquid phase air heaters are used either alone or to boost the inlet drying air temperature when the steam pressure is not high enough. The heater system consists of a heater, which can be gas- or oil-fired, and an air heat exchanger. Between these two components, a special food-grade oil or heat transfer fluid, which does not crack at high temperatures, is circulated at high speed.

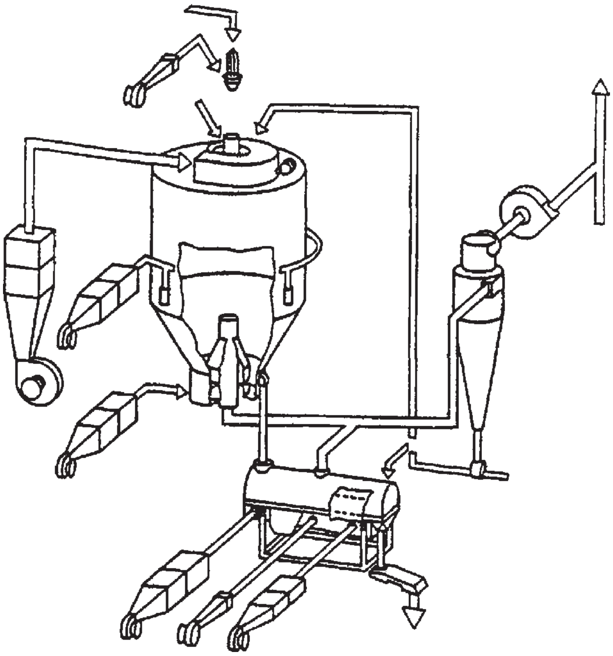

Figure 5 Compact spray dryer with VIBRO-FLUIDIZER™ as agglomerator/instantizer (CDI).

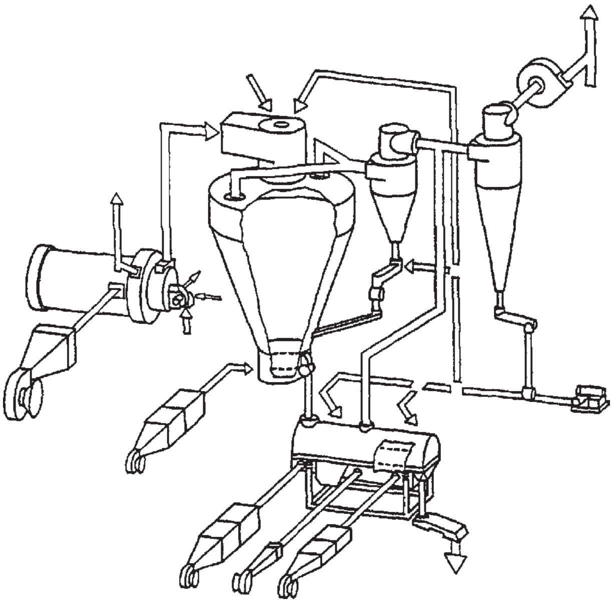

Figure 6 Multistage spray dryer (MSD).

The main advantage of a hot oil liquid phase heater is that it is an open, pressureless system.

Electrical air heaters have for many years been used mainly for laboratory and pilot plant spray dryers. This heater has low investment costs, but previously the operation costs were considered to be too high for commercial production. However, as the price of electricity in certain parts of the world can be very low during off-peak periods, it is becoming more common to use electrical heaters as boosters instead of, for example, hot oil liquid phase air heaters.

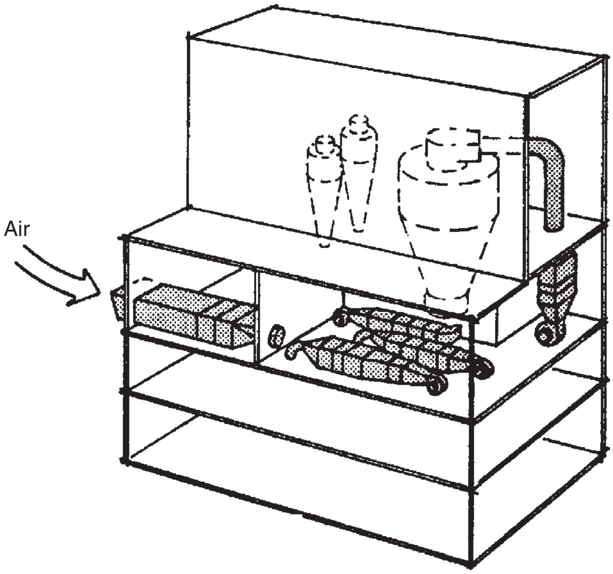

Figure 7 Filtration of process air.

Direct heating

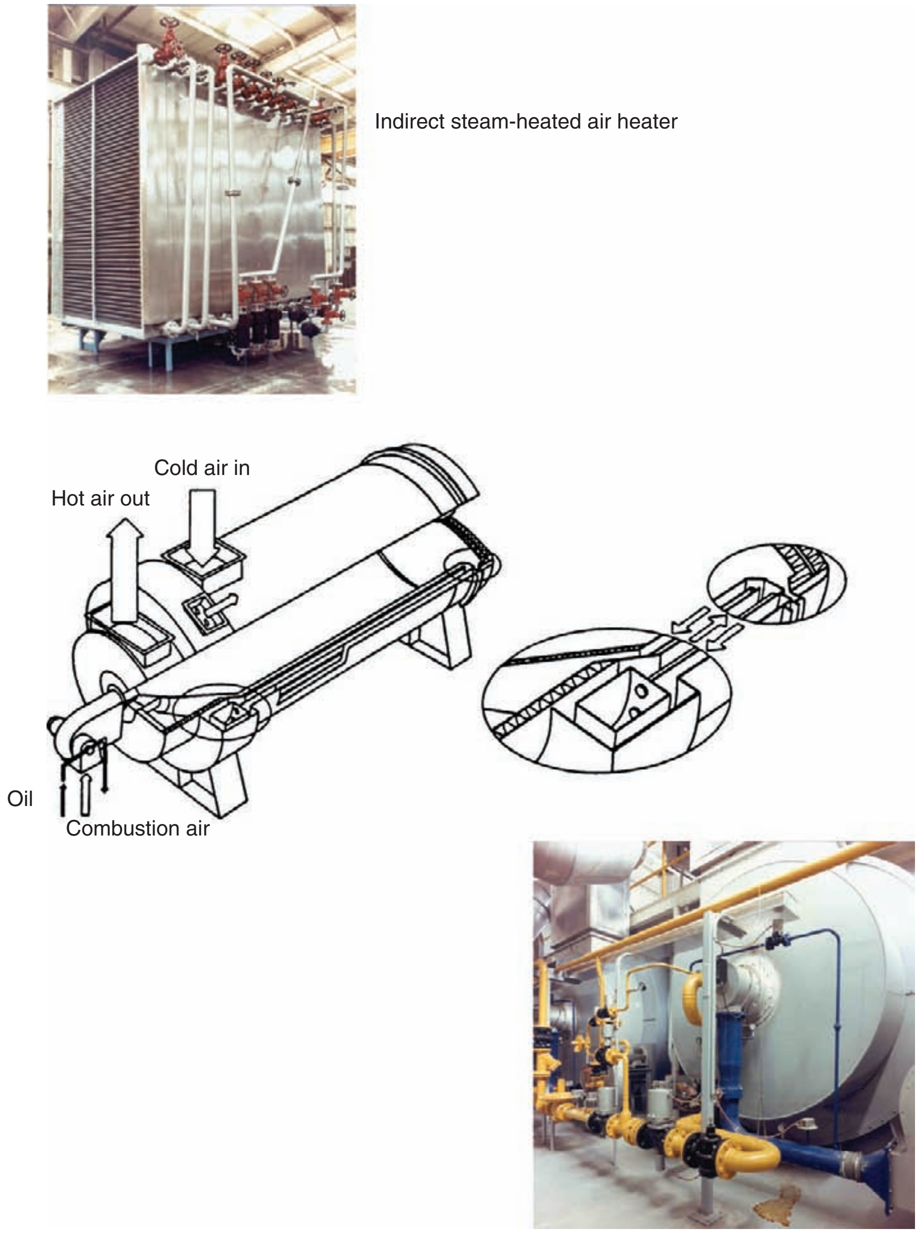
Direct gas heaters are used only when the combustion gas can be allowed to come into contact with the product. They are, therefore, not common in the dairy industry. Direct gas heaters are inexpensive, they have a high efficiency, and the obtainable temperature can be as high as 2000 °C. When a plant is designed with an air heater with direct combustion, it is necessary to calculate the amount of vapor resulting from the combustion (44 mg kg^{-1} dry air °C^{-1}), as this will increase the humidity of the drying air. The outlet temperature has therefore to be increased to compensate for this increase in humidity and to maintain the relative humidity.

The heater system can be designed with separate heaters for each consumption point or with fewer heaters, of which some supply two or more consumption points. By mixing warm air from the main air heater with cold air, the entire dryer can be run with only one heater.

Air Distribution System

Drying-air distribution is one of the most vital functions in a spray dryer. There are various systems depending on the plant design and the type of product.

The most common system is where the air disperser is situated on top of the dryer ceiling, and the atomizing device is placed in the middle of the air disperser, thus ensuring an optimal mixing of the air and the atomized droplets. In cylindrical vertical dryers, the whole ceiling may be perforated, thus creating a plug-flow air stream – numerous nozzles are situated in the perforated plate to



Indirect steam-heated air heater

Hot air out
Oil
Combustion air

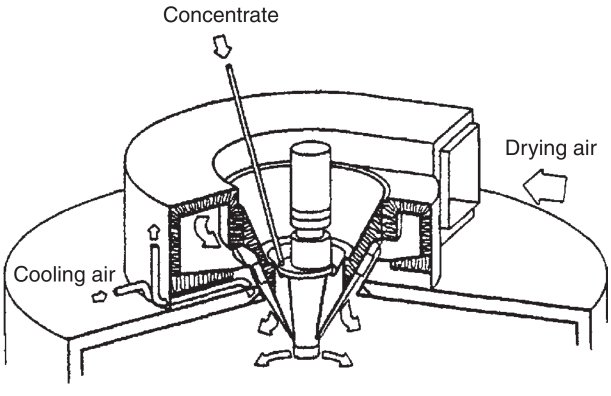
Figure 8 Indirect air heaters.

ensure that the air is cooled by the concentrate. This system, however, operates with a low air velocity, and it makes fines return complicated. It is therefore not suitable for all dairy products. It should be noted that an air disperser should have the ability to guide the air and the atomized droplets in the right direction to avoid deposits in the drying chamber.

Two different types of air dispersers are currently used in spray dryers for food and dairy products:

Rotary air stream

The air enters tangentially into a spiral-shaped distributor housing (see **Figure 9**), from where the drying air is



Concentrate
Drying air
Cooling air

Figure 9 Ceiling air disperser with adjustable guide vanes.

led radially and downward over a set of guide vanes provided for adjustment of air rotation. This type of air disperser is used for rotary atomizers and nozzle atomizers placed in the center of the air disperser and is used in conventional drying chambers.

Plug flow air stream

The air enters radially through one side (see **Figure 10**) and is distributed through a specially designed air guiding arrangement, which ensures a uniform air flow pattern in the entire air disperser area. This enables a very precise, laminar, high-velocity plug flow, which is required in TALL FORM™ dryers or multistage dryers.

This type of air disperser is used for nozzle atomizers only, and has excellent possibilities for nozzle position adjustment and thereby the adjustment of agglomeration structure.

Feed System

The feed system (see **Figure 11**) is the link between the evaporator and the spray dryer, and comprises the following:

1. Feed tanks
2. Water tank
3. Concentrate pump
4. Preheating system
5. Filter
6. Homogenizer/high-pressure pump
7. Feed line, including return line for cleaning-in-place (CIP)

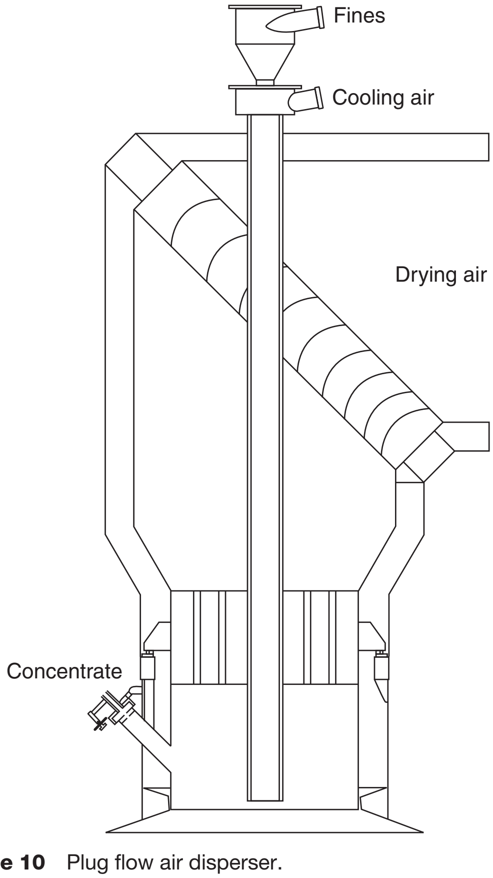


Figure 10 Plug flow air disperser.

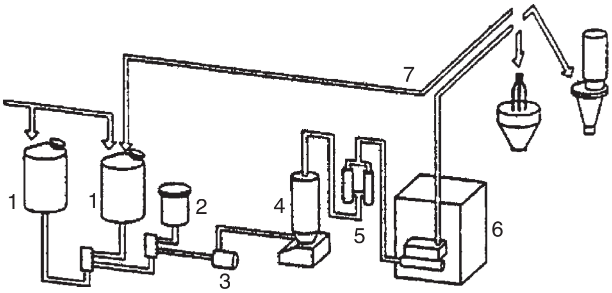

Figure 11 Feed system. 1, Feed tanks; 2, Water tank; 3, Concentrate pump; 4, Preheating system; 5, Filter; 6, Homogenizer/high-pressure pump; 7, Feed line, including return line for CIP.

Feed Tanks

If feed tanks are used, the use of two tanks is recommended so as to change from one to the other at least once an hour to avoid the risk of bacteria growth. One is therefore in use while the other one is being cleaned. The size of each tank should correspond to 15–30 min of the feed capacity of the dryer. The feed tanks are very often omitted, and the last-stage evaporator is designed as a buffer tank under vacuum. The evaporator then operates as a 'slave' to the dryer, because the level switches in the evaporator buffer tank control the inlet feed to the evaporator.

Water Tank

The water tank is used during the start and stop of the plant, and during the run if there is a sudden shortage of concentrate. It is used only when the evaporator is used as a buffer tank. As an alternative, a direct water supply to the feed line is often used.

Concentrate Pump

If a rotary atomizer is used, the most common feed pump is the mono type, as it has lower energy consumption and can handle concentrates of high viscosity. In plants equipped with homogenizers for the production of whole milk powder, the homogenizer is used as a feed pump. In plants equipped with high-pressure nozzles, a high-pressure pump is used – often combined with a homogenizer.

Preheating System

Preheating of the concentrate to a higher temperature than that coming from the evaporator is advantageous, not only from a bacteriological point of view. It also produces a decrease in viscosity, which together with the applied calories results in a capacity increase of the spray dryer and an improved solubility of the powder produced.

The heating can be either indirect or direct. Indirect preheaters may be of the following types:

1. Spiral-tube heat exchanger
2. Plate heat exchanger
3. Scraped-surface heat exchanger

Spiral-tube heat exchanger

The spiral-tube heater (see **Figure 12**), often with corrugated tubes, is able to heat a concentrate with high solid content to a higher temperature without frequent scaling and cleaning owing to high product velocity and a low ΔT throughout the heater. Furthermore, this type of heater has no moving parts; hence, maintenance costs are minimized.

Plate heat exchanger

A plate heat exchanger system is inexpensive, but if the concentrate should be heated to >70 °C, if the solid content is >46%, or if a 20 h run is aimed at, it is necessary to have two interchangeable heaters allowing one to be cleaned while the other is being used. Steam or warm water can be used as the heating medium.

Scraped-surface heat exchanger

In the scraped-surface heater, the heat transfer surface is continuously scraped off by a fast-rotating scraper made of food-grade synthetic material to avoid any product adherence. The scraped-surface heater is especially suitable for products with high solid content and when high temperatures are required. They can operate continuously for 20 h and are cleaned together with the remaining feed system. The disadvantages are high cost of maintenance as well as big variation in holding time.

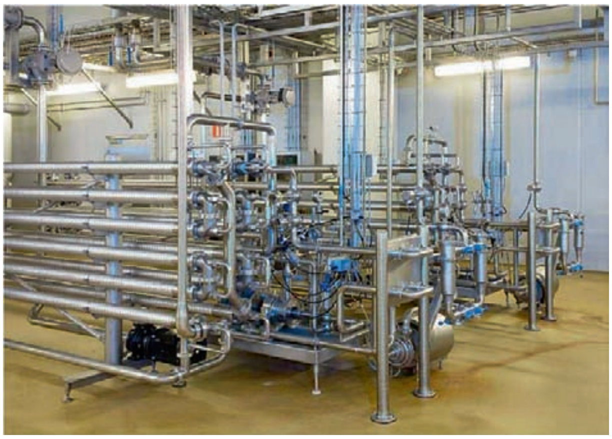

Figure 12 Spiral-tube heat exchanger.

Direct preheaters may be of the following types:

- Direct steam injection (DSI)
- Lenient steam injection (LSI)

Direct steam injection

In the DSI unit, steam is introduced into the milk concentrate via a nozzle, producing relatively big steam bubbles resulting in a superheating of some parts of the concentrate, which leads to protein denaturation.

Lenient steam injection

In the LSI unit, steam is mixed into the concentrate by a dynamic mixer. Very small steam bubbles are created, and superheating/denaturation is avoided. Therefore, a much higher steam pressure can be used. The LSI unit can be used in combination with the spiral-tube heat exchanger if temperatures above 80 °C are required in the concentrate.

Filter

An in-line filter is always incorporated in the feed system after the heater to avoid lumps, etc., passing to the atomizing device.

Homogenizer/High-Pressure Pump

If whole milk powder is to be produced, it is recommended that a homogenizer be incorporated to reduce the free-fat content in the final powder. A two-stage homogenizer is preferred; the first stage is operated at 50–100 bar g, and the second stage at 25–50 bar g.

Usually the homogenizer and feed pump are combined in one unit. If nozzle atomization is used, then a higher pressure (up to 250 bar g for the nozzles + 150 bar g for homogenizing) is required, and a combined homogenizer/high-pressure pump is chosen.

Temperatures of ≥80 °C are needed to produce a whole milk powder with a good coffee stability. In view of calcium phosphate precipitation – which is abrasive – the pistons should be made of a ceramic material.

Feed Line

The feed pipe should be of stainless steel and, of course, of the high-pressure type if atomization is to be carried out by means of nozzles. The dimensions of the pipe should be such that the feed velocity is $\geq 1.5\,\mathrm{m\,s^{-1}}$. In a feed system, a return pipe should also be included for the cleaning solution, so that the entire equipment can be cleaned thoroughly.

Atomizing Device

The aim of atomizing the concentrate is to provide a very large surface from which evaporation can take place. The smaller the droplets, the bigger the surface and the easier the evaporation; and thus a better thermal efficiency of the dryer is obtained. The ideal from the point of view of drying would be a spray of drops of the same size, which would mean that the drying time for all particles would be the same to obtain an equal moisture content.

As mentioned previously, air distribution and atomization are the factors key to the successful utilization of the spray dryer. Atomization is directly responsible for many distinctive advantages offered by spray drying: First, the very short drying time of the particles; second, a very short particle retention time in the hot atmosphere and a low particle temperature (wet bulb temperature); and, finally, the transformation of the liquid feed into a powder with long-storage stability ready for packing and transport.

In summary, the primary functions of atomization are

- to create a high surface-to-mass ratio resulting in a high evaporation rate
- to create particles of the desired shape, size, and density

To comply with these requirements many atomization techniques have been used in spray dryers. However, the most common ones can be summarized as follows:

- pressure nozzles using pressure forces
- two-fluid nozzles using kinetic forces
- rotating discs using centrifugal forces

Pressure Nozzle Atomization

The basic function of pressure nozzles is to convert the pressure energy supplied by the high-pressure pump into kinetic energy in the form of a thin film, the stability of which is determined by the properties of the liquid such as viscosity, surface tension, density, and quantity per unit of time, and by the medium into which the liquid is sprayed.

Most of the commercially available pressure nozzles are designed with a swirl chamber giving the liquid a rotation, so that it will leave the orifice as a hollow cone (see **Figure 13**). Capacity can usually be assumed to be directly proportional to the square root of pressure retain:

$$\text{Capacity } (\text{kg h}^{-1}) = K \times \sqrt{P}$$

As a rule of thumb, higher viscosity, liquid density, and surface tension, and lower pressure will result in bigger particles. Typically, a feed rate of 1000–1500 kg h^{-1} per nozzle is used in industrial dryers. The advantages when using high-pressure nozzles are as follows:

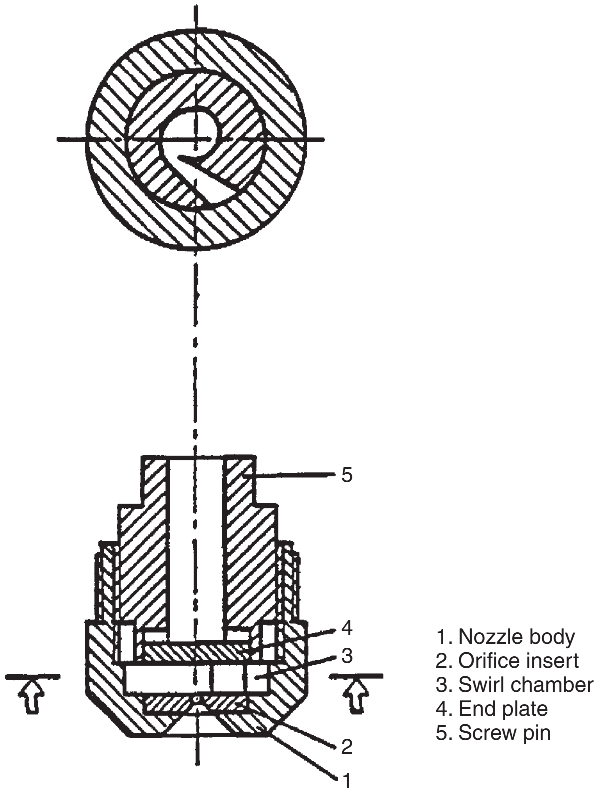

Figure 13 High-pressure nozzle ‘Delavan’.

- Powder with a low level of occluded air
- Powder with a high bulk density
- Improved flowability, especially for whole milk
- Tendency to form less deposits in the drying chamber when difficult products are produced
- Ability to produce big particles

Two-fluid nozzle or pneumatic atomization

The energy available for atomization in two-fluid atomizers is independent of liquid flow and pressure. The necessary energy (kinetic) is supplied by compressed air. Two-fluid atomization is the only successful nozzle method for producing very small particles, especially from highly viscous liquids. It is not normally used in the drying of milk products. However, it is often used in secondary systems such as lecithin application to the powder.

Rotary atomization

In rotary atomizers the liquid is accelerated continuously to the wheel’s edge by the centrifugal forces produced by the rotation of the wheel. The liquid is distributed centrally, then extended over the wheel surface in a thin sheet and discharged at a high speed at the periphery of

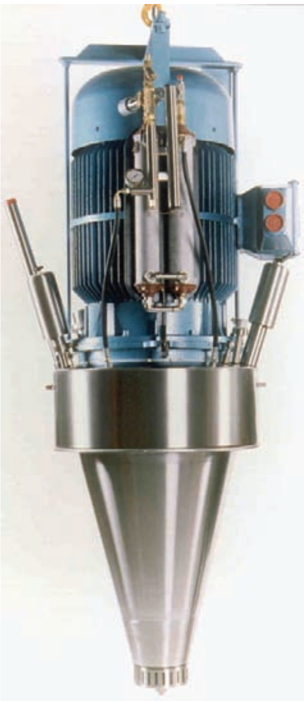

Figure 14 Rotary atomizer with direct drive.

the wheel. The degree of atomization depends upon peripheral speed, properties of the liquid, and feed rate (**Figure 14**).

To select an optimal atomizer wheel, the following factors should be taken into consideration:

Liquid feed rate

Droplet size varies directly with feed rate at a constant wheel speed and will increase with increased feed rate.

Peripheral speed

The peripheral speed depends on the diameter of the wheel and the wheel speed, and is calculated as follows:

$$V_\mathrm{p} = \frac{\pi \times D \times N}{1000 \times 60}$$

where V_p is the peripheral speed (m s^{-1}), D the diameter of the wheel (mm), and N the speed of the wheel (rpm).

Peripheral speed is widely accepted as the main variable for the adjustment of droplet size. However, it has been shown that droplet size does not necessarily remain constant when equal peripheral speeds are produced in wheel designs of various diameter–speed combinations, as there is a tendency for bigger wheels to produce bigger particles, all other things being equal. However, in the choice of wheel diameter, one should rather look at the reliability of the atomizer, as the differences in spray characteristics are negligible.

Viscosity of the liquid

Droplet size varies directly with viscosity, and bigger particles are obtained when the viscosity of the feed is higher. To ensure an optimal atomization, the viscosity is therefore normally kept as low and as constant as possible, often by heating the concentrate prior to atomization. Regarding droplet size distribution, it becomes broader with increased viscosity – an effect sometimes used when bulk density of the powder is to be increased.

