The typical clinical presentation of MMN allows differentiation from ALS. These features include an indolent time course and progression, asymmetric limb weakness, a non-myotomal pattern of weakness, and absence of significant muscle wasting, upper motor neuron signs, and bulbar weakness [4, 9]. In this clinical context, one should test for serum antibodies against gangliosides, especially GM1 [3, 4, 20]. It should be noted, however, that low titers of IgM anti-GM1 antibodies are nonspecific and can be found in normal subjects as well as in a variety of neurologic and autoimmune disorders including ALS, sensorimotor polyneuropathy, chronic inflammatory demyelinating polyneuropathy (CIDP), Guillain-Barré syndrome, myasthenia gravis, and systemic lupus erythematosus (SLE) [4, 32–34]. High titer anti-GM1 antibodies may predict a more severe clinical presentation in MMN patients (severe weakness, disability, and axonal loss) compared to antibody-negative patients [20]. However, the diagnostic significance of this observation is undetermined, as no differences were observed regarding response to intravenous immunoglobulin (IVIG) between these groups of MMN patients [19].

The EDX findings typically show focal conduction block along motor axons that spares sensory axons along the same peripheral nerve segment [7, 8]. The conduction block in MMN is often chronic and may remain unchanged for several years. Conduction blocks may go undetected unless multiple segments of several nerves are tested [8]. Definite conduction block has been defined as a greater than 50 % reduction of the compound motor action potential (CMAP) amplitude and area over a long nerve segment or a CMAP amplitude and area reduction of at least 30 % over a short distance (2.5 cm) detected by inching. Probable conduction block has been defined as a reduction in CMAP amplitude and area of at least 30 % over a long segment of an arm nerve. Both definitions require the distal CMAP amplitude to be at least 1 mV [7, 8, 12, 35] (Fig. 22.1). A careful interpretation of conduction block is required to differentiate conduction block from a decrease of CMAP amplitude and/or area due to temporal dispersion and phase cancellation [36]. Other electrophysiologic signs of demyelination such as temporal dispersion, slowed motor conduction velocities, prolonged distal motor latencies, and prolonged or absent F-waves may occur in association with the conduction blocks [7, 8]. The needle EMG exam shows typical neurogenic changes, including reduced recruitment of motor unit action potentials (MUAPs) in weak muscles. Secondary axonal changes may be seen, including fibrillation potentials and large, prolonged MUAPs.

Cerebrospinal fluid (CSF) is acellular, but protein levels may be elevated (usually <100 mg/dl). Serum immunofixation is normal in the majority of patients but an IgM monoclonal protein can be detected in some cases. Creatine kinase can be mildly elevated in up to two-thirds of patients [12]. MRI of the brachial plexus has been reported in MMN patients to show increased signal intensity and in some cases may co-localize with the conduction block seen on nerve conduction studies [37, 38]. Ultrasonography may also demonstrate abnormalities in the brachial plexus and nerves [39].

Treatment and Management

Human IVIG is considered standard treatment for MMN and its beneficial effects, demonstrated by improvement in strength, have been verified by several controlled [40–44] and uncontrolled clinical trials [21, 45–52] and retrospective studies [19, 20, 53]. The dose of IVIG is usually a total of 2 g/kg given in divided doses over 2–5 days. Pretreatment with 50 mg oral diphenhydramine (Benadryl®), 100 mg IV hydrocortisone, and 650 mg acetaminophen may be used to prevent side effects. Some degree of improvement occurs in up to 80 % of patients with MMN treated with IVIG, with 50–60 % of patients experiencing significant useful functional benefit. Despite improvement in strength, IVIG treatment usually does not reduce serum anti-GM1 antibody titers [21, 52, 54]. The onset of improvement in strength varies from 1 to 7 days after treatment, and maximal improvement is reached by an average of 2 weeks [54]. The duration of improvement varies from patient to patient but tends to be reproducible in each patient. Typically, the optimal benefit persists for 3–6 weeks. In approximately 10 % of patients, the effect may last longer, up to a year after a single treatment. The dose and frequency

of IVIG infusion should be based on the treatment response of the individual patient, and the period of maximal improvement after IVIG infusion should be monitored in each patient. The minimal dose that produces an optimal improvement is used for long-term maintenance treatment. Lack of improvement after two to three courses of IVIG infusion is considered a treatment failure. Over several years of treatment, effective IVIG dose requirements tend to increase by 30 % [17]. Subcutaneous immunoglobulin is an emerging alternative for IVIG. It can be self-administered and has been reported to be as effective for chronic MMN treatment [12].

The side effects of IVIG are usually minor and occur in less than 10 % of patients. Common side effects include mild headache, fatigue, and myalgias, but more severe side effects including anaphylactic reaction (seen in patients with IgA deficiency), thromboembolic events secondary to increased serum viscosity, aseptic meningitis, and acute renal tubular necrosis may occur [55–57]. Patients with more prominent muscle wasting often show reduced or shorter duration of improvement. With time, IVIG treatment may become less efficacious, with reduced recovery in weakness and shorter duration of remission [12, 52, 58].

Cyclophosphamide has been reported to produce sustained long-term benefit in 50–80 % of the patients with MMN. However, its side effect and toxicity profile, including an increased risk for neoplasms such as transitional cell cancer of the bladder with high cumulative lifetime doses (>75 g), has somewhat limited its utility in MMN. The use of monthly IV pulsed therapy for up to 6 months may limit the likelihood of serious side effects [7, 59]. Corticosteroid treatment is usually ineffective in the treatment of MMN. In fact, steroids may occasionally worsen weakness experienced by patients with MMN [3, 60, 61].

Rituximab, a monoclonal antibody directed against the B-cell surface membrane marker CD20, was reportedly beneficial in open-label studies and case series, but further studies could not establish its efficacy in MMN [12, 62, 63].

Course and Prognosis

The clinical course of MMN is usually benign, although the severity of weakness in some patients can be severe and debilitating [4, 5, 18, 21–23]. The response to various treatments is generally good. As noted above, the treatment response may lessen compared to the initial response, or the duration of the effect after each treatment may become shorter following long-term IVIG infusion therapy. In resistant or refractory cases, other immunosuppressive treatments may be considered. Weakness usually progresses slowly and can usually be stabilized or improved with immunosuppressive or immunomodulating treatment. Respiratory and bulbar weaknesses are exceedingly rare [28–30], and the disorder does not shorten the life span. Early diagnosis and initiation of IVIG treatment may help to delay the occurrence of axonal loss and irreversible neurological deficits [17].

Other Presumed Immune-Mediated Lower Motor Neuron Syndromes

Patients with a pure lower motor neuron disorder with localized regions of motor conduction blocks at non-entrapment sites that spares sensory axons are diagnosed as having MMN with conduction block. However, there are groups of patients with slowly progressive asymmetrical lower motor neuron weakness with a clinical presentation similar to those with MMN, in whom conduction block or other signs of demyelination are not detected [5]. These patients may be divided into those with either predominantly distal or proximal weakness. Patients presenting with distal weakness are more common and are difficult to clinically distinguish from patients with MMN with conduction block. The similar clinical characteristics between patients with MMN with and without conduction block suggest that conduction block may be undetected instead of absent or activity dependent [64, 65]. High titers of anti-GM1 antibodies were seen in 64 % of all such patients in one series [5]. Patients with predominantly proximal weakness are less common and have a later age of onset. This presentation occurs more commonly in men, who present with proximal lower motor neuron weakness that often remains confined to one or two extremities over the next 3–5 years [5].

EDX studies show evidence of motor axonal loss in a segmental distribution, without conduction block. Differentiating between a motor neuropathy and ALS, especially the progressive muscular atrophy variant of ALS (see below), is consequentially quite difficult. The diagnosis may depend on other investigations including laboratory tests to look for very high titers of antibodies to GM1 or a therapeutic trial of IVIG to look for a treatment response [4, 5, 54]. High-titer serum IgM anti-GM1 antibodies, when present, are a useful indicator that the lower motor neuron syndrome may be immune-mediated and potentially treatable [54, 66, 67]. In contrast, there has been no clear response to cyclophosphamide therapy in patients with predominantly proximal weakness or with low anti-GM1 antibody titers [64]. The decision whether to treat patients with a lower motor neuron syndrome without electrophysiologic evidence of conduction block is difficult.

Nonimmune-Mediated Lower Motor Neuron Syndromes

Spinal Muscular Atrophy

The spinal muscular atrophies (SMAs) consist of a complex heterogeneous group of genetic motor neuron disorders. A detailed discussion of the spinal muscular atrophies is provided in Chap. 21. The characteristic clinical presentation is that of progressive, symmetric, proximal muscle weakness, and atrophy, without upper motor neuron signs. In the three

major forms of this disorder, onset is in infancy or early childhood, with an autosomal recessive inheritance pattern linked to chromosome 5q. In the most severe form, Werdnig-Hoffman disease, death occurs by age two. However, other SMA variants exist with differences in their pattern of inheritance, gene linkage, age of onset, progression, distribution of weakness, and prognosis. Rare patients present in adulthood, with proximal or distal weakness. This chapter focuses on a specific form of adult-onset spinal muscular atrophy, X-linked recessive bulbospinal muscular atrophy.

X-Linked Recessive Bulbospinal Muscular Atrophy (Kennedy Disease)

In 1968, Kennedy and his colleagues described a clinical syndrome in 11 males from 2 families, with an X-linked recessive inheritance, characterized by adult-onset slowly progressive weakness, atrophy and fasciculations of bulbar and proximal muscles, and hyporeflexia or absent muscle stretch reflexes. Elevated serum CK (up to ten times normal) was common [68]. Some patients also had gynecomastia, impotence, and an essential tremor [68]. This clinical syndrome was named Kennedy-Stefanis disease in 1981 [69]. In 1991, LaSpada et al. identified a mutation in the androgen receptor gene as the cause of Kennedy disease [70–72]. The mutation is characterized by an increase in the size of a cytosine-adenosine-guanine (CAG) repeat within the first exon of the androgen receptor gene on chromosome Xq11-q12.

Etiology and Pathogenesis

Kennedy disease or bulbospinal muscular atrophy (BSMA) is an X-linked recessive disorder caused by a mutation within the first exon of the androgen receptor gene corresponding to an expansion of tandem CAG repeats on the X chromosome [70, 72]. The number of CAG repeats ranges from 40 to 62, which is only double the number seen in normal individuals. The phenotypic expression varies between and within affected families and does not usually correlate with the size of the mutation in most of the case series reported [73]. However, there is a correlation between the number of CAG repeats and age of onset, with a larger number of CAG repeats associated with earlier age of onset [74, 75].

While partial loss of androgen receptor function mediated by decreased receptor expression and activity occurs in Kennedy disease, this is unlikely to be the major cause of motor neuron degeneration. Experiments in a transgenic mouse model of bulbospinal muscular atrophy provided evidence to support the hypothesis that the polyglutamine expansion results in a *toxic gain of function* that leads to accumulation of abnormal proteins and degeneration of motor neurons [76, 77]. Furthermore, pathologic findings in patients with Kennedy disease reveal intranuclear aggregations containing androgen receptor protein in the brainstem and spinal cord motor neurons [78, 79]. However, the mechanism by which this intranuclear aggregation leads to neuronal degeneration is not well defined [79].

Point mutations in the dynactin-1 gene have been identified to cause BSMA with predominance of distal muscle weakness and wasting (distal BSMA). These patients commonly present with bilateral vocal fold paralysis and weakness and wasting of the face, hands, and distal legs [80, 81].

Clinical Presentation

Clinical features vary from asymptomatic hyperCKemia to severe muscle disease with bulbar involvement requiring artificial ventilation [80]. HyperCKemia may occur a decade in advance of symptom onset [82]. Kennedy disease typically presents in men in the third to fifth decade with gradually progressive weakness. Initial symptoms may include perioral or postural tremor, proximal or distal weakness, dysarthria, dysphagia, jaw drop, contraction fasciculations, or flexor muscle cramps. In most cases, weakness starts in the lower limbs, followed by the upper limbs, the bulbar muscles, and lastly the facial muscles. Muscle weakness and wasting usually have an asymmetric distribution and are more marked proximally. Distal weakness, if present, is often more prominent in the upper extremities, and muscle wasting of the intrinsic hand muscles is not uncommon. Fasciculations are often found in appendicular muscles. Muscle stretch reflexes are depressed or absent. Myalgia and muscle cramps may precede weakness for years. Some patients complain of exercise-induced muscle cramps and hand tremor several years before weakness develops. The hand tremor (found in up to 80 % of reported patients) has the characteristics of an essential tremor, is sometimes responsive to propranolol [68, 83–89]. Upper motor neuron signs are absent.

A classic and striking clinical feature of BSMA is the presence of facial fasciculations, most prominent around the mouth and chin. Fasciculations are present at rest but appear more prominent with contraction and are best elicited by having the patient whistle or blow out their cheeks. Facial fasciculations are reported in more than 90 % of case reports. Weakness and atrophy of the bulbar muscles, primarily of the facial muscles and muscles of mastication occur in variable degrees on neurological examination. Tongue wasting and fasciculations are also common and may predate the onset of bulbar symptoms. Despite weakness and fasciculations of the bulbar muscles on neurological examination, very few patients report dysarthria or dysphagia. The latter symptoms do not usually occur until very late in the disease course, usually more than 10 years after the initial presentation [68, 83, 85–92].

Sensory symptoms are unusual, but distally impaired vibration and pinprick perception have been described [92]. Despite the lack of sensory complaints or physical findings,

most patients studied have absent or low amplitude sensory nerve action potentials (SNAPs) on nerve conduction studies [73, 83, 89]. The underlying pathology responsible for sensory abnormalities in Kennedy disease is unclear. Kennedy found mild axonal loss in the peripheral nerves with intact dorsal roots in one autopsy case [68]. Sural nerve biopsies in other series have shown mixed features, including marked loss of myelinated nerve fibers, axonal atrophy, and segmental remyelination [73, 87, 93].

Female carriers may develop fasciculations, mild distal weakness, muscle cramps, or hyperCKemia later in life in about 50 % of cases. Tongue atrophy and fasciculations may occur in one fifth of these individuals by the seventh or eighth decade [80].

Systemic manifestations reported in most patients with Kennedy disease include gynecomastia and impotence. These are attributed to androgen insensitivity as a direct consequence of the expanded trinucleotide androgen receptor gene repeats. Diabetes mellitus may occur in a minority of patients with Kennedy disease, although its relationship with the gene defect is still uncertain.

Differential Diagnosis

The differential diagnosis of Kennedy disease includes disorders that present in the third to fifth decade with primarily proximal lower motor neuron weakness and bulbar signs. These include the progressive muscular atrophy variant of ALS, immune-mediated motor neuropathies, other late-onset SMAs, and myopathies including inflammatory, endocrine, and late-onset metabolic or inherited myopathies. These are usually distinguished by a careful family history, laboratory testing including CK level, serum anti-GM1 antibody titers, and TSH if indicated, as well as EDX testing to look for evidence of neurogenic versus myopathic changes. If EDX testing shows chronic neurogenic changes, a careful search for conduction block or other signs of demyelination is warranted. Genetic testing can be performed if clinically indicated to differentiate BSMA from late-onset SMA. In indeterminate cases, muscle biopsy may distinguish between neurogenic versus myopathic etiologies, excluding inflammatory, metabolic, or inherited myopathies.