Rotary atomizer has been known and used in the dairy industry for many years; its main advantages are as follows:

- Flexibility in throughput
- Ability to handle large quantities
- Ability to handle highly viscous concentrates
- Different wheel designs giving different powder characteristics
- Ability to handle products containing crystals
- Ability to handle higher solid content in the feed; therefore, better economy

To decide whether to use a pressure nozzle or rotary wheel is therefore a question of achieving the demanded properties of the final dried product, given the properties of the feed.

Powder Separation System

As the drying air leaving the chamber will contain a small proportion of the powder (10–30%), it is necessary to clean it by separating the powder particles. This powder fraction is usually referred to as the ‘fines’, as they normally represent the smallest particles.

The most widely used separators in the milk powder industry are

- Cyclone
- Bag filter
- CIP-able bag filter
- Wet scrubber
- Combinations of the above

Cyclone

Cyclone has some obvious advantages, such as high efficiency, if constructed properly. It is easily maintained, as there are no moving parts. Furthermore, it is easy to clean if the construction is with a fully welded center cyclone.

The operation theory is based on a vortex motion where the centrifugal force is acting on each particle and therefore causes the particle to move away from the cyclone axis toward the inner cyclone wall. However, the movement in the radial direction is the result of two opposing forces where the centrifugal force acts to move

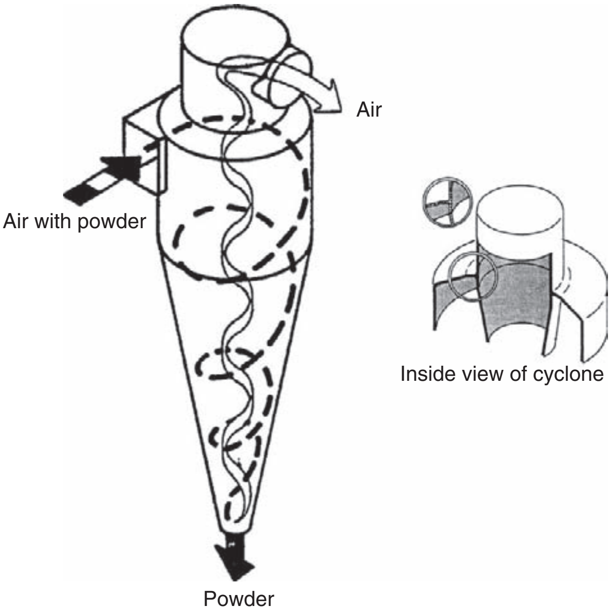

Figure 15 Cyclone.

the particle to the wall, while the drag force of the air acts to carry the particles into the axis. As the centrifugal force is predominant, separation takes place.

Powder and air pass tangentially into the cyclone at equal velocities. The mixture swirls in a spiral form down to the base of the cyclone separating the powder out to the cyclone wall. Powder leaves the bottom of the cyclone via a locking device. The clean air spirals upward along the central axis of the cyclone and leaves the cyclone at the top (see **Figure 15**).

The centrifugal force that each particle is exposed to is given by the following equation:

$$C = \frac{m \times V_t^2}{r}$$

where C is the centrifugal force, m the mass of the particle, V_t the tangential air velocity, and r the radial distance to the wall from any given point.

From this equation it can be concluded that the higher the particle mass, the better the efficiency. Also, the shorter distance the particle has to travel, the better the efficiency; that is, the closer the particle is to the wall, the better the efficiency, because the velocity is the highest and the radial distance is short.

However, time is required for the particles to travel to the cyclone wall, so a sufficient air residence time should be taken into consideration when designing a cyclone.

From the above equation, it is evident that small cyclones (diameter <1 m) will have the highest efficiency, a fact that is generally accepted.

However, as the big-tonnage dryers in operation in dairy industry today would require many cyclones, a compromise is sought with bigger sizes at the expense of high efficiency. Thus, the cyclones have become bigger and bigger and are now constructed with diameters of up to 4.0 m.

When designing a cyclone, various key factors should be taken into account to obtain the highest efficiency. This is achieved if

$$\frac{\text{cyclone diameter}}{\text{exit duct diameter}} \approx 3$$

$$\frac{\text{cyclone height}}{\text{exit duct diameter}} \approx 10$$

Increased air throughput (velocity V_t) and increased pressure drop will also increase the efficiency, but the energy requirement will also increase simultaneously, so in general the upper limit is 175–200 mm WG for skim milk powder. For whole milk, 140–160 mm WG is the maximum so that deposits and final blocking can be avoided.

To determine a cyclone's efficiency, the following terms have to be defined:

- critical particle diameter
- cut size
- overall cyclone efficiency

Critical particle diameter is defined as the particle size that will be completely removed from the air flow (100% collection efficiency). However, as there is no sharply defined point where a particle size is 100% separated or 100% lost, the critical particle diameter is not very valuable.

Cut size is defined as the size for which 50% collection is obtained and is a much more useful parameter for stating the efficiency of cyclones. To determine a cyclone's cut size, grade efficiency curves are constructed by systematically operating the cyclone with a uniform particle size dust (see **Figure 16**).

Overall cyclone efficiency is the one obtained when handling a product of definite size distribution. Knowing the grade efficiency curve of the cyclone and the particle size distribution of the powder passing to the cyclone, the overall efficiency can be calculated, that is, the powder loss can be predicted.

Another method for determining cyclone efficiency is by a simple powder loss measurement at the exit of the cyclone. A very small fraction of the outgoing air is passed through a high-efficiency minicyclone or through microdust filters. The amount of powder collected is directly proportional to the powder loss, which will mainly be a result of

- Feed with low solid content or feed containing air
- High outlet air temperature
- Low particle density (e.g., as a result of the above)
- Leaking product outlet on account of old-fashioned nonadjustable rotary valves

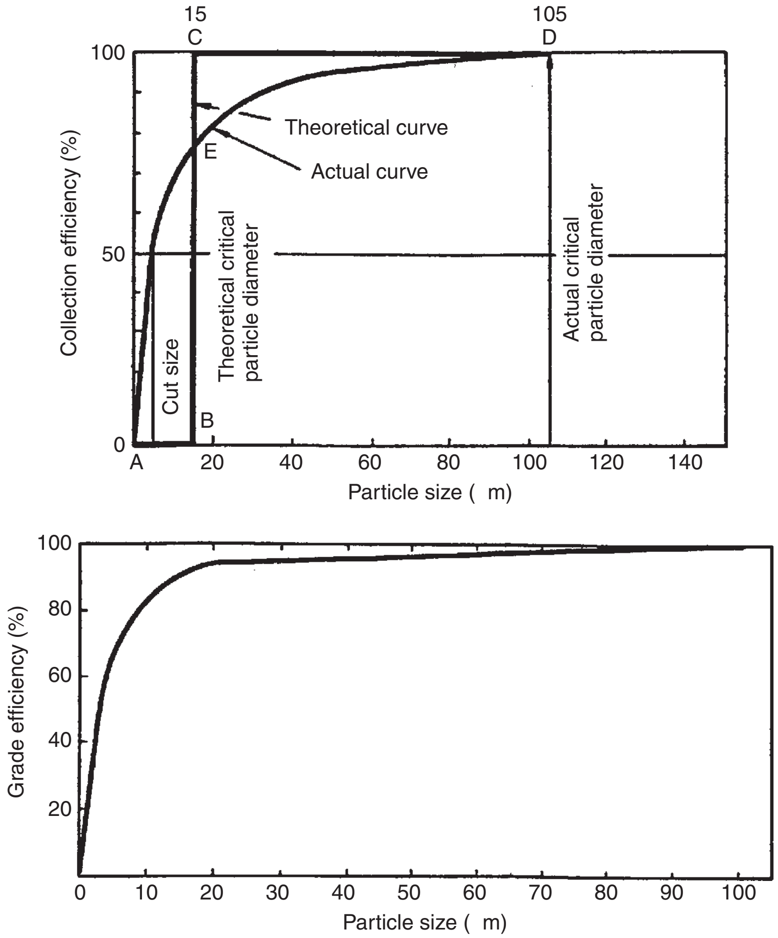

Figure 16 Critical particle diameter vs. grade efficiency curves for a cyclone.

- Blocked cyclone
- Changes in drying parameters resulting in a decrease in mean particle size

Average powder loss from a normal, high-efficient cyclone should not exceed 250 mg Nm^{-3} when spray drying skim milk.

Bag Filters

However, local authorities in general conclude that 250 mg Nm^{-3} is too high, thus requiring a final cleaning of the air. This is usually done by using bag filters consisting of numerous bags or filters arranged in such a way that all bags receive almost equal quantities of air. The direction of the air is from the outside, through the filter material, to the inner part of the bag from where the cleaned air enters an exhaust manifold. With a correct selection of filter material high efficiencies can be achieved, and collection of 1 μm particles has been reported by manufacturers. The collected powder is automatically shaken off by blowing compressed air through the filter bags from the inner side. This powder is collected at the bottom via a rotary valve (see **Figure 17**).

Wet Scrubbers

The wet scrubber is based on the venturi scrubber principle. The droplet separator is designed according to the well-known cyclone principles, however, with a modified outlet, resulting in a minimum liquid level, thereby minimizing bacterial growth, and a design ensuring deaeration, thus avoiding foam building.

The principle of venturi wet scrubbers is as follows (see **Figure 18**). The outlet air from the spray dryer containing powder particles is accelerated to a high velocity in the venturi inlet, where the liquid also is injected through full-cone nozzles. Due to the different velocities of the air/particles and the liquid droplets, they will collide, and the powder will dissolve in the liquid droplets. Passing through the subsequent diffuser this process will continue simultaneously with a certain pressure recovery of the air–droplet mix.

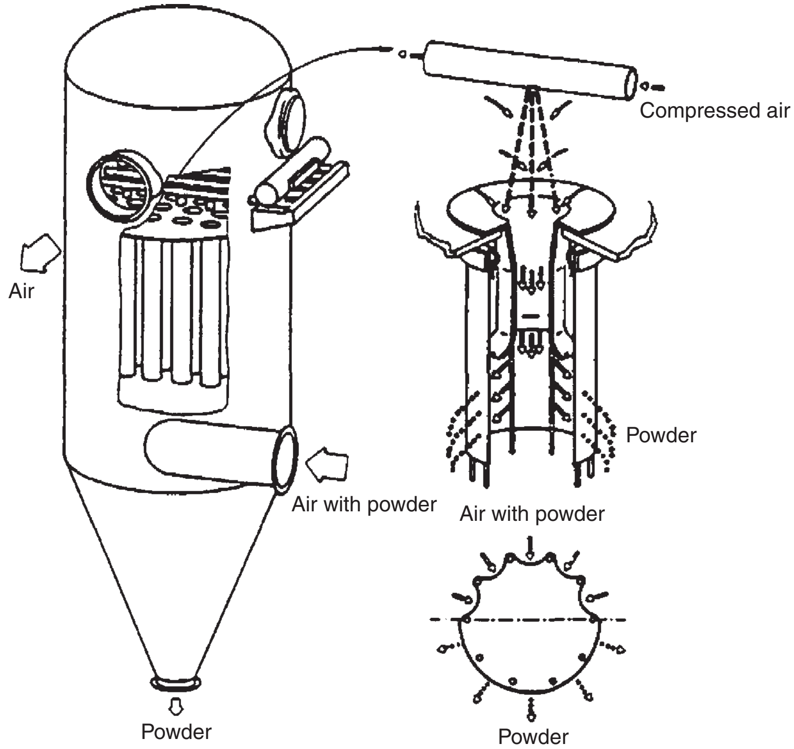

Figure 17 Bag filter.

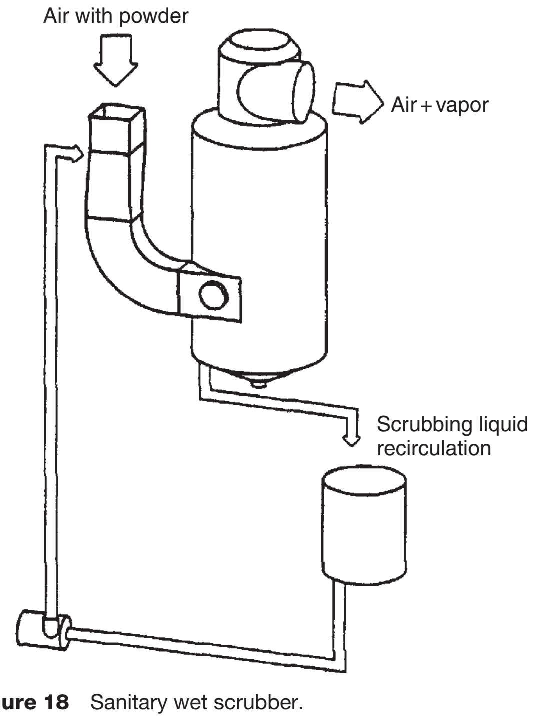

Figure 18 Sanitary wet scrubber.

Passing through the separator, the air and the liquid are separated. The air leaves through the central duct and the liquid through the bottom outlet for further processing or recycling depending on the system selected.

Recirculation of water

According to the above description of the principle, water is recycled by means of a centrifugal pump. The flow is controlled by a valve. The level is kept constant in the separator by a tank with an adjustable float simultaneously ensuring addition of water to make up for the evaporation taking place in the scrubber. The evaporation takes place owing to the high temperature of the air from the dryer, which is 90–95 °C for example, being cooled to the wet-bulb temperature (45–50 °C), at the same time evaporating the water (see **Figure 19**).

As the temperature of the water continues to be around 40–45 °C, bacterial growth must be expected after some time, and a CIP-able system is therefore recommended. The scrubbing liquid is used as animal feed.

CIP-Able Bag Filters

Common for all powder separators is the pressure drop across the cyclones, bag filters/scrubbers, or combinations thereof. In a continued effort to comply with the authority's demand for reduced powder emission and the powder producer's demand for lower energy consumption figures and reduced space requirements, an optimized powder recovery system has been developed – the CIP-able bag filter – which replaces the cyclones as well as the bag filter.

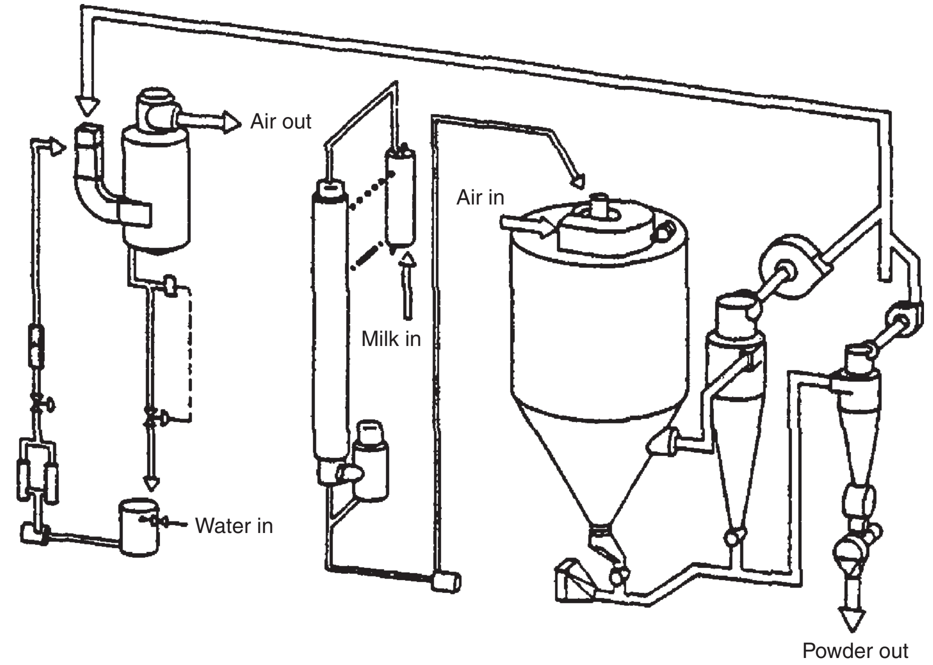

Figure 19 Wet scrubber recycled with water.

Based on almost 10 years of research, development, and testing of a CIP-able bag filter by GEA Niro, the SANICIP™ filter has reached a point where it is setting the standard for almost all dryers.

The SANICIP™ bag filter

The SANICIP™ bag filter (see **Figure 20**) is of the reverse-jet type. It consists of a cylindrical bag housing with a spiral-shaped air inlet, a clean-air plenum on top, and a conical bottom with fluidized powder discharge. During operation, the product collected on the outside of the filter material is removed by a compressed-air jet stream from the inside of each bag. The bags are clean-blown individually, resulting in a very even discharge of the powder.

The air supply system for the fluidizing bottom has a multiple purpose: During production, the cone of the bag house is first heated by the warm air, which subsequently is used for fluidizing the powder in the bottom. This ensures an even powder flow out of the bag house. During standstill, the air is used for the heating of the cone alone and is in a closed loop.

The filter bags are made from a special three-layer gradient polyester material, which is heat-treated to give a special dust-releasing surface. Each bag is supported on a stainless-steel cage and is easily dismountable.

In the SANICIP™ filter, a special reverse-jet air nozzle positioned above each bag (see **Figure 21**) is

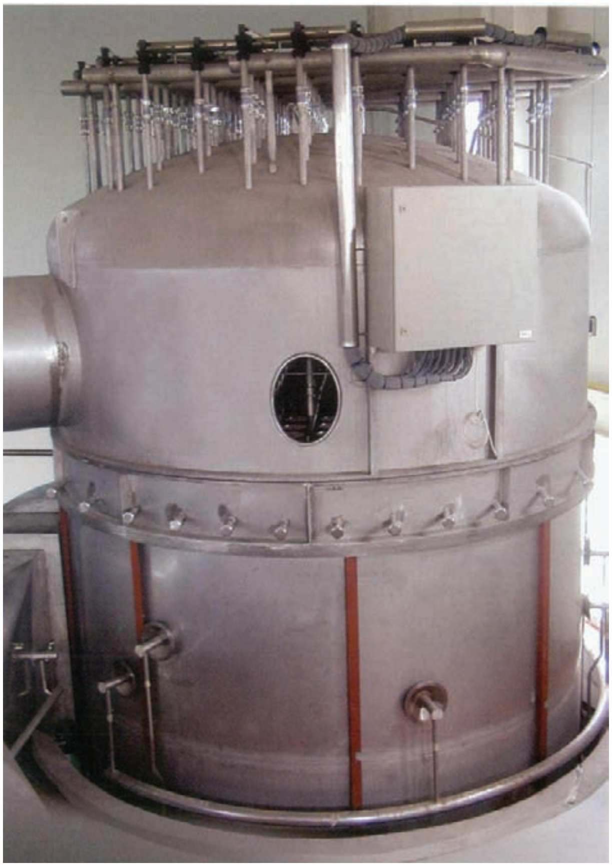

Figure 20 SANICIP™ CIP-able bag filter.

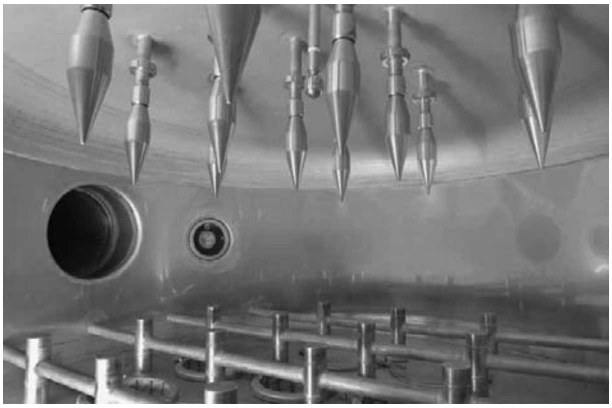

Figure 21 Reverse-jet air nozzle.

used. Compressed air is blown into the bag through this nozzle. A jet is formed that draws into the bag air from the clean-air plenum as well, thereby saving compressed air.

The CIP system of the bag house is divided into the following main items:

1. The internal bag CIP system cleans the bag from the inside toward the powder side (outside). Clean water is injected into the inside of the bag through the reverse-jet nozzle and the water is atomized by compressed air. Powder that has penetrated into the bag material is forced out toward the powder side by the water spray. No recirculation of water in this step.
2. The clean-air plenum CIP cleans the clean-air plenum of the bag filter above the hole plate. No recirculation of water in this step.
3. The hole plate CIP cleans the bottom side of the hole plate and the snap ring area of the bag using a specially designed nozzle, also with a dual purpose: During the process, the nozzle is purged with compressed air to keep the hole plate free of deposits, thereby avoiding discoloring/denaturation. The water is recirculated.
4. The shell CIP is performed by means of standard retractable CIP nozzles. The water is recirculated.

Normal acid and caustic are used as CIP agents. The CIP is followed by bag drying. Estimated time for complete CIP and dry out is 10 h.

Advantages of the SANICIP™ filter as follows:

- Low pressure loss across the bag filter and, thus, across the entire exhaust system; that is, reduced energy consumption and noise emission
- Designed for optimum air-to-cloth ratio and powder load (owing to one bag being blown at a time)
- Higher yield from raw materials owing to the absence of second-grade products
- Designs with 4 or 6 m bags to suit specific building requirements
- Reduced space requirements for new installations
- Easy replacement of cyclones for retrofits without major building changes
- Short dry-out time, as compared with other CIP-able bag filters

The pros and cons of all the above-mentioned powder recovery tools are listed in **Table 1**.

Final Drying and Cooling of Powder

Pneumatic Conveying and Cooling System

A pneumatic conveying system is established when powder has to be conveyed from one place to another. The conveying medium is air, and the quantity is determined by the product. Products with a high fat content require more air (5 times the powder) than that required by skimmed milk (4 times the powder). It is, however, not recommended that powders with

Table 1 Comparison of powder separators

Sanitary conditions	Good	Relatively good	Less good	Good

a fat content higher than 30% be conveyed, as blocking may occur in the ducts.

Air at any temperature may be used, and the powder temperature will naturally follow the air temperature. If hot air is used there will be a drying effect. This will, however, be minimal, as the residence time is short (air velocities of 20 m s^{-1}).

A pneumatic conveying system is inexpensive and can handle large quantities of powder, but it will destroy any agglomerates, resulting in a powder with maximum bulk density. The powder is separated from the conveying air in a cyclone.

Fluid Bed After-Dryer/Cooler

In modern dryers, pneumatic conveying and cooling systems are replaced by a VIBRO-FLUIDIZER™, which is designed also as an after-dryer, that is, drying is divided into two or more steps. The first step is done in the spray drying chamber transforming the liquid into powder particles and evaporating the main portion of water. The subsequent drying is done in a fluid bed (see **Figure 22**). The fluid bed drying technology has proved especially suitable, as the residence time in the fluid bed is so long that the moisture from the center of the particle can reach the surface from where evaporation takes place.

The VIBRO-FLUIDIZER™ is a horizontal box divided into an upper and a lower section by a perforated plate welded to the side wall of the box (see **Figure 23**). For drying, or alternatively cooling, warm or cold air is introduced into the air plenum chamber, which is distributed evenly over the whole area of the perforated plate. The perforation and amount of air are determined by the air velocity necessary for the fluidizing of the powder; however, special care must be taken to avoid attrition of agglomerates.

The temperature and area are determined according to the required evaporation duty. The hole size in the perforated plate is chosen to give an air velocity high enough to fluidize the powder on the plate. The air velocity should be so high that the fines powder becomes airborne and leaves the fluid bed with the air, and is returned to the atomizing zone for agglomeration.

The fluid bed can also be designed as a static back-mix bed integrated in the drying chamber.

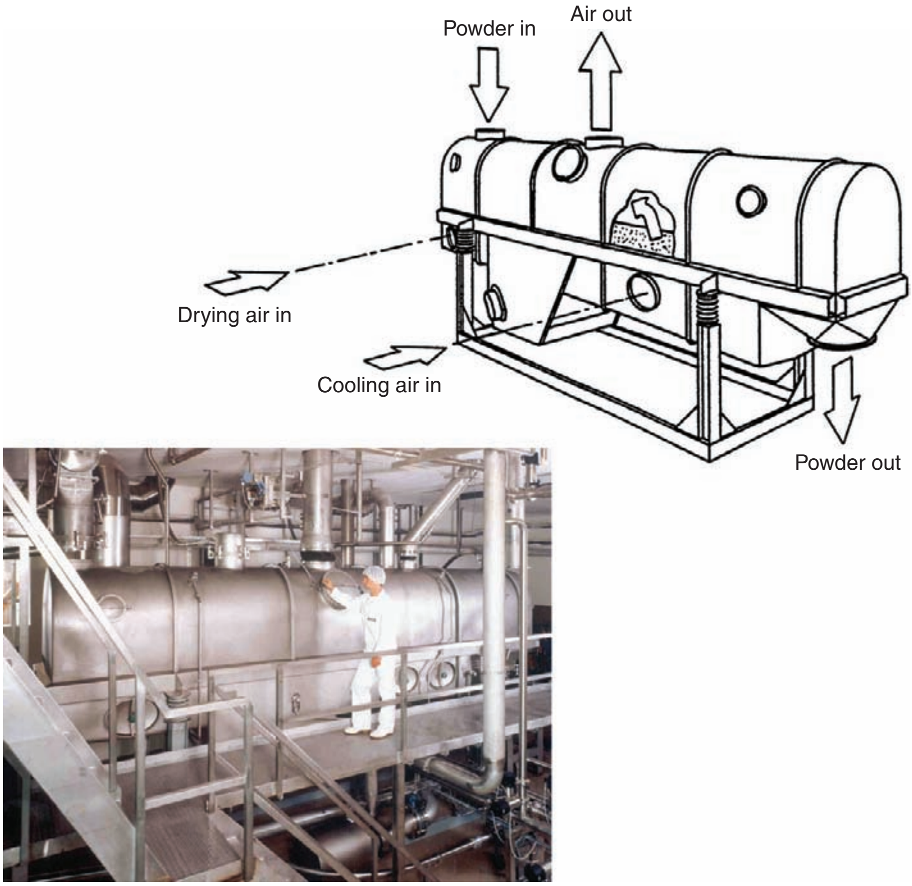

Figure 22 VIBRO-FLUIDIZER™.

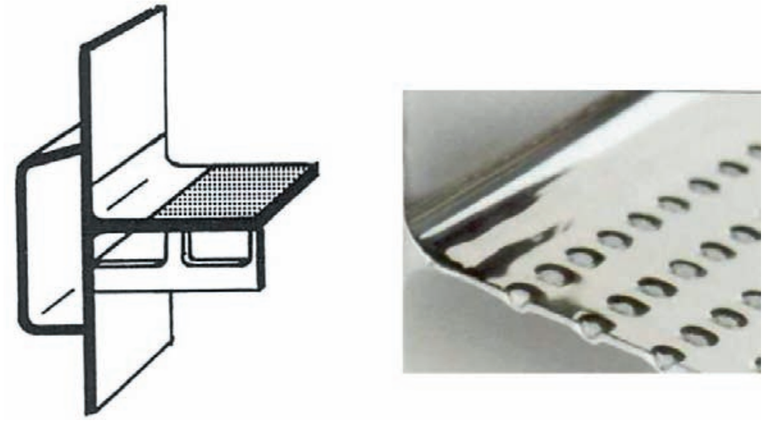

Figure 23 Construction detail of a sanitary VIBRO-FLUIDIZER™.

Fines Return System

Agglomeration means getting smaller particles to adhere to each other to form a powder consisting of bigger conglomerates/agglomerates, which are essential for easy reconstitution in water. By means of a fines return system, the cyclone fraction(s) is(are) conveyed back to the atomizer mist, the static fluid bed, or the VIBRO-FLUIDIZER™, depending on the required degree of agglomeration.

Fines return systems consist of the following:

- High-pressure blowers (the quantity of air is dependent on the amount of fines – typically, 1 kg of air can convey 3–5 kg of powder)
- Blow-through valves (devices to discharge powder from cyclones and/or bag filters into the conveying line)
- Conveying line/diverter valves to convey the fines powder to the desired destination – typically a 76–102 mm (3–4 inch) pipe
- Fines introduction to the atomization zone

The aim is to bring the fines as close as possible to the atomizer wheel. In modern dryers, fines are introduced from above through the air disperser (FRAD system) via four fines pipes situated just above the atomizer cloud. Deflector plates at the end of each fines pipe ensure a correct introduction and distribution of the fines (see **Figure 24**).

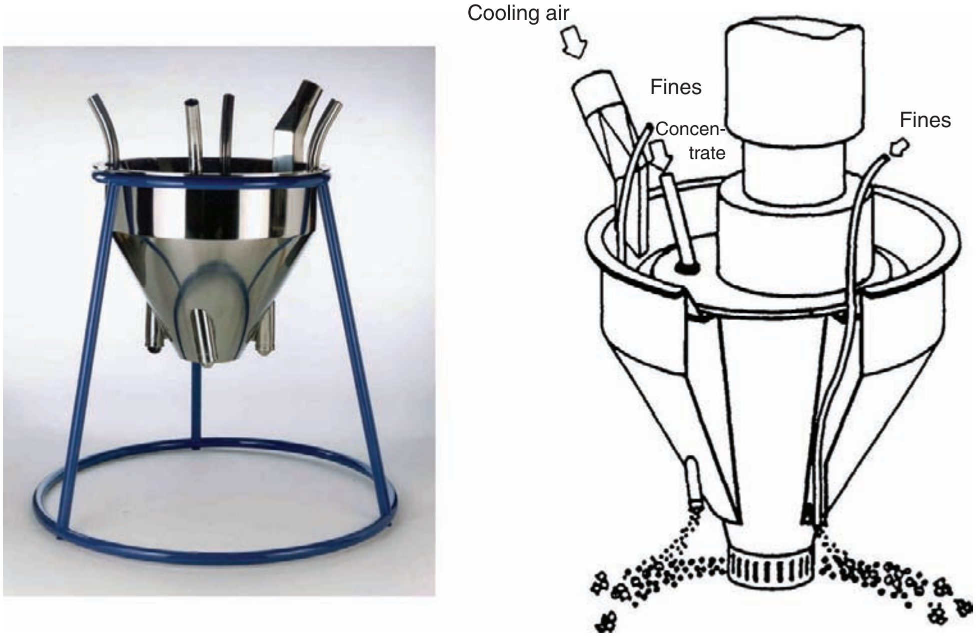

Figure 24 Fines return for rotary atomizer FRAD.

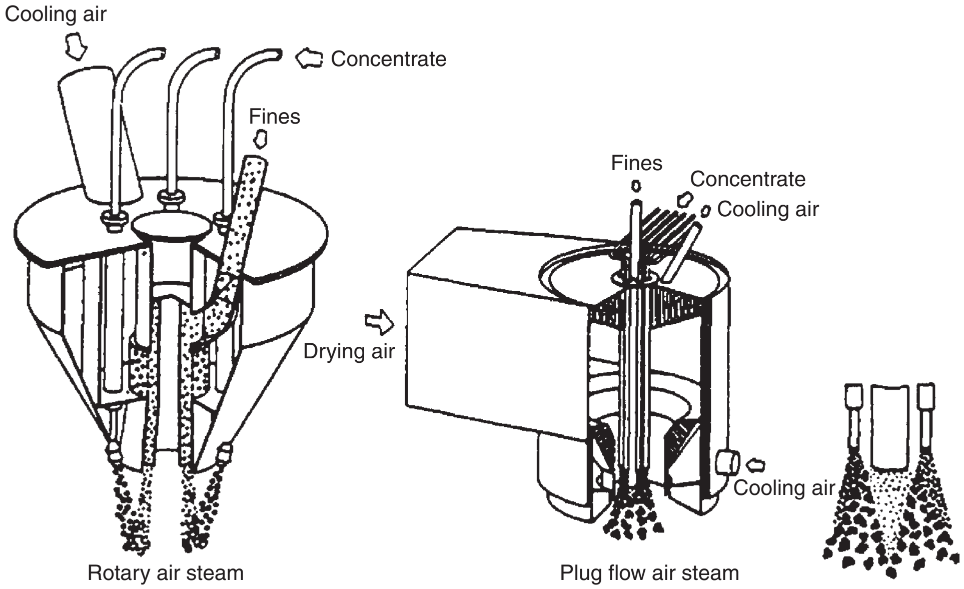

Figure 25 Fines return for nozzle atomizer.

For nozzle atomization, the fines return is an integral part of the nozzle unit with the fines duct in the center surrounded by nozzles at the periphery (see **Figure 25**), provided the dryer is designed for rotary air flow or is with vertical air flow.

Conclusion

Spray drying plants are designed today to fulfill many requirements, including low energy consumption, high final-product quality, reduced space requirements, and a high degree of environmental protection – a challenge taken up by the designers and suppliers of the dryers.

Introduction

Industrial evolution in the second half of the twentieth century was influenced mostly by four types of interrelated factors: progress in digital technology, advances in science, evolution of societal requirements and demands and, particularly over the last 30 years, evolution of business concepts.

Developments in digital technology and in systems theory led to major progress in sensor and information technology and a revolution in the availability of distributed control systems and open software applications. New concepts, particularly knowledge-based measurement and advanced control methodologies, are slowly but steadily being brought into the practice of process operation, performing online and in real time.

Societal and economic factors have driven evolution in the same direction. The increasing concern for health, safety and sustainability issues, market quality requirements, economic pressure and the evolution of company strategy from local to global business concepts – the so-called knowledge economy concepts – all together reflected on plant investment decisions, favoring process automation for cleaner and safer operation, higher product quality and improved process efficiency and productivity.

Discussing plant automation from a technical point of view means a discussion on instrumentation, control system configurations, data communications and theoretical control structures.

This article deals with instrumentation, addressing in particular both basic and advanced concepts concerning sensors and the issue of how to integrate local hardware for automatic control, usually dispersed throughout the plant.

Basics of Plant Automation

There are well-established methodological steps for the design and implementation of a control structure: (1) designing and implementing an appropriate, flexible, control configuration; (2) performing first-level data acquisition and process monitoring, including record keeping and first-level alarms; (3) performing data interpretation (implementing second-level process monitoring); and (4) designing and implementing optimization and control solutions.

In plant-wide distributed control configurations, as illustrated in **Figure 1**, the backbone of transmission is all digital. Communication protocols (some open, some proprietary) ensure data transmission for centralized data interpretation, for monitoring and for plant scale optimization. Control at sector and unit level is usually performed locally. Local-level signal transmission has for many years been analog only; initially, pneumatic signals and later electric (current or voltage) signals. However, more and more, information also flows digitally between (smart) sensors and controllers.

At a local level, process control system instrumentation includes: (1) sensors for measurement of process variables; (2) controllers, for implementing a proper (digital) control structure (e.g. proportional-integral derivative (PID), predictive or adaptive controller, etc.); (3) final control elements for manipulation of process inputs; and (4) support devices such as general signal conditioners of both input and output signals, electric (V/I and I/V) transducers, electric-to-pneumatic transducers and hold elements.

The range of instrumentation and control systems is very large today. Nowadays, industrial users are available through the internet information sites of instrumentation manufacturers with very detailed information on all types of instrumentation and control systems configurations, including data communications, related to plant automation.

A relevant management decision in the automation of older plants – and most fall into this category – is how to step from existing local control solutions to integrated distributed control. Investment in a complete new solution is high and the tendency is to try to adopt a solution that makes use of available equipment. This is often hard to achieve and leads to a final configuration that mixes too

many different control equipment suppliers, with the related costs of operation and maintenance.

Measurement Instrumentation

A key limitation to the application of process control is the lack of appropriate sensors for many process variables. This is so in dairy processes and therefore measuring techniques for online use in the dairy industry are subject to considerable research and manufacturing interest. Basic concepts and the main measurement techniques are reviewed in this section.

Basic Characteristics of Sensors

A sensor is composed of a sensing element and a transmitter, as indicated schematically in **Figure 2**. The sensor output, whether analog or digital, should be a standard signal suitable to be supplied to a controller.

Figure 2 Schematic representation of stages in a digital control system.

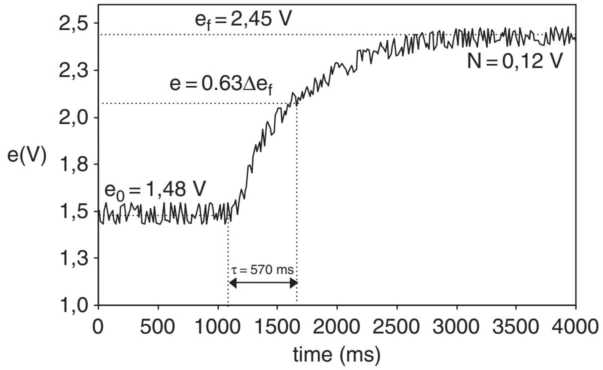

Figure 3 Time response of a pH electrode to a step change in pH (4–7).

Most transmitters respond rapidly. When the sensor element response is also fast, then measurement dynamics can be neglected in view of modeling process dynamics. Such a case is indicated in **Figure 3**, which shows the time response of a pH electrode to a step change in pH from 4 to 7. The characteristic first-order time constant for the sensor dynamics (the time required for the response change to reach 63% of the step change) is in the order of milliseconds ($\tau \cong 570$ ms). There are, however, cases where the measurement dynamics, particularly time lag, may be significant and ignoring it can lead to control difficulties.

Sensors can exhibit linear or non-linear behavior. This is related to and expressed by the relation between the variation of the property value and that of the transmitted signal. Sources of non-linearity usually lie on the sensing element. For a linear sensor, the gain for a given calibration is constant and equal to the ratio between the set span and the range of the sensor output. Nowadays, with digital data acquisition, transducer non-linearities are easily incorporated in the data interpretation software and cause no practical difficulties.

Specialized Sensors/Measurement Systems

The most important properties of dairy processes subject to measurement that reflect both process operation and product quality are classified as objective or subjective. Examples of the former are pH, temperature, flow rates, pressure and level. Sensors for online measurement of such properties have been available for a long time. Properties such as taste, flavor, color and consistency are considered to be subjective and difficult to measure.

Commercial sensors applied in the dairy industry are subject to several quality constraints, such as sanitary, safety and environmental requirements. A trend in new sensor design technologies is the increasing integration of the sensing elements into silicon chip micro-circuits. These new measurement devices directly incorporate all circuitry needed to self-compensate for environmental changes and yield an output that is suitably amplified for transmission to standard electronic controllers. These sensors offer the advantage of small size, reduced price and practically no mechanical parts to wear out.

Next, measurement techniques and instrumentation for the most important objective properties in the dairy industry are considered.

pH

pH measurements are of paramount importance for quality control in milk fermentation and related processes. For example, inadequate pH can be a cause of excess free whey and excess or inadequate tartness in fermented products; pH changes are related to the viscoelastic properties of yogurt and they are also correlated to the physiological state of bacteria in the lactic acid fermentation. Also, the final pH value is normally a feature of the final product: fermentation converts lactose to lactic acid, causing a drop in pH to a value in the range of 4.25–4.5; rapid cooling at the correct level of lactic acid then stops bacterial action.

pH electrodes can be in direct contact with food, if they meet sanitary requirements. In general terms, pH measurements, particularly in conjunction with electrical conductivity measurements, constitute an important means for continuous, real-time process monitoring.

Temperature

In industrial applications, the main measuring devices for low temperatures (below 250 °C) are based either on thermoelectric effects (thermocouples) or on resistance changes (e.g. platinum resistance temperature devices (RTD), thermistors). Measurement characteristics, particularly sensitivity and the degree of (non)linearity, favor the use of platinum RTD; the most widely used is the so-called PT100 device.

Thermal processing is a key stage in most dairy process operations. As an example, during pasteurization of yogurt the temperature is raised to 85–90 °C to destroy undesirable microorganisms and denature the whey to improve viscosity and prevent syneresis. Then, the product is cooled to 40–45 °C so that the mix is ready for inoculation. Also, freezing and refrigeration are used to prevent the growth of unwanted microorganisms. In general, these operations and process units require a reliable and accurate temperature-monitoring and control system.

Level, density or interface level

Liquid height, density or interface level between two liquids can be measured either by differential pressure (d/p cells) sensors or by measurement of buoyancy force on a displacer suspended in a liquid. An electronic transmitter converts the output of the sensing element to an appropriate analog or digital output signal.

Nowadays, instrumentation companies offer the dairy industry a variety of special transmitters for level monitoring and control applications in inventory tanks and clean-in-place (CIP) vessels.

Pressure

In most process operations, particularly when thermal processing is required, pressure regulation is one of the essential control loops. Pressure sensors are thus among the most commonly used on-line sensors. D/p cell transmitters for either gauge or absolute pressure are the solution which is generally adopted.

Thermal conductivity

Thermal conductivity expresses the ability of a substance to conduct heat. The most common thermal conductivity probes consist of an assembly of an electric heated wire and a temperature measurement system (based on thermocouples or thermistors) from where heat fluxes are measured and heat conduction is inferred.

Thermal conductivity measurements find wide application in dairy chemistry and biochemistry and in food process engineering. The measurement of thermal conductivity by line heat source probes may be used for in-line determination of the coagulation time of milk for cheese curd and yogurt production and may be helpful for automating these processes, aiming at maximizing the yield of cheese and yogurt. Coagulation time may be detected by the sharp increase in the temperature difference between probe temperature and initial milk temperature.

Electrical conductivity

Electrical conductivity (*G*) expresses the ability of a substance or medium to conduct electricity. It is employed for quality control and further finds on-line use in identifying features of fermentation states. For example, electrical conductivity measurements allow the urease activity and the acidification activity in lactic acid fermentations to be distinguished. For example, electrical conductivity measurements allow the urease activity and the acidification activity in lactic acid fermentations to be distinguished.

In a dairy plant where many fermentations are performed, either simultaneously or sequentially, the real-time prediction of fermentation completion time is very important for scheduling raw material supply and energy utilization. Data-driven models (e.g. neural network-based) relating characteristic properties of the fermentation state (model outputs) to pH and electrical conductivity (model inputs) can be firstly identified (trained) and subsequently used to monitor the fermentation process and to predict fermentation times.

Viscosity

The main items of equipment for viscosity measurement are process viscometers. Shear viscosity for Newtonian fluids can be measured by a capillary flow viscometer. Cone and plate viscometers are suitable to determine the shear viscosity of time-independent non-Newtonian fluids. From the changes in viscosity, the stages of aggregation and gel formation can be described and calculated. The viscosity can finally be used as an objective measure for the control of coagulation processes.

In industrial operations involving slurries, pulps, grease or other similar media, consistency, rather than viscosity, is measured by rotation and oscillation rheometers. These devices allow, for example, the continuous online monitoring of the transition of milk fluid into a viscoelastic gel structure.

NIR spectroscopy

Infrared and near-infrared (NIR) spectroscopy can be used to measure the levels of water, fat and protein in liquid milk and related products on-line (and *ex situ*). This is a commonly used technique for quality control, but may also be used for on-line closed-loop control.

Optical density

Optical density (OD) is commonly used to measure biomass concentration on-line and *ex situ.* The measurement principle is based on the individual or combined use of measurements of transmission, reflection or scattering of light. The interpretation of the signal is complex, but it is normally linearly correlated to biomass concentration in diluted solutions.

Final Control Elements

Final control elements (FCE) are devices, driven by controller signals, used to manipulate process control variables. In most cases control actions consist of adjusting flow rates of process input or output streams (solid, liquid or gas) or cooling and heating fluids. The most widely used FCE are flow regulator valves.

Designing a valve involves taking decisions on valve size, choice of body material, choice of type of valve (signal-to-close or signal-to-open) and choice of flow versus aperture characteristics (essentially linear or equal percentage valves).

Valve sizing (computing the *Cv* parameter) and the choice of valve flow characteristics require consideration of hydrodynamic aspects, particularly pressure drops along the piping. The choice of material depends on the properties (corrosive, slurry, etc.) of the process fluid. For the dairy industry, stainless-steel valves are most common. The decision on working with normally open or normally closed valves derives directly from answering the safety question of how the valve should stay in an emergency due to energy failure.

Regulator valves are typically driven by a pneumatic signal (range 3–15 psig or 0.02–0.1 MPa). Signals are normally transmitted to the FCE as analog current signals (4–20 mA), being converted locally by a current-to-pneumatic transducer. Alternatively, a step motor, driven by a digital signal from the controller, can actuate valves.

On–off valves normally use electrical or pneumatic actuators. They are used mainly for sequential control and during start-up and shutdown procedures. Other final control elements, namely displacement devices and pumps, are increasingly digitally actuated by step motors.

Digital Control Equipment

Digital control instrumentation represents the new standard and indeed has introduced a major change of mindset with respect to control system structures and solutions, with new procedures concerning communications and calibration routines. Digital control instruments offer the computing power required to implement advanced model-based monitoring and control algorithms (software sensors and predictive control) at local level and in real time. They enable the implementation of plant-wide monitoring, optimization and control solutions through the available distributed control architecture.

Distributed Control Systems

A distributed control system (**Figure 1**) is simply an arrangement whereby control devices and computer processing power are distributed through a network instead of being centralized.

The main devices in a distributed control system are essentially microprocessor-based sub-systems such as programmable logic controllers (PLC), smart sensors, supervisory and engineering stations and other input–output (I/O) devices (e.g. FieldPoints, device integrators, etc.). All devices in the network must be integrated with proper hardware and software for communications.

PLC are today's industrial standard for local digital control. They are reliable special-purpose computers for control in the industrial environment, consisting of a set of I/O modules and a programmable central processing unit. They can perform analog-to-digital (AD) and digital-to-analog (DA) conversion and have special-purpose digital I/O ports (PLCs were originally designed mainly for event control). PLC normally use proprietary programming languages.

Smart sensors are devices that through their digital system can be connected to the network, communicating bidirectionally with the other devices. In particular, they accept remote commands for remote calibration.

General-purpose computers (PC, workstations) may be interconnected in the control system network to carry out inferential measurement procedures, high-level data analysis, supervisory duties or more sophisticated dedicated control tasks.

FieldPoints are modular I/O devices that connect a bank of analog and/or digital I/O modules to an industrial network, being able to perform AD/DA signal conversion.

The key feature of a distributed control system is thus that the measurement and control tasks are distributed out into the field. Integrated hierarchical control configurations may be built where high-level tasks, like process supervision and optimization, are fully integrated with the low-level data acquisition and local control tasks.

Communication Standards

Industrial communications refer to the networking hardware and software, together with the respective communications protocol.

A number of industrial network standards, designed to meet different application requirements, are available today: Ethernet, DeviceNet, Foundation Fieldbus, PROFIBUS and controller area network (CAN). Details of these industrial network standards can be found in **Table 1**.

Some specify low-level sensor–controller–actuator communication protocols (like CAN and DeviceNet), whereas others are specially oriented for distributed control systems in the process industries (Fieldbus and PROFIBUS). They differ on communications bus specifications, on velocity of data transfer, on communications protocol used and on the communications model. For distributed control systems in large factories, Fieldbus and PROFIBUS are the two most important standards.

Ethernet is the most widely used local area network (LAN) technology. An Ethernet LAN may use coaxial cable, special grades of twisted pair wiring, or fiber optic cable. 'Bus' and 'star' wiring configurations are supported. Ethernet devices compete for access to the network using a protocol called carrier sense multiple access with collision detection (CSMA/CD). Ethernet conforms to the IEEE 802.3 specifications and runs commonly under the high-level transfer communication protocol–internet protocol (TCP–IP) (although many others are possible). The Fieldbus standard has adopted a second alternative for the physical layer that is based on Ethernet, thus providing a solution for factory-to-factory communication.

Basics of Analog-to-Digital and Digital-to-Analog Signal Conversion

All digital control systems contain a data acquisition interface that performs AD/DA conversion. Such tasks are commonly performed by standard computers with AD and DA cards, by FieldPoint modules or by PLC.

It is worth examining basic aspects of the data acquisition and control problem, namely the flow of information from the 'process property' to the 'binary word in the

Table 1 Industrial communications standards

Standard	*Description*	*General features*	*Application areas*
DeviceNet	Low-level network designed to connect industrial devices (sensors, actuators) to higher-level devices (controllers)	Powered bus consisting of two separate twisted-pair cables Built on CAN protocol Producer–consumer model for data transfer	Mainly manufacturing industries
Foundation Fieldbus	Digital network standard designed specially for distributed process control; expected to substitute for the 4–20 mA analog standard	H1-powered 31.25 kb s^{-1} bus (standards ISA S50.02-1992; IEC 61158-2) or high-speed 10/100 Mb s^{-1} Ethernet (HSE) Fieldbus (communication) protocol (IEC 1158-2)	Mainly process industries
PROFIBUS DP/FMS/ PA	Family of communication standards. Leading open Fieldbus system in Europe; PA is mainly used in the process industries	DP and FMS: RS485 serial line with baud rates up to 12 Mb s^{-1} PA: Fieldbus standard (IEC 1158-2)	Manufacturing and process automation
Ethernet	EtherNet is an industrial standard that defines only the physical layer. Some industrial standards are built on top of Ethernet	• Coaxial cable with BNC connectors or telephone wiring with RJ45 connectors or fiber-optic cable (10–1000 Mb s^{-1}) (standard IEEE 802.3) • Ethernet does not define itself as the communication protocol. It runs commonly under the TCP–IP	Mainly in LANs for PC-to-PC communication.
CAN	Designed originally for in-vehicle automotive communications	CANbus (serial bus) with CANbus communication protocol	Also for process industries

CAN, controller area network; LAN, local area network; PA, process automation; DP, decentralized periphery; FMS, Fieldbus message specifications; BNC, bayonet nut connector; TCP–IP, transfer communication protocol–internet protocol.

computer' and the feedback from the 'binary decision variable' to final control element.

Data acquisition

The data acquisition chain is represented schematically in **Figure 2**. The design stage of the data acquisition system should start with a qualitative analysis, addressing the following main considerations:

- The sensor should be chosen with the objective of maximizing sensitivity for the desired measurement interval. This means that calibration should be such that the sensor measurement span should match the measurement interval and be mapped into the full range of the output signal.
- Industrial analog-to-digital conversions (ADCs) are nowadays standard. A 12-bit AD converter is generally sufficient. The input range is not a problem, assuming that the required signal conditioners are available.
- Signal conditioning should be such that the sensor output signal V_0 is transduced into a signal V_2 that exhibits the same range as that of the ADC. This situation maximizes the overall resolution of the acquisition chain.

Still at the design stage, the quantitative analysis must be performed in steps from the process to the computer:

- The sensor normally delivers an analog electrical signal (V_0), which should be a known function of the process property, *P*. Assuming, for simplicity, a linear relationship, eqn [1] holds:

$$V_0 = k_0\rho + z_0 \qquad (1)$$

- This signal will generally undergo some form of conditioning (transduction, amplification, attenuation, etc.), after the sensor and before the ADC, depending mainly on aspects related to compatibility and range of transmission signals (V_1 and V_2). These types of transformations can usually be adequately expressed by linear relationships of the form:

$$V_1 = k_1 V_0 + z_1 \qquad (2)$$

$$V_2 = k_2 V_1 + z_2 \qquad (3)$$

- Considering an *n*-bit ADC, with an input range [$V_{\min}$, $V_{\max}$], the digital word *D*, corresponding to V_2, is given by:

$$D = \mathrm{INT}\left[\frac{V_2 - V_{\min}}{V_{\max} - V_{\min}} 2^n\right] \qquad (4)$$

The corresponding discretization error is given by $\pm 0.5(\mathrm{V}_{\max} - \mathrm{V}_{\min})/2^n$. For a 12-bit converter this error is well inside industrial requirements, generally lower than all other errors in the chain.