Evaluation and Diagnosis

The diagnostic mainstay of Kennedy disease is primarily clinical: the classic clinical presentation and a supportive family history of X-linked inheritance. The diagnosis is confirmed by genetic testing. Serum CK levels are usually elevated, ranging from 900 to 8,000 IU/l, much higher than the CK elevation found in other anterior horn cell diseases, and sometimes implicating the diagnosis of myopathy [73]. Nerve conduction studies (NCS) often demonstrate low amplitude or absent SNAPs [68, 83, 85–89]. Motor NCS are normal except that CMAP amplitudes may be low if recorded from weak and wasted muscles. Needle electromyography (EMG) shows neurogenic changes, including increased insertional activity and reduced recruitment of large, prolonged duration, polyphasic motor unit action potentials (MUAPs) in affected muscles. Needle EMG examination of the facial muscles, such as the mentalis muscle, may show *grouped repetitive motor unit discharges* that occur with mild activation of the facial muscles. Such discharges are highly characteristic of Kennedy disease [85, 89]. Since these discharges occur with mild voluntary contraction rather than spontaneously, they are distinguished from myokymic or neuromyotonic discharges. Muscle biopsy reveals variability of fiber size with groups of angular atrophic fibers, grouped muscle atrophy, and pyknotic nuclear clumps. There is usually no fiber-type grouping [80]. Frequent atrophic groups containing mixed fiber types may be seen in Kennedy disease and other motor neuron syndromes or motor neuropathies [94, 95]. Nonspecific myopathic features, including increased central nuclei and necrotic fibers are also seen, which might also explain the abnormally high CK level. The diagnosis is confirmed by DNA analysis for the CAG mutation within the first exon of the androgen receptor gene on chromosome Xq11-q12.

Treatment and Prognosis

Currently, there is no specific treatment for Kennedy disease. The overall life expectancy is normal or only slightly shortened, as the nature of the disease is very slowly progressive. Bulbar weakness occurs relatively late in the course of the disease. Severe dysarthria or dysphagia that leads to aspiration pneumonia occurs rarely [68, 91].

Monomelic Amyotrophy (Hirayama Disease)

Monomelic amyotrophy is a rare form of motor neuron disease, first reported in the Japanese literature by Hirayama in 1959. He described the condition as a "juvenile muscular atrophy of a unilateral upper extremity" [96, 97]. Although most cases since the original report have been reported from Japan and India, the disease has been described in young adults from all parts of the world. Many different names have been used for this entity. These include Hirayama disease, monomelic atrophy, benign focal atrophy, benign focal amyotrophy, Sobue disease, and juvenile segmental muscular atrophy [97–104].

Etiology and Pathogenesis

The etiology of monomelic amyotrophy is unknown. Postulated mechanisms include subtle ischemia of the spinal cord, especially the anterior horn cells which lie in the watershed area, possibly precipitated by trauma to the arm or neck. Immobilization after trauma was associated with

monomelic amyotrophy in one small series [105]. Breig et al. proposed that forward bending of the neck could flatten the spinal cord from front to back and stretch the vessels sideways, possibly inducing a secondary vascular disorder [106]. Another proposed process involves an overstretch mechanism associated with compression of the dura and spinal cord against the vertebra during neck flexion [96]. It has been suggested that there is a short length of the cervical dural canal that cannot compensate for the flexion-related increased length of the vertebral canal. Thus, the dural canal becomes tight during neck flexion, resulting in anterior shift of the posterior dural wall as well as the spinal cord. The spinal cord also gets flattened against the C5–C6 vertebral body. There is forward movement of the posterior dura mater, obliterating the subarachnoid space and leaving a large posterior epidural space with prominent epidural venous plexus during neck flexion [107].

Hirayama reported a single patient with monomelic amyotrophy who died of lung cancer at the age 38, 23 years after the disease onset. The autopsy revealed shrinkage and necrosis of the anterior horn cells, with decrease number of large and small nerve cells and mild gliosis in the C5–T1 spinal segments, especially at C7–C8. The posterior horn was normal and the white matter was well preserved. The intra- and extramedullary vascular system of the spinal cord showed no abnormalities. The necropsy findings were suggestive of circulatory insufficiency of the lower cervical cord, although the true mechanism remained unknown [96].

Clinical Presentation

The true incidence and prevalence of monomelic amyotrophy is unknown. Most cases are sporadic, although a familial form has been reported. The male to female ratio is 5:1. The majority of patients are between 18 and 22 years old. Patients present with an insidious onset of unilateral weakness and atrophy of the hand muscles. In most cases, no particular precipitating infection or trauma is identified. The weakness tends to progress slowly over 1–3 years and then stabilizes. It is usually asymmetric and mainly affects the C7–T1 myotomes; however, proximal weakness in the arm can also be observed. Bilateral symmetric involvement has been reported in 10 % of cases, though in most the onset is unilateral [107]. Muscle atrophy is limited to the muscles of the hand and forearm, often sparing the brachioradialis muscle. This pattern of forearm involvement is referred to as *oblique amyotrophy.* In approximately one fourth of patients, the weakness is worse with cold exposure (cold paresis). Tremulousness of fingers in outstretched hands, or *mini-polymyoclonus*, has also been reported [107]. Muscle stretch reflexes are usually normal, and upper motor neuron signs are absent. Sensation in the affected extremity is preserved, except for rare and mild sensory abnormalities over the dorsum of the hand [96, 102, 104–106, 108–119].

Differential Diagnosis

The differential diagnosis of monomelic amyotrophy includes diseases that present with painless weakness and atrophy of a distal upper extremity, including syringomyelia, intramedullary spinal cord neoplasms, spinal cord infarction, inherited, or sporadic distal myopathies that affect the upper extremities before the lower extremities, rare adult-onset forms of spinal muscular atrophy, and the early stages of ALS. MMN is also worth considering in the differential diagnosis, although marked atrophy is notably absent early on in the disease. These disorders are differentiated by a careful family history, laboratory testing including CK level, and anti-GM1 antibody, as well as EDX testing to look for evidence of neurogenic versus myopathic changes. If EDX testing shows evidence of neurogenic changes affecting only motor axons or neurons or both, a careful search for conduction blocks or other signs of demyelination is warranted. The clinical course is also useful in differentiating these disorders, since stabilization of deficits usually occurs in monomelic amyotrophy, but not in the other disorders.

Evaluation and Diagnosis

The diagnosis is often made based on the classic clinical presentation of distal hand weakness and atrophy, usually in a young male. Laboratory investigations, including blood chemistries and cerebrospinal fluid (CSF) analysis, are normal, with the exception of the serum CK which may be slightly elevated. On EDX testing, motor NCS may be normal, or reveal asymmetrically low median or ulnar CMAP amplitudes. Slightly prolonged distal motor latencies or slightly slowed conduction velocities may occur, depending on the degree of axonal loss. The SNAPs are always preserved. On needle EMG, fibrillation potentials are not prominent and are found in slightly less than half of the patients. MUAPs are large and prolonged in duration, and recruitment is invariably reduced in muscles innervated mostly by the C7, C8, and T1 roots. Muscles innervated by the C5 and C6 roots are either normal or minimally affected. Low-amplitude, short-duration MUAPs, which represent early reinnervated motor units, occur in approximately 20 % of patients. Interestingly, similar EDX abnormalities are also detected, to a much lesser degree, in clinically unaffected limbs, particularly in the contralateral hand. Findings on muscle biopsy are often consistent with neurogenic atrophy without inflammatory infiltrates [96, 102, 103, 109, 112–115]. Features described on MRI performed in neck flexion include flattening of the spinal cord against C5–6 vertebral bodies, forward movement of the posterior cervical dura mater, obliteration or marked reduction in the size of posterior cervical subarachnoid space, and contrast-enhancing crescent-shaped posterior cervical epidural space. Segmental atrophy of the lower cervical and upper thoracic spinal cord has also been described [96, 107, 109, 120–123].

Course and Prognosis

The course in monomelic amyotrophy is generally benign. Distal weakness and atrophy usually progress slowly over 1–3 years, followed by relative stabilization. In one long-term series, disease progression subsided within 5 years in 75 % of 102 patients [111].

Brachial Amyotrophic Diplegia (Flail Arm Syndrome)

There are a few case reports of patients with sporadic adult-onset chronic progressive severe bilateral arm weakness and atrophy, without lower extremity involvement, presumably secondary to anterior horn cell loss. The clinical presentation is typically that of pure lower motor neuron weakness. The progression of the disorder is much slower than in typical ALS. EDX studies show denervation restricted to the proximal arm muscles.

The first case was reported by Mulder in 1957, describing a patient with weakness confined to the arms, and used the term "hanging arm syndrome" for the disorder [124]. In 1998, Hu et al. used the term *flail arm syndrome* to describe 39 patients who presented with severe bilateral arm weakness [125]. This presentation accounts for around 10 % of patients with motor neuron disease [126]. This subset of patients had a longer median survival of about 60–70 months compared to bulbar-onset and limb-onset ALS population with a median survival rate of 27–35 months [125, 126]. In 1999, Katz et al. described ten patients with sporadic slowly progressive proximal arm and shoulder girdle muscle weakness and atrophy, with variable degrees of distal arm involvement, which they termed *brachial amyotrophic diplegia*. Respiratory and bulbar muscles were spared. Eight of the ten patients had a pure lower motor neuron syndrome that was strictly confined to the upper extremities, both by clinical and EMG criteria. The other two patients had evidence of denervation on EMG in the upper and lower extremities, and one of them had upper motor neuron signs. More importantly, seven of the ten patients showed no signs of weakness in other regions after 67 months of follow-up, implying a slower progression than expected in typical ALS [127]. A case series by Sasaki et al. in 1999 described eight patients with a similar presentation of slowly progressive lower motor neuron weakness involving shoulder girdle and proximal arms. EDX studies revealed denervation in the upper extremities in all patients. In 2009, Wijesekera et al. reported on two ALS cohorts followed for over 12–14 years. The flail arm syndrome represented 11 % of a large cohort of ALS patients from London, England (1,188 patients), and 5 % of a smaller cohort from Melbourne, Australia (432 patients). In addition to better survival (60–70 months), the median time to spread to a second region of the neuraxis was 29 months in the flail arm syndrome. This was significantly longer when compared to limb-onset ALS (8 months), bulbar-onset ALS (12 months), and progressive muscular atrophy (14 months) [126]. Autopsy, performed in one patient, showed degeneration of the pyramidal tracts and loss of anterior horn cells in the cervical cord and brainstem motor neurons, similar to the pathologic findings in ALS [128].

The pathogenesis of this disorder is unknown. The clinical presentation is different from typical ALS given the slowly progressive course, restriction to the proximal arm and shoulder girdle muscles, and lack of upper motor neuron signs. It also differs from monomelic amyotrophy, which occurs in a younger age group, affects predominantly the hands, and is mostly asymmetrical in its presentation. The EDX studies in the flail arm syndrome show no evidence of conduction block or other features of demyelination, as noted in MMN with conduction block. It can be distinguished from the rare inherited cases of adult-onset proximal spinal muscular atrophy as well as various myopathic disorders by the lack of lower extremity involvement. Other disorders to be considered in the differential diagnosis include bilateral anterior cerebral artery (ACA)-middle cerebral artery (MCA) watershed infarcts, cervical spondylosis, anterior spinal artery infarction, and post-radiation amyotrophy, as well as early ALS [125, 127, 128].

Progressive Muscular Atrophy

A lower motor neuron syndrome is seen in patients with the progressive muscular atrophy variant of ALS (see Chap. 20). These patients present with slowly progressive, asymmetric weakness, wasting, and fasciculations, which may progress for years and ultimately lead to death. These patients have no evidence of upper motor neuron dysfunction, although corticospinal tract involvement has been observed in some autopsied cases. EDX studies reveal evidence for denervation and chronic reinnervation.

Progressive Bulbar Palsy

Another group of patients with ALS present with progressive bulbar dysfunction exhibiting both upper and lower motor neuron signs, such as tongue atrophy, weakness and fasciculations, and spastic speech (see Chap. 20). These patients eventually develop classic ALS.

Fazio-Londe Disease and Brown-Vialetto-Van Laere Syndrome

Fazio-Londe and Brown-Vialetto-Van Laere syndrome (BVVLS) are now considered to be the same disease entity with addition of deafness in the latter [129]. Recessive mutation

in the C20orf54 gene on chromosome 20p13 which encodes the human homolog of a rat riboflavin transporter has been implicated as being causative of this disorder [130]. BVVLS is characterized by progressive pontobulbar palsy (weakness of bulbofacial and extraocular muscles) and bilateral sensorineural hearing loss. The clinical course is progressive, with rate of progression variable between affected families. Long tract signs, lower motor neuron dysfunction, cerebellar ataxia, and respiratory muscles weakness may become apparent with disease evolution. The age of onset varies from infancy to adulthood. A recent report suggested abnormality of riboflavin transport and improvement with supplementation of riboflavin [129].

Hereditary Spastic Paraplegia

Hereditary spastic paraparesis (HSP) comprises a group of clinically and genetically heterogeneous neurological disorders that share the common feature of an insidiously spastic progressive gait disorder and associated weakness of the lower extremities. HSP is generally classified as *uncomplicated* or pure when motor symptoms are restricted to lower extremities, with variable mildly decreased vibration sense in toes and urinary urgency, and as *complicated* when there are associated symptoms like amyotrophy, ataxia, seizures, neuropathy, deafness, cataracts, mental retardation, thin corpus callosum, and ichthyosis in addition to the spastic paraparesis [131, 132].

Etiology and Pathogenesis

HSP mode of inheritance can be autosomal dominant, autosomal recessive, and X-linked. There are over 17 genes related to HSP and 52 loci, designated SPG, numbered in order of their discovery. Uncomplicated HSP (uHSP) on postmortem studies shows axonal degeneration limited to the CNS affecting primarily the caudal aspects of the descending cortical spinal tracts with maximal involvement in the thoracic spinal cord, and rostral aspects of the ascending fasciculus gracilis with maximal involvement in the cervicomedullary region. Decreased number of cortical pyramidal and anterior horn cells has been observed [95, 133].

The diversity of proteins involved in different forms of HSP suggests that axonal degeneration in HSP is caused by variable biochemical abnormalities. The molecular processes possibly involved in the pathogenesis of HSP include abnormalities in primary axonal transport, the Golgi apparatus, mitochondria, myelin synthesis, and corticospinal tract development [133, 134].

Clinical Presentation

The clinical presentation including age of onset, degree of deficit, and associated symptoms varies both within and between families. The different subtypes of uncomplicated HSP usually cannot be differentiated based on phenotype [131, 132].

Symptoms of HSP may begin at any age. When symptoms begin at early age (before 2 years of age), HSP may manifest as "toe walking" and look like spastic diplegic cerebral palsy without much functional worsening over decades. If onset is after infancy (after age 6) or during the teenage years or later, the gait disorder usually slowly progresses over many years, causing variable degrees of disability. Urinary urgency is common and may be an early symptom of HSP [133].

The neurological examination in uHSP consists of increased tone in lower extremities, weakness particularly in flexor muscles (iliopsoas, hamstrings, tibialis anterior), hyperreflexia, extensor plantar responses, and variable mildly decreased vibration sense in toes. High-arched feet are common, but not invariably present. Upper extremities reflexes may be brisk but dexterity, muscle strength, and tone remain normal in uHSP. A sudden onset and symptom progression over weeks or months is not typical for HSP and would suggest an alternative or coexisting disorder. Other features that suggest alternative diagnoses include marked asymmetry, spasticity and weakness in the upper extremities and bulbar muscles, and a cutaneous sensory level. Muscle atrophy and fasciculations are not typical for uHSP but can be seen in many types of complicated HSP (cHSP), including Troyer syndrome (SPG20) and Silver syndrome (SPG17) [132, 133].

Limited generalization can be made regarding cHSP, as each disorder represents a unique clinicopathological entity. It is useful for practical purposes to recognize three clinical phenotypes: (1) spastic paraplegia associated with peripheral motor neuropathy and/or distal wasting (e.g., Troyer and Silver syndromes); (2) spastic paraplegia associated with cognitive impairment (e.g., SPG11 which is often associated with a thin corpus callosum and considered to represent 50 % of recessively inherited HSP); and (3) spastic paraplegia associated with additional neurologic and systemic abnormalities [132, 133].

Differential Diagnosis and Evaluation

The diagnosis is usually straightforward if there is a known family history of pure progressive spastic paraparesis. If there is no known family history, other diagnoses to be considered in the appropriate clinical context include human T-cell lymphotropic virus type 1 (HTLV-1)-associated spastic paraparesis (see below), vitamin B12 deficiency, vitamin E deficiency, multiple sclerosis, primary lateral sclerosis, cervical spondylotic myelopathy, neurosyphilis, and spinal cord tumor.