- For the choice of the sampling time (*t*) in the implementation, a simple rule of thumb is often used in industrial applications, adopting a sampling time value of about one-tenth of the process characteristic time constant.The implementation stage of local signal acquisition corresponds to effectively programming the multiplexing, ADC, data reading (binary value *D*) and data decoding (getting the property *P* from the binary value *D*).
- For each scanning (multiplexing and data reading) of input channels, performed at every time interval *t*, programming of data decoding is performed by successively computing the values from the binary word *D* to the property *P*, by solving eqns [4], [3], [2] and [1] with respect to V_2, V_1, V_0 and *P*, respectively.

$$V_2 = V_{\min} + (D + 0.5)\frac{V_{\max} - V_{\min}}{2^n} \qquad (5)$$

$$V_1 = (V_2 - z_2)/k_2 \qquad (6)$$

$$V_0 = (V_1 - z_1)/k_1 \qquad (7)$$

$$P = (V_0 - z_0)/k_0 \qquad (8)$$

- At this stage, process values are available in the data acquisition application for all types of desired actions, namely data interpretation, data plotting, bookkeeping, analysis of alarms and related actions, computing of control actions and output of control commands.

Control action

It is outside the scope of this article to analyze control algorithms. Assuming that a control decision has been taken, given by a binary word *C*, such a command is transmitted from the control system to the final control element through an elementary chain including the digital-to-analog conversion (DAC) (with a hold element), and, in the more general case where the final control element is a valve, a signal conditioner, a power buffer amplifier and a current-to-pneumatic signal transducer (**Figure 2**). For design purposes, assuming that the DAC is set for a voltage output, eqn [9] represents the DA conversion, where *n* is the number of conversion bits of the DAC, V_{ref} is the reference voltage (corresponding to an output interval of $0 - V_{\max}$, with $V_{\max} \cong V_{\text{ref}}$):

$$V_3 = V_{\text{ref}^*} C/2^n \qquad (9)$$

The industrial standard for DA converters is normally of 12 bit. Most common ranges of output signals are 0–10 V or 4–20 mA.

Finally, referring back to signal conditioning, care must be taken to ensure that wiring is correct, that instruments and source grounds are of good equivalent level (a comment that also applies to wiring in AD lines) and that appropriate buffer amplifiers are used to protect control devices from high currents.

Advanced Topics

Two topics closely related to the state of the art in both information technology and systems theory are now discussed: how to make measurable what is not so; and how to integrate information and manage large-scale systems.

Software Sensors

In many cases, key process variables and characteristic parameters, namely kinetic and transport parameters, are not available directly on-line and in real time, either because they are really not measurable or simply because measurements may be expensive and/or unreliable.

Software sensors are algorithms for the on-line computation of those state variables and parameters that are not measurable in real time, from more easily accessible (accurate and inexpensive) related measurements. The concept is closely related to those of inferential measuring and of state observers, widely discussed in the specialized systems engineering literature. The design and implementation of software sensors provide in some cases a suitable answer to cope with the lack of instrumental sensors. It may require the computational power of a dedicated computer in the distributed control network, a requirement that nowadays represents no technical or economical problem.

A software sensor relies on a process (sub-system) model that establishes the relationship between measured and estimated properties. Hence, the key for success (or failure) of a software sensor is the availability of knowledge/information about the relationship between measured and unmeasured properties, i.e. the accuracy and robustness of the underlying model. With respect to and in the context of dairy industries, the kinetics in fermentation tanks are the most difficult part of the process to model. Traditionally, designing adaptive observation/estimation algorithms, of which the most frequently reported technique is the extended Kalman filter, circumvents the problem. This type of method requires a number of simplifying assumptions that are not always acceptable. More recently, knowledge-based software sensors have been reported. They rely on artificial intelligence (AI) models like artificial neural networks (ANN) and fuzzy or hybrid neuro-fuzzy models, combined with mechanistic expressions of process behavior. Though models reported in the literature are excellent in their ability to predict based on minimum information, the requirements of both know-how and computational power for implementation are still substantial. This hinders its industrial application on a wide scale, in the short term.

Measurement of Subjective Properties

Properties such as taste, flavor, and consistency are subjective properties that are extremely important for process operation in food industries. At present operators use their human senses, i.e. smell/aroma, feel, taste, as a gauge for the acceptability of products. Measurement techniques for subjective properties are reported to be under intensive investigations. The electronic nose concept is maybe the best-known example. The electronic nose mimics the human nose to detect specific aromas and smell. This technology is commercially available today. Image analysis is now a well-developed technique. Properties such as material visual aspect can be inferred from these techniques, providing new information for further and new automatic processing.

Factory-to-Factory Automation

As a final point, with the internet, it has become clear that the information flow scheme of **Figure 1** in an automated factory may move down the hierarchy. As this technology becomes reliable and secure, we may speak of a factory-to-factory (worldwide) automated information flow and distributed processing. Whilst this does not represent a state-of-routine automation solution, it represents a real management tool in the context of prevailing business concepts.

Conclusions

Basic measurement concepts and control instrumentation applied in the dairy industry have been reviewed in this article. The intention was to provide an insight to the main principles and characteristics of classical and more advanced sensor devices and control equipment.

The measurement mechanisms considered range from the commercially available sensors for important objective properties of dairy processes to more sophisticated model-based software sensors and new technological solutions for monitoring subjective properties in a variety of food industries.

The discussion of digital control system instrumentation is also focused on core items such as final control elements, distributed control systems with respective communications standards and signal conversion required for data acquisition.

Though the topics considered are far from being a complete overview of all research and industrial developments in this area, the article provides structured information on the main instrumentation aspects routinely implemented or potentially applicable in the dairy industry.

Introduction – Dairy Industry, Aims, Trends

Dairy processing industries worldwide have undergone rationalization, with a trend toward fewer but larger plants specialized in a limited range of products and operated by fewer people. Plants producing market milk and products with short shelf-life, such as yogurts, creams, and soft cheeses, tend to be located on the fringe of urban centers close to consumer markets. Plants manufacturing items with longer shelf-life, such as butter, milk powders, cheese, and whey powders, tend to be located in rural areas closer to the milk supply.

Basic dairy processes have changed little in the past decade. However, changing global needs and the pressure of globalization create contemporary challenges related to rapid development of new, high-value-added products, improvements of production efficiency, and more energy-efficient, cost-saving, and environmentally friendly processes. Issues such as pollution prevention and reduction of waste loads and product losses are critical for the dairy industry. To achieve these requirements, an integrated smart production policy is expected based on a holistic plant-wide representation of the production chain from process control level, through plant management, to corporate management. Modern dairy technology consists of a few hierarchical stages:

Enterprise resource planning (ERP), which refers to a system that sits at the top of an integrated dairy infrastructure to manage the demands of business, in terms of functions such as sales and distribution, accounting, materials management, asset management, and plant maintenance.

Manufacturing execution (ME) refers to a system that centers on the product as it moves through the plant.

Supervisory control and data acquisition (SCADA) is a system that provides the operator and other users with access to direct regulatory process control, such as programmable logic controllers (PLCs). The SCADA system works in real time and provides graphical status displays and process monitoring. Though the PLCs form the basis of most traditional process control systems in the dairy industry, the use of more sophisticated control systems, information technology (IT)-based modern control equipment, and new control algorithms are solutions implemented by an increasing number of companies. For example, specialized processes such as ultrafiltration and modern drying processes have increased the opportunity for the recovery of milk solids that were formerly discharged.

ME provides a bridge between ERP systems and real-time control supplied by PLC and SCADA systems, for functions such as batch process control and production scheduling.

Batch and Semibatch Process Operation

Batch or fed-batch mode of operation is a typical production scheme for a large group of dairy processes. It is related to the formulation of control problems in terms of the economic or performance objective at the end of the process; for example, milk powder production quality is evaluated by the total quantity and concentration of solids at the end of the process. The main challenge of batch production is the large batch-to-batch variation of the final characteristics. This lack of process repeatability is an inherent consequence of the variability of raw materials and uncontrolled parameters and not necessarily due to improper control policies, though the latter would greatly enhance the problem. Over the past 10 years, a number of control methods have been researched to cope with process constraints and different objectives derived from economic or environmental considerations with the objective to drive the process to its optimal state of profit maximization and cost minimization. Some of the most typical control paradigms and new model-based control trends are presented in the rest of this article.

Classical Closed-Loop Process Control – Established Control Engineering Practice

Any control system in which the output is monitored (measured), compared (subtracted) with the reference (desired) input, and the difference (the error) used to actuate the controller until the output equals the

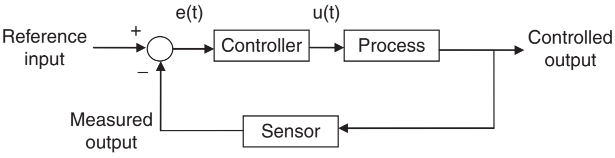

Figure 1 Closed-loop process control.

reference is called a closed-loop or feedback control system (see **Figure 1**).

The controller design consists of computing the PID parameters K_p, K_I, K_d such that the closed-loop performance and stability requirements are achieved. Each parameter is related to one of the terms (proportional, integral, or derivative) of the control law.

Proportional action. The magnitude of the contribution of the proportional term to the overall control action is determined by proportional gain, K_p. A high proportional gain results in a large change in the output for a given change in the error. If the proportional gain is too high, the system can become unstable. In contrast, a small gain results in a small output response to a large input error and a less responsive (or sensitive) controller. In the absence of disturbances, pure proportional control will not settle at its target value but will retain a steady-state error that is a function of the proportional gain and the process gain.

Integral action. The contribution of the integral term is proportional to the error magnitude and error duration. Summing the instantaneous errors over time (integrating the error) gives the accumulated offset. The magnitude of the contribution of the integral term to the overall control action is determined by the integral gain, K_I. The integral action (when added to the proportional action – PI controller) accelerates the movement of the process toward the setpoint and eliminates the residual steady-state error that occurs with a proportional-only controller. However, because the integral term responds to accumulated errors from the past, it increases oscillations and overshoots of the setpoint.

Derivative action. The rate of change of the process error is calculated by determining the slope of the error over time (its first derivative over time) and multiplying this rate of change by the derivative gain, K_d. The magnitude of the contribution of the derivative action to the overall control action is termed the derivative gain, K_d. The derivative action slows the rate of change of the controller output and thus decreases oscillations and overshoots, an effect that is most noticeable close to the controller setpoint. However, differentiation of a signal amplifies noise, and thus this term in the controller is highly sensitive to noise in the error term and can cause a process to become unstable if the noise and the derivative gain are sufficiently large.

Statistical Process Control

Statistical process control (SPC) is one of the most powerful tools for process improvement. Although SPC is new to the dairy industry, it is not really a new approach. It has been used successfully in manufacturing businesses for more than 60 years. SPC is a set of analytical tools of which the control chart is one of the most important. Control charts are helpful in signaling that a change has occurred. The fundamental concept of control charts is to distinguish between inherent random variation and real changes in output, quality, or measured performance. SPC methods can be used to signal emerging problems and to evaluate the positive or negative impact of a change in a management practice or the implementation of a new product. Next, some of the most commonly used online multivariate SPC techniques are presented briefly.

Empirical Linear Techniques

Batch process modeling and monitoring has been always a challenging problem in dairy engineering due to the presence of nonlinear behavior and serial correlation, correlated and/or collinear data, varying batch lengths, and multiproduct production. Current state of the art empirical techniques include the bilinear approaches of multiway principal component analysis (MPCA), the multiway partial least squares (MPLS), and the trilinear methodologies of parallel factor analysis (PARAFAC) and PARAFAC II. Although the above bilinear and trilinear techniques have been applied successfully to batch processes, they experience a number of limitations. For example, they do not incorporate the process dynamics, and with the exception of PARAFAC II, the duration of the batches is assumed to be constant. Moreover, for online monitoring, it is required that the whole batch trajectory is known or is predictable. This requirement results in certain assumptions being made to in-fill the unknown future values of the batch trajectory. Finally, all these techniques are linear and to a greater or lesser extent fail to capture the nonlinear nature of a batch process. Alternative approaches that overcome the issues of data in-filling and unequal batches are presented next.

Moving Window Principal Component Analysis

In moving window principal component analysis (MWPCA), typically, measurements from a batch process are arranged in a three-dimensional matrix **X** ($NB \times NV \times NT$) where NB, NV, and NT are the number of batches, variables, and time instants (**Figure 2**(**a**)). The three-dimensional matrix **X** can be transformed to a bidimensional matrix by unfolding over the batch dimension ($NB \times (NV \times NT)$), as shown in **Figure 2**.

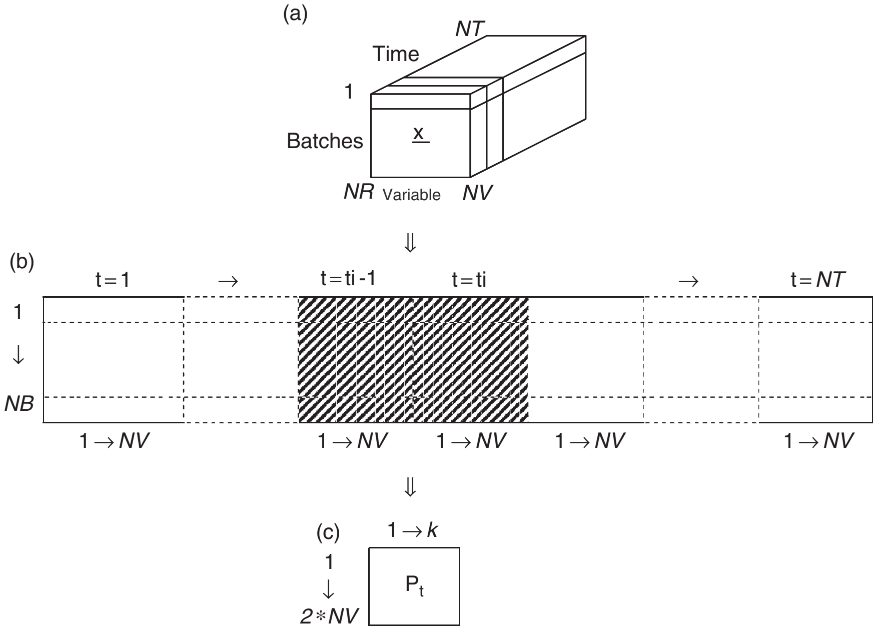

Figure 2 Moving window principal component analysis (MWPCA).

A scaling is usually applied to the unfolded matrix **X** before an ordinary principal components analysis (PCA). The mean of each column of **X** is subtracted from each data element of this column. This way of mean centering is very important as it results in the removal of the main nonlinear component in the data. Furthermore, by scaling the variables in each column of **X**, the differences in the measurement units between variables can be handled to allow equal weight to be given to each variable at each time interval. A PCA model is then developed on a moving window of data. Having selected the length of the moving window (L), MWPCA then develops $NT{-}L+1$ PCA models for each time interval by decomposing the ($NB \times NV$) matrix **X** into a systematic and noisy part:

$$\mathbf{X} = \mathbf{T}_k\mathbf{P}_k^T + \mathbf{E} \qquad [1]$$

where $\mathbf{T}_k$ and $\mathbf{P}_k$ are the matrices of the k retained principal component scores and loading respectively, and **E** is the matrix of the residuals. The number of the retained principal components, k, is usually determined by the means of cross-validation. For the application exemplified, the order of the moving window was selected to be $L = 2$. For each PCA model, the loading matrix $\mathbf{P}_k$ is stored. Having performed a PCA analysis, a set of online monitoring tools can then be developed. Typically, these tools are Hotelling's T^2 and squared prediction error (SPE) control charts. For instance, considering that a new batch $\mathbf{x}_{\text{new}}$ is to be monitored, the Hotelling's T^2 is calculated using the k retained PCA scores by:

$$\mathbf{t}_k = \mathbf{x}_{\text{new}}\mathbf{P}_k \qquad [2]$$

$$T^2 = \mathbf{t}_t\mathbf{S}_t^{-1}\mathbf{t}_t^T \qquad [3]$$

where $\mathbf{t}_k$ are the k retained PCA scores and **S** is their covariance matrix. The SPE is then calculated as follows:

$$\text{SPE} = \mathbf{e}_t\mathbf{e}_t^T \qquad [4]$$

$$\mathbf{e} = \mathbf{x}_{\text{new}}\left(\mathbf{I}-\mathbf{P}_k\mathbf{P}_k^T\right) \qquad [5]$$

Batch Dynamic Principal Component Analysis

The MWPCA approach does not capture the dynamic behavior within a batch process. The batch dynamic principal component analysis (BDPCA) is an alternative method that uses lagged variables to incorporate process dynamics. More specifically in BDPCA, each batch is isolated from the others (see **Figure 3**(**a**)). A matrix $\mathbf{X}_{iv}$ ($NT \times NV$) is formed for each iv batch. Then each of the NV variables is lagged d times resulting in a lagged $\mathbf{X}_{iv}$ $[(NT - d) \times (NV \cdot (d+1))]$ matrix (see **Figure 3**(**b**)). The covariance matrix of the lagged $\mathbf{X}_{iv}$ matrix, $\mathbf{S}_{iv}$, is then calculated (see **Figure 3**(**c**)). The procedure is repeated for all NB batches, resulting in NB $\mathbf{S}_{iv}$ covariance matrices. The elements in each of the $\mathbf{S}_{iv}$ matrices are a measure of the dynamic relationship between variables in batch iv. Having calculated these dynamic correlations for all NB batches, an average covariance matrix, $\mathbf{S}_{\text{avg}}$, is then calculated based on the NB $\mathbf{S}_{iv}$ covariance matrices (see **Figure 3**(**d**)):

$$\mathbf{S}_{\text{avg}} = \frac{(NT-d-1)\sum_{iv=1}^{NB}\mathbf{S}_{iv}}{NV(NT-d)} \qquad [6]$$

The average covariance matrix, $\mathbf{S}_{\text{avg}}$, expresses the average dynamic relationships between the process measurements. A PCA model is then developed based on $\mathbf{S}_{\text{avg}}$ (see **Figure 3**(**e**)). The resulting BDPCA model is finally used to calculate the T^2 and SPE statistics for monitoring purposes.

Batch Observation Level

The batch observation level (BOL) method considers the problem with unequal batch lengths. In BOL, the original three-way data is unfolded over the variable's dimension (see **Figure 4**(**a**)). A dummy y-variable that can be a time index or a batch maturity index is then specified. Data are scaled and matrix X is transformed into a systematic and noisy part as in eqn [1]. Partial least squares (PLS) analysis is then performed between the unfolded matrix **X** and the dummy **y** vector:

$$\mathbf{y} = \mathbf{T}_k\mathbf{c} + \mathbf{f} \qquad [7]$$

where **c** is the regression vector of **y** onto the PLS scores $\mathbf{T}_k$ (see **Figure 4**(**b**)) and **f** are the PLS model residuals. The number of PLS latent variables to be retained are selected as those that provide an adequate description of both the **X** and **y** spaces. For setting up an online monitoring scheme, the PLS scores retained are then rearranged over the batch dimension resulting in an $[NB \times (NT{\cdot}k)]$ matrix (see **Figure 4**(**c**)) and their mean and standard deviation calculated for each sample point and stored (see **Figure 4**(**d**)). In an online situation,

when a new sample is obtained, the scores are calculated initially and then scaled using the mean and the standard deviation of the corresponding sample point. These scaled scores are plotted against their control limits in univariate score plot charts. Similar to the previous approaches, T^2 and SPE charts can also be constructed.

Time-Varying State Space Modeling

Time-varying state space (TVSS) modeling is an alternative approach for batch process modeling and monitoring with the following state space model:

$$\mathbf{t}_{t+1} = \mathbf{C}_t \mathbf{t}_t + \mathbf{w}_t \qquad [8]$$

$$\mathbf{y}_t = \mathbf{H}_t \mathbf{t}_t + \mathbf{e}_t \qquad [9]$$

where **t** is the system states, **y** is the available process measurements, and **w** and **e** are the state and output residuals with covariance matrices **Q** and **R,** respectively. Finally, **C** and **H** are the state space model matrices, which are assumed to be time-varying as they aim to describe a nonstationary process. To develop the model, the data are initially unfolded and scaled as in MWPCA. The procedure to compute the TVSS matrices **C** and **H** then proceeds through the identification of the system states. For a time interval $t = k$, the past and the future of the system are defined as shown in **Figure 5**(**a**). The past (***p***) of the process is associated with the past process measurements of all batches at time *k* up to a specific lag (in **Figure 5**(**a**), the time lag, *K*, was set to a value of two):

$$\mathbf{p}_t = \left[\mathbf{y}_{t-1}\ \ \mathbf{y}_{t-2} \cdots \mathbf{y}_{t-K}\right]^T \qquad [10]$$

The future (***f***) of the process is the current and future process measurements of all batches (in **Figure 5**(**a**), the future horizon, *L*, is set up to a value of one):

$$\mathbf{f}_t = \left[\mathbf{y}_t\ \ \mathbf{y}_{t+1} \cdots \mathbf{y}_{t+L}\right]^T \qquad [11]$$

Now, by applying any one of either PLS, principal component regression (PCR), or canonical variate analysis (CVA) between the past (eqn [10]) and the future (eqn [11]) of the process, new latent variables that provide a reliable approximation of the true system states can be calculated. PCR scores capture the variability between process measurements, while PLS and CVA latent variables are those linear combinations of the past that include the information required to predict process future. The result of applying either a PCR, PLS, or CVA analysis is a weighting matrix $\mathbf{J}_t$, which is used to identify the system states through the past vector $\mathbf{p}_t$:

$$\mathbf{t}_t = \mathbf{J}_t \mathbf{p}_t \qquad [12]$$

Once the system states have been identified, the state space matrices can be computed using a least squares solution.

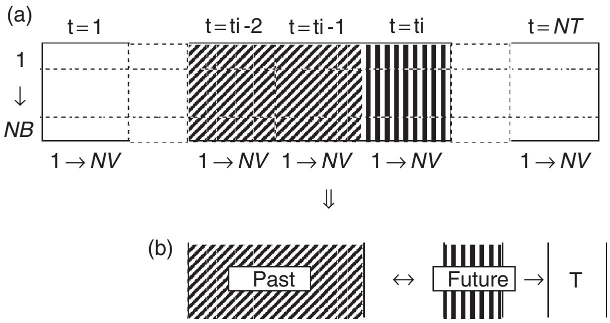

Figure 5 Time-varying state space model (TVSS).

Intelligent Control

The process modeling and monitoring techniques discussed in the section ‘Statistical Process Control’ are the first step toward developing modern computer-based control systems able to collect a large amount of process operational data, store it in databases, and display it to the operator. The next step is the subsequent decision making that still relies mainly on the human operators; however, new concepts and methodologies for automatic analysis and developing a computationally intelligent control (IC) are slowly being introduced in dairy manufacturing. IC deals with the application of data mining, machine learning, and knowledge discovery paradigms, artificial intelligence, expert systems, fuzzy logic, and neural networks for controlling complex physical processes that are difficult to control using conventional methods. The main modules of an IC system are discussed below.

Perception Subsystem

Information from the plant and the environment is collected and processed into a form suitable for perception. Basic elements of a perception subsystem are

- Sensor arrays – provide raw plant and environmental data
- Signal processing – transforms data into information and knowledge
- Data fusion and pattern recognition – uses multidimensional and varying nature data spaces to extract underlying patterns describing the plant and the environment

Cognition Subsystem

In an IC framework, cognition is concerned with the decision-making process under conditions of uncertainty. Basic activities of a cognition subsystem are

- Reasoning – using knowledge-based algorithms and fuzzy logic
- Strategic planning – using adaptive search and genetic algorithms for optimum policy evaluation and path prediction
- Learning – using adaptive supervised (teacher supported) or unsupervised (self) learning paradigms

The Actuator Subsystem

The actuators operate using signals from the cognition subsystem to drive the plant to some desired state. In the event of actuator/sensor failure, the IC system has to be able to reconfigure its control strategy.

Though milk production is a traditional dairy process for which conventional controllers have been used intensively, IC appears to be quite plausible for such processes. If the temperature drifts during processing, safety can be compromised or the product flavor or texture might be ruined. To perform the delicate balancing act that dairy products demand, plant operators need complete control, including the ability to know precisely what is happening at every moment and to perform urgent changes on time. It is not easy, especially when the product is hidden from sight in tanks and pipes more than 90% of the time. Companies that process the same products day in and day out have experience on their side, but those that change frequently have to be very agile and adaptable. In this sense, fuzzy and model predictive controllers are very good examples for building IC systems that are well accepted generally in the process industry.

Fuzzy Logic Control System

The basic structure of a fuzzy logic control system (FLCS) is shown in **Figure 6**.

Fuzzification Module

Fuzzification is a process of mapping the input variables to the fuzzy logic controller (FLC) into a set of membership functions, known as fuzzy sets. Fuzzy set theory provides a means for representing uncertainty. In general, probability theory is the primary tool for analyzing uncertainty and assumes that uncertainty is a random process. However, not all uncertainty is random, and fuzzy set theory is used to model the kind of uncertainty associated with imprecision, vagueness, and lack of information.

Conventional set theory distinguishes elements that are members or not members of a set, with very clear, crisp boundaries between them. For example, temperatures between 20 °C and 30 °C belong to the crisp set 'medium temperature', and all temperatures between these boundaries have a membership value of one ($\mu = 1$). The central concept of fuzzy set theory is that the membership function μ can have a value between 0 and 1. The shape of the membership function is also known as the universe of discourse. Among the most typical fuzzy set shapes are symmetrical triangles, trapezoids, and Gaussian or bell-shaped curves. Each set is given a linguistic label to identify it; for example, positive big (PB), positive small (PS), about zero (Z), negative big (NB), negative small (NS). The size of the universe of discourse depends on the range of the variable and the number of the sets. The number and shape of fuzzy sets are a trade-off between precision of control action and real-time computational complexity.