In some cases, HSP can be confirmed by genetic testing. However, a family history may be absent with autosomal recessive or X-linked inheritance patterns, incomplete genetic penetrance, spontaneous (*de novo*) mutations, genetic anticipation (child affected before parents), and in cases of wrong paternity. These individuals with a clinical picture of HSP and no apparent family history are usually designated as having "apparently sporadic" spastic paraplegia. Genetic penetrance is age_dependent and high but typically incomplete [132, 133]. HSP should be considered a diagnosis of exclusion when there is no family history.

If there is a known family history, but other neurologic or systemic features are present, the differential diagnoses widen to include metachromatic leukodystrophy, globoid cell leukodystrophy, adrenoleukodystrophy, adrenomyeloneuropathy, spinocerebellar atrophy, hexosaminidase A deficiency, and familial ALS. In such cases, the diagnostic evaluation should include MRI of the brain and spinal cord; HTLV-1 and HIV antibodies; vitamin B12 and E levels; VDRL, FTA-ABS, or MHA-TP; plasma very long chain fatty acids; arylsulfatase A; and galactocerebrosidase, copper, and ceruloplasmin levels. CSF analysis for cell count, protein, glucose, VDRL, oligoclonal bands, and IgG synthesis rate/index may be considered, depending on the clinical presentation.

The evaluation of both complicated and uncomplicated HSP requires EMG study, neuroimaging, and laboratory tests to exclude alternate disorders. The most common MRI abnormality observed is thinning of the cervical and thoracic spinal cord. Other MRI abnormalities include loss of corpus callosum volume and higher incidence of cerebral white matter lesions. Nerve conduction studies and needle EMG are normal in most cases of uHSP, as is the CSF analysis. Lower limb somatosensory evoked potentials may show central conduction delay or low amplitudes. Central motor conduction times are delayed or non-recordable from the lower limbs [132, 134].

Genetic Subtypes of HSP

Autosomal Dominant (AD) HSP

SPAST-Associated HSP

SPAST gene encodes the *spastin* protein. This is the most common form of AD uHSP (40–45 % of cases). Its onset is variable from childhood to late adult life with a bimodal peak distribution in the first decade and above age 30. *SPAST* mutations are thought to mostly cause uHSP and an excess of males has been identified. Complex phenotypes with cerebellar ataxia, tremors, epilepsy, thinning of corpus callosum, mental retardation, and lower motor neuron dysfunction have been described. Progressive cognitive decline has also been reported [134–137].

SPG3A

This is the second most common AD HSP (10 % cases), and the gene encodes for the protein *atlasin*. Its onset is usually before age 10 and it manifests with an uncomplicated phenotype. An association with axonal peripheral neuropathy has been reported [134, 138].

Other AD HSP forms include *SPG6*, associated with NIPA1 gene, manifesting with an uHSP phenotype; *SPG 8* associated with the KIAA0196 gene, characterized by severe spasticity and reduced vibration sense; *SPG 13*, associated with the gene HSPD1, with a typically uHSP phenotype with late onset; and *SPG 17*, due to mutation in BSCL2 gene that manifests as a cHSP with associated amyotrophy of the small hand and feet muscles, onset in early teens to late 30s (Silver syndrome). Other AD HSP forms include SPG 9, 10, 12, 18, 19, 29, 33, 34, 36–38, 41 and 42 [95, 132–134].

Autosomal Recessive (AR) HSP

Examples of AR HSP include *SPG5A*, associated with the CYP7B1 gene, and an uHSP phenotype; *SPG 7*, associated with the *paraplegin* gene, accounting for about 5 % of AR HSP cases. This mutation is associated with uncomplicated and complicated phenotypes with ataxia, dysarthria, nystagmus, pale optic discs, and peripheral neuropathy; *SPG11*, associated with mutations in the gene that encodes *Spatacsin* and characterized by uHSP or cHSP variably with a thin corpus callosum, cognitive impairment, and lower motor neuron or sensorimotor axonal neuropathy; *SPG 15*, associated with mutations on ZFYVE26 gene, manifests as a cHSP accompanied by mental impairment, pigmentary retinopathy, cerebellar dysfunction, and distal amyotrophy; *SPG20*, associated with mutation in *spartin* gene causes Troyer syndrome, characterized by spastic tetraparesis, dysarthria, distal amyotrophy, short stature, and learning difficulties; *SPG 21*, associated with the gene encoding *maspardin*, produces Mast syndrome with associated dementia, cerebellar and extrapyramidal signs, and a thin corpus callosum . Other recessive forms are rare and include SPG 14, 23-28, 30, 32, 35, 39, 43-48, and 50-52 [95, 132–134, 139, 140].

X-Linked HSP

SPG1, associated with a mutation in L1CAM gene, is characterized by hydrocephalus, mental retardation, and adducted thumbs. The clinical spectrum also includes X-linked hydrocephalus with aqueduct of Sylvius stenosis, MASA syndrome (*m*ental retardation, *a*phasia, *s*pastic paraplegia, and *a*dducted thumbs), and X-linked agenesis of corpus callosum; *SPG2*, associated with a mutation in the proteolipoprotein gene (PLP1), manifests mainly as a cHSP, and may be associated with a peripheral neuropathy and white matter changes on MRI; *SPG 16* is another X-linked HSP that presents with aphasia, decreased vision, and mild mental retardation [95, 132, 134].

Treatment and Prognosis

Treatment of HSP aims to reduce muscle spasticity through medication (e.g., baclofen or tizanidine) and muscle stretching exercises to prevent contractures. Physical activity can be useful to improve endurance and lower extremity strength. Urinary urgency may respond to anti-cholinergic medications such as oxybutynin. Uncomplicated HSP gait spasticity and weakness may worsen insidiously over many years. Upper extremity, speech, swallowing, and respiration muscles remain unaffected. Life expectancy is not altered in uHSP. The prognosis of cHSP is quite variable and dependent on the clinical phenotype and associated medical comorbidities [132, 133].

Multiple System Disorders with Prominent Motor Signs

Adult-Onset Hexosaminidase A Deficiency (Late-Onset Tay-Sachs Disease)

The adult-onset form of hexosaminidase A deficiency (also known as late-onset Tay-Sachs disease) is a rare disorder, recognized only in the last three decades. The disorder is characterized by slowly progressive degeneration of the cerebellar and upper and lower motor neuron systems. Some patients have psychiatric disturbance, including psychosis and depression. The onset is usually during childhood, although symptoms are often not recognized until the second or third decade of life. The adult-onset form is quite different from the well-known rapidly progressive infantile form of hexosaminidase A deficiency, known as Tay-Sachs disease [141, 142].

Etiology and Pathogenesis

Hexosaminidase is a lysosomal enzyme that participates in the metabolism of GM2 ganglioside. Deficiency of the enzyme causes accumulation of lysosomal GM2 ganglioside, which leads to the neuronal degeneration. There are two major isoforms of hexosaminidase: hexosaminidase A, which consists of two different subunits (α [alpha] and β [beta]), and hexosaminidase B, consisting of only β [beta] subunits. The gene encoding for the α (alpha) and β (beta) subunits are located on chromosomes 15 and 5, respectively. A defect in the gene encoding for either the α (alpha) or β (beta) chains results in a deficiency of hexosaminidase A. An absolute deficiency of hexosaminidase A causes infantile Tay-Sachs disease, whereas a partial deficiency results in the late-onset form of Tay-Sachs [142].

The infantile form of the disease is characterized by progressive dementia, myoclonus, seizures, pyramidal signs, cerebellar involvement, and a macular cherry red spot. The disorder is inherited in an autosomal recessive manner and is more prevalent in the Ashkenazi Jewish population than in other ethnic groups. Late infantile and juvenile-onset forms of the disease with a slowly progressive clinical course also exist [142–145]. However, it was not until 1973 that Navon et al. first reported four adult siblings with hexosaminidase A deficiency with apparently no clinical symptoms [146]. Neurological symptoms became apparent with subsequent evaluation [147].

The study of enzyme activity in patients with the adult-onset form reveals significant residual enzyme activity, in contrast with patients with the infantile form in whom enzyme activity is totally absent or very low. Different types of mutations exist, leading to partial hexosaminidase A deficiency in different families and prominent clinical heterogeneity in the late-onset form. Some patients are homozygous for a single mutation, whereas others are compound heterozygotes, with two abnormal alleles on the homologous chromosome [148–153].

Clinical Presentation

The age of onset is usually in the second decade, although the age at time of diagnosis varies from 11 to 67 years [151]. The disorder is inherited through an autosomal recessive mode of transmission. Neurological manifestations result from degeneration of the pyramidal cells, lower motor neurons, cerebellum, and cerebellar connections. Sensory and cranial nerve involvement are unusual features, but early and severe sensory loss has been reported [154]. Twenty seven percent of patients were found to have evidence of an axonal polyneuropathy in one cohort with 30 patients [155]. A sensory neuropathy with internuclear ophthalmoplegia was reported in one patient [156]. Although the disorder affects multiple systems, the *cerebellum* is the most prominently affected in all reported cases. Dysarthria and truncal ataxia are usually the earliest manifestations and precede appendicular ataxia. In some patients, cerebellar signs are mild and of little functional significance. Nearly every patient reported also has *lower motor neuron* involvement. Weakness and atrophy initially involve the lower extremities and are more prominent in the proximal muscles. Indeed, it is not uncommon for patients to be misdiagnosed as Kugelberg-Welander disease (a variant of spinal muscular atrophy) early on in the disease course. In one case series, 9 of 14 patients also had upper motor neuron signs, but severe spasticity was rare [152]. The neurological picture may resemble spinal muscular atrophy when lower motor neuron signs predominate or ALS when prominent upper and lower motor neuron signs coexist [148, 151, 157–169].

Another important manifestation of adult-onset hexosaminidase A deficiency is *recurrent psychosis*. The psychosis may precede or follow the neurological manifestations [148, 157–161]. Rare patients present with psychosis as the sole manifestation [148, 152, 170, 171]. Depression is also

common. Patients with psychotic episodes may have more severe neurologic symptoms compared with those patients without psychosis. This may be secondary to treatment with various psychoactive drugs which have been shown to be toxic to lysosomes in vitro and may actually worsen the lipidosis or deplete hexosaminidase (see below) [152, 170–173]. Other clinical manifestations reported in some patients include dementia [174], extrapyramidal findings, and dystonia [152, 175, 176].

Differential Diagnosis

The differential diagnosis includes juvenile and adult-onset forms of spinal muscular atrophy, especially when lower motor neuron signs predominate, as well as the spinocerebellar ataxias (see below), myopathy, multiple sclerosis, and ALS. These disorders are differentiated by a careful family history, MRI of the brain to look for evidence of white matter disease or cerebellar degeneration, laboratory testing including creatine kinase (CK) level, as well as EDX testing to look for evidence of neurogenic versus myopathic changes. Genetic testing may be performed if clinically indicated.

Evaluation and Diagnosis

Adult-onset hexosaminidase A deficiency should be considered in the differential diagnosis of patients with lower motor neuron manifestations accompanied by spinocerebellar degeneration, especially those with a history of psychosis or psychiatric disorder such as depression. Laboratory investigations, including serum CK level, are usually normal. Neuroimaging studies of the brain usually show cerebellar atrophy. EDX studies may show abnormal sensory conduction studies. Motor nerve conduction studies are usually normal, unless recorded from weak muscles, in which case the CMAP amplitudes are low, with normal or slightly slowed conduction velocities. The needle EMG examination shows abnormal spontaneous activity including complex repetitive discharges, fasciculations, and fibrillation potentials. Long-duration, high-amplitude, and polyphasic MUAPs with reduced recruitment are seen in affected muscles [148, 152, 155, 174]. Muscle biopsy shows neurogenic changes including fiber-type grouping [148, 158–161, 174]. Pathologic findings on rectal biopsy and the appendix include swollen and abnormal neurons in the myenteric plexus on light microscopy [152].

A definitive diagnosis is made by measuring hexosaminidase A activity in leukocytes or fibroblasts. Hexosaminidase A activity is significantly reduced in serum, leukocytes, and skin fibroblasts in adult-onset patients, in contrast to the total or nearly total absence of the enzyme in the infantile type [148–152, 159, 166, 167, 174]. Once the diagnosis is established, DNA testing can be performed in specialized laboratories to determine the specific gene defect [177]. Prenatal diagnosis for this condition is possible [178].

Currently, the standard screening for Tay-Sachs carriers is performed by testing a blood sample for hexosaminidase A enzyme activity. This does not screen for the gene defect itself. While standard screening identifies abnormal individuals, it does not differentiate between the infantile and late-onset carrier states. When both parents are identified as carriers, DNA testing can be carried out to determine whether the defective gene is that of the infantile or the late-onset type. This testing is recommended for couples whose decision regarding the pregnancy would be altered by whether they were at risk for having a child with infantile or late-onset Tay-Sachs.

Treatment and Management

There is currently no known specific treatment for late-onset Tay-Sachs disease. Treatment consists primarily of symptom management. This includes physical therapy for gait and balance training, speech therapy for dysarthria, and occupational therapy as clinically indicated. Aggressive physical therapy is important to prevent complications from falls, which can result in life-threatening injuries. Because some of the medications used to treat psychosis and depression are known to be toxic to lysosomes and can worsen symptoms, these medicines are best avoided [152, 170–172, 179]. Such medications include neuroleptics such as phenothiazines as well as antiepileptic drugs used as mood stabilizers and antidepressants. In a retrospective and short-duration prospective review of medication adverse effects in late-onset Tay-Sachs patients, certain psychotropic medications, particularly haloperidol, chlorpromazine, and risperidone, worsened neurologic symptoms. Benzodiazepines such as lorazepam and clonazepam were relatively safe and carbamazepine was the mood stabilizer with the least frequent neurologic worsening [179]. Enzyme testing and prenatal diagnosis are available and genetic counseling for the patient and their families cannot be overemphasized [148, 152, 159, 161, 174].

Course and Prognosis

The clinical course in adult-onset hexosaminidase A deficiency is slowly progressive and varies widely between individuals. Some patients manifest with mild dysarthria and ataxia with slow progression over years, while others are wheelchair bound by the fourth or fifth decade of life from a combination of ataxia and weakness. Recurrent psychotic episodes can also be severely debilitating.

Spinocerebellar Degenerations

There are several multiple system disorders in addition to late-onset Tay-Sachs disease that present with ataxia as a prominent feature yet are accompanied by lower motor neuron signs. Other accompanying features include spasticity,

dementia, optic atrophy, ophthalmoplegia, peripheral neuropathy, or extrapyramidal signs. These features easily distinguish them from typical ALS. They are broadly classified as autosomal dominant or autosomal recessive cerebellar ataxias, and the genetic basis of many of these disorders is now known [180, 181].

Adult Polyglucosan Body Disease

Adult polyglucosan body disease (APBD) is an exceedingly rare neurological disorder. The clinical presentation is pathognomonic: progressive upper and lower motor neuron dysfunction, sensorimotor peripheral polyneuropathy, gait disturbance, urinary incontinence, and dementia. All components of the disorder may not be present initially. Some cases appear to be sporadic, and some familial, with a high proportion occurring in families of Ashkenazi Jewish descent. The pathological hallmark of the disease is the presence of a large number of polyglucosan bodies, which structurally resemble Lafora bodies or corpora amylacea, in central and peripheral neuronal processes and astrocytes [182]. The clinicopathological characteristics of the disease were first recognized in the late 1970s [183].

Etiology and Pathogenesis

The presumed cause of APBD is genetic, especially in patients of Ashkenazi Jewish descent. A Tyr329Ser mutation in the glycogen branching enzyme gene on chromosome 3, causing a glycogen branching enzyme deficiency, has been described in Ashkenazi Jewish patients with APBD [184, 185]. Ubogu et al. reported a single APBD patient with reduced glycogen brancher enzyme activity associated with a heterozygous point Tyr329Ser mutation [186]. Ziemssen et al. reported the first patient of non-Jewish descent with a novel missense mutation (Arg515His and Arg524Gln) in the glycogen branching enzyme gene [187].

The true pathogenic mechanism for the clinical manifestations of APBD remains unknown. Since a deficiency of the glycogen branching enzyme is found in only a subgroup of patients with APBD, primarily those of Ashkenazi Jewish descent, the disease may have more than one biochemical basis [184]. The accumulation of polyglucosan bodies in the nervous system is the pathologic hallmark of the disease [182, 183, 188, 189]. However, accumulation of polyglucosan bodies is also seen in other diseases such as Lafora's disease and type IV glycogenosis [190] and may occur as a nonspecific phenomenon in the aging nervous system (corpora amylacea). Structurally, polyglucosan bodies are composed primarily of glucose polymers, with a small variable component of phosphate and sulfate groups and a minimal protein component, the nature of which is unknown [182, 191]. Polyglucosan bodies in APBD are seen in the central nervous system, predominantly within astrocytic processes in the subpial and subependymal regions, cerebellum, and in myelinated axons in the peripheral nervous system (Fig. 22.2). There is severe loss of anterior horn cells. Deposition of polyglucosan bodies is also seen in myocardium, liver, smooth muscles, and to a lesser extent in skeletal muscles [170, 180]. The mechanisms responsible for tissue damage include impairment of astrocytic processes secondary to massive accumulation of polyglucosan bodies, or the underlying metabolic defect may damage the neuron directly, with the accumulation of polyglucosan bodies occurring as a secondary effect [192].

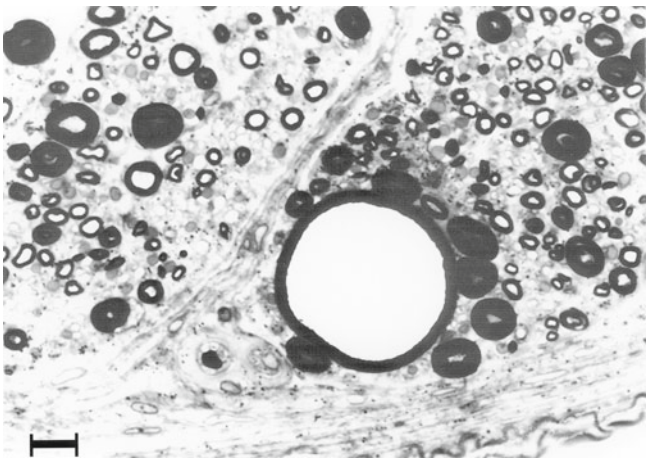

Fig. 22.2 Transverse section of the sural nerve from a 62-year-old man with adult polyglucosan body disease. Note intra-axonal location of polyglucosan body, measuring approximately 50 μm, and distending the axon. Polyglucosan bodies are composed primarily of glucose polymers, with a small variable component of phosphate and sulfate groups and a minimal protein component (Bar = 10 μm; magnification = ×1028)

Clinical Manifestations

As noted above, APBD can be sporadic or familial. The pattern of inheritance appears to be autosomal recessive in some case reports. Most patients present between the fourth and sixth decades, and there is no gender predisposition. The clinical manifestations include progressive upper and lower motor neuron dysfunction, peripheral neuropathy with prominent sensory loss in the lower extremities, gait disturbance, urinary incontinence, and dementia [188, 189, 193, 194]. However, all of the clinical manifestations may not be present, and the severity of clinical manifestations varies among patients [195]. Cognitive impairment tends to occur during the advanced stages of the disease. Of the 24 patients reported in a review series, 11 patients did not have dementia and four patients lacked urinary incontinence [189]. Some patients present with dementia, urinary incontinence, and gait disturbance, without upper or lower motor neuron signs [196, 197], while others present with only upper and lower motor neuron signs and resemble ALS, with only minimal non-motor CNS manifestations [195].

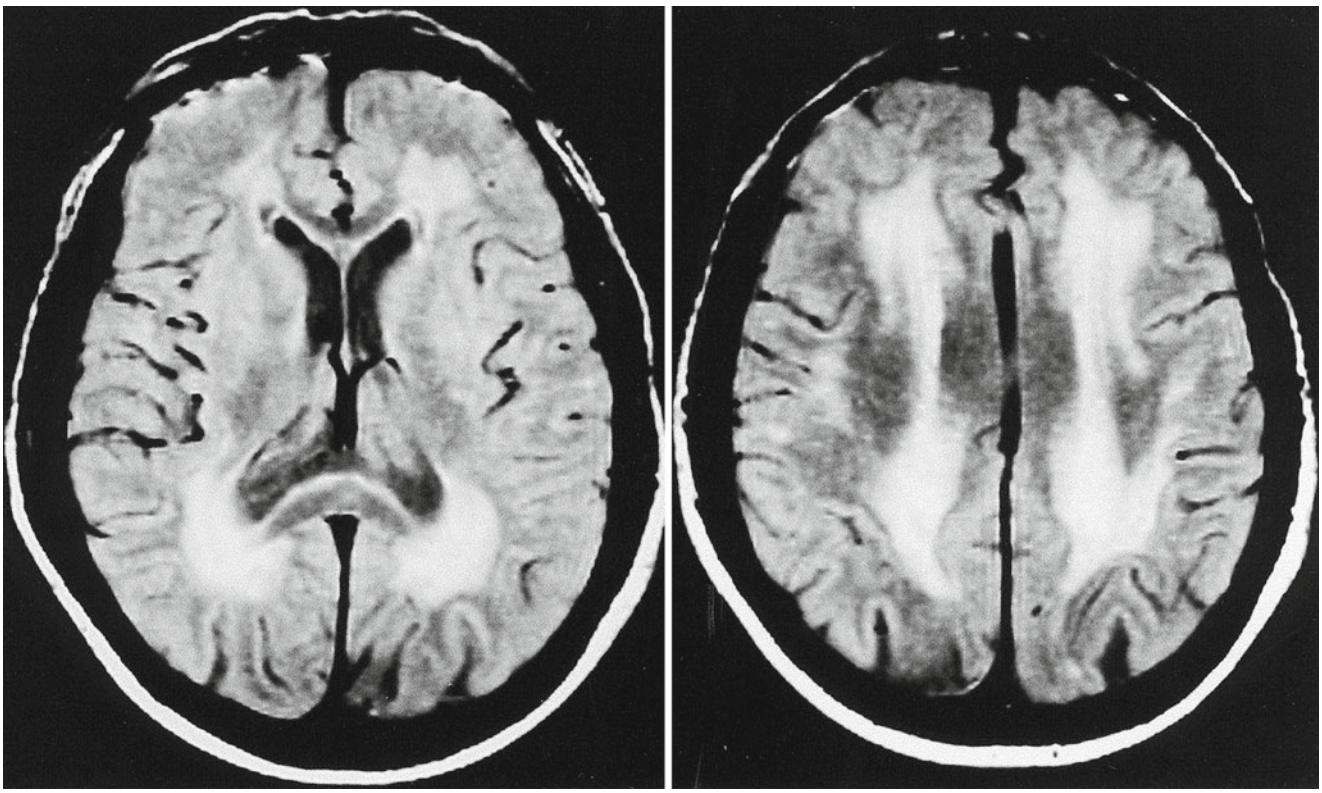

Fig. 22.3 Double echo non-contrasted axial brain MRI images of a 62-year-old man with adult polyglucosan body disease. Note diffuse bilateral white matter signal abnormalities in periventricular and subcortical white matter characteristic of adult polyglucosan body disease

Differential Diagnosis

Clinically APBD must be differentiated from other neurological disorders with progressive upper and lower motor neuron dysfunction, including ALS, primary lateral sclerosis, late-onset multiple sclerosis, and other multisystem disorders with upper and lower motor signs including vitamin B12 and E deficiencies, metachromatic leukodystrophy, globoid cell leukodystrophy, adrenomyeloneuropathy, and spinocerebellar atrophy.

Evaluation and Diagnosis

The clinical context that should prompt an evaluation for APBD is progressive upper and lower motor neuron dysfunction and gait instability that may resemble typical ALS but is accompanied by dementia and urinary incontinence. Distal sensory loss may be found on clinical exam. Extensive white matter abnormalities are seen on brain MRI (Fig. 22.3) [187, 188]. EDX studies reveal mild-to-moderate slowing of motor nerve conduction velocities and low amplitude or absent SNAPs [189]. Routine laboratory investigations are usually normal. A definitive diagnosis is based on pathological findings of widespread deposition of polyglucosan bodies in the central and peripheral nervous systems. Sural nerve biopsy shows multiple intra-axonal polyglucosan bodies (see Fig. 22.2), which in the appropriate clinical context, can confirm the diagnosis of APBD [188, 193]. Axillary skin biopsy may show polyglucosan bodies in the myoepithelial cells of apocrine glands, confirming the diagnosis as well [198]. Reduction of leukocyte glycogen branching enzyme activity is found mainly in Ashkenazi Jewish patients but may be demonstrated in non-Ashkenazi Jewish patients as well [184, 187].

Treatment, Course, and Prognosis

There is no specific treatment for APBD. Supportive therapy is the mainstay of treatment, geared toward symptom control. The disease usually progresses over a period of 1–21 years, eventually leading to death [188, 189, 192].

Other Multiple System Disorders

Other multiple system disorders that may have prominent lower and upper motor neuron signs include Hallervorden-Spatz disease (pantothenate kinase-associated neurodegeneration), Guamanian Parkinson-ALS, Creutzfeldt-Jakob disease, Huntington's disease, Pick's disease, and the Shy-Drager syndrome (multiple systems atrophy). Each, however, has distinctive clinical presentations that easily differentiate them from typical ALS.

Other Atypical Motor Neuron Syndromes

Motor Neuron Disease Associated with Electrical Injury

There are rare case reports of adults and children who develop a delayed upper and lower motor neuron syndrome after exposure to an electrical injury or lightning. Weakness begins in an upper extremity, usually at the site of trauma, and evolves into a diffuse motor neuron syndrome.

Etiology and Pathogenesis

The underlying mechanism of the electrical injury and its relationship to spinal cord damage, in particular damage to the anterior horn cells, is unclear. While pathologic changes in the central nervous system (CNS) of experimental animals, or individuals executed by electrocution, include petechial hemorrhages, swelling and dissolution of myelin sheaths and axons, neuronal ischemia, and death, similar findings are not seen in autopsies of patients with motor neuron disease associated with electrical injury [199]. Autopsy findings in one patient with motor neuron disease after an electrical injury revealed the classic changes found in ALS, including loss of anterior horn cells, cells in hypoglossal nuclei, and degeneration of the corticospinal tract. There was no evidence of vascular-mediated injury or mechanical distortion of the spinal cord [199].

Transient weakness and paraplegia that occur immediately or shortly after an electrical injury usually recover within a few hours to 4 days in most cases [199–203]. Permanent neurologic sequelae are usually seen when weakness develops days to years after the injury, as noted in one case series of 27 patients with spinal cord injury after an electrical accident [201]. This may reflect a group of patients with delayed anterior horn cell injury. The possible relationship of motor neuron disease to antecedent electrical injury is also described in various small case studies [204, 205]. One proposed mechanism for delayed spinal cord injury after an electrical injury includes vascular occlusion secondary to slow endothelial fibrosis and intimal thrombosis, which then leads to ischemia in the microvascular circulation. Another proposed mechanism involves injury to cellular DNA secondary to thermal, mechanical, or vascular insult leading to cell death [206]. To date, evidence supportive of a true causative relationship between electrical injury and the delayed development of motor neuron disease remains elusive. A systematic review of the literature supports a syndrome of nonprogressive spinal cord damage following electrical injury with lower and upper motor neuron components. The more severe the shock, the more likely affected individuals developed a nonprogressive motor syndrome. For the progressive and nonprogressive motor neuron syndromes, the median interval between electrical injury and disease onset was 2.25 years and 1 week, respectively. The relationship between electric injury and ALS was less certain, and the evidence reviewed did not support a causal relationship between ALS and electric shock [207].

Clinical Presentation

Electrical injuries usually occur from high voltage lines, household circuits, or lightning. Transient neurological deficits immediately after an electrical shock are well described, and recovery usually occurs within 4 days. If a persistent motor neuron syndrome occurs, it develops at variable time periods after the electrical injury. Weakness and atrophy usually begin in the extremity of the original site of injury, commonly the upper extremity. Weakness then progresses in an ALS-like fashion to the contralateral limb. Bulbar weakness and upper motor neuron signs develop later on [199, 201, 206–211]. Sensory symptoms can occur in the region of the electrical injury.

Treatment, Course, and Prognosis

The clinical course of the motor neuron disorder associated with electrical injury is similar to ALS, with death occurring within 30–36 months after initial disease presentation. There are no known specific treatments; care consists of supportive measures similar to those provided in ALS [199, 211].

Post-radiation Motor Neuron Syndrome

In 1948, Greenfield and Stark reported three patients who developed a progressive pure lower motor neuron syndrome in the lower extremities 3–5 months after receiving radiation therapy for testicular cancer, with a calculated tissue dose of 5,000–6,000 rad to the retroperitoneal and para-aortic region [212]. Since this report, there have been multiple case reports of a similar clinical syndrome occurring after ionizing radiation therapy for various tumors, including testicular tumors, pheochromocytomas, lymphoma, medulloblastomas, and papillary carcinomas of the kidney [213]. The term *post-radiation motor neuron syndrome* has been proposed. The syndrome consists of painless, flaccid weakness usually involving the lower extremities without sensory manifestations, pain, sphincter dysfunction, or long tract signs.

Etiology and Pathogenesis

The pathogenesis of delayed radiation injury to the spinal cord is not well defined. Furthermore, the primary site of pathology is debatable. Some evidence suggests that the disease process involves damage to the lumbosacral ventral nerve roots, while other evidence suggests anterior horn cell pathology. A single autopsy case demonstrated evidence of demyelination and axonal loss in sensory and motor roots, with chromatolytic changes in the lumbar anterior horn cells,

presumably due to nerve root involvement. No vascular changes were seen in the spinal cord [214].

The underlying process responsible for the motor nerve root or anterior horn cell damage is unclear. However, based on purported pathogenic mechanisms in delayed radiation myelopathy and encephalopathy, it is likely that a combination of factors is involved in post-radiation motor neuron syndrome. These include direct radiation-induced damage to glial cells and neurons and ischemic changes secondary to radiation-induced damage to vascular endothelial cells [214–216].

Clinical Presentation

The clinical syndrome is characterized by progressive weakness of the lower extremities, with marked atrophy and fasciculations that develops months to years after radiation therapy. Muscle stretch reflexes are depressed or absent in the lower extremities. Sphincter function and sensation are spared, and upper motor neuron signs are absent [217–227]. Interestingly, the lower extremities are preferentially involved, although radiation may have included the entire neuraxis. The weakness generally stabilizes after several months, although in some patients, weakness is progressive over several years. A delayed lower motor neuron bulbar palsy, consisting of dysarthria, dysphagia, and in some cases neck weakness, has also been reported following radiation therapy to the head and neck for various neoplasms [228].

Evaluation and Diagnosis

The diagnosis is based on a history of lower motor neuron weakness primarily involving the lower extremities, months to years following radiation exposure. The dose of radiation exposure in reported cases ranges from approximately 3,500 to 5,600 rad. CSF is usually normal, although there may be a mild elevation of CSF protein to approximately 50 mg/dl [216]. MRI and CT myelogram of the spine are normal. On EDX studies, nerve conduction studies show low amplitude CMAPs in the lower extremities, with intact SNAPs. On needle EMG, fibrillation potentials are often present in the lower extremities. Myokymic discharges may also be seen in lower extremity muscles. Long-duration, high-amplitude, and polyphasic MUAPs with reduced recruitment is present in both lower extremity muscles, sometimes asymmetrically. EDX testing of the upper extremities is normal in most cases, depending on the site of radiation [216–221]. It is important to exclude other causes of progressive lower extremity weakness, such as tumor recurrence (in cases of spinal cord tumor), ALS, and myopathies.

Treatment and Management

As is the case with most motor neuron disorders, there is no specific treatment for post-radiation motor neuron disease, other than supportive symptom management. Treatment with anticoagulation has been utilized in patients with delayed radiation-induced cerebral radionecrosis and myelopathy with some recovery of function. The presumed mechanism of action is anticoagulation-mediated arrest and reversal of small vessel endothelial injury; the fundamental pathology of radiation necrosis [229]. However, lack of vascular changes in previous autopsy reports of post-radiation-induced motor neuron disease suggests that its pathogenesis may differ from radiation-induced myelopathy or cerebral radiation necrosis [214, 216]. Therefore, treatment modalities used for cerebral radiation necrosis may not be as useful in radiation-induced motor neuron disease.