Fuzzy Rulebase Module

The fuzzy rulebase consists of a set of antecedent-consequent linguistic rules of the form

$$\text{Example: OR IF } e \text{ is PS AND } ce \text{ is NS THEN } u \text{ is PS} \qquad [13]$$

where e is the error (process reference – measured value), ce is the rate of change of the error $ce = \dfrac{\mathrm{d}e(t)}{\mathrm{d}t}$, and the objective of the FLC (see **Figure 6**) is to minimize e and ce.

In this example, the FLC input variables are e and ce, the fuzzy logic controller (FLC) output variable is u, and

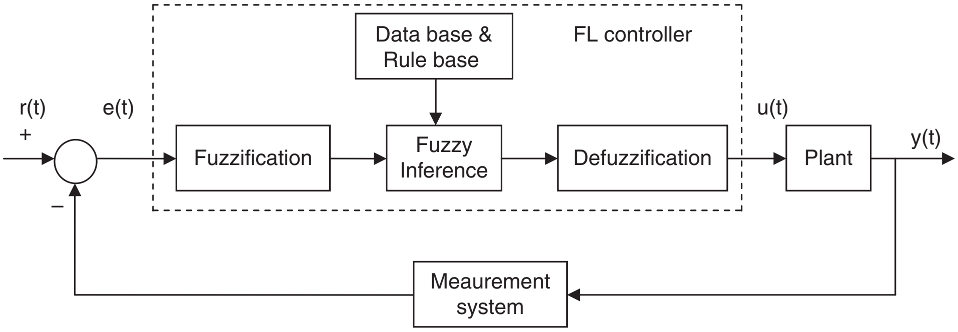

Figure 6 Fuzzy logic (FL) control system.

they all have values defined as fuzzy sets. The fuzzy conditional statement eqn [13] is often called a Mamdani-type rule after Mamdani who first used it to control a steam plant. The rule base is constructed using *a priori* knowledge from the following sources:

- Physical laws that govern the plant dynamics.
- Data from other controllers.
- Imprecise heuristic knowledge obtained from experienced plant operators and experts.

Fuzzy Inference Module

Fuzzy inference is the process of mapping membership values from the input variable(s) through the rulebase to the output variable(s).

Example (continued): If at a certain moment the membership values of the input variables are

$$\mu_{PS}(e) = a,\ \mu_{NS}(ce) = b \qquad [14]$$

based on fuzzy set operations and the fuzzy rule eqn [13], the membership value of the control action u is computed as

$$\mu_{PS}(u) = \max[\min(\mu_{PS}(e), \mu_{NS}(ce))] \qquad [15]$$

Equation [15] is referred to as the max-min inference process or max-min fuzzy reasoning.

Defuzzification Module

Defuzzification is the process of mapping from a set of inferred fuzzy control signals belonging to fuzzy sets to a nonfuzzy (crisp) control signal. The center of area is the most well-known defuzzification technique, which can be expressed as

$$u\,(\text{crisp}) = \frac{\sum_{i=1}^{n} C(A\mu(u_i))A\mu(u_i)}{\sum_{i=1}^{n} A\mu(u_i)} \qquad [16]$$

where $A\mu(u_i)$ is the area of the ith membership function computed at the previous step (the fuzzy inference), and $C(A\mu(u_i))$ is the center of the respective area.

Model-Based Predictive Control

Modeling Approaches

Process modeling strategies can be divided into the following main streams:

- The analytical approach (*white-box models*) is concerned with building the so-called mechanistic model, also known as first-principles model, which is a set of mathematical expressions that reflect the dynamic (differential equations) or static (algebraic equations) behavior of the modeled plant. The mechanistic model is a result of extensive, specially designed experiments and domain knowledge on the physical laws that govern the process at hand. Analytical modeling is time and resource consuming, but it has the main advantage of permitting good generalizations and scale-up.
- Data-driven alternatives (*black-box models*) are based on data mining and machine learning techniques and aim at extracting process knowledge from databases collected during the normal operation of the plant. The development of data-driven models usually takes less time and resources; however, their generalization outside the data space used to build the model is poor. One of the most common black-box models is the artificial neural network (ANN) paradigm, which will be described in more detail later.
- Hybrid modeling (*gray-box model)* is a combination of the two previous approaches and is also known as knowledge-based hybrid modeling (KBHM). KBHM offers a reasonable compromise between the extensive efforts to obtain a fully parameterized structure and the poor generalization of the data-driven models.

Process modeling for the dairy industry is strongly influenced by the recent trends in building data-based or KBHM models. For example, fouling, the unwanted formation of deposits on heated surfaces, is a major unsolved problem in the dairy industry. A direct consequence of fouling is reduction in the processing efficiency, because the material deposited disturbs both the fluid flow and the heat transfer, which in turn may impair product quality. Additionally, the deposit removal shortens the running time between cleaning cycles and thus increases the costs. As a result, daily cleaning is a common practice in the dairy industry and is necessary for hygienic and product quality requirements. The additional annual costs in the dairy industry caused by fouling are estimated at US$260 million per year. A relevant model of fouling would be a powerful tool for the development of strategies to avoid or reduce this unwanted process. However, due to its very complex nature, milk fouling is only partially understood, and its modeling is a challenging issue. A KBHM model combining parameterized equations (for fluid flow, heat and mass transfer) with qualitative knowledge in fuzzy logic form (for protein and salt deposition) was developed a few years ago. The model describes the fouling behavior with regard to the temperature and the pressure drop in a time-dependent manner, and it is not restricted to a certain dairy product or plant configuration. KBHM was successfully used for testing technological improvements in the heat treatment of milk in tubular heat exchangers.

Model Predictive Control – General Formulation

The term model predictive control (MPC) does not refer to a particular control method; instead, it corresponds with a general control approach. The MPC concept, introduced in the late 1970s, has evolved to a mature level and has become an attractive control strategy implemented in a variety of process industries and in the dairy industry in particular. The main difference between the MPC configurations is the model used to predict the future behavior of the process or the implemented optimization procedure. First, the MPC based on linear models gained popularity as an industrial alternative to PID control, and later nonlinear cases such as tubular heat exchangers and drying processes were reported as successfully MPC-controlled processes. MPC is an optimization-based multivariable constrained control technique that uses a dynamic model, from the types described in the previous section, for process output predictions.

At each sampling time, the model is updated on the basis of new measurements and state variables estimates. Then, the open-loop optimal manipulated variable moves are computed over a finite (predefined) prediction horizon with respect to some performance index, and the manipulated variables for the subsequent prediction horizon are implemented. The prediction horizon is shifted or shrunk by usually one sampling time into the future, and the previous steps are repeated.

Artificial Neural Networks

Over the past 20 years, ANNs became a well-established methodology not only as a reliable classifier with countless applications but also as a data-driven modeling framework. The remarkable success of the ANN approach is in great part due to the following features:

1. ANNs are universal approximators. It has been proved that any continuous nonlinear function can be approximated arbitrarily well over a compact set by a multilayer ANNs, which consists of one or more hidden layers.
2. Learning and adaptation. The intelligence of ANNs comes from their generalization ability with respect to unknown data. Online adaptation of the weights is possible.
3. Multivariable systems. ANNs may have many inputs and outputs, which makes it easy to model multivariable systems.

ANNs have been applied to design robust neural controllers with guaranteed stability and reference tracking. The neural control problem can be approached in a direct or indirect control design framework. Direct ANN control means that the controller has an ANN structure, whereas in the indirect ANN control scheme, first an ANN is used to model the process to be controlled, and this model is then used in a more conventional controller design. The implementation of the first approach is simple, but the design and the tuning are rather challenging. The indirect design is very flexible, the model is typically trained in advance, and the controller is designed online. Moreover, the ANNs appear to be rather convenient numerical models when dealing with nonlinear systems or in general with systems for which data are available but little is known on the physical mechanisms that determine their dynamics.

The most popular ANN structures for modeling reasons are feedforward networks (FFNNs) and recurrent networks (RNNs). The RNNs are most suitable for dynamic system modeling, due to the memory introduced by the recurrent (delayed and/or fed back) signals (see **Figure 7**). Normally, the RNN has two vector inputs (*r* and *p*) formed by past values of the process input and the network output, respectively. A linear activation function is often located at the output node (layer 2), and S-shape functions are usually the hidden nodes (layer 1).

ANN Error Tolerant Model Predictive Control

MPC controllers proved to be the most promising alternative to the traditional PID control that has the potential to overcome the problem of the lack of repeatability and related product recycling or loss increase. It has been applied successfully in batch dairy processes assuming linear process dynamics. However, online execution of MPC with predictions running on a large number of empirical and analytical nonlinear algebraic differential equations (the process model) make this alternative computationally more demanding or even

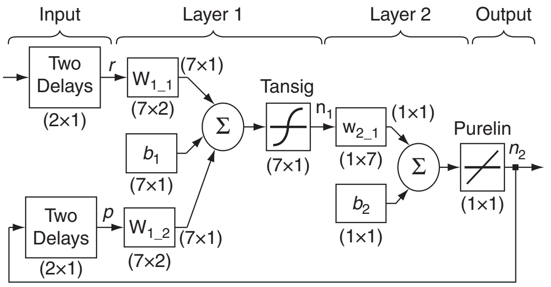

Figure 7 Recurrent neural network (RNN) architecture.

unfeasible for dairy processes with fast nonlinear dynamics. Even for processes where the standard control approach (e.g., ladder logic) is not the best solution, the implementation of MPC is impeded due to high computational costs.

A recent modification of the classical MPC, termed ANN Error Tolerant (ET) MPC, reduces considerably the average duration of each optimization step and makes the MPC computationally more efficient and attractive for industrial applications (see **Figure 8**). The ANN model is integrated into the controller, and the optimization procedure is executed only when the error is above a predefined value.

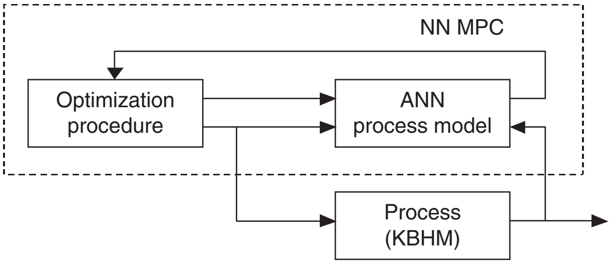

Figure 8 ANN-based model predictive control (MPC).

The discretized version of the modified performance index is

$$u(t+k) = \begin{cases} u\text{:}\left\{ \min\limits_{[u(t+k),u(t+k+1,\ldots u(t+H_c))]} \quad F = \lambda_1 \sum_{k=1}^{H_p} (e(t+k))^2 - \lambda_2 \sum_{k=1}^{H_c} (\Delta u(t+k))^2, \text{if } E_{\sum} > \alpha \right. \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad , \alpha \in R^+ \\ u^* \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad , \text{if } E_{\sum} < \alpha \end{cases} \qquad [17]$$

where $E_{\sum} = \frac{1}{H_p}\sum_{k=1}^{H_p} \left| e\,(t+k) \right|, e(t+k) = ref\,(t+k) - y_p(t+k), \Delta u(t+k) = u(t+k-1) - u(t+k-2)$, is the prediction model response. The prediction horizon H_p is the number of time steps over which the prediction errors are minimized, and the control horizon H_c is the number of time steps over which the control increments are minimized. $u\,(t+k),\ u\,(t+k+1), \ldots u\,(t+H_c)$ are tentative values of the future control signal, which are limited by $u_{\min}$ and $u_{\max}$. The controller is denoted as an ET MPC formulation because the optimization is performed only when the error function $E_{\sum}$ is bigger than a predefined real positive value α. To reduce the computational burden when the error is less than α, the control action is equal to u^*, which is the last value of u, computed before the error enters the α strip. Note that $E_{\sum}$ in eqn [17] is defined as the mean value of the future errors, between the predicted output and its reference along the next H_p steps.

Conclusion

In new integrated dairy plants, each process is carried out in multiple phases, and there exists strong nonlinear and dynamic effects between the variables. Therefore, modern process control systems have usually a hierarchical architecture including decentralized controllers, remote input and output (I/O) modules, fieldbus systems, local area networks (LANs), and smart sensors and other devices. The huge amount of information flows are stored and used online or off-line for executing the IC alternatives like FLC, ANN MPC, or SPC, all methods described in this article.

Introduction

Robots are electromechanical devices that perform repetitive operations otherwise carried out by humans. In a modern dairy factory, human handling is rare in processing equipment; from liquid milk to packaged product, there are few, if any, manual operations. Even packaging lines have been highly automated, and operators in a modern dairy plant are needed mostly to load/unload some machines, check the controls, and react to production problems. The interest in robots in dairy lies mostly in the two extremes of the process: (1) milking and herd management; (2) final palletizing and stock management.

Robots rarely look like humans, as they only need to have the parts that perform the specific action. In essence, an industrial robot must have sensors to detect positions, shapes, and forms, a program that allows it to identify what it will be handling, moving parts with grippers for grabbing and handling, and other sensors directing the moving parts to place what it is handling in the correct position. They may also have valves, pumps, and other devices, depending on the nature of the action they need to perform. Robots must be programmable, so that the actions can be set up by the operator with the required flexibility. This is the main reason why robots are a solution where automation is otherwise not possible. Usually, a period of training of the program will be necessary, so the accuracy of the action can be adjusted to the inputs from the sensors.

Dairy offers a good example of the difference between automation and robotics. The latter implies the former, but not the reverse. It is possible to milk a cow using automated systems that collect the milk and even detach the cups from the teats automatically, once they detect that milking should cease. However, it takes a human to place that automated milking device on a cow, because individual animals have their own size and anatomy and teats may be affected by some illness or defect and cannot be handled as if they were all the same. Furthermore, mastitis or any problem with teats or the udder needs to be assessed, and individual animals may need individual attention in feeding or medication. Using robots means that humans are no longer needed for these actions. Simple automation can work only for standardized situations, while robotics can provide the flexibility that the human analysis gives, by mimicking what that analysis does.

Robots can have several advantages. The most obvious are that they can have much higher productivity and consistency than humans, and that they minimize labor costs. In the food industry, in general, they also have the advantage of high hygienic conditions and ease of sanitizing, compared to humans, therefore ensuring more aseptic conditions. Whether they are a valuable investment or not depends, therefore, on their costs versus labor costs, productivity gains, and lower quality rejection costs. There are other benefits that may accrue in some specific cases, and milking is one of those.

Milking Robots

Milking robots have been one of the most popular applications of robotics in agriculture. The first farm to implement such a system in Europe did so in 1992; the first installation in North America was in 1999 (Canada). Interest in the subject rose steadily in the 1990s. In 1997, *Computers and Electronics in Agriculture* devoted a special issue to robotic milking. In 2000, the European Union commissioned a project on the introduction of automatic milking on dairy farms, under its R&D Framework Programme, which also produced substantial information and analysis (completed in 2003, but the website is still accessible). The Future Dairy project run in Australia also provides comprehensive information and details to assist farmers in evaluating the interest these systems may have for them. In 2006, there were over 4000 farms worldwide reported to use robotic milking.

The need to lower farming costs, and particularly labor costs, in developed countries is the most obvious driver for investment. Lack of human resources for farming is also a growing problem in these countries, as the average age of farmers continues to increase, and less people are willing to work as salaried peasants. Robots that facilitate strenuous farm activities have also been claimed to permit farmers to work to a later retirement age, and to be able to take care of themselves better (e.g., cows need to be milked daily even if the farmer needs to be in hospital for a couple of days). Labor issues are therefore a primary reason for a dairy farmer to decide investing in robotic milking, but it should be noted that in farming that is more than just costs. Furthermore, a fully automated milking system (AMS) has other advantages:

1. The increased sanitization and hygienic conditions from the absence of humans minimize cross-contamination of mastitis and health problems in general (not only between animals, but also between animals and humans), which improves well-being and minimizes health costs.
2. Milking can take place at any time throughout the day, therefore avoiding that animals may need to wait for long times, thus improving their general well-being.
3. Animals can be milked more than the conventional 2 times daily. It has been found that increases in milk production of 5 up to 25% typically result from increasing milking from 2 times daily to 3 times daily.
4. Each animal can set the regime that suits it best, instead of a 'one-size-fits-all' scheduling of conventional milking (with robotic milking, the animal decides when to be milked). As a result, well-being and production are improved.
5. Feed regimes can be individualized. Typically, animals are attracted to the milking robot by feeding, and so milking robots can also control the feed and nutrient intake, as well as any medication needed.
6. Milking robots can also detect illnesses, such as mastitis, and presence of blood or contaminants in the milk with sensors, besides knowing if the specific animal is going through some medication regime, and automatically divert contaminated milk, thus allowing for an easy management of health-related issues in milk collection.

Milking robots cannot be confused with automatic milking systems operated by people, where the animal traffic is controlled by farmers, the animals are placed in position, and automated milking cups are then placed by farmers on the teats for automatic pumping and collection in vats, such as in a rotary dairy parlor. Relatively new dairies may have quite some automation already, such as in-shed computer-managed feeding, automatic cup removal (ACR), teat spraying, and drafting. In fact, one could consider that the only new element of the robot is automatic cup attachment (ACA), so why not add just that one element in an already fairly automated process? Unfortunately, retrofitting a rotary dairy for robotics is not feasible, and in general, any previous automations are made redundant if a farmer invests in milking robots.

Typically, robotic milking goes together with free animal traffic, and the animal is motivated to go to the robot, rather than being pushed or forced in some way. Feeding is the usual attraction. As an animal approaches an available robot, its entrance gate opens, the animal goes in to feed, and the gate then closes. The robot detects the individual animal from its collar or tag (if fitted with a relevant device, such as a small radio frequency tag), and may therefore dispense a tailored feed (with eventual medication or supplementation needed). The sensors detect the position and size of the animal, and activate an electromechanical arm that reaches under the udder and puts the automated milking cups in place. Teats are brushed first and cups attached one at a time. The robot will also have sensors to detect the flow rate of milk, so it controls the milking amount (thus avoiding overmilking), as well as color, conductivity, and presence of blood. It can therefore divert the milk collection in case of contamination. It may also decide not to collect milk from one of the cups and hence not handle a teat, if there is any reason for the system to do so, such as a health issue. The cups are removed in sequence; as the milk flow rate falls below a given threshold, it removes the quarter teat cup, and so on, until all quarters are milked. Milk collection management by quarter instead of overall udder mix is one of the advantages of AMS, especially if one of the teats has any particular problem. A teat spray is then applied to improve hygiene. All information regarding each individual animal is stored in the system. The animal is released through the exit gate, and the entry gate can then open for the next one. Animal traffic management can be designed to optimize the performance.

New animals are trained relatively fast (2–6 milking days have been reported in the literature, with heifers being trained more easily than cows), and adjust their daily cycles to distribute themselves regularly throughout the whole day (and night). Studies showed that cows visit robots an average of 3–4 times a day, and that the number of cows that do not attend a robot for milking over a day, for no apparent reason (thus called 'lazy cows'), can reach a figure as high as 10%. This was found to relate quite strongly to the palatability of the pelleted concentrate added to the feed, so feed composition plays an important role in motivating the animals to the robot.

Ideally, the barn itself should be designed with the implementation of the robots and animal traffic in mind, rather than retrofitting. The design of the infrastructure, farm layout, laneways, ramp, automatic control gates, and strip grazing layouts are very important. Both management and facilities need to be redesigned to integrate AMS successfully. It is not surprising that the herd manager will spend more time servicing the equipment and reading and interpreting the information collected in the system about each individual animal than in actual attending to the animals themselves. The data collected by the sensors will detect estrus, as well as mastitis and other illnesses, and the farmer can plan medication and feeding in the robot, so the health care seems to take place by proxy. On the other hand, the farmer has more time to devote to analyzing the detailed information, which allows for more informed and speedy decisions to maximize efficiency and profitability.

The economics of robotic milking are not straightforward. Some analyses indicate that the financial benefits are clearer for smaller producers, while others point to a break-even level of investment that is about twice that of a conventional parlor milking system and hence a greater financial clout than that of small farms. Cost factors vary from year to year and location to location, and which benefits are more important to individual farmers also vary substantially, depending on various factors such as size of herd, type of management, lifestyle, age, and availability of human resources on the farm. Each farm therefore needs to consider its specific situation to evaluate the feasibility of implementing AMS properly. There may be various reasons for robotic milking to be attractive to one farmer and not to the neighbor.

It should be noted that milking robot costs are not just investment. Running costs of a milking robot include maintenance of a sophisticated system and electrical power supply. Typically, a robot will require between 15 and 25 kW per tonne of milk, while being capable of harvesting 2–2.5 tonnes of milk per day.

The most important factor to bear in mind is the need for a strategic approach to the whole milking and farming process. The use of electronic tagging and automated gates permits a full herd management approach based on the individuality of each animal, thus including health management to the detail of medication and feeding of individuals, which maximizes the well-being and the benefits. Personalized feeding may prove financially more beneficial than saving labor costs, as the former account typically for 45–50% of the dairy farm costs, compared to 8–15% for labor (approximately half the labor costs are due to milking). The better hygienic handling and more precise health management can also lower health costs. Robotic milking is not only a cost analysis, as gains need to be factored as well, namely the increased milk production resulting from more efficient health and feed management and more frequent milking.

The main manufacturers of milking robots are Lely and DeLaval. The former has been on the market for longer and is the market leader. The latter reported selling its 5000th unit in April 2009. Supplier support and training has been considered crucial and therefore a good working relationship between farmers and manufacturers is essential.

Palletizing Robots

Once individual containers of any dairy product are bundled in secondary packages (carton boxes, or simple plastic wrapping of individual containers, as with many liquid milk cartons), these must be piled on palettes at the end of the packaging line. These will be stored in warehouses and later loaded onto trucks for sale. The palettes are moved around with forklifts, and often piled on several layers in warehouses. All these operations can be robotized.

Figures 1–3 show a robotic palletizing solution for 1 l containers. Robots are fed from two fully automated packaging lines for the 1 l containers that begin by forming them out of reels of the packaging material, and fill them volumetrically in one machine. Both lines can then send them individually to the next room, or group them in packs of 10 (or 12) with plastic wrapping in another machine. Conveyors then transport the individual 1 l containers or the packs of 10 or 12 in separate lines from the packaging to the palletizing room, one conveyor line for each robot. **Figure 1** shows one of the conveyors delivering the packs of 10 or 12 to robot 1 for palletizing. This robot moves a double gripper that can pick up and then place two packs at a time on one of two palettes. This is the most usual type of palletizing robot, which can also handle other types of boxes, such as yogurt and butter containers. Note in **Figure 1** that the packs of 10 were moved so they are not aligned, and that 3 were placed at the base. This will not be a problem for the robot, as its sensors allow it to know exactly where the packs are, when to close the gripper, and to what strength, so that two packs are picked up and placed gently in place.

Figure 2 shows the whole palletizing room, and gives a different view of this first robot. It is placing two packs of 10 packages of 1 l at a time on two palettes. In order to improve stability, the stacking patterns are changed from layer to layer. The robot stacks the layers on the palettes

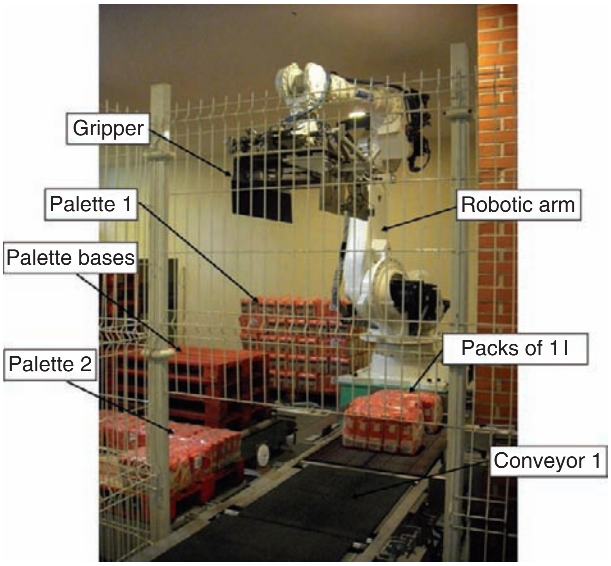

Figure 1 Palletizing robot with a double gripper. It is picking up two packs of ten 1 l containers at a time and stacking them with varying patterns on two palettes, alternately. The palette (wooden) bases are moved by the robot itself from the stack at the commencement of each palletizing. A conveyor brings the packs to the robot from the packaging room. Photographed by the author, courtesy of Ernesto Morgado S.A.

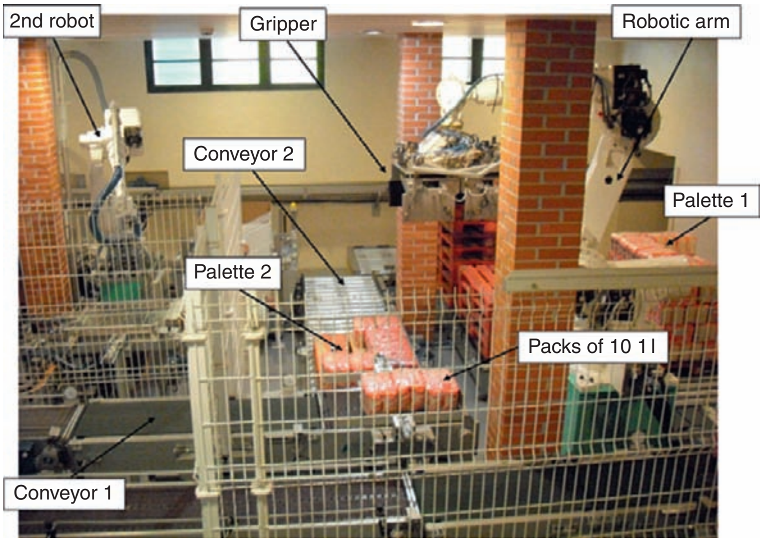

Figure 2 Example of a robotic palletizing room implemented in a tight space. The robot in **Figure 1** is on the right, behind a column. One of the roller conveyors that slide palettes away when ready can be seen at the center. A train line then transports the palettes to the next room. A second robot is on the top left of the figure. Each of the robots in this room is handling over 1000 containers per hour, a rate that is actually controlled by the rate at which conveyors move packs and packages rather than by rate constraints of the robot itself, and could thus be increased further to about 2500 per hour. Photographed by the author, courtesy of Ernesto Morgado S.A.