Course and Prognosis

The clinical course is slowly progressive, with symptoms usually confined to the region of the spinal cord exposed to the original radiation. Most patients stabilize after several months and usually survive for 15–20 years after the initial presentation, although the weakness can be quite severe and debilitating.

Paraneoplastic Motor Neuron Disease

Paraneoplastic disorders occur as a remote effect of cancer. Whether MND occurs as a paraneoplastic syndrome is controversial. The concept of paraneoplastic MND was introduced by Brain et al. in 1965, based on the description of 11 patients with cancer and MND [230]. They suggested that these patients differed from patients with classical ALS due to the prominence of lower motor neuron involvement and the relatively slow clinical course. Autopsy of two patients revealed loss of anterior horn cells, with upper motor neuron involvement observed in a single patient. Norris observed an unexpectedly high incidence of malignancy in a series of ALS patients (6 %) compared with the general population [231].

Since these original reports, many have questioned whether the association of cancer and MND is simply a coincidence of two relatively common diseases or if there is a true etiologic relationship between the two conditions. Several epidemiologic studies have failed to find an increased incidence of cancer in patients with ALS compared with the general population, although several small studies have reported a co-occurrence of cancer and MND, at frequencies higher than incidence expected in the general population [232–234].

Etiology and Pathogenesis

Evidence supportive of the existence of paraneoplastic MND includes the following: (1) the observation that MND may occur in association with cancer, (2) reports of neurologic symptom remission or stabilization following tumor treatment [235–237], (3) the detection of antibodies to neuronal

and tumor cell antigens in some patients with cancer and MND, and (4) reports of MND or lower motor neuron involvement in patients with other well-known paraneoplastic disorders associated with neuronal antigens [232, 238].

The proposed pathogenesis of paraneoplastic MND is an immune-mediated disease process, similar to the mechanism involved in other paraneoplastic syndromes. However, the particular antibody or antibodies responsible for lower motor neuron dysfunction has not been identified. The disorder appears to be associated with several autoantibodies, depending on the clinical manifestations and the type of cancer. Antibodies associated with a motor neuron syndrome in some patients with cancer include (1) anti-Hu antibodies with small cell lung cancer [239, 240], (2) anti-Yo antibodies reported in one patient with ovarian carcinoma [241], (3) increased M protein in patients with lymphoproliferative disorders [242], (4) antibodies to the ganglioside GD1b in patients with thyroid adenoma [243], and (5) anti-neuronal antibodies that react with the initial segment of axons and nodes of Ranvier in a patient with breast cancer [244].

Clinical Presentations

Paraneoplastic motor neuron syndromes can be roughly classified into the following:

1. Motor neuron syndrome as a component of paraneoplastic encephalomyelitis in association with anti-Hu antibodies. In 1992, Dalmau reported that 20 % of patients with anti-Hu antibody associated paraneoplastic encephalomyelitis and sensory neuronopathy also showed signs and symptoms of lower motor neuron involvement [239]. However, pure or predominant motor neuron involvement without encephalomyelitis is rarely reported. A predominant lower motor neuron syndrome with anti-Hu antibodies is described in one patient with small cell lung cancer and one patient with prostate cancer. The motor neuron syndrome can mimic typical ALS, and the onset of neurological symptoms often precedes the diagnosis of cancer by 4–10 months. The progression of neurological symptoms appears to be similar to typical ALS. Death occurs within 5–23 months after the onset of symptoms. The disorder responded poorly to any type of immune-modulatory therapy, and treatment of the associated cancer was non-beneficial to the neurological deficits [232, 239, 240].
2. Lower motor neuron syndrome associated with Hodgkin's and non-Hodgkin's lymphoma. A clinical syndrome characterized by subacute progressive, painless lower motor neuron weakness with minimal or absent sensory symptoms has been reported in association with lymphoma. The progression of neurological symptoms varies. In some patients, the clinical progression is slow and some demonstrate improvement or normalization of neurological deficits, independent of the underlying cancer course. In others, the disease is relentlessly progressive. Upper motor neuron signs eventually develop in most cases, with a clinical course similar to typical ALS [232, 241, 245–248].
3. Clinical syndrome resembling typical ALS with upper and lower motor neuron manifestations. This syndrome has been reported in association with a variety of tumors including non-small cell lung cancer, Hodgkin's lymphoma, ovarian cancer, uterine cancer, and breast cancer [230, 232, 235, 236, 241, 249]. The syndrome consists of progressive upper and lower motor neuron manifestations in a fashion resembling typical ALS, though progression tends to be slower than expected with ALS. Studies of patients with lymphoproliferative disorders and motor neuron disease demonstrate that the combination of upper and lower motor neuron signs occurs more often than the pure lower motor neuron syndrome alone, although a true etiologic relationship between the MND and cancer in this group of patients is difficult to prove [242, 246]. The onset of neurological deficits can follow or precede the diagnosis of cancer. Death from respiratory complications occurs within 18–30 months from the onset of neurological symptoms. The response to immune-modulatory treatments and to the treatment of the underlying cancer is poor.
4. A predominant upper motor neuron syndrome resembling primary lateral sclerosis in association with breast cancer. The clinical presentation is due to upper motor neuron dysfunction, with onset of the neurological syndrome preceding the diagnosis of breast cancer in most cases. The clinical course is often chronic progressive, but some patients also develop lower motor neuron signs and progress to typical ALS, following the expected clinical course [232, 250, 251]. Thus far, no associated antibodies have been identified with this syndrome.

Treatment, Course, and Prognosis

Despite several reports of improvement or stabilization of neurological symptoms following treatment of the underlying cancer, the long-term response of paraneoplastic MND to immune-modulatory therapy and treating the underlying cancer is generally poor based on large patient series [232]. The clinical course of paraneoplastic MND is variable and dependent on the particular clinical syndrome. In general, the clinical progression is slightly less rapid than in typical ALS.

Since the neurological features commonly precede the diagnosis of cancer in many patients, it may be reasonable to search for cancer in specific clinical settings. For example, Forsyth and Dalmau recommend that patients with pure upper motor neuron syndromes resembling primary lateral sclerosis undergo screening mammography to search for breast carcinoma [232]. Patients with motor neuron involvement and encephalopathy should be screened for anti-Hu antibodies and small cell lung cancer. Patients with an atypical motor neuron syndrome and monoclonal protein on serum immunofixation or immunoelectrophoresis, elevated

CSF protein, or other laboratory evidence suggestive of a lymphoproliferative disorder should undergo skeletal survey and bone marrow biopsy [232, 242, 245, 246, 252, 253].

Motor Neuron Disease Associated with Various Toxins and Drugs

A possible relationship between environmental toxins, in particular heavy metals, and MND has been a topic of interest for years [254]. However, definitive evidence of a causal relationship is scarce. A lead-induced motor neuron syndrome was described by Boothby et al. in 1974. They reported a 50-year-old male battery worker with progressive weakness, muscle wasting, fasciculations, and increased muscle stretch reflexes, especially in the distal upper extremities, with increased urine lead output. EDX studies showed normal NCSs, with needle EMG evidence of denervation and reinnervation in the hand muscles and thighs [255]. Systemic symptoms were present, including irritability and anemia, with basophilic stippling in the red blood cells, characteristic of lead intoxication. His neurological deficits gradually improved after treatment with penicillamine. However, there have been no subsequent reports that support the relationship between chronic lead exposure and typical MND with upper and lower motor neuron signs. Chronic lead exposure, as seen with battery workers and car radiator repairers, may result in a progressive lower motor neuron syndrome that most prominently affects the wrist and finger extensors and intrinsic hand muscles. Constitutional symptoms, such as weight loss, abdominal pain, constipation, fatigue, mood changes, and microcytic anemia with basophilic stippling, are common [255, 256]. The diagnosis is made by elevated lead levels in urine.

A possible relationship between heavy metals and Guamanian Parkinson-ALS syndrome has been postulated. There is one report of elevated aluminum levels in the CNS tissue of a patient with Guamanian neurodegenerative disease, but subsequent studies failed to demonstrate any significant elevation in serum and urine heavy metal levels in patients with Guamanian Parkinson-ALS compared with normal control groups [257].

Drugs including *dapsone* and *nitrofurantoin* may rarely result in a lower motor neuron syndrome that generally reverses following drug withdrawal.

Motor Neuron Syndrome Associated with Hyperparathyroidism

An association between hyperparathyroidism and muscle weakness was first reported over 50 years ago [258]. Primary hyperparathyroidism may be associated with neuromuscular symptoms including symmetric proximal weakness in the lower extremities, hyperactive reflexes, spasticity, hoarseness of voice, and dysphagia. These symptoms are usually accompanied by mild sensory symptoms and abnormal cognition which helps to distinguish it from typical ALS [258]. Although the neurological complications of primary hyperparathyroidism are common and relatively minor, in a few cases, these may be severe enough to imply an untreatable neurological disorder [259]. However, epidemiological studies have failed to support a definite causal relationship between hyperparathyroidism and MND, despite several case reports suggesting an association with primary hyperparathyroidism. A few patients reportedly showed improvement of neuromuscular symptoms after parathyroid adenoma resection [260–264].

In 1974, Patten et al. reported an ALS-like syndrome in five patients with primary hyperparathyroidism. Two of these patients had complete functional recovery of their clinical syndrome after undergoing parathyroid adenoma resection [265]. However on subsequent review, one of these patients had normal MUAP morphology on needle EMG, and the other had large MUAPs without abnormal spontaneous activity, making the diagnosis of MND unlikely in these patients [258, 265].

In 1998, Jackson et al. reported five patients with ALS and primary hyperparathyroidism, among approximately 600 ALS patients seen in their neuromuscular clinic over a period of 6 years [258]. Patients with a diagnosis of ALS were screened with a serum calcium and parathyroid hormone level and were also questioned if they had ever been treated for hypercalcemia or hyperparathyroidism. All patients had muscle weakness, atrophy, and fasciculations. In four patients, the symptoms began in the lower extremities. One patient presented with bulbar weakness. Upper motor neuron signs including spastic tone and hyperactive reflexes were noted in all five patients. In three patients, the hyperparathyroidism was discovered during their evaluation for ALS, and in two patients the diagnosis of hyperparathyroidism preceded the diagnosis of ALS. Needle EMG examination revealed widespread denervation in all patients. All of the patients died within 2–3 years of their parathyroid adenoma resection, secondary to MND progression. This study called into question the causal relationship between MND and hyperparathyroidism, since removal of the parathyroid adenoma did not alter the progression of the neurologic illness. Nonetheless, screening tests for hyperparathyroidism may be considered in patients with MND, as these are cost-effective and the potential for reversibility exists following tumor resection.

Retrovirus-Associated Motor Neuron Disorders

Infection with human immunodeficiency virus (HIV) is associated with a variety of neuromuscular disorders (see Chap. 38). HIV infection may cause a progressive vacuolar myelopathy associated with dementia and an axonal polyradiculopathy in

patients with AIDS. Experimental studies in mice show that retroviruses can induce a lower motor neuron syndrome, implying a causal relationship between retroviruses and MND pathogenesis [266–270]. There are rare reports of patients with HIV infection and classic ALS, or a clinical syndrome resembling primary lateral sclerosis or progressive spinal muscular atrophy, without other explainable causes [271–274]. Bibrachial amyotrophic diplegia or flail arm syndrome has been reported as a neuromuscular manifestation of HIV infection [275, 276].

The human T-cell lymphotropic virus type 1 (HTLV-1) is a well-known cause of spastic paraparesis in endemic areas, termed tropical spastic paraparesis or HTLV-1-associated myelopathy (HAM). Bladder dysfunction and mild sensory symptoms commonly accompany the lower extremity weakness. A motor neuron syndrome mimicking ALS has been described in a series of patients with HTLV-1 infection [277]. Spastic paraparesis or features of typical ALS associated with minor sensory findings or bladder dysfunction should prompt a screen for HTLV-1 antibodies, particularly in endemic areas.

Post-poliomyelitis Syndrome

Post-poliomyelitis syndrome is characterized by slowly progressive muscle weakness that occurs decades after recovery from acute paralytic poliomyelitis (see Chap. 19). The clinical presentation includes muscle pain, fatigue, and weakness and atrophy usually in previously affected limb(s), often accompanied by fasciculations [278]. Fatigue is usually the most prominent initial manifestation. Weakness of bulbar and respiratory muscles may also occur. Upper motor neurons signs are not seen [279, 280]. The clinical course is very slowly progressive.

The possible mechanisms responsible for the clinical manifestations of post-poliomyelitis syndrome include death of residual functional motor neurons as part of the normal aging process, premature aging of anterior horn cells previously infected by the polio virus, loss of the number of muscle fibers per motor unit with aging, and a delayed immune-mediated disease process [278]. The diagnosis is made after excluding other possible etiologies such as radiculopathy, neuromuscular junction disorders, and myopathy.

Introduction

Historical Perspective

The term "tabes dorsalis" (translated as "wasting of the back") is said to have first used by Hippocrates to describe the unsteady walk of those give to venereal excess [1]. In the nineteenth century, it was Stanley [2] who made the correlation between incoordination and posterior column disease [2], although the distinction of cases of incoordination without paraplegia from those with paraplegia is ascribed to Todd [3], who used two postmortem studies to document the hypothesis that incoordination alone can arise from posterior column disease with two autopsy cases [3]. In 1858 Duchenne used the term l'ataxie locomotrice (locomotor ataxia) to describe patients with progressive incoordination and preserved muscular strength [4]. Some 30 years later, Gowers commented that in his day syphilitic tabes dorsalis was a common disorder resulting from disease of either the posterior columns or the peripheral sensory nerves or both [5, 6].

As Treponema pallidum infection and its late neurologic complications faded from common medical practice in the early twentieth century, so did patients with isolated sensory impairment. Although a case report of predominantly sensory neuropathy in a patient with carcinoma was made in 1934 [7], primary degeneration of dorsal root ganglion neurons in humans was first described by Denny-Brown in 1948 [8]. He reported two cases of "primary sensory neuropathy" associated with carcinoma of the lung, which were pathologically distinct from tabes dorsalis. In these cases there appeared to be a primary loss of dorsal root ganglion neurons with secondary loss of axons in the posterior roots, posterior columns, and peripheral nerves. This contrasted with the pathology of tabes where severe loss of myelinated fibers in the posterior columns was accompanied by relative preservation of dorsal root ganglion neuron cell bodies [8, 9]. The primary disease process in tabes is probably inflammatory and occurs at the level of the spinal root [9]. Diabetic and alcoholic pseudotabes or pure sensory neuropathies were also recognized by Denny-Brown who identified the primary pathologic process in these disorders to be in peripheral nerve sensory fibers [8].

Pure sensory neuronopathy associated with malignancy was subsequently reported by many authors [8, 10–19]. The syndrome was most commonly associated with lung cancer, although a variety of other malignancies were included in case reports. Wilkinson and colleagues were the first to report that this syndrome might be antibody-mediated [18, 20]. Non-paraneoplastic sensory neuronopathy was recognized

by Wartenberg [21] who reviewed the reports of Martin [22] and Barré [23]. These cases resembled a pure sensory form of Guillain-Barré syndrome. Subsequently, there were a series of reports [24–27] describing an indolent progressive or subacute sensory syndrome which was not associated with malignancy but had many clinical features similar to the cases described by Denny-Brown [8]. Malinow and colleagues [28] first described an association between sensory neuronopathy and Sjögren syndrome which has subsequently been observed by others [29–31].

Metabolic causes for sensory neuronopathy were identified during the search for essential nutrients. Wintrobe and colleagues [32–34] found severe degeneration of dorsal root ganglion neurons in swine fed diets deficient in vitamin B6 and pantothenic acid. More recently, it has been demonstrated that excess vitamin B6 may produce a pure sensory syndrome in humans [35] and in rats [36]. In both cases this appears to involve degeneration of peripheral and central dorsal root ganglion axons with relative sparing of the cell bodies. Degeneration of dorsal roots and posterior columns in vitamin E-deficient rats was reported in the 1940s and 1950s [37–41]. The dorsal root ganglion cell bodies were almost completely spared. This was similar to vitamin E-deficient patients with chronic malabsorption [42] or a selective defect of vitamin E absorption [43, 44].

Although many toxins produce predominantly sensory symptoms, pure sensory ganglionopathy or ganglioneuropathy is rarely seen. Cisplatin causes a pure sensory syndrome which was first described 20 years ago [45, 46]. There is evidence to suggest that the dorsal root ganglion neuron is the primary target for the neurotoxicity of this drug [47, 48]. Other toxins which have a predilection for causing pure sensory neuropathy or ganglionopathy include alkyl mercury compounds and organophosphates [49].

Development of the Dorsal Root Ganglion

Dorsal root ganglia develop from the neural crest during early embryogenesis. Both neurons and satellite cells originate from the neural crest. Other cells derived from the neural crest include Schwann cells, some cranial sensory ganglion neurons, sympathetic and enteric autonomic neurons and glia, adrenal chromaffin cells, connective tissues of the head and neck, the facial skeleton, melanocytes, thyroid C cells, and carotid body type I cells [50]. The origin of the perineurial sheath cells of the ganglion is still controversial. They are probably derived from mesodermal fibroblasts [51, 52]. Soon after the neural crest separates from the neural tube, it organizes into segmental collections of cells. The work of Le Douarin and colleagues demonstrated that neural crest cells differentiate into specific lineages (neuron, satellite cell, melanocyte, etc.) at the time of ganglion formation [50]. The precursors of Schwann cells, melanocytes, and adrenal chromaffin cells migrate out of the ganglion. The remaining cells terminally differentiate into neurons and satellite cells. The final neuron cell division occurs shortly after the ganglion has formed.

Following terminal cell division, the neurons begin a complex process of differentiation. Initially the cells are bipolar. As axonal growth begins, one process enters the primordium of the root; the other enters the origin of the segmental nerve. As the newly formed axons extend, the cell body changes shape so that the axons coalesce into the final mature pseudounipolar configuration. The axons grow toward targets in the periphery or spinal cord as Schwann cells migrate along the growing axons. During axonal growth, the Schwann cells surround bundles of axons and segregate them into single axons that are destined to be myelinated or into small bundles destined to be nonmyelinated axons [53]. Within the ganglion, the neuron cell bodies are ensheathed by satellite cells which share many characteristics with Schwann cells.

Anatomy of the Dorsal Root Ganglion

The dorsal root ganglia lie in the intervertebral foramina at the point where the dorsal and ventral roots converge (Fig. 23.1a). The fascicles of sensory and motor fibers come together, but individual axons do not commingle until after they leave the ganglion in the segmental nerve. Most of the intermixing of motor and sensory axons to form mixed peripheral nerves occurs as the fibers pass through the plexus. Within the ganglion, cells are clustered around the fascicles of sensory fibers (Fig. 23.1b).

The ganglion appears grossly as a thickening of the perineurial sheath where the roots meet. The sheath of the ganglion is continuous with the sheath of the roots and segmental nerves. The perineurium and epineurium of the nerve are also continuous with the dura as the roots enter the spinal canal, forming a continuous sheath from the peripheral nerve, over the ganglion and roots to the dura. This tough sheath explains why traction of the peripheral nerve usually results in avulsion of the roots from the cord rather than a tear in the plexus or nerve. The perineurial sheath around the ganglion has the same cellular composition as the perineurium of nerve. It is composed of 10–20 layers of flat cells which are interleaved. Cells are attached to their neighbors with frequent tight junctions. The perineurium is one of the barriers to diffusion which constitutes the blood-nerve barrier. The blood supply to the ganglion comes from perineurial arterioles derived from segmental arteries. Although detailed studies of ganglion vascular supply have not been completed, blood flow has been found to be intermediate between that of peripheral nerve and brain [54, 55].

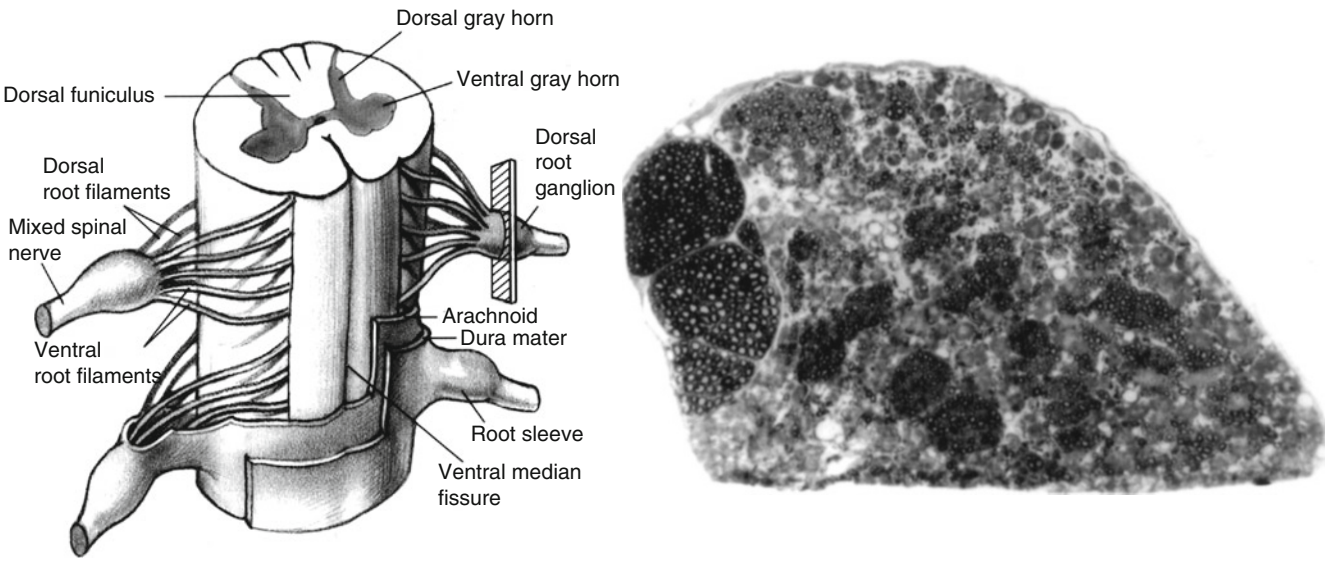

Fig 23.1 DRG anatomy

Perforating arterioles leave the epineurial vessels and pass through the perineurial sheath. The capillaries within the ganglion are fenestrated which result in a low barrier to diffusion between blood and endoneurium of the ganglion. This is different from the peripheral nerve trunk where the capillary endothelial cells form a significant diffusion barrier and are joined by tight junctions [56]. Dorsal root ganglion neurons are therefore exposed to toxins or drugs present in serum. This may be one of the factors that render sensory neurons prone to toxic injury.

The microanatomy of the ganglion is relatively simple. Clusters of ganglion cells are composed of neurons that vary from 10 to 100 μm in diameter. There is a direct relationship between neuron cell body size and size of nerve fibers leaving the cell [57]. The initial single axon leaving the cell is often coiled in a complex glomerulus-like shape immediately adjacent to the cell body. The central and distal axonal processes are formed immediately after the glomerulus [58]. The work of Coggeshall has shown that each ganglion cell may give rise to several peripheral and several central axons presumably due to branching soon after axons leave the ganglion [59, 60].

There is a continuous spectrum of dorsal root ganglion neuron diameters. There are, however, two distinct classes of cells by light and electron microscopy: large clear cells and small dark cells. Cells can now be classified into many different types depending on their surface growth factor receptors (e.g., Trk A, B, and C) or the class of neurotransmitter predominating in the cell (e.g., calcitonin gene-related peptide, substance P). Since these markers associate with cells of different sizes, they may reflect different functional specializations. The direct relationship between size, sensory modality, growth factor receptor, and neurotransmitter has, however, not been established.

A sheath of 4–6 flattened satellite cells (or satellite glial cells) encapsulates each neuron cell body. These cells are of the same lineage as Schwann cells. The satellite cell is, in turn, covered by a basal lamina which is continuous with the basal lamina of the Schwann cells that ensheath or myelinate the axon. Recent studies of neuron-satellite cell interactions have demonstrated that ATP released from the somata of dorsal root ganglion neurons activates satellite cells. These in turn exert complex excitatory and inhibitory modulation of neuronal activity under normal and injurious conditions [61].

Neurochemistry of the Dorsal Root Ganglion

With the exception of some cranial nerves, all somatic and visceral input makes its way to the central nervous system by way of primary afferents that initially synapse in discrete regions of the dorsal gray horn of the spinal cord. Several lines of evidence suggest that these afferents communicate with the central nervous system by excitatory neurotransmitters; morphologic studies of first-order synapses demonstrate synaptic vesicles, end plate thickening, and synaptic clefts, while microneurophysiologic techniques provide evidence of monosynaptic EPSPs (but not monosynaptic IPSPs) and synaptic delay [62]. Painstaking pharmacologic studies have demonstrated a number of substances that fulfill strict criteria for candidate neurotransmitters in dorsal root ganglion cells. These molecules must be (1) identified in the afferent terminals of the primary afferent, (2) present in the fraction collected with depolarization of the afferents in question, (3) able to mimic the physiologic effects of depolarization when applied exogenously, and (4) responsible for the same

physiologic response in the postsynaptic neuron whether released by physiologic stimuli or with exogenous application [62].

The ever-expanding list of substances found in dorsal root ganglion cells which appear to meet the above criteria began with the excitatory amino acids glutamate and aspartame [63] and has come to include a host of neuropeptides such as substance P [64], somatostatin [65], VIP [65], cholecystokinin [66], angiotensin II [67], bombesin [68], CGRP [68, 69], NGF [70], and multiple neurotrophins [71–73].

Neurophysiology of the Dorsal Root Ganglion

Basic Neurophysiology

Sensory information is conveyed from the peripheral sensory receptor via the dorsal root ganglion cell, through the peripheral and then the central axon, to the dorsal gray matter of the spinal cord or to higher second-order sensory neurons in the cuneate and gracile nuclei. The observation that some dorsal root ganglion cell bodies have low thresholds to electrical excitation suggests that this property may be required to insure the reliable propagation of impulses past the pseudounipolar axon junction and into the spinal cord [74]. The primary afferents that synapse segmentally in the dorsal gray relay single impulses and trains of spikes from their respective receptive fields when particular stimuli occur that mediate their excitation. Although the second-order sensory relay neurons may be driven by dorsal root ganglion inputs from a variety of different sensory modalities, the primary sensory nerve cells are thought to be activated most effectively by a single modality [75]. These include *cutaneous mechanoreceptors* [76] which distribute their large Aβ axons to Rexed laminae III, IV, V, and the dorsal portion of VI; *cutaneous nociceptors* [77] which relay information via small-diameter Aδ fibers to laminae I, II, and V; *cutaneous thermoreceptors* [78] which extend processes to the dorsal horn via small-diameter Aδ and C fibers but whose specific patterns of termination have not been well established; *muscle receptors* [79] which convey proprioceptive data to the cord from primary muscle spindle endings (Aα afferent fibers) to laminae VI and VII, secondary muscle spindle endings (Aβ afferent fibers) to laminae IV, V, VI, VII, and IX, and Golgi tendon organs (Aα afferent fibers) to laminae V, VI, and VII; and *visceral receptors* [80] which terminate in laminae I and V.

Given the complexities of neural circuitry and the wide array of dorsal root ganglion afferents which impinge on second-order sensory relay neurons in the dorsal horn, it comes as no surprise that sensory coding mechanisms involve a large range of variables, including modality specificity, spatial factors, and a range of temporal factors including frequency coding, temporal transformation, impulse interval patterning, and intrinsic as well as extrinsic modulatory influences [81].

Clinical Neurophysiology

While the intricacies of recording individual dorsal root ganglion cell responses to a variety of stimuli are largely the focus of bench physiologists, the tools of clinical neurophysiology provide the clinician with a useful arsenal of methods to study the dorsal root ganglion cell with both its peripheral sensory axon and its central sensory axon. Sensory nerve conduction studies assess the integrity of the peripheral sensory axon and the dorsal root ganglion cell body but often are unaffected by disease proximal to the dorsal root ganglion cell body level [82]. Lesions at or distal to the dorsal root ganglion cell body characteristically result in reduction or loss of amplitude in the sensory nerve action potential [83].

Quantitative sensory testing, on the other hand, is a set of psychophysiologic methods which assess the entire sensory system from the peripheral receptor to the postcentral gyrus [84]. Disease at any level can result in elevation of sensory detection thresholds and, if sufficiently severe, insensitivity. Reliable methods for determining vibratory, cold, and heat pain/visual analog pain scale threshold values have been described and used extensively in both research [85–87] and clinical applications [71, 88]. It must be remembered that while sensory nerve conduction studies can be performed without the cooperation of the patient, and in practiced hands are not liable to surreptitious falsification by the test subject, because quantitative sensory testing depends on subjective responses of what the individual perceives, this type of testing cannot overcome a bias toward abnormality in test subjects.

The central axon which projects from the dorsal root ganglion cell body to relay nuclei in the medulla oblongata can also be assessed by electrophysiologic means. In addition to quantitative sensory testing (see above), somatosensory evoked potentials (SEPs) can interrogate the whole of the sensory pathway from periphery to cerebral cortex. SEPs are the electrical responses of the nervous system, from the peripheral nerve trunk to the parietal cortex, to specific, and typically electrical, stimuli. The commonly used SEP techniques involve stimulation of a mixed or cutaneous peripheral nerve with recording over the nerve, plexus, spine, and scalp, most reliably with signal averaging of several hundred responses so as to extract reproducible recordings of well-defined responses between 1 and 50 uV in amplitude from an electrically noisy background [89]. The combination of an abnormal SEP suggesting a spinal cord localization combined and a normal peripheral sensory nerve action potential raises the possibility of disease affecting the central sensory axon of the dorsal root ganglion cell (central sensory syndrome, see below).

Disorders

Malignant Inflammatory Sensory Polyganglionopathy

Introduction

The 1948 report of Denny-Brown is now widely acknowledged to the first recognized account of two patients with profound sensory deficits and, albeit only by postmortem examination, small cell carcinoma of the lung; the postulated mechanism for the neurologic syndrome was a metabolic abnormality produced by the malignant cells [8]. A survey of the literature shows that there have been many clearly described such cases of malignant inflammatory sensory polyganglionopathy (MISP) [7, 8, 10–17, 19, 90–116]. The terms "malignant" and "nonmalignant inflammatory sensory polyganglionopathy" are used because they are descriptive and parallel the terms in place for disease of roots (polyradiculoneuropathy) and nerves (polyneuropathy) [117]. Other synonyms used in the literature include subacute sensory neuronopathy (SSN) or paraneoplastic SSN [118–130].

Etiology and Pathogenesis

A variety of neoplasms have been associated with MISP, the most common being small cell ("oat cell") lung carcinoma (SCLC) (see Table 23.1). Virtually every patient with MISP and primary lung carcinoma smoked cigarettes or used other tobacco products. In the majority of cases (123/165 patients), neurological symptoms preceded discovery of carcinoma by several months (median 8, range 0.5–62 months) [7, 8, 11, 13, 14, 16, 17, 19, 90–110, 116, 131], although in some cases (35/165 patients) the reverse was true (median 6, range 0.5–36 months) [13, 19, 90–93, 97, 99, 111, 113, 115]. In 6/165 patients neurological symptoms and diagnosis of cancer were simultaneous [15].

Lucchinetti and colleagues found that SCLC was the most common cancer associated with ANNA-1 (anti-Hu) positivity in their series of 162 patients with paraneoplastic neurologic disease [132]. Among their 162 patients, SCLC was not found in at initial evaluation in 56 %. After discovery of the ANNA-1 seropositivity, more aggressive evaluation sometimes led to discovery of a previously occult neoplasm. MRI of the chest demonstrated a definite mass in 10 of 45 individuals with equivocal findings by conventional radiography or CT scanning. In seven subjects for whom imaging failed to disclose a tumor, SCLC was discovered by bronchoscopy, mediastinoscopy, or thoracotomy. Among 21 individuals with a nondiagnostic bronchoscopy, SCLC was documented by either mediastinoscopy or thoracotomy. Seven ANNA-1-positive patients with no direct evidence of SCLC in life were found to have the malignancy at autopsy, while another three individuals lacked evidence of the tumor even at autopsy [132]. Importantly, these workers at Mayo Clinic found an unrelated primary malignancy coexisting with SCLC in 13 % of patients with ANNA-1 seropositivity (Table 23.2), six of which proved to be renal cell carcinoma and in another four a second primary lung neoplasm [132].