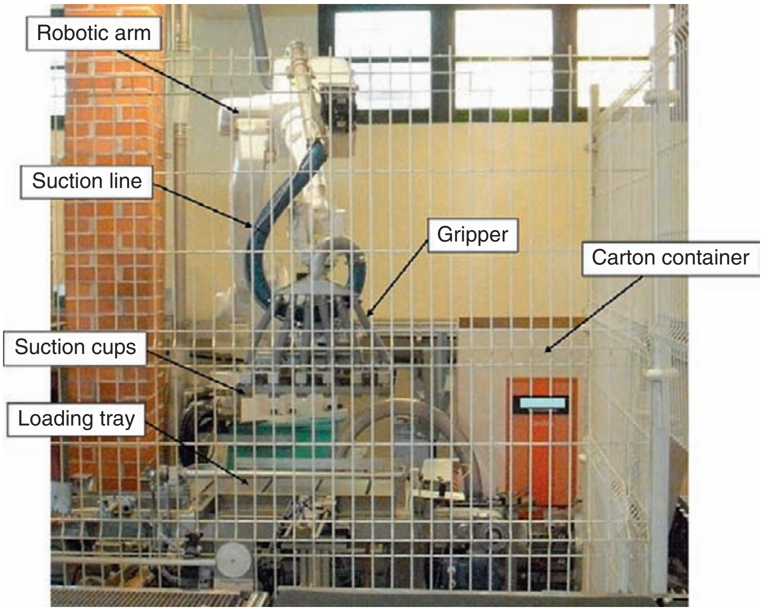

Figure 3 Palletizing robot with suction cups. One-liter packages are transported by a conveyor from the packaging room and accumulated as a 6 × 8 layer of 1 l packs at the bottom plate. The gripper plate, with 48 suction cups, picks up the layer and stacks it on the carton container seen on the right of the picture. When ready, it is slided out to the train line by a roller conveyor, and then moved to the next room. Photographed by the author, courtesy of Ernesto Morgado S.A.

so they will be ready to move on alternately (when one is ready, the other is about half done). When ready, each palette slides with roller conveyors to a train line (near the wall) that will carry the palettes to another room, where they will be automatically wrapped with plastic for extra rigidity, and are then ready for forklifts to carry them to the warehouse. A second robot is also seen on the left of **Figure 2**. Note also in this example how robots can be operated in a very tight space, and work around the constraints of an awkward building. Each of the robots in this example is handling over thousand 1 l containers per hour, working at less than 50% of its maximum achievable rate (this is because in these lines the rates are constrained by the rates of the packaging machines).

Achieving these productivities with human handling would require a much bigger room.

The second robot can be seen in more detail in **Figure 3**. It has a different gripping system, so it can handle a whole layer composed of individual 1 l packages into a big carton container. This robot uses a plate with suction cups to pick up a 6 × 8 layer of individual 1 l packages from the bottom plate, which is fed by the other conveyor coming from the packaging room. These two robotic solutions reflect the client requirements of this particular company. Some clients wish to have packs of 10 or 12 to place on shelves at the point of sale; others prefer to receive a big carton container that is placed like that at the shop floor.

From the beginning of forming the 1 l containers to the fully wrapped palettes, the only human intervention in this case is placing the reels of packaging material in the packaging machines and the base of the palettes in the robot stack. In addition to increased productivity and reliability, this has eliminated human intervention, which can be strenuous and prone to employee absence for health reasons, such as 'bad back'.

There are many manufacturers of such systems, such as Robomatic, Robotworx, Kuka, and Yaskawa (Motoman make).

The example shown has no more robotic solution, so the forklifts to handle the palettes are still operated by humans. It is however possible to robotize that step also and actually run an entire automated warehouse, with robotic vehicles forklifting and moving the palettes to the warehouse, placing them in locations that its own management program defines, and retrieve them when necessary also according to the store management program of the automated system. Instead of small vehicles, it is also possible to operate the system with hoists and cranes moving around the ceiling, although this would be rather expensive for handling palettes the size of those in **Figures 1–3**.

A robotic warehouse for palettes is rarer, though, because the economic advantages are less significant than those of palletizing. Replacing one or two persons operating forklifts (which is not a strenuous task) by an expensive robotic system likely results in investment costs that are difficult to recoup. Automated warehouses can be found in retailing, where a high turnover of small items is needed, or in assembly lines using a large amount of small components (as in electronic manufacturing).

Some manufacturers who offer these solutions include RMT Robotics and Kiva Systems.

Corrosion

P D Fox, 90 Old Quarter, Ballincollig, Cork, Ireland

© 2011 Elsevier Ltd. All rights reserved.

Introduction

Corrosion is the deterioration of metals by an oxidation–reduction reaction, usually with loss of the metal to solution. Metals are generally found in their natural state in the Earth as metal oxides or ores. Most metals are more thermodynamically stable as oxides rather than as pure metals, with perhaps the exception of the noble metals, for example, gold and platinum. Mining and refining a metal is therefore an energy-intensive process, that is, there is an input of energy, and corrosion can be seen as the return of the metal to a more thermodynamically stable state. Corrosion causes the loss of billions of dollars per annum, and in industrial nations constitutes a large fraction of the gross national product. These losses are due to replacement of materials and labor costs, as well as plant downtime. Losses due to leaking or contamination of product and heat transfer problems are also significant. Conservation of natural resources is enhanced by the prevention of corrosion. In order to understand corrosion, one needs to be familiar with the basic principles of thermodynamics and electrochemistry.

Thermodynamics and Electrochemistry

The change in the Gibbs free energy, ΔG, of a reaction indicates whether or not the reaction will proceed. A reaction is said to be spontaneous if ΔG is negative. At constant temperature and pressure, the maximum amount of work, ω_{max}, a system can perform is given by the Gibbs free energy, that is, $\Delta_r G = \omega_{\text{max}}$. The Gibbs free energy of a reaction under non-standard conditions can be related to the equilibrium quotient, Q, by the following equation:

$$\Delta_r G = \Delta_r G^o + RT \ln Q \qquad [1]$$

where $Q = \Pi_j a_j^{\upsilon j}$ and υ is the stoichiometric number of the species j. Terms that make up the equilibrium quotient include the activities of metal ions, protons, and gases. In an electric cell, work is due to transfer of charge in the form of electrons across an electrochemical potential, E, between two electrodes. Therefore, the product of charge and potential results in work:

$$\Delta_r G = \omega_{e\ \text{max}} = \upsilon FE \qquad [2]$$

The Gibbs free energy can be related to electrochemical potential using the Nernst equation:

$$E = E^0 - \frac{RT}{\upsilon F} lnQ \qquad [3]$$

This equilibrium relates potential to standard potential and the equilibrium under non-standard conditions.

Standard Reduction Potential

Electrochemical reactions involve the transfer of electrons resulting in a change of oxidation state:

$$Cu^{2+}(aq) + Zn \rightarrow Cu + Zn^{2+}(aq) \qquad [I]$$

Reaction [I] can be broken down into a combination of two half-cell components, one for reduction (IIa) and one for oxidation (IIb):

$$Cu^{2+}(aq) + 2e^- \rightarrow Cu \qquad [IIa]$$

$$Zn \rightarrow Zn^{2+}(aq) + 2e^- \qquad [IIb]$$

Half-cell reactions occur at specific potentials. The overall potential of a reaction is the difference between the individual half-cell potentials. However, it is not possible to measure the absolute potential of an electrochemical process; so it is necessary to define a standard half-cell reaction relative to which the potential of all others is measured. For this purpose, by convention, a hydrogen electrode, also known as the standard hydrogen electrode (SHE), was chosen and arbitrarily assigned a value of 0 V:

$$H^+(aq) + e^- \rightarrow \frac{1}{2}H_2(g),\ E(H^+, H_2) = 0V \qquad [4]$$

The standard reduction potential of a test electrode is defined by whether it is oxidized or reduced when connected to a standard hydrogen electrode. If electrons flow from the hydrogen electrode to the test electrode, causing reduction of the test electrode, the measured potential is positive. The standard reduction potential is negative if the electrons flow in the opposite direction, that is, from the test electrode to the hydrogen electrode, thus oxidizing the test electrode. Using the standard hydrogen electrode as reference, tables have been constructed for all other electrodes, the reduction potential of which is either positive or negative relative to hydrogen. A partial list is given in **Table 1**.

The same principle applies to any two electrodes when constructing an electrochemical cell. The electrode with the lower standard reduction potential is the

Table 1 Standard reduction potentials for selected half-cells

Electrode	E° *V*
$Au^+ + e^- \rightarrow Au$	+1.83
$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$	+1.23
$Ag^+ + e^- \rightarrow Ag$	+0.80
$Fe^{3+} + e^- \rightarrow Fe^{2+}$	+0.77
$Hg_2Cl_2 + 2e^- \rightarrow 2Hg + 2Cl^-$	+0.27
$Cu^{2+} + 2e^- \rightarrow Cu$	+0.34
$Co^{2+} + 2e^- \rightarrow Co$	−0.28
$2H^+ + 2e^- \rightarrow H_2$	0.00
$Fe^{3+} + 3e^- \rightarrow Fe$	−0.04
$Fe^{2+} + 2e^- \rightarrow Fe$	−0.44
$Zn^{2+} + 2e^- \rightarrow Zn$	−0.76
$2H_2O + 2e^- \rightarrow H_2 + 2OH^-$	−0.83
$Al^{3+} + 3e^- \rightarrow Al$	−1.68
$Mg^{2+} + 2e^- \rightarrow Mg$	−2.37

anode, where oxidation occurs, and that with the higher potential is the cathode, where reduction occurs. The difference in the standard reduction potentials of the two electrodes, that is, cathode potential minus anode potential, is the overall cell potential. Using **Table 1** the potential of the cell in eqn [I] is found to be 1.1 V and when substituted into eqn [2], gives a negative Gibbs free energy. The current generated by this cell arises from the spontaneous flow of electrons from the zinc anode to the copper electrode. The flow of electrons from copper to zinc is a non-spontaneous process and requires external energy, as in the recharging of a battery by the electric mains.

Thermodynamics of Corrosion

The basic concepts of electrochemistry and half-cells can also be applied to corrosion. In fact, corrosion is the combination of a metal electrode (IIIa) with a water/oxygen electrode (IIIb). In this section, iron and various grades of stainless steel, due to their extensive use in the dairy industry, will be used to illustrate thermodynamic and kinetic data regarding corrosion:

$$2Fe(s) \rightarrow 2Fe^{2+}(aq) + 4e^- \qquad [IIIa]$$

$$2H_2O(l) + O_2(g) + 4e^- \rightarrow 4OH^-(aq) \qquad [IIIb]$$

$$2Fe(s) + 2H_2O(l) + O_2(g) \rightarrow 2Fe(OH)_2(s) \qquad [IIIc]$$

V, VI. or VII, therefore as in the previous example, the reaction can be broken down into its individual half-cell components and their corresponding standard reduction potentials as in **Table 1**:

$$Fe^{2+}(aq) + 2e^- \rightarrow Fe(s), E = -0.44V \qquad [IV]$$

The exact form of the water/oxygen electrode half-cell depends on the chemical environment, which can be acidic or alkaline.

In acidic solution:

$$2H^+(aq) + 2e^- \rightarrow H_2(g), E = 0V \qquad [V]$$

$$4H^+(aq) + O_2 + 4e^- \rightarrow 2H_2O(l), E = +1.23V \qquad [VI]$$

In alkaline solution:

$$2H_2O(1) + O_2 + e^- \rightarrow 4OH^-(aq), E = +0.40V \qquad [VII]$$

As shown in the previous section, when two electrodes are combined, the electrode with the lower standard reduction potential is the anode and undergoes oxidation. The electrode with the higher standard reduction potential is the cathode and is reduced. Since iron has a lower standard potential (IV) than the half-cells , V, VI or VII, therefore it undergoes oxidation when in contact with water/oxygen. This leads to an overall positive potential and a negative Gibbs free energy, showing that oxidation, that is, corrosion of iron, is a thermodynamically favorable process.

A common method for illustrating the thermodynamic data of a metal involves the use of a Pourbaix diagram, which is shown for iron in **Figure 1(a)**. It shows the most stable species of iron as a function of potential and pH. The activities of iron and other ions in solution determine at which pH and potential the transitions between different metal phases occur. Water is stable between the lines **a** and **b** (reactions [V] and [VI], respectively). A potential below line **a** causes the reduction of water to hydrogen, while above line **b**, water is oxidized and oxygen is evolved. However, the activity of protons in solution is pH dependent. Substitution of **a** or **b** into the Nernst equation [3] allows potential to be expressed as a function of proton activity or, more conveniently, as a function of pH:

$$E = 0.00 - 0.059 \text{ pH} \qquad [5]$$

$$E = 1.23 - 0.059 \text{ pH} \qquad [6]$$

The potential for the oxidation and reduction of water, lines **a** and **b**, respectively, decreases by 59 mV for every increase of 1 pH unit. In the Pourbaix diagram of iron (**Figure 1(a)**), the horizontal lines represent equilibrium reactions that are independent of pH, while the vertical lines represent reactions that do not involve the transfer of electrons. Diagonal lines are reactions that involve electron transfer and are pH dependent. The exact position of these lines is determined by the concentration of iron ions or by the presence of other ions in solution. All these reactions can be substituted into the Nernst equation [3] to derive expressions relating potential to standard potential, pH, and ion concentration. For a more complete description of the phase diagrams of

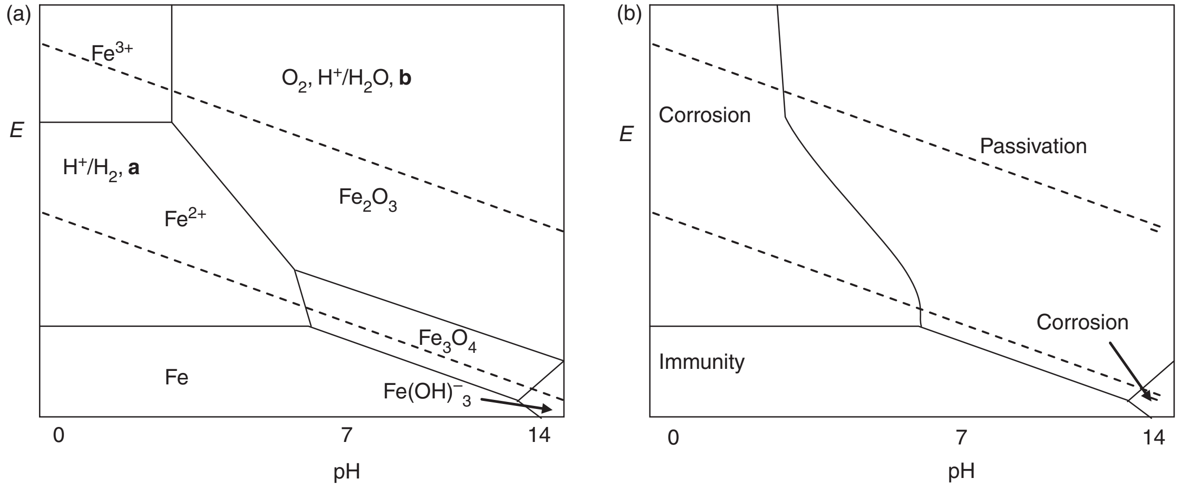

Figure 1 (a) Pourbaix diagram for most stable species of iron in pure water. (b) Pourbaix diagram showing regions of immunity, passivation, and corrosion.

iron, as well as many other electrodes, the reader is referred to the Further Reading section.

Figure 1(a) shows that at low pH and potential, iron is stable. Increasing the potential at low pH results in hydrated Fe^{2+} and Fe^{3+} and so corrosion occurs. At high pH, iron exists as oxides or hydroxides, with the oxidation number increasing with potential. If the oxide is soluble, further corrosion occurs. However, if the iron oxide is insoluble in water, a thin layer of oxide builds up on the surface. This oxide then protects iron from further oxidation and the metal is said to be 'passivated'. A similar effect is seen in the formation of green copper oxide, for example, on rooftops where the initial oxidation of copper forms a protective film and prevents further oxidation. **Figure 1(b)** shows the regions of immunity, corrosion, and passivation for iron.

Kinetics of Corrosion

Potential measurements and Pourbaix diagrams indicate whether or not corrosion is thermodynamically favorable. However, thermodynamic data provide no information about the rate of corrosion. Therefore, it is necessary to develop kinetic methods to measure the rate of corrosion. Kinetic information in electrochemistry is usually represented by a Tafel plot. When an electrode is at equilibrium, oxidation and reduction currents of equal magnitude but opposing direction result in zero net current. This equilibrium current is known as the exchange current, i_0, and the potential at equilibrium is E_{eq}. In order to measure i_0, a positive or negative polarizing current is applied resulting in an overpotential, η. Overpotential is defined as the deviation of potential from E_{eq}, that is, $\eta = E_{eq} - E$. At high overpotential, a plot of $\ln|i|$ as a function of η is linear(see **Figure 2**). Extrapolation back to E_{eq} gives the value of exchange current:

$$ln|i| = lni_0 + \frac{\alpha nF\eta}{RT} \qquad [7]$$

The slope gives information about the symmetry, α, of the reaction, which relates the reactant and the product to the activated complex along the reaction coordinate. A value of 0.5 means that the structure of the activation complex resembles that of the reactant and product equally.

Corrosion is a two-electrode system at equilibrium. The combination of two electrodes results in a mixed potential, known as corrosion potential, E_{corr}. Corrosion current, I_{corr}, is equal to the absolute values of the opposing oxidation and reduction currents. When the Tafel

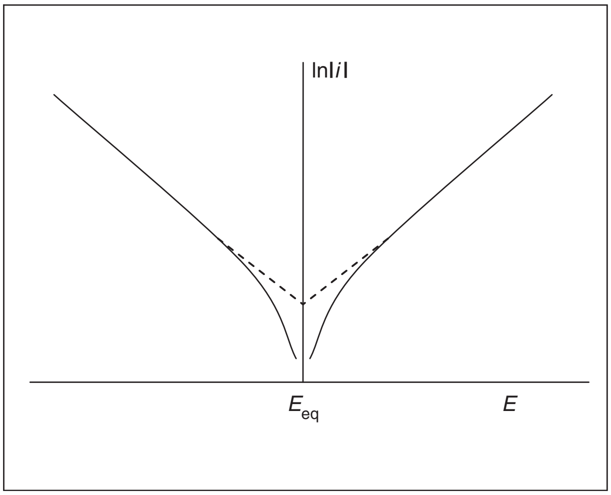

Figure 2 Tafel plot for the measurement of exchange current, i_0. Transfer coefficient, α, is measured from the slope and has a typical value of 0.5.

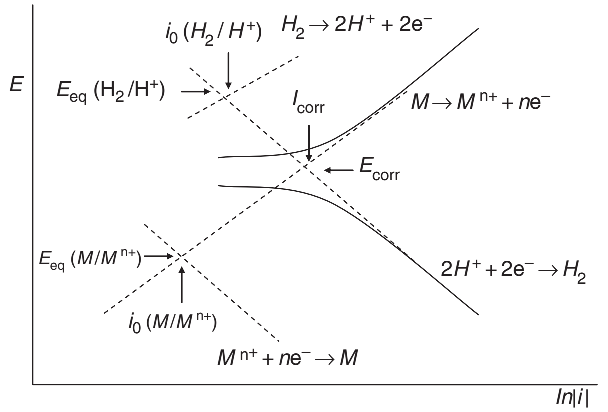

Figure 3 Tafel plot for corrosion of a metal in water showing equilibrium potential, E_{eq}, and exchange current, i_0, of hydrogen and metal electrodes. Extrapolation of both slopes yields corrosion potential, E_{corr}, and corrosion current, I_{corr}.

plots for both hydrogen and metal are combined (see **Figure 3**), the point of intersection gives the corrosion potential and corrosion current. The exchange current and equilibrium potential for the individual hydrogen and metal electrodes are also shown in the figure.

Stern and Geary derived a simplified version of the Tafel relationship, using empirical values of b, which does not require knowledge of the surface:

$$I_{corr} = \frac{1}{2.3}\frac{b_a - |b_c|}{b_a + b_c}\frac{I_{appl}}{\Delta E} \qquad [8]$$

where $b = 2.3RT/\alpha nF$. When the potential is varied by not more than ±10 mV of E_{corr}, it varies linearly with applied current, I_{appl}. The slope, I_{appl}/E, is known as polarization conductance, K_{corr}. The rate of corrosion, R_{corr}, can be related to the corrosion current by Faraday's law:

$$R_{corr} = \frac{I_{corr} Mt}{nF\sigma A} \qquad [9]$$

where M is the molecular mass ($\mathrm{g\,mol^{-1}}$), σ the density ($\mathrm{g\,cm^{-1}}$), A the area ($\mathrm{cm^2}$), and n the number of electrons transferred. Integration of this equation for $t = 1$ year gives the more common expression for corrosion, $\mathrm{cm\,yr^{-1}}$.

Properties and Types of Steel

Alloying of iron is an effective approach to increasing mechanical strength and resistance against corrosion. Stainless steel is a chromium–iron–nickel alloy, with a low carbon content, which has good mechanical properties and is resistant to corrosion. There are three different types of steel, martensitic, ferritic, and austenitic, which differ in their crystal structure (*see* article **Plant and Equipment**: Materials and Finishes for Plant and Equipment). The most popular steel in use in austenitic stainless steel, which contains 18% chromium and 8% nickel and is more commonly known as 18-8 austenitic steel. The carbon content is kept low (0.08%) to ensure that chromium, which is necessary for the prevention of corrosion, is not precipitated as chromium carbide.

Types of Corrosion

There are many types of corrosion. A plant engineer should know the rate of corrosion but should also be aware of the various modes of attack. This information has to be taken into account for plant design. Corrosion of iron or steel is always a result of exposure to air and water. The time span for corrosion can vary dramatically, from hours to years. The amount of damage also depends on the exact form of the corrosion process, which can be influenced by the chemical environment, mechanical stresses, or metallurgical properties. The exact reason for corrosion can be due to any one or a combination of these factors.

Pitting and Crevice Corrosion

Uniform corrosion of a metal results in an easily measurable loss of metal. However, metal surfaces are rarely homogeneous and are usually covered with a protective layer of oxide or hydroxide. Pitting and crevice corrosion are two forms of localized corrosion where anodic and cathodic areas, that is, regions where oxidation and reduction occur, develop on the metal surface. The anodic area undergoes severe corrosion, whereas the cathodic area is unaffected.

Environments containing aggressive species often result in the formation of deep pits on the surface of the metal. This is known as pitting corrosion. The most common cause of pitting is the chloride ion, which is able to penetrate the porous oxide layer (see **Figure 4**). Pitting generally occurs locally, due to variations in the structure and thickness of the oxide film or due to surface defects, rather than over the entire surface. Chlorides compete with oxygen for adsorption onto metal sites. Once adsorbed on the metal, chloride ions encourage hydration of metal ions and removal from the surface rather than the buildup of a passive oxide layer. Due to a difference in oxygen concentration, a large potential gradient of up to 0.5 V builds up between the anodic area within the developing pit and the cathodic bulk steel, which allows for a considerable current flow between the anodic and cathodic sites. More highly mobile chloride is then attracted into the pitting site in order to balance the charge built up by iron ions. Iron chloride undergoes hydrolysis, further decreasing pH,

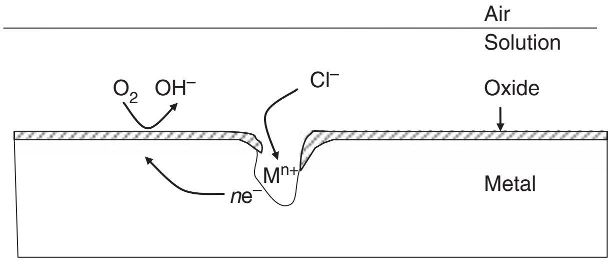

Figure 4 Schematic illustration of pitting corrosion. Pitting corrosion occurs when the protective oxide layer is breached by chloride. It is an example of localized corrosion on a metal surface, which arises from concentration gradients.

and so pitting corrosion continues in an autocatalytic manner. Therefore, corrosion continues in areas where pitting has been initiated rather than starting at new sites. In this way, the pit can grow very quickly. A Pourbaix diagram for iron modified for a chloride solution shows a region where pitting occurs in addition to areas of passivity, immunity, and corrosion (see **Figure 5**).

Crevice corrosion occurs in areas where movement of electrolyte is likely to be confined, such as between bolts, washers, or gaskets (see **Figure 6**). The electrolyte within the crevice is stagnant and has different oxygen and metal ion concentrations from bulk surface metal causing a potential gradient. Metal ions released within the crevice cause the local pH to be lowered by up to 6 units. As in pitting corrosion, chloride ions migrate into the crevice to balance the charge. As a result, passivity within the crevice is broken and the potential gradient is increased further, accelerating the rate of corrosion. Another cause of crevice corrosion arises if the protective oxide layer is breached due to a scratch, thereby exposing the metal. A potential is again built up between the two sites and crevice corrosion is initiated.