Although pathogenic antibodies have been described in a number of paraneoplastic neuromuscular disorders including Lambert-Eaton myasthenic syndrome (voltage-gated calcium channel antibodies) and myasthenia gravis (acetylcholine receptor antibodies), a clear pathogenic role for antibodies in MISP (antineuronal nuclear or anti-Hu antibodies) has not been established; rather, these antibodies can be thought of as helpful markers for MISP and the tumor which is most often associated with it (small cell carcinoma of the lung) [133]. There is increasing evidence that cytotoxic T lymphocytes are involved in MISP, both in dorsal root ganglia as well as affected central nervous system structures [134–136].

Table 23.1 Tumor type or location in 159 MISP patients

	Number (% of total)
Lung	136 (85.5)
Small cell/"oat cell" carcinoma	128 (80.5)
Anaplastic	3 (1.9)
Bronchial	3 (1.9)
Squamous cell carcinoma	2 (1.3)
Hodgkin disease	5 (3.1)
Prostate carcinoma	3 (1.9)
Breast	2 (1.3)
Ovary	1 (0.6)
Uterus	1 (0.6)
Adrenal carcinoma	1 (0.6)
Chondromyxosarcoma	1 (0.6)
Colon (adenocarcinoma)	1 (0.6)
Epidermoid carcinoma	1 (0.6)
Esophagus (squamous cell carcinoma)	1 (0.6)
Gastric carcinoma	1 (0.6)
Mediastinal carcinoma	1 (0.6)
Neuroblastoma	1 (0.6)
Reticulum cell sarcoma	1 (0.6)
Synovioma	1 (0.6)
Testicular seminoma	1 (0.6)
Total	159 (100)

Table 23.2 Tumors coexisting with SCLC in ANNA-1-positive patients (After Lucchinetti et al. [132])

Renal cell carcinoma	6
Non-SCLC lung carcinoma	4
Prostate carcinoma	3
Breast carcinoma	3
Bladder carcinoma	1
Ovarian carcinoma	1
Choroid papilloma	1
Cervical carcinoma	1
Total patients with coexisting tumor(s)[a]	17 (13 %)

[a]Three patients had more than one coexisting tumor

Clinical Presentation

There are three major presentations of MISP – an ataxic syndrome, a hyperalgesic-ataxic syndrome, and an ataxic or hyperalgesic-ataxic syndrome with prominent gastrointestinal dysmotility, the latter not thought to occur often as part of nonmalignant inflammatory sensory polyganglionopathy (NISP). Although the hyperalgesic-ataxic syndrome appears to be the most frequently encountered presentation of MISP to neurologists, the ataxic or hyperalgesic-ataxic variety with gastrointestinal manifestations may be more common than realized. Because the syndrome can present as isolated intestinal pseudo-obstruction with subclinical neurologic deficits in the limbs, these individuals may present to non-neurologist physicians such as internists and gastroenterologists who elect not to pursue neurologic consultation. In addition to sensory ataxia with or without hyperalgesia or gastrointestinal dysmotility, MISP patients on occasion present with variable degrees of flaccid weakness and atrophy, generalized dysautonomia (including tonic pupils, orthostatic hypotension, and sudomotor dysfunction), cerebellar ataxia, brainstem signs (including nystagmus, dysphagia, and cranial nerve palsies), myelopathy, and limbic encephalomyelopathy [90].

The primary clinical manifestations of MISP appear to reflect the subpopulations of neurons involved, whether large-diameter dorsal root ganglion neurons (resulting in ataxia as well as vibratory and proprioceptive sensory loss), small-diameter dorsal root ganglion cells (neurons which convey pain and temperature sensation), or gastrointestinal myenteric plexus neurons (giving rise to severe constipation and other manifestations of alimentary dysmotility). Denny-Brown described MISP patients presenting with ataxia [8], as did Dodgson [10], Heathfield [11], Henson [12, 98], and others [13, 16, 18, 19, 90, 92, 93, 101, 137]. MISP patients with a combination of hyperalgesia and ataxia were reported by Weber [7], Denny-Brown [8], Henson [12], Smith [14], and others [15, 17, 19, 113, 114, 131, 90, 93, 103]. MISP patients with the ataxic or hyperalgesic-ataxic syndrome and gastrointestinal dysmotility were discussed by Lhermitte et al. [111], Chalk et al. [93], and Dalmau et al. [90].

Diagnosis

Symptoms

In the literature reports of the ataxic variety, so-called positive sensory symptoms such as "numbness" and a "pins and needles" sensation were among the most common presenting symptoms. Other presenting symptoms included gait unsteadiness and diminished fine motor control; pain was never a prominent initial symptom. In patients with the ataxic-hyperalgesic-type aching in the limbs, shooting limb pains, "burning" sensations, and painful paresthesia were frequent initial symptoms, usually followed later in the course of disease by gait unsteadiness, incoordination, and loss of manual dexterity. Patients with ataxic or ataxic-hyperalgesic MISP with gastrointestinal dysmotility typically sought medical attention with abdominal complaints, including belly pain, nausea, vomiting, and severe constipation; limb symptoms such as pain, paresthesia, and incoordination were often absent and seldom prominent. The patient reported by Lhermitte et al. reported at first of nausea, dysphagia, and rectal pain, followed shortly thereafter by acute intestinal obstruction (no cause being discovered at laparotomy) and pain in all four limbs; on physical examination he was noted to have generalized wasting of muscles, loss of deep tendon reflexes, and distal sensory loss [111]. Some individuals with this third type of MISP complained only of gastrointestinal symptoms, although subclinical sensory loss and hyporeflexia were detected on examination.

Signs

On neurologic examination, the majority of MISP patients demonstrated normal strength or perhaps mild weakness, as well as greater or lesser degrees of both distal and proximal diminished sensation (particularly vibration and joint position sense) which was not uncommonly asymmetric, and deep tendon hypo- or areflexia – frequently most pronounced in the lower extremities. In profoundly affected individuals the posterior column modality sensory loss was often so marked as to lead to pseudoathetosis. Other deficits, which were noted most often in the ataxic and ataxic-hyperalgesic groups, suggested disease beyond the primary sensory neuron. In the series of Horwich et al. 1/5 of patients had relatively isolated sensory loss and ataxia, while 3/5 demonstrated eye movement abnormalities (including nystagmus in 3/5 and gaze palsy 1/5), 3/5 showed some level of weakness (1/5 moderate proximal weakness and 2/5 mild either proximal or diffuse weakness), and dementia and confusion were each reported in 1/5 [19]. Among the patients of Anderson et al. 8/12 patients were brought to medical attention with sensory polyganglionopathy as their "main clinical syndrome," although other examination abnormalities in these seven included mild, diffuse, or patchy weakness, sensorineural deafness, cerebellar ataxia, urinary retention, and a unilateral extensor plantar response [138]. In the other 4/12 patients, the "main clinical syndromes" included MISP with either autonomic failure (not further specified) or lower motor neuron weakness; one of these patients presented with MISP, autonomic failure, encephalopathy, cerebellar ataxia, and diffuse weakness [138]. Chalk et al. reported cerebellar dysfunction in 4/26, encephalopathy in 2/26, and other CNS abnormalities in 7/26 of their patients with MISP [93]. Patients in the series of Dalmau et al. [90] were identified by presence of the antineuronal nuclear antibody (anti-Hu); they observed asymmetric sensory deficits as well as common involvement of the face and trunk. Although brainstem signs were recorded in 32 % of the patients of Dalmau et al. all patients who came to autopsy were found to have brainstem abnormalities [90].

Laboratory Tests

Normal to moderately elevated CSF protein values were seen in most MISP patients. Of the five patients reported by Horwich et al. the mean CSF protein level was 63 mg/dl (range 12–120) [19]. In Anderson's series the mean concentration in 11 patients was 127 mg/dl (range 36–315) [138]. CSF pleocytosis was not a typical finding in this population. In the series of Horwich et al. [19], the CSF nucleated cell count was "usually normal," while in Anderson's patients only 2/10 had abnormal nucleated cell counts at 62 and 105 cells/mm^3 [138]. In the 26 patients in the series of Chalk et al. 18 had CSF examinations; of these, 13 had elevated protein levels (mean 104 mg/dl, range 48–230); one subject has an increased protein value accompanied by mild lymphocytic pleocytosis (protein 90 mg/dl; 8.0 lymphocytes/uL) [93]. Among these 26 patients, no individual had malignant cells by cytologic examination [93].

As early as 1965, Croft et al. reported four patients with MISP associated with small cell carcinoma of the lung ("oat cell" carcinoma) with complement-fixing antineuronal antibodies which reacted against whole brain [18]. Using a fluorescent antibody technique later that year, Wilkinson and Zeromski confirmed antineuronal antibodies in these same four patients [20]. It has more recently been determined that these antineuronal antibodies in MISP patients react specifically with the nuclei of neurons in the central and peripheral nervous systems but not with non-neuronal nuclei [131, 138, 139]. Antineuronal nuclear antibodies type 1 (also called anti-Hu antibodies) demonstrate specificity for a number of neuronal nucleoprotein antigens between 35 and 40 kD in molecular weight [131]. In reviewing the case records of 162 sequential ANNA-1 positive adult patients with symptoms and signs suggestive of a paraneoplastic disorder without any other plausible explanation (such a metastasis, metabolic, vascular, or iatrogenic process), Lucchinetti and co-workers found 103 with a pure or predominant sensory syndrome and/or gastrointestinal dysmotility [132]; interestingly, most of these patients were not known to have cancer at the time of the serologic testing, and in one-fifth of the cases, the seropositivity for ANNA-1 was an incidental finding. Lennon et al. using an indirect immunofluorescence assay, described immunoglobulin G antibodies reactive with neurons of the myenteric and submucosal plexuses in the gastrointestinal tracts of 4/5 patients with severe gastrointestinal dysmotility and small cell lung carcinoma, some of whom had evidence of peripheral neuropathy [140]; in all four patients symptoms of intestinal pseudo-obstruction preceded diagnosis of small cell carcinoma by months or years (mean 13, range 4–28 months).

Other serologic markers sometimes seen in specific connective tissue disorders, such as antinuclear antibodies (directed toward non-neuronal nuclei), antibodies to extractable nuclear antigens, rheumatoid factor, and antineutrophil cytoplasmic antibodies, are not typically found in MISP patients. Neither antisulfatide antibodies – reported to occur in some cases of idiopathic axonal sensory neuropathy – nor antibodies against myelin-associated glycoprotein (MAG) sometimes found in patients with an immunoglobulin M monoclonal protein and progressive demyelinating sensorimotor neuropathy, were found by Pestronk et al. in 12 patients with MISP or NISP [141].

Electrophysiologic Tests

Nerve conduction studies in patients with MISP frequently showed low-amplitude or absent sensory nerve action potentials. Motor (compound muscle action potential) amplitudes were normal or relatively preserved. Needle electromyography (EMG), although typically normal, sometimes demonstrated mild abnormalities such as enlarged motor unit potentials or usually low-grade fibrillation potentials, pointing to some degree of involvement of motor neurons.

Of the four patients in the Horwich series which were studied, no sensory evoked responses were obtained (2/2), and motor nerve conduction studies were normal in 3/4; of the three patients who had EMG, one was normal, one had enlarged motor unit potentials but no increased insertional activity, and one showed both abnormal motor unit potentials and fibrillation potentials [19]. Similarly, in Anderson's patients, sensory nerve action potentials were absent or low in amplitude, motor nerve conduction velocities were either normal or mildly slowed, and except in the few patients with clinical evidence suggesting lower motor neuron involvement, EMG did not demonstrate evidence of denervation [138]. Among Chalk's patients, sensory nerve action potentials were absent in all but four individuals, each of whom had one or more preserved sensory response. Of the 65 sensory nerve conduction studies performed in this group, there were only two within the normal amplitude range. Sensory nerve conduction velocities could not be determined in that no individual had recordable responses with proximal stimulation of sensory nerves. By contrast, mean compound motor action potential amplitudes and motor nerve conduction velocities did not differ significantly from established normal values. Eleven of Chalk's subjects had no abnormal resting electromyographic activity, while eight others had occasional fibrillation potentials in intrinsic foot, head, or paraspinal muscles. Mild motor unit potential enlargement was found distally in all but three patients [93]. Auger et al. found that the trigeminal "blink" reflex was normal in 17/17 patients with MISP, while 20/43 subjects with NISP has abnormal "blink" reflexes [142].

Imaging Studies

Dalmau and coworkers obtained head CT scans in 21 patients, none of whom were thought to have abnormalities related to their paraneoplastic disease; cranial MRI studies were obtained in 32 individuals, 23 of which were said to be normal. Of the remaining scans, three had changes not related

to their paraneoplastic disease, two had changes possibly related to paraneoplastic processes (one with periventricular hypodensities and bifrontal atrophy thought to be related to limbic encephalopathy, the other with cerebellar atrophy related to paraneoplastic cerebellar degeneration), and four had MRI changes clearly related to their paraneoplastic disorders (all four had limbic encephalopathy and high intensity lesions on T2-weighted sequences in temporal and/or frontal lobes) [90]. Lauria and colleagues studied two subjects with MISP associated with ANNA-1 positivity who found to have T2-weighted magnetic resonance imaging high signal intensity in the posterior columns of the cervical spinal cord [143]. When screening for a tumor and conventional radiological methods (CT, MRI) are negative, whole-body [18F] fluorodeoxyglucose positron emission tomography (18FDG-PET) can be considered [144–146]. In 15 patients with a paraneoplastic neurological syndrome and ANNA-1 (anti-Hu) antibodies, radiological methods led to the diagnosis of cancer in 12 patients but not in the other 3, whereas 18FDG-PET showed abnormal uptake in the mediastinum in all 15 patients, in accordance with the expected location of the malignancy [144].

Pathology Studies

The primary locus of disease in MISP appears to be the dorsal root ganglion. Horwich et al. reported the principal neuropathologic features as: (1) degeneration of the dorsal root ganglion cells with inflammation and phagocytosis in the acute phase and decreased numbers of neurons accompanied by fibrosis in the chronic phase; (2) degeneration of the posterior roots and peripheral sensory nerves, with loss of myelinated fibers followed by Schwann cell proliferation and fibrosis; and (3) degeneration of the posterior columns of the spinal cord, in early stages with nerve fiber degeneration and infiltration by macrophages and reactive astrocytes and in the long-term with myelinated fiber loss and gliosis [19]. Twenty-seven MISP patients have been described in the literature with detailed neuropathologic accounts. In essentially every case the dorsal root ganglia, posterior roots, and dorsal columns of the spinal cord were affected [19]. Findings included neuronal loss in the dorsal root ganglia in 26/26 patients, residual nodules of Nageotte in 25/26, and inflammatory cell infiltrates in 13/26 [19, 137, 138]. Horwich et al. came to the conclusion that patients with ganglionopathy lasting less than 7 months tended to have dorsal root ganglia inflammatory infiltrates, while those with clinical symptoms of ganglionopathy more than 11 months had no marked inflammation; there was, however, a single exception of a patient who had such changes in only one dorsal root ganglion [19].