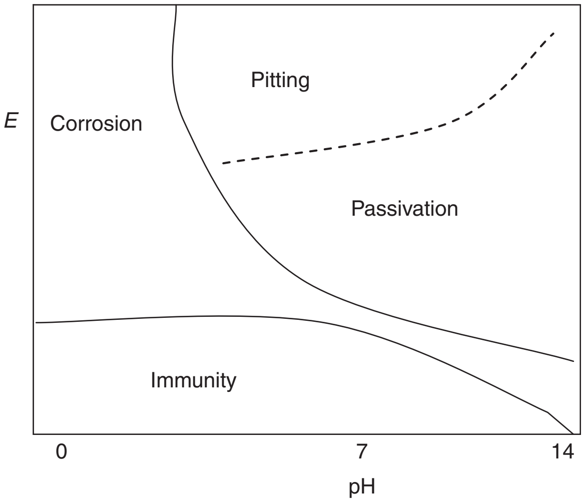

Figure 5 Pourbaix diagram for iron in salt solution showing four regions: immunity, passivation, corrosion, and pitting.

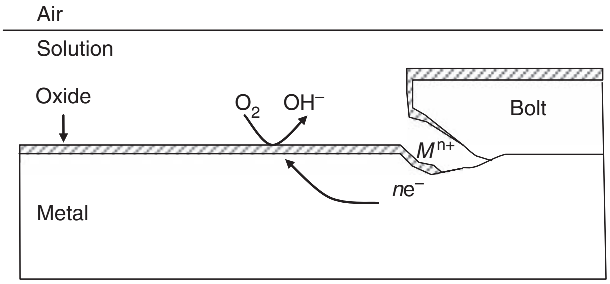

Figure 6 Schematic illustration of crevice corrosion. Crevice corrosion occurs when the electrolyte is stagnant, such as under a bolt. Differing electrolyte composition within the crevice compared to the bulk results in a potential difference and localized corrosion.

The main difference between pitting and crevice corrosion is that pitting starts only when a critical pitting potential is reached, as shown in **Figure 5**. Crevice corrosion depends on whether passivity due to the oxide layer can be breached within the crevice and can also proceed with ions other than chloride, such as sulfates, nitrates, or acetates.

Intergranular Corrosion

Intergranular corrosion is a localized attack at metal grain boundaries, which form during the cooling process in steel production where several nucleation points for crystal growth exist. The orientation of each crystal is random and so when two crystals meet they are often out of phase and a grain boundary is formed. The Gibbs free energy at the boundary is higher than that of the bulk metal and the boundary is preferentially corroded. It is thought that the intergranular corrosion results from improper, or sensitizing, heat treatments of the metal during production or welding. Sensitizing heat treatment of stainless steel depletes the grain boundary of chromium, which precipitates as chromium carbide; chromium is necessary for corrosion protection. Corrosion of this type penetrates the whole boundary, reducing mechanical strength and resulting in failure, even though actual loss of metal is low.

Stress Corrosion Cracking

Stress corrosion cracking results from tensile or residual stress on a metal in a corrosive environment. Without the corrosive environment, the stress would not induce cracking. Stress corrosion cracking can be initiated at metal discontinuities, pits, or intergranular boundaries. Whether propagation of the crack is intergranular or transgranular depends on the exact chemical environment and pretreatment of the metal.

Corrosion Fatigue

When subjected to a repeated alternating stress, a metal will fail after a number of cycles; this is known as metal fatigue. In a corrosive environment, the number of cycles required to cause failure is reduced; this is known as corrosion fatigue and is usually generally transgranular and branched. The damage caused by corrosion fatigue is greater than the sum of the individual effects of corrosion and fatigue due to branching.

Cavitation

Cavitation occurs under conditions of rapid fluid velocity, where repetitive high- and low-pressure areas are developed and bubbles are formed, which then collapse at the metal–liquid interface. The metal becomes deeply pitted due to mechanical damage and chemical removal of the protective oxide film. Cavitation often occurs on rotors and turbine blades. This is a physical process, not chemical, and it is therefore a form of erosion rather than corrosion proper. It is appropriate, however, to list it as well.

Galvanic/Bimetallic Corrosion

Galvanic corrosion occurs when two metals separated by an electrolyte are in close contact. The metal with a lower standard reduction potential is oxidized, whereas the other is reduced. A common source of galvanic corrosion are bolts used to attach a fixture to steel; corrosion then occurs at the joint. Another cause is the welding together of two different grades of steel.

Cathodic protection refers to the preferential oxidation of the metal with a lower standard reduction potential over another when two different metals or alloys are in contact with oxygen; the second of the two metals remains unaffected by corrosion. This approach to protection against corrosion is a common practice on ships where a zinc block, which has a lower standard potential than steel, is attached to the hull and is preferentially corroded by seawater while the steel hull remains uncorroded.

Environmental Factors Affecting Corrosion

The availability of oxygen is critical for the corrosion process and its availability is affected by a number of interrelated factors. This is the basis of corrosion prevention methods, such as painting, where oxygen availability is suppressed. Steady-state corrosion is dependent on the diffusion rate of oxygen to the metal surface. Therefore, at low oxygen concentrations, corrosion is proportional to the concentration of oxygen. However, above a certain critical concentration, corrosion decreases with increasing oxygen level due to oxide passivation of steel. The critical concentration is increased by increasing salt concentration and/or temperature but is reduced by increasing fluid velocity and pH.

Since corrosion is controlled by diffusion of oxygen, its rate increases with temperature. However, at high temperatures, oxygen availability is reduced and the rate of corrosion decreases. Moving liquids supply oxygen to the surface and hence increase the rate of corrosion. At higher flow rates, partial passivity occurs. However, at very high flow rates, mechanical removal of the oxide layer or the prevention of passive oxide layer formation increases the rate of corrosion. Also, in the presence of chlorides, as in brines, oxide layers are not formed and corrosion will continue to increase with flow rate. Increasing the NaCl concentration reduces the solubility of oxygen. However, corrosion increases to a maximum at 3% NaCl, due to Cl^-, and then declines; this is due to breaching in the passive oxide layer.

Continuous Process Improvement and Optimization

J C Oliveira, University College Cork, Cork, Ireland

Introduction

Origin of the Concept

'Continuous process improvement' is a term that emerged from the studies undertaken in American business science on the manufacturing strategies used by the Japanese industries. As such, it is often known by its Japanese term 'kaizen'. There are many other terms that became popular and are related to managerial and operational strategies from Japanese practice, of which continuous process improvement is one element, such as quality engineering, lean manufacturing, value engineering, manufacturing excellence, and world-class manufacturing, and even six sigma can be related to it. Six sigma is discussed further in the article **Plant and Equipment**: Quality Engineering. The methodologies developed for continuous process improvement are now regarded as crucial for ensuring competitiveness in a global market, and as such, have been permeating across all sectors of the manufacturing industry.

It is worthwhile to understand the origins of the concept. Following World War II, Japanese industry was devastated. In the 1950s, products made were of generally poor quality and the lack of economies of scale and of investment capacity seemed to condemn Japanese industry to a secondary role for a long time, compared to the paradigms of the day, the US industry. However, by the 1970s, American companies began recognizing that the Japanese products were of superior quality and lower price, beating them in their own markets. One of the industrial sectors more strongly affected by the giant leaps of quality and efficiency of the Japanese industry was car manufacturing. It was obvious by then that some time during the 1950s and 1960s Japanese manufacturing was able to find methods to produce high-quality products at a cheaper rate, even though it did not avail (at that time) of the economies of scale that the 'Detroit giants' (Ford, Chrysler, and General Motors) had. As the Toyota Motor Company was at the forefront of these developments, and it practiced a notable open philosophy about itself, it became the most widely studied by American business science researchers. Toyota was not the only company developing these approaches in Japan, nor the creator of all the methodologies used, but was one of the pioneers, and became the best known. In a sense, the fact that various people analyzed various aspects of what was later called the 'Toyota Production System' (TPS) and then added their own perspectives and interpretations has ultimately led to the emergence of several 'westernized' concepts, such as just-in-time, total quality management, continuous process improvement, and lean manufacturing. However, the Japanese, and Toyota in particular, would not consider any of these concepts as an independent methodology, but as part of a whole.

The first studies of TPS brought to global attention a completely different way of organizing production, with just-in-time stock management, a production pull system rather than push system, and a revolutionary approach to the role and intervention of operators in the process, which in itself sparked a new philosophy about teamwork. Studies of the TPS became known as the first paradox (how can quality be achieved with low cost when there are few economies of scale?) after another influential work addressed what it called the second Toyota paradox, which deals with the new product development approach of Toyota (how can a new product development cycle be faster and cheaper by delaying decisions as much as possible?). Another landmark in the dissemination of these practices was the seminal work on lean manufacturing, The Machine That Changed the World.

From Car Manufacturing to Dairy

There is a very important conclusion to bear in mind from the historical backgrounds of continuous process improvement and all the TPS-related paraphernalia of modern management best practices and fads: they were not developed and implemented by Toyota, the biggest car manufacturer in the world (that is not what Toyota was then). They were developed and implemented by Toyota, a small company producing low-quality products at a high cost because it had no economies of scale, and therefore had very little financial capacity for investments. What it had was the belief that it could do better, that it could solve the paradox 'high quality and low cost even without economies of scale'. Toyota did not develop its famous TPS by hiring expensive consultants to design optimum solutions by applying best-in-class principles. It had no financial or human resources to do so. It started with months of observation of what happened in the reality of the factory floor, what operators really did and how. Then, considering what was the best in class, how could those efficiencies be emulated? And finally, finding out that they could actually be bettered. It is very informative to know what really happened: Liker provides a historical account that is well worth a read.

The relevance of this to modern industries is obvious, as emulating means that abstract principles can be applied across industrial sectors, and there is none that has been immune to the application of the principles of continuous process improvement, lean manufacturing, six sigma, and other improvement programs (see for instance, the list of main clients of the Kaizen Institute – one of the many consultancy groups providing services in this area – at its website). For the dairy industry, see the cover story by Markgraf on an American dairy.

It is however crucial to bear in mind the main lesson of Toyota's origins: if deploying continuous process improvement (or any associated principles) requires an expensive engagement of external experts who will propose an optimum solution from their analysis, then the proposition negates the philosophy right from the start. Continuous process improvement (1) must be a transformation that comes from within (albeit guidance by external experts facilitates commencement, cuts corners, and can thus save time and money), (2) must be ardently desired by the most senior management, and (3) should require few, if any, costs.

Continuous Process Improvement or Process Optimization?

As the name suggests, continuous process improvement uses methodologies to improve a manufacturing process, so the first question should be what is the target of improvement – costs? productivity? quality? This is a methodology to improve what? The answer is simple: everything. That is one of the reasons for using the word 'paradox' in relation to the TPS: How can everything be made better, when reality usually requires compromises and trade-offs? How can costs be reduced and quality improved? The second feature of the term is the word 'continuous': process improvement is a never-ending journey, the process is to be made better all the time, one improvement after another, because optimum is an ideal, and as such, unreachable.

Semantics, therefore, show that the concept implies an incremental approach (one step at a time), where no improvement is too small (summing enough small improvements leads to a big improvement). This, therefore, reveals a fundamental difference between continuous process improvement and the 'western' counterpart, process optimization. The practice in the United States (and Europe) had been to design an optimum process. This implies defining what the optimum target is, often accepting that the multicriteria nature of 'optimum' will require some compromise or trade-off, and from that conceptual definition of what the optimum should be, the process is then designed in one single go to reach that optimum, using sophisticated methods. As the design is complex, it needs advanced knowledge, so the designer is an expert in designing, does so expensively, and is unlikely to be engaged in the actual daily operation of that design. On the other hand, the operators are typically not involved in the design, and are supposed to do exactly as told and exactly as planned in the design. This is, of course, a gross generalization, but the underlying nature of the approach can lead to such extreme dichotomy between the optimum abstract ideal of the design and the practical reality on the factory floor.

Therefore, continuous process improvement (kaizen) experts often like to boast of the improvements they were able to extract out of what was supposedly an 'optimum' process. Notwithstanding, process optimization methodologies are not to be discarded, some kaizen engineering design methods over rely on simplified approaches, and 'western' engineering design has developed some more consistent and comprehensive ones. From a practical point of view, of course, semantics are irrelevant, and what matters is the efficacy of the methods deployed to improve competitiveness.

Operational Improvements

The first step for improving a manufacturing process is to analyze its operations, from procurement to sales, and not only on the factory floor. Starting with purchase orders (when are ingredients purchased and how, where are they stored and for how long?) and ending with sales (manufacture-to-stock, or manufacture-to-order?) means that stock management strategies are an integral part of process improvement. In relation to the manufacturing process itself, the whole sequence of operations needs to be considered, including not only the actual processing functions, but also its associated functions, such as quality control. In essence, a factory organizes a series of operations, generically, buy → make → test → sell (not necessarily linearly). The first core principle of kaizen is to analyze the operations from the point of view of the flow of the product itself, which already brings in a difference from 'western' conventions, where processes tend to be described from the managerial perspective.

In order for a process to be improved, this combination of operations must be the most efficient. Redesigning the entire set can be associated to the concept of business process reengineering (BPR), a management concept that gave mixed results and was therefore more popular in the 1990s than it is today. BPR considers the 'western' approach: that an optimum can be designed from scratch by best principles applications, using sophisticated methods if necessary, and isolated from real practice if need be. A BPR proposes a giant leap to an ideal world. It is not a useless concept, and it can give very good results (and has in reported literature), but obviously, the more reality deviates from ideality, the greater the chance that the giant leap may be toward a big hole. Literature also reports negative experiences of companies with BPR. Incremental approaches therefore have this big advantage: they may be more modest but will always lead to a better situation, and over several incremental steps, the gains will become significant. Critics will contest that incremental solutions may not explore areas of the solution space beyond convention, while advocates prefer to explore without excessive risk in the explorations, and point to practical end results that are equally enviable. It is noted that BPR often shows up associated to the introduction of novel solutions from information technologies (IT) to reorganize business processes. This is a special case of BPR, where it comes associated with the digestion of new IT procedures by company and staff, which in itself (with BPR or not) has its own success and failure factors. Introducing IT may facilitate process improvement, or it may not, and it is not a concern here. IT is a tool; it should be recognized that in fact IT always facilitates kaizen from a conceptual (theoretical) perspective – but how will it work in practice? kaizen in itself is not about a better business concept, it is about a better business reality.

Continuous process improvement will suggest starting more modestly than reinventing from scratch, by analyzing all operations and apply what is also known to some extent as value engineering. Of all the business operations involved in manufacturing, some add value to the product and thus to the end client, but some do not. They may well be necessary for some reason, or they would not be there, but if they do not add value, then they are a waste from the point of view of the product and of the client. The Japanese word for wasteful activity ('muda') is often cited in this context. A better process will be one where waste is nonexistent, so these operations should, ideally, be eliminated. Therefore, it is logical to start improving a process by eliminating non-value operations (why spend time and resources improving those that are best eliminated altogether?).

This analysis is not as straightforward as it looks, because company executives and operators are not used to think from the point of view of the client or of the product. A typical example is quality control: from the point of view of the product or the client, it is a wasteful operation. This might seem an excessive comment, but a more detailed analysis shows the philosophy at play here. Quality control is a problem of the manufacturing company, not of the client. The client expects that quality, indeed, he paid for it. If the company is not able to deliver that quality, that is the company's problem that becomes a client's waste. From the point of view of the product, being stored somewhere waiting for the results of a quality control test is a waste of time. The product should have quality unless the process is faulty. An improved process should not be faulty, so the product should have quality all the time. This would lead to the concept of quality by design, which is discussed in detail in the article **Plant and Equipment**: Quality Engineering.

A second principle is that the flow of the product must be continuous. From entering the raw materials storehouse to leaving for sale, the product (ingredients/components, etc.) must not stop; if it does, it is lying idle, and so there is a waste. Hence, storage is a waste, and so the concept of just-in-time, one of the first that was immediately grasped for its financial advantages. The best way to ensure this continuous flow is to pull the product from the end, that is, the last operation sends an order to the before last, and so forth, so the product is pulled from the end. A pull operation (request for a product or part needed) was originally sent with a card in Toyota, or 'kanban' in Japanese, a term that endures as synonym of just-in-time operations by a production pull strategy.

A good starting point for analysis of the improvements that can be made by eliminating wasteful operations (and hence become 'lean') is to apply the lean questionnaire developed by MIT (LESAT – Lean Self Assessment Tool), available for free at the website of the Lean Advancement Initiative of MIT (this site contains plenty of other free tools and studies under the 'products' menu). It may help to give a different perspective on what can be classified as waste, and how much waste there is in a normal business operation when it is analyzed from the perspective of the value to the client, or of the product flow.

Waste is not confined to operations that should be eliminated because they do not add value; TPS deals with two other types of waste. An obvious waste comes from product variability and consequent loss of quality, which is addressed in the article **Plant and Equipment**: Quality Engineering, and often referred to by its Japanese term 'mura'. The third is waste resulting from overcomplexity ('muri' in Japanese). This means that every operation and sequence of operations should be as simple and direct as possible. Standardization of simple operations and their straightforward combination are the ideal basis to eliminate this type of waste and hence maximize productivity. In some industrial sectors where operations involve manual handling, eliminating muri requires appropriate ergonomic design of the workplace and workstations (the operation should be easy and simple to perform, thus minimizing energy, effort, and time).

Process Engineering Improvements

General Approach

The operational and managerial implications of kaizen leave a highly flexible, efficient, and productive factory floor, alongside an entire lean supply chain. Operations on the factory floor involve a series of equipment units where the product components are progressively incorporated and turned into the final product. Each of these operations must now be improved.

In the context of a process industry such as dairy, the raw materials undergo transformations toward a product of a different nature (e.g., fermentation in yogurts, coagulation in cheese) or that hinder microbial activity to provide shelf life (e.g., ultra-high temperature (UHT) processing, drying). These operations are controlled by a number of variables or control factors, such as temperatures, flow rates, amounts of ingredients, and time of operation. The company decides on the settings (values) of these factors from its knowledge of the system, characteristics of the equipment, recipes, and other things. Each of these control factors can be set at any value within a range of physical interest, and there is an infinite number of combinations of settings of these factors that result in a final product, although not all combinations are possible. Some, however, result in products that are better than others, or in processes that are cheaper, or more productive, or use less energy, and so on (for instance, the objective of reaching a given microbial lethality in the thermal treatment of liquid milk can be achieved equally at a higher or lower temperature, with the processing time being longer the lower the temperature, but the quality characteristics of the product, such as nutrient retention and taste, are better at higher temperature-short time than at low temperature-long time). In this context, process improvement will deploy methods to find a combination of settings of the control factors that will result in a better performance.

It may be possible to estimate better combinations of these settings by developing mathematical models that mimic the operation of the equipment by applying first principle equations (laws of conservation of mass, energy and momentum, thermodynamics, kinetics, heat and mass transfer, etc.). However, such models will need to make assumptions that may or may not be good images of reality, and may also be too complex. The continuous process improvement concept prefers to 'let the system speak by itself', and obtain process data from which to infer improvements. Process optimization does the same, only that it assumes that a single giant leap is possible, and that the absolute optimum is identifiable. Kaizen is prepared to move stepwise.

The need for process data to infer directions of improvement is an issue in some industrial sectors, such as dairy. If the equipment operates with large quantities of product at any given time, and the business margins are small, there is little room to perform tests with the equipment, each of which could cost many kilograms of product that run the risk of being unsuitable for sale (when the test happens to try settings of the control factors that do not lead to a suitable product). However, process data can also be collected simply from the historical records of the process. This has the huge disadvantages of providing data that have not been planned, with many data points around the same settings, with uncontrolled variabilities, and a scan of the solution space decided by chance and the inaccuracies of the control systems. However, it is 'free' data and may reveal useful information about the system, if handled properly.

Design of Experiments

Kaizen recommends an experimental plan, and as such it starts by giving great importance to the planning of the tests. It is obvious that if each test involves the actual process and equipment, the most information needs to be obtained from the least amount of data, and therefore, it is not surprising that the area of statistics dealing with design of experiments (DoE) must be brought in.

The most widely used approach in Japan is due to Genichi Taguchi, and is generally known as the Taguchi method of robust engineering design. The method seeks to achieve improvement of performance and also consistency of performance, and as such it is the foundation of quality engineering too, discussed in the article **Plant and Equipment**: Quality Engineering. In the context of performance improvement or optimization, it is noted that in order to minimize experimental requirements and take as much information as possible from the data, Taguchi chose designs based on orthogonal arrays (aka Latin squares). They are usually designated as L-4, L-8, L-9, L-12, L-16, L-27, and so on, where L stands for 'Latin squares', and the number indicates the number of rows of the array, which is also the number of tests that needs to be performed. When consistency of performance is to be considered as well, the whole set must be repeated a number of times, and therefore, using arrays with as few rows as possible is important. Each array will allow testing a number of control factors, which depends on the array, with one factor associated to a column of the array. That column will contain the settings to be used for the factor. Some arrays have only two different settings (two-level design), others have three (three-level design), and other commonly used arrays have four by combining columns of two-level factors (for instance, M-16 or L-16M refers to the L-16 array modified, which tests four different settings of factors, but it can be used for much less factors than the original L-16). There are also some mixed level designs. **Table 1** shows an example, the L-8 array, which can be used to test up to seven factors with only two settings used for each.

These experimental designs are very good for limiting the number of tests that need to be performed, but come at a cost: the design generates an intricate set of confoundings that may be difficult to separate. 'Confounding' is the statistical name given to a combination of terms or factors in the design that results in their effect being indistinguishable. It does not mean that the confounded factors are confounded by nature, it is a consequence of the experimental design that their impact is confounded (pooled together). For instance, if a design tests a system at 20 and 30 °C, and also considers a flow rate of 1 or $2\,\mathrm{l\,s^{-1}}$, but in all tests performed the flow rate of $1\,\mathrm{l\,s^{-1}}$ was always used with 20 °C and the flow rate of $2\,\mathrm{l\,s^{-1}}$ was used only with 30 °C, then when analyzing the data it is not possible to know if the differences were due to (1) the temperature increase, with flow rate change being irrelevant, or (2) the flow rate increase, with the change in temperature being irrelevant, or (3) both changes. Orthogonal arrays do not produce confoundings between factors, but they do between the effects of factors and the effects of their interactions.

An 'interaction' is a basic feature of nonlinearity in a system. It means that the way that a factor influences a system depends on the actual value of another factor. For instance, if increasing the flow rate has no effect at lower temperature but is important at higher temperature, there is an interaction between flow rate and temperature.

Table 1 L-8 orthogonal array

Test no.	*1*	*2*	*3*	*4*	*5*	*6*	*7*
1	1	1	1	1	1	1	1
2	1	1	1	2	2	2	2
3	1	2	2	1	1	2	2
4	1	2	2	2	2	1	1
5	2	1	21	2	1	2	
6	2	1	2	2	1	2	1
7	2	2	1	1	2	2	1
8	2	2	1	2	1	1	2

Control factors are assigned to columns, and the rows indicate the settings of each factor for each of the eight tests that need to be performed. Each factor is tested with only one of two settings. Designs should be replicated, if possible.

For this reason, 'western' statisticians prefer other experimental designs that provide a better differentiation between different effects, such as the 'central composite design'. This design uses five settings for each factor, and tests some combinations of those settings that conform to a particularly well-balanced view of the solution space, which minimizes error regions of mathematical models then used to interpret the data. However, it requires a large amount of data than the orthogonal arrays.

Whatever DoE is chosen, it is noted that it can be considered as a plan for tests that will be done (the ideal scenario), or as a filter to be used to collect data from historical records in order to ensure minimum bias of the analysis of those data (even if only a small subset of data are thus collected; this is preferable to overweighing parts of the solution space).

Stepwise Approach

The Taguchi method advocates a comprehensive approach including meetings, brain-storming, and teamwork, that is not detailed in this text, but it is noted that the first step must be to consider how many factors may influence the system. Usually, this analysis compiles a large number of factors that may be interesting to analyze. If the system should 'speak for itself', then one should not curtail the list by rational thought; instead, it is better to rely on Vilfredo Pareto's famous principle, the 80/20 rule, and use a first experimental plan to zoom in on the 20% of factors that may be causing 80% of the consequences. This is also where analyzing historical records could be helpful, and provide 'free' information. A simple two-level orthogonal array design can be used for this purpose. An L-8 can test up to 7 factors with 8 runs, an L-16 allows one to consider up to 15 factors with only 16 runs, and an L-32 would allow for up to 31 factors with just 32 runs (can, and should, be repeated), and so on, so that the selection can be done quite efficiently.

It is noted that the consequences of the confoundings of this design are that some factors that may be considered important in the data analysis could actually be negligible (and this would be because one of the confounded interactive effects was relevant), but if a factor is judged to be negligible, then it is, and so are all effects confounded with it. That means that nothing of importance is lost by analyzing in this way which factors are more crucial for improving the performance.

There are possibilities for overlooking important issues with these two-level designs, though: if a factor has an influence that shows a maximum or minimum of its average impact on the performance, it is possible that by a stroke of bad luck the averages at the two extremes used for the settings (low and high, 1 and 2) are similar, and the data analysis will then infer that the factor was negligible, while data from a design with three levels would conclude otherwise. Continuous process improvement is however prepared to be incremental – there will always be time to go back into more analysis and improvements.

Once two, three, or at most four control factors are chosen for being the most crucial ones, then a design with more levels (three, four, or a central composite design) can be used and the solution space explored in more detail to reveal regions of improved performance.

Data Analysis: Identifying Crucial Factors

The Taguchi method does not need to fit mathematical models to the data obtained with the orthogonal array design. Instead, it applies an analysis of variance (ANOVA), a statistical method that quantifies the variability of the data collected by its variance, and then determines how much of it can be explained by the fact that each of the factors changed its settings. If the amount of data is sufficient to have enough degrees of freedom with the DoE used, a significance test can also be applied to ascertain which factors have a statistically significant effect. Results can be shown in the form of a pie chart, which gives a very good image of what is more important and what might be neglected in a first approach.

A typical result from ANOVA, with the most relevant outcomes in the form of a table and pie chart for a situation where the relevance of seven factors was tested with an L-8, is shown in **Figure 1** (case study regarding a particle coating process). In this example, the design was replicated (2 runs for each condition, totaling 16 data points), which gives enough degrees of freedom to test for significance. The pie chart shows not only the relative importance of each factor, but also how much of the variability of the data is unexplained. The unexplained amount of the variance may be due to (1) the relevance of interactions and the consequences of the intricate confounding of the design, (2) the influence of other factors that were not controlled and not considered in the design, and (3) the natural variability, or white noise, which may come from variability in control factors, in the characteristics of the materials or process, and also of the method of analysis of the performance, which is similar to random experimental error. The example shown suggests that changing the settings of three of the factors accounts for a large proportion of the changes that can be achieved in the performance.

Data Analysis: Identifying Settings for Improved Performance with the Taguchi Method

The estimate of which is the combination of settings of the control factors that gives the best performance is done in the Taguchi method by simply choosing for each factor the setting that had the best average performance. This has the advantage of not relying on any model fitting, and the disadvantages are that it will suggest settings for all factors from only among those that were used in the experimental design (even if the best combination is not one of those tested), and that it does not account for interactive effects. It is possible to include a correction for the effect of some interactive effects if the DoE has enough degrees of freedom for that, but it is a matter of interpretation which interactive effects are being tested because of the intricate nature of the confoundings. Taguchi recommends the calculation of a severity index to at least evaluate the relative potential importance of all interactions between pairs of control factors, but the extent to which this effectively gives unique results is not clear. Furthermore, when searching for a region of optimum performance, the designs usually have at least three (if not more) settings, and in this case it is virtually impossible to properly account for any interaction, unless one is effectively using a full factorial design (e.g., only two factors in an L-9). Therefore, the best combination of settings obtained by the Taguchi method assumes in practice that interactions between factors are negligible. Taguchi recommends validation tests for the new settings, of course.

Figure 2 gives an example of the graphs showing the averages of the data for each setting of each factor, known as the 'means plots', for a system where three factors were changed with four levels, according to a modified L-16. The maximum performance in that case is suggested for the combination of settings 3-4-2 of the three factors. The estimated performance of the system for that combination of settings is 99.08, obtained simply by adding to the global average of the data (81.29 in that case) the incremental benefit of choosing the respective setting of each factor, as per the means plots. Estimating performance in this way may lead to physically inconsistent values in some cases (for instance, performance above 100% or losses below 0%), which can be improved by a logarithmic transformation, such as the omega transformation.

Data Analysis: Identifying Settings for Improved Performance with Response Surface Method

An alternative that has been widely applied in Europe and the United States is the response surface method (RSM; or response surface analysis (RSA)). It can be applied to any design, including the central composite design, and is based on postulating a mathematical model to describe the influence of the factors (and interactions) on the performance. It has the advantage that designs such as the central composite design that have much less confounding issues can be handled, but

ANOVA table for data

FACTORS	SS	df	VARIENCE	F
Torque	0.000 798	1	0.000 798	0.739 589
Rotational speed	0.001 58	1	0.001 58	1.464 292
Temperature	9.51E-05	1	9.51E-05	0.088 097
Oil viscosity	0.008 145	1	0.008 145	**7.548 277**
Drip feed rate	0.037 733	1	0.037 733	**34.96 838**
Drip concentration	0.021 098	1	0.021 098	**19.551 75**
Coating	0.037 153	1	0.037 153	**34.430 41**
Error	0.008 633	8	0.001 079	
Total	0.115 234	15	0.007 682	

Total no. of data points:	16	F-limit: 3.457 919 Ne: 2

(a)

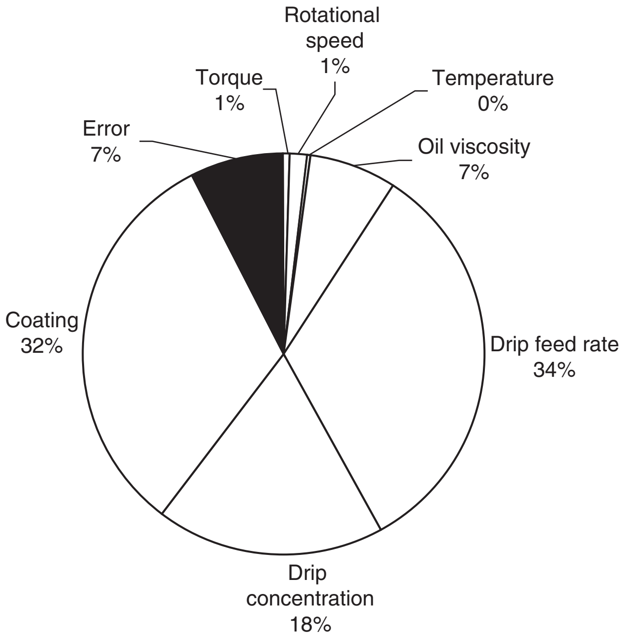

Figure 1 Example of an analysis of variance (ANOVA) table (a) and pie chart of the corrected sums of squares (b) for a system potentially influenced by seven factors, tested with an L-8 design replicated once. Factors in bold in the ANOVA table have statistical significance at a 90% confidence level. Ne is the effective number of data points, which is equal to the actual number of data points divided by 1+ the sum of degrees of freedom of the factors used to produce the estimate. The table and graph were produced in MS Excel.

the disadvantage is that the results will assume the validity of the mathematical model, and so the lack of fit is added to the overall amount of unexplained variance. The simplest model is a quadratic multifactorial polynomial, that is, the sum of linear, interactive, and quadratic terms. A linear term is proportional to the value of the factor, an interactive term is proportional to the product of the value of one factor and the other, and a quadratic term is proportional to the square of the value of the factor. All values must be normalized between maximum and minimum, which is called 'coding' (numerically, −1 and 1 are common, but can also be 0 and 1, or 0 and 100%). While being useful in terms of all parameters of the model having a very clear meaning, it assumes parabolic curves for all effects, which tends to suggest points of minimum or maximum that do not really exist.

Once a model is fitted to the data and its goodness of fit accepted, it can be used to pinpoint the location of the best combination of settings (searching for the point of maximum or minimum within the constraints of the solution space). The goodness of fit is typically quantified by the coefficient of determination (designated R^2), which quantifies the percentage of the variance of the data that is explained by the model, and values over 90% are usually desired.

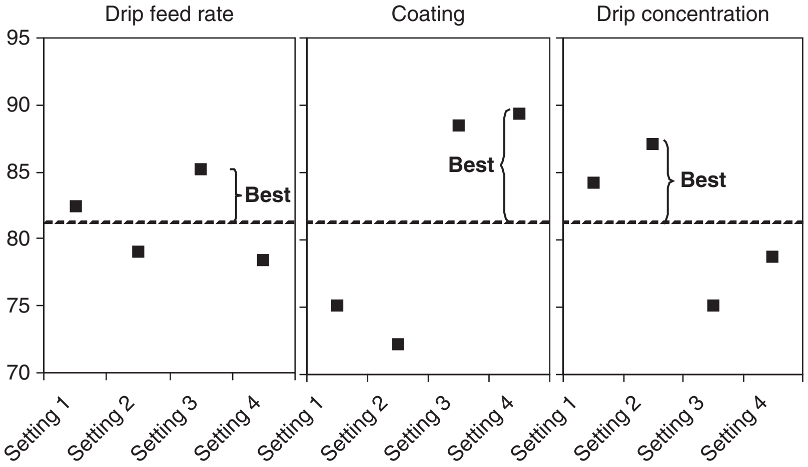

Figure 2 Example of means plots of the performance of a system affected by three factors changed with four settings each, according to a modified L-16 array. The dotted line indicates the average of all data. For each factor, the data are divided in four subsets according to the setting of that factor and the dots show the four averages. Calculations and plots were produced in MS Excel.

There are two useful plots, Pareto charts and surface plots. The Pareto chart represents the standardized effects as horizontal bars, and as such the limit of statistical significance can also be represented as a vertical line. The bigger the bar, the more important the effect. Standardized effects are the effects divided by the standard errors, and when using a model they are also equal to the parameters of the model divided by their confidence intervals. An example is shown in **Figure 3** (case study of loss of an active ingredient in a pasteurization process, as affected by flow rate, inlet temperature, and length of holding section). Surface plots can only be made for a pair of factors at a time, and they can be represented in three dimension (3D) or two dimension (2D) (**Figure 4**) to help visualizing the regions of improved performance, as predicted by the model.

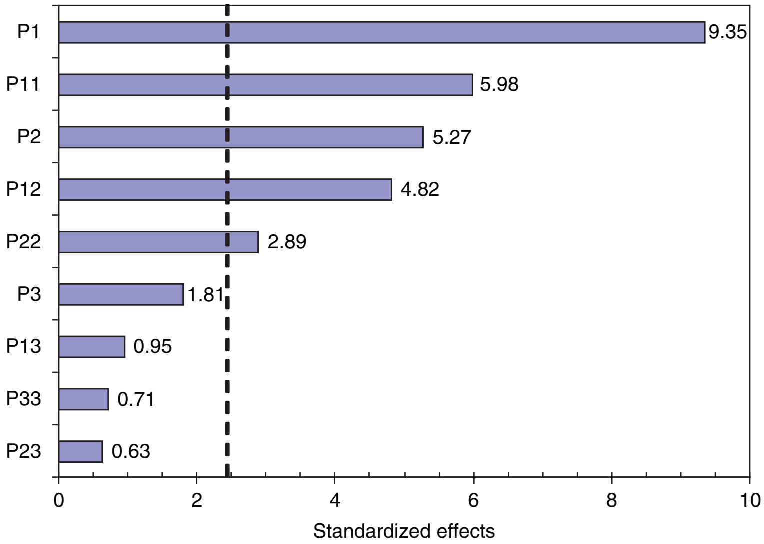

Figure 3 Example of a Pareto chart for a system affected by three factors, which was tested with a central composite design, fitted with a quadratic model. The vertical line represents the limit of significance at a 95% confidence level. The notation 1, 2, or 3 refers to the linear effects (linear terms of the model), 11, 22, and 33 to the quadratic effects, and 12, 13, and 23 to the interactive effects, where 1, 2, and 3 are the generic names of the factors. In this example, factor 3 and all its interactions are not statistically significant. Factor 1 is the most important, and its effect is strongly nonlinear, showing a significant curvature (quadratic effect very relevant) and an influence affected by the settings of factor 2 (interactive effect 1 × 2 significant). In this case study, the factors were inlet temperature, flow rate, and length of holding section in a pasteurizer. The calculations and graph were produced in MS Excel.

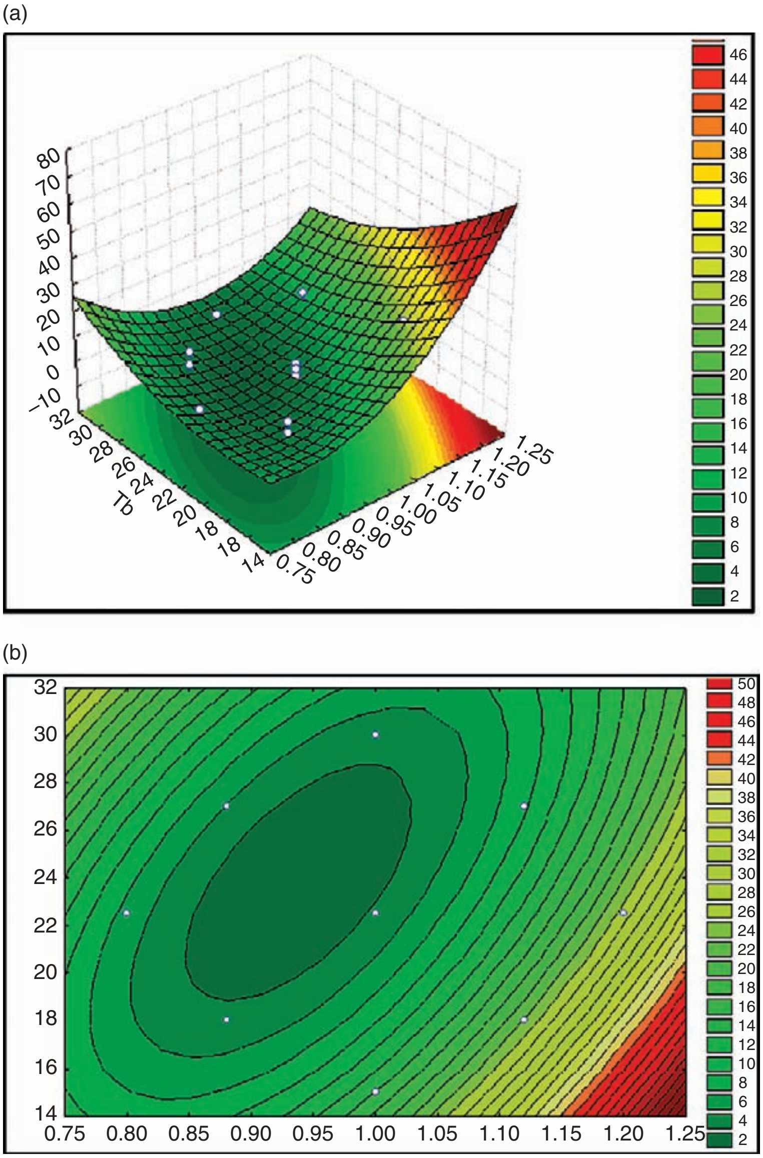

Figure 4 (see color plate 89) Examples of three-dimensional (a) and two-dimensional (b) plots of the influence of two factors on the performance of a system predicted by a model (other influential factors are kept at a constant setting). In the example, optimum performance means minimum losses of a valuable active ingredient, and the two factors shown are inlet temperature and flow rate. The plots were made using the Statistica software (Statsoft).

Quality Engineering and Quality by Design

Engineering is the application of scientific and empirical knowledge to create a new good or service. To 'engineer' something means to design what it should be, how it should be made, and how the process of making it should operate. 'Quality engineering' therefore means that the quality of a product (or service) can be engineered in its production process itself, so that it becomes a characteristic inherent to the product every time it is manufactured in the process. Quality not being a characteristic that is measured, but a consequence of the design of the process and of the way that it operates, leads to the term 'quality by design' (QbD) alternatively used to express this concept.

Conventional quality control systems act on the end result: products are tested for quality and compared to the desired specifications. Non-conformity of a product to the specifications results in a waste: the product must be discarded or reprocessed, depending on whether something can be done to ensure conformity. Quality control is therefore a waste-generating activity. On the other hand, having no quality control can result in a worse consequence, from simple loss of market image to more serious impact, such as that resulting from inadequately processed foods unsafe for consumption. Quality control therefore implies a lack of trust on the capacity of the process to perform consistently and provide quality products all the time. As the process will certainly have been developed properly, this means that it is subjected to variability in its conditions and/or materials it uses, and that variability may result in non-conformities. Not knowing how these sources of variability can present themselves and what can be done to compensate for them, the only option is to check the result at the end, and pray that it is on target most of the time.

Achieving QbD, therefore, implies one of two things: (1) eliminate all sources of variability, controlling obsessively everything so that there is no variation and the system repeats itself exactly the same, time after time; (2) analyze the variabilities of the system inputs, know what their impact will be, and operate the system so that it dampens those variabilities to oscillations within conformity. The first case requires good control systems, and the second needs good process intelligence.

The first concept would be hopeless in most food industries because of the natural variability of biological materials: for instance, in dairy, the composition of milk varies throughout the year, with the lactating cycles of the animals. However, there are sectors where such variability in raw materials does not occur, and one could then envisage that tight control systems would suffice. One should consider, though, whether the cost of such tight control would be an acceptable proposition. In the pharmaceutical industry, there has been a growing deployment of process analytical technologies (PATs), one feature of which may be that more sophisticated sensors measure better aspects of the process so that it may ensure better consistency. Some companies have acquired mass spectrometers for applications such as these. However, some simple calculations should be considered: How much does a mass spectrometer cost to buy and to run? What is the value of the quality gains from the better control? How long does it take for the investment to be recovered? In the pharmaceutical industry, it may well be that the product margins are such that expensive equipment is paid for in some years; in the case of the dairy industry, those margins might point to a few centuries. This has led to a much less interest of the food industry in general for PAT, as deployed in the pharmaceutical sector, which is a pity, because in fact PAT does not necessarily imply that very expensive analytical technologies are used to monitor the process and enable a proactive approach to quality control.

It is therefore useful to focus on the second option described above, go back to basics, and work out a better system by using process intelligence to achieve QbD, independent of whether acquiring that intelligence requires expensive analytical technologies or not.

The Principles of the Taguchi Method

The pioneering work of Genichi Taguchi was a very influential basis of the modern QbD approach. Appointed to lead the Electronic Communications Laboratory (Nippon Telephone and Telegraph Co.) of Japan in 1950, he was faced with ensuring consistently good communications on resources devastated by war. The problem required solutions to be found fast and there were few resources to help and little money to invest. Taguchi spent the best part of the next 12 years developing methods to improve quality and reliability. One of the companies that took up his concepts early on was Toyota, and through it and the Toyota Production System (*see* **Plant and Equipment**: Continuous Process Improvement and Optimization), the Taguchi method began permeating US and then European industrial practice in the late 1980s. That such a story is at the origin of QbD is very relevant, as it shows that the essence of the system is all about being able to solve problems without throwing money at them.

There are two important concepts at the basis: differentiating between control factors and noise factors, and the loss of quality function.

The performance of a system is influenced by factors that are controlled by the operator, probably within tight margins, such as temperatures, flow rates, and pressures. It is, however, also influenced by factors that are not controlled, and these may vary more or less significantly depending on random or non-random effects. For instance, milk composition varies throughout the year and also from producer to producer, as it is influenced by animal feed too, not to mention the genetics of the animals. Although control factors may have a bigger influence on the performance, as they are controlled tightly, the variability of performance may be due more to noise factors than to improper control of the control factors. Therefore, more sophisticated control systems for the control factors may be almost pointless. First and foremost, the sources of variability, and how they influence product variability, must be understood. For instance, a pasteurizer may be set to work at 92 °C, and the control system does not give better than ±1 °C. On the other hand, the pasteurizer was designed considering that ambient temperature was a given constant figure (e.g., 15 °C). However, depending on the location, this may vary during the year from anywhere between −20 and 40 °C. Even though ambient temperature in itself may be less important than the operating temperature for the design of the equipment, in the operation of the pasteurizer its variability may cause more fluctuations than that of the process temperature. However, it is obvious that controlling ambient temperature tightly is a preposterous idea, so controlling variability may not be an option, and the only possibility may be to find a way to live with it.

As an engineer, Taguchi knew that changing the settings of a system influences its inertia and so the way that it amplifies, or dampens, the input oscillations. Therefore, one should look for the settings of the control factors that lead to a system that dampens the input oscillations as much as possible: hence the term robust design. A system has a robust design when it performs consistently in spite of the variability of the inputs.

The concept of loss of quality function was another original contribution of Taguchi. Previously, the norm was to consider that a product was either acceptable (within the range of specifications defined) or not acceptable, so there was full acceptance or full loss of a product. Taguchi considered that every time that the product is not exactly on target, there is a loss, which is bigger the further the result is from the target. Taguchi used a simple parabolic function to quantify the loss of quality as the quality indicator deviates from the target value. In fact, if quality is below expectations, there is loss to the client, which over time becomes loss to the company in terms of market image, market share, and so on. If quality is above expectations, there is loss of opportunity for the company, which could have made use of that better quality to get a better price or greater market share. Furthermore, if that higher quality is presented to a client once, that client will then expect the same higher quality next time, and therefore there can be a greater loss of quality by underperforming to expectations the next time. Therefore, the quality loss function should be minimized, and the process should be steered to the quality indicator value that can be delivered more consistently. This means that one would even prefer a business where the product has a lower average quality but that can be delivered consistently, to one with a greater variability even though on average it may be better. In the long term, the second case is going to pile up client dissatisfaction for one reason or another and hurt the business. It can be argued that the evolution of the world wine markets between French producers and New World producers offers a case in point.

In order to improve both average quality and its consistency, Taguchi defined the signal-to-noise ratio (S/N) as the objective of an optimization approach: search for the combination of settings of the control factors that gives the maximum S/N. S/N integrates the two objectives: best average quality and best quality consistency. There are three mathematical definitions of S/N, depending on the type of problem, known as 'bigger is best' (the higher the average of the quality indicator, the better), 'smaller is best' (the lower the average of the quality indicator, the better), and 'nominal is best' (the closest the average of the quality indicator is to a nominal target, the better). In essence, the Taguchi method for robust engineering design consists in deploying an experimental plan and statistical data analysis procedure to identify the combination of settings of the control factors that maximizes S/N (for the methods that Taguchi selected for experimental design and data analysis, *see* **Plant and Equipment**: Continuous Process Improvement and Optimization).

The Taguchi method does not consist solely of applying statistics to plan and then analyzing a set of tests, but it considers the entire framework of operation, teamwork, and other things. See articles in Further Reading for more information.

It is noted that once the 'process intelligence' has been gathered in terms of availing of a simple model that relates input variability, control factor settings, and output variability (S/N), it is possible to develop a proactive approach to process control (also known as feed forward; *see* **Plant and Equipment**: Instrumentation and Process Control: Process Control). By measuring the input factors and their variability (even if they are not controlled, as noise factors), the model can predict what the outcome will be, and hence correct the settings of the control factors to ensure the robustness of the operation (*see* **Plant and Equipment**: Instrumentation and Process Control: Process Control).

Recently, Charteris advocated the use of experimental design methods and the Taguchi method in particular for competitive quality systems in the food, and specially dairy, industry. The increasingly extensive application of the method in various companies across industrial sectors is its greatest selling point.

Theoretically, the Taguchi approach has been contested, mostly for two reasons: it relies on orthogonal arrays in the experimental design, which leads to intricate confoundings (*see* **Plant and Equipment**: Continuous Process Improvement and Optimization), and the S/N ratio concept integrates average and standard deviation, and therefore model predictions bundle them together. It may also be noted that in practice maximizing S/N assumes no interactions between factors (*see* **Plant and Equipment**: Continuous Process Improvement and Optimization). However, by giving more and due importance to variability and repeatability, it often leads to good results from a limited amount of data.

Statistical Process Control

As Taguchi was beginning his work in Japan, 'western' statisticians were also assisting industry to develop methods for improving quality consistency. That a proactive approach to quality control was needed was also concluded early. The process should be monitored at several key moments, the variability must be addressed then, and actions must be taken immediately, as needed. The concepts of statistical process control (SPC) were thus developed (for more details, *see* **Plant and Equipment**: Instrumentation and Process Control: Process Control). In this case, the type of variability is categorized between common and special causes. The former are identified primarily due to the randomness of variability, while the latter are pinpointed by a clear pattern in the data that cannot be due to chance.

The original practice involved using process charts to identify the sources of variability and progressively eliminate or squeeze them, which an enthusiast of the Taguchi method might regard as too laborious and hence not pro-active enough. It also has the obvious disadvantage of relying on process data, which means that the range of values considered for the control factors may be too small and the data excessively biased.

SPC is basically very good for ensuring that the oscillations in a given process are minimized, but is not really designed to establish best conditions of operation that offer a more robust operation. It may also lead to the over-zealousness of controlling factors with increasingly expensive methods even if such control results in savings that do not justify the costs. Quality engineers deploying SPC may need to resist the temptation for expensive applications of information technologies (IT) or PAT, unless the benefits are clear upfront. For further details, see articles in Further Reading.

Six Sigma

The best practice of modern manufacturing industries is generally regarded to be the six-sigma system, although there is some controversy on this. Its name reveals its primary focus on maximizing consistency and thus eliminating waste, as sigma is the Greek letter used in statistics to denote the standard deviation, a quantitative measure of the spread of a series of data. If the data are normally distributed, then the band defined by the average $\pm 6\sigma$ contains 99.999 998 1% of the data. Bringing some element of reality of process operations, the six-sigma creators discounted 1.5σ from this, saying that over time a process becomes more 'sloppy' than the original design by this much, that is, a process is said to be 6σ when the range of average $\pm 4.5\sigma$ is within the specification range: thus, one would be out of spec only 3.4 times in one million (99.999 66% of the data of a normal distribution within $\pm 4.5\sigma$). In practice, it really means that the process is designed/operated to deliver consistency all the time, or as sometimes stated in business science literature, 'first time right, every time right'.

It is generally accepted that the origin of the system lies in Motorola in the early 1980s, and that it was particularly disseminated by Jack Welch, a charismatic former CEO of General Electric (who famously stated that 'variation is evil'). In broader terms, six sigma results from giving an American managerial approach and organization to projects aimed at eliminating variation that apply much of the concepts and methods of Japanese manufacturing, with the Taguchi concepts being particularly eminent. Six sigma is a method, or work system, not a tool, and therefore it collects and deploys whatever tools can assist to achieve its objective better. Just like the Taguchi method, it involves a comprehensive approach including teamwork, planning, and other things, and it is data driven, that is, it relies on obtaining and analyzing actual process data. In that respect, six sigma is more an American version of the Taguchi approach than the Taguchi method is a part of six sigma. There is some confusion in the literature as to what is a tool and what is a system, and often the Taguchi method is taken as the distillation of its statistical approaches – that, however, is only a part of the whole.