Although detailed pathologic studies of MISP patients are not reported frequently, a few descriptions have found their way into the neurologic literature. Ohnishi and Ogawa demonstrated selective loss of large-diameter neurons in the L5 dorsal root ganglion, marked decrease in the density of large myelinated fibers in the dorsal root and sural nerve, and almost total loss of myelinated fibers in the posterior column fasciculus gracilis in an MISP patient who succumbed to small cell carcinoma of the lung 29 months after symptoms of ataxic sensory neuronopathy began [137]. These investigators performed postmortem studies of the sural nerve, L5 dorsal root ganglion, L5 dorsal and ventral roots, and fasciculus gracilis, reporting quantitative morphometric data at each of the four levels examined. The sural nerve showed decreased large (diameter >5.62 μm) and small (diameter <5.62 μm) myelinated fibers (number of myelinated fibers per square mm of fascicular area), the densities measuring 50 (3,086 ± 461, mean ± SD, in controls) and 2,031 (5,422 ± 344 in controls) for large and small myelinated fibers, respectively. The total number of neurons in the L5 dorsal root ganglion was 35,632 (52,815 ± 2,881 in controls); the numbers of large (diameter >45 μm) and small (diameter <45 μm) nerve cell bodies were 2,494 (18,050 ± 2,283 in controls) and 33,138 (33,872 ± 2,279 in controls), respectively. The total number of myelinated nerve fibers in the L5 dorsal root was 17,533 (42,026 ± 2,066 in controls), with numbers of large and small myelinated fibers measuring 877 (14,332 ± 923 in controls) and 16,656 (27,694 ± 1,743 in controls), respectively. In the L5 ventral root, myelinated fiber total number approximated normal limits at 7,380 (8,179 ± 466 in controls). In the corresponding fasciculus gracilis, the myelinated nerve fiber densities (number per square mm of fascicular area) were 2,785 (21,819 ± 714 in controls) and 932 (22,058 ± 512 in controls) at the T5 and C3 spinal cord levels, respectively (122). Wanschitz and coworkers presented detailed autopsy findings in a case of a 69-year-old woman with MISP and autonomic dysfunction associated with ANNA-1 antibodies and SCLC [107]. They described inflammatory infiltrates in dorsal root and autonomic ganglia consisting of endoneurial T cells, B cells, and plasma cells. Some of these ganglion cells demonstrated cytoplasmic and nuclear staining for IgG. CD8+ T cells were found to be adherent to the surface of both IgG positive and IgG negative neurons, which these workers interpreted as providing evidence that both T-cell-mediated destruction and humoral mechanisms are involved in MISP [107]. A broad overview of the neuropathologic findings in paraneoplastic syndromes including MISP is provided by Scaravelli and associates [147].

Similar pathologic alterations (including neuronal loss, gliosis, perivascular inflammation, and fibrosis) have also been described as occurring variably at other sites in the nervous system including the cerebral hemispheres, basal ganglia, brainstem, cerebellum, and spinal cord (posterior and anterior horns) of some MISP patients. Some of these had clinical evidence of disease beyond the primary sensory

neuron, while in others the pathologic findings were subclinical [18, 19, 95, 99].

In patients with MISP and severe gastrointestinal dysmotility as well as in those who presented with isolated paraneoplastic intestinal pseudo-obstruction – sometimes with subclinical evidence of neuropathy, the main pathologic abnormality was in the myenteric plexus innervating the gastrointestinal wall. Lhermitte et al. [111] described marked neuronal loss, nodules of Nageotte, and Schwann cell proliferation in the small bowel myenteric plexus, with infiltration lymphocytes and macrophages strictly confined to the region of the myenteric plexus in the esophagus, stomach, colon, and rectum. They also documented chronic inflammatory lesions in the posterior and anterior spinal roots as well as in the Gasserian ganglion [111]. Schuffler et al. presented abnormalities in the myenteric plexus throughout the gastrointestinal tract, with infiltration with plasma cells and lymphocytes and, in addition, large areas of plexus devoid of neurons; dorsal root ganglia findings included neuronal loss and lymphocytic infiltrates. Others have described similar neuropathologic alterations [140, 148, 149]. Written accounts of one of the first documented MISP cases, originally reported by Denny-Brown in 1948 [8] and subsequently by Wyburn-Mason [94], noted that the patient was said to have died "after severe and intractable vomiting, with abdominal pain and distension." JG Greenfield performed the autopsy, noting that the "liver was normal but pushed to the right by great enlargement of the colon and stomach" and that "the colon was enormous throughout, being about 4 in. in diameter. Even the rectum was considerably larger than normal" [94]. Although descriptions of histological findings in the intestines were not provided in these reports [8, 94], this may have been an early demonstration of paraneoplastic pseudo-obstruction in a patient with ataxic MISP.

Treatment and Management

There are no controlled clinical trials in MISP. Even so, treatment of patients on a case-by-case basis – and particularly those with SCLC – has been largely disappointing. Horwich et al. reported that a variety of treatments, including steroids, azathioprine, nitrogen mustard, and radiation therapy, were universally unsuccessful in reversing the neurologic syndrome, although treatment of the underlying neoplasms in three patients (one each with synovioma, breast carcinoma, and Hodgkin lymphoma) appeared to have prolonged survival (mean survival 43 months, range 10–96 months [19], compared with a mean survival of 11 months in 119 MISP patients, range 0–96 months) [7, 8, 10–20, 90, 92, 95, 96, 98–103, 111–115, 131, 138–140]. Anderson et al. observed that treatment with corticosteroids coincided with remission of limbic encephalopathy in one of their patients but noted that symptoms and signs of MISP appeared during the steroid therapy which did not respond to an increased dose of prednisone [138]. Sagar and Read reported a patient with MISP associated with Hodgkin disease, whose tumor (stage 3b, mixed cellularity) and neurologic deficits (including limb clumsiness and inability to walk due to profound sensory ataxia) responded to treatment with prednisolone, procarbazine, nitrogen mustard, and vinblastine, the patient noting only slightly impaired manual dexterity and minor dysesthesia 23 months after treatment was begun [114]. Brunet et al. described two similar patients with MISP in Hodgkin disease whose clinical neurological deficits improved significantly following treatment, in one case with 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU), vincristine, and procarbazine and in the other case with CCNU, vincristine, prednisone, and procarbazine after a trial of nitrogen mustard, vincristine, prednisone, and procarbazine had failed; the authors noted that some symptoms persisted despite treatment, including paresthesia (both patients), impaired sensation (one patient), and gait ataxia requiring a cane to walk (one patient) [113]. Chalk and colleagues had adequate follow-up data on 14/26 patients; the mean duration of follow-up was 18 months (range 1–60 months). Among these 14, 12 received antineoplastic treatment (7 with SCLC, 3 breast cancer, 1 lymphoma, and 1 adenocarcinoma of unknown primary site); 9 of the 12 had clear-cut improvement in their cancer, but none had neurologic improvement. The MISP worsened relentlessly in seven patients, while in five others, progression appeared to halt after the cancer was treated [93]. Hughes and coworkers note that seldom do neurologic deficits improve significantly following treatment of underlying lymphoma in patients with MISP [150]. Uchuya and coworkers studied responses of patients with a variety of paraneoplastic neurologic syndromes to high-dose intravenous immunoglobulin; of 13 patients with MISP, one refused treatment, one improved (from not being able to walk unassisted to being able to walk easily, ride a bicycle, and go hunting, remaining improved 15 months later), and five remained stable – although some were already stable prior to institution of the treatment [151]. Oh and associates reported two cases of MISP as well as six others from the literature with some degree of response to various forms of immunotherapy early in the course of neurologic disease [106]. Keime-Guibert and associates reported an open treatment trial of intravenous immunoglobulin, cyclophosphamide, and methylprednisolone on ten patients with MISP associated with encephalomyelitis and seven patients with paraneoplastic cerebellar degeneration; of the seven patients (initial Rankin scores greater than or equal to 4), none improved, while among nine patients who were initially still ambulatory (Rankin scores less than or equal to 3), none improved but two stabilized (two with MISP) [152]. In a retrospective study of 200 patients with paraneoplastic encephalomyelitis (PEM)/MISP (SSN), treatment of the tumor was an independent predictor of improvement and stabilization

of the neurological disorder suggesting that an early diagnosis of the cancer may provide a better chance of stabilizing the neurological disorder [153].

Prognosis

While one of the most common patterns of onset of neurological symptoms in MISP is subacute (over days to weeks); occasional patients have more abrupt presentations (over hours), while others report gradual symptom onset over weeks to months. In its most severe form, many patients become bedridden and succumb from complications of bed rest or inactivity rather than from direct cancer progression [153]. Of five MISP patients reported by Horwich et al. the mean time from onset of neurologic symptoms to death was 28 months (range 6–96 months), with one survivor (greater than 24 months at last follow-up) among 5 patients [19]. In the 12 patients described by Anderson et al. with MISP and small cell lung carcinoma, the mean time from neurologic symptom onset to death was 10 months (range 1.5–37 months), with 3 survivors (2–37 months since last follow-up) among 12 patients [138]. According to accounts in the peer-reviewed medical literature, at least three patients with MISP associated with Hodgkin disease had significant neurologic improvement following successful treatment of the underlying lymphoma, with a mean follow-up of more than 29 months (range 15 to greater than 36 months) [113, 114].

Nonmalignant Inflammatory Sensory Polyganglionopathy

Introduction

In 1968, Dyck et al. [24] described the clinical and pathological features of two cases of acute pure sensory neuropathy without malignancy, similar to those in the entity discussed by Wartenberg [21], concluding that multifocal radicular sensory loss with selective loss of large-diameter sural nerve fibers suggested dorsal root ganglia as the primary site of disease. Sterman et al. later reported an additional three patients in whom no neoplasm was identified, who presented with subacute widespread sensory symptoms (paresthesia and dysesthesia), ataxia, and severe sensory loss, none of whom recovered; these clinicians postulated a disease process confined to the dorsal root and Gasserian ganglia, noting the similarity to the pattern of deficits between their patients and animals with experimental pyridoxine and doxorubicin intoxications [25]. Dalakas published a longitudinal study of 15 patients with usually slowly progressive distal paresthesia and sensory ataxia who were found to have profound loss of large-diameter fiber sensation, areflexia, and normal strength, but neither malignancy nor antineuronal antibodies [154]. With four of these patients having monoclonal paraproteinemia, the authors suggested that immune mechanisms might have played a role. More recently Windebank et al. presented the clinical, laboratory, neurophysiologic, and pathologic findings in 42 patients with acute or subacute sensory neuropathy, discussing the natural history and response to treatment in individual cases [31]. They concluded that the acute or subacute, often focal or asymmetric, onset of symptoms in the absence of inflammation in distal peripheral nerve suggested an immune-mediated or vascular process at a proximal level, either at the posterior root or dorsal root ganglion. In another series, Griffin et al. described 13 patients with acute, subacute, or chronic ataxic sensory neuropathy, often with autonomic features, associated with Sjögren syndrome [30]. These investigators reported clinical, laboratory, and electrodiagnostic data and in addition presented detailed sural nerve, posterior root, and dorsal root ganglion pathology, emphasizing the differences between their patients and those with either idiopathic or malignant sensory polyganglionopathy. They advocated that Sjögren syndrome be considered in patients with severe sensory and autonomic neuropathy with ataxia and proprioceptive sensory loss. Additional series and individual case reports describe more than 100 patients with acute or subacute sensory neuropathy without malignancy [26, 28, 155–161].

This section discusses disorders of the dorsal root and spinal ganglia which are thought to be immune, excluding cases associated with malignancy or toxins affecting primary sensory neurons, that is, nonmalignant inflammatory sensory polyganglionopathy (NISP). With these exclusions the remaining conditions affecting proximal peripheral divisions of the dorsal root ganglion cell appear to be inflammatory. In the few cases in which biopsy material has been obtained, inflammation was often striking, implying immune mechanisms. At least some of these conditions previously described as of unknown localization were convincingly shown to specifically target dorsal roots proximal to the dorsal root ganglion. Sinnreich et al. described these patients presenting with gait ataxia, large fiber sensory loss, and paresthesias with frequent falls characterized by normal nerve conduction and EMG studies, characteristic somatosensory evoked potential (SEP) abnormalities with delayed central responses, elevated CSF protein levels, thickened lumbar nerve roots on MRI scans, inflammatory demyelinating changes on lumbar rootlet biopsies, and favorable response to immune-modulating treatment. The authors named the condition "chronic immune sensory polyradiculopathy (CISP)" reflecting the immune pathophysiology as well as the localization the disorder [162].

Etiology and Pathogenesis

Although nonmalignant inflammatory sensory polyganglionopathy (NISP) has been associated with Sjögren syndrome [28, 30, 31, 154, 156, 157, 160], paraproteinemia [31, 154],

celiac disease [155], and a rare complication of Epstein-Barr virus infection [163], with others having been reported as the sensory form of Guillain-Barre syndrome [164, 165], or predominantly sensory neuropathies associated with serum antibodies to chondroitin sulfate C [166] or sulfatide [141], many NISP patients are not found to have an underlying etiology and therefore fall into the unsatisfying category of "idiopathic."

Hainfellner and colleagues described a case of NISP presenting with acute painful sensory loss, areflexia, ataxia, urinary retention, and constipation who died 5 weeks into his illness [167]; autopsy demonstrated widespread inflammatory infiltration of dorsal root and autonomic ganglia with evidence of a prominent CD8+− mediated attack on these ganglion cells. Gherardi and coworkers found clonal populations of T cells in 80 % of patients with NISP as opposed to 20 % of elderly controls [168]. These reports suggest that cell-mediated immune mechanisms are at work in NISP as well as in sensory ganglionopathies associated with malignancy (see above).

Clinical Presentation

Although there is considerable clinical heterogeneity, three syndromes tend to predominate among patients with NISP – an ataxic presentation, a hyperalgesic presentation, and a mixture of the two. The extent to that a patient falls into one or another type appears to depend on the subset of neurons affected, the rapidity of involvement, and perhaps other factors. In the ataxic presentation predominantly large-diameter neurons are impaired or destroyed, giving rise to proprioceptive deficits and sensory ataxia. In the hyperalgesic syndrome dysfunction of small-diameter neurons which convey pain and temperature sensation is postulated. In the latter presentation there may also be a variable degree of autonomic involvement. The majority of NISP patients, however, have combinations of ataxia and pain or dysesthesia. NISP patients presenting with ataxia have been described by Sterman et al. [25], Kaufman et al. [26], Dalakas [31], Griffin et al. [30], and others [28, 156, 158, 159, 161]. NISP patients with prominent hyperalgesia were reported by Dyck et al. [24], Mitsumoto et al. [157], Laloux et al. [160], and Windebank et al. [31].

Diagnosis

Symptoms and Signs

In the ataxic syndrome presenting symptoms were numbness and tingling, unsteadiness of gait, diminished fine motor control, and occasionally pain, although this latter symptom was rarely prominent. In patients with the hyperalgesic syndrome, shooting limb pains, burning numbness, and painful paresthesia sometimes were among the presenting symptoms. Patients with ataxic and hyperalgesic NISP develop difficulty walking, poor coordination, and loss of manual dexterity. In hyperalgesic NISP pain, burning sensations, lancinating pains, and dysesthesia were sometimes prominent. Neurologic examination characteristically demonstrated normal strength, varying degrees of both distal and proximal diminished sensation (particularly vibration and joint position sense), and deep tendon hypo- or areflexia. In severely affected individuals the deafferentation was often so profound that limbs drifted off into space without the patient knowing (pseudoathetosis); in certain cases nocturnal eye protection was needed to prevent inadvertent ocular injury from a wandering finger. Autonomic manifestations such as Adie pupils, loss of sinus arrhythmia, or abnormal valsalva ratio values were sometimes apparent [30].

Laboratory Testing

Most NISP patients were found to have normal to slightly elevated CSF protein values. Of the 15 patients reported by Dalakas, the mean CSF protein value was 42 mg/dl (range 19–128) [154]. In Windebank's series of 30 patients, the mean value was 48.5 mg/dl (range 17–146), although two patients who presented acutely were found to have readings of 300 and 290 mg/dl [31]. On repeat CSF analysis later in the course of disease, both of these individuals had normal CSF protein determinations. CSF pleocytosis is not considered a typical feature of inflammatory demyelination and when present suggests infiltrative or infectious conditions (e.g., HIV infection) [169]. One of Windebank's patients who presented acutely, however, initially had a CSF nucleated cell count of 115 lymphocytes/mm^3; a subsequent lumbar puncture showed normal cells [31]. What is the significance of these cerebrospinal fluid (CSF) abnormalities? An elevated protein level in the absence of pleocytosis, as seen in both Guillain-Barré syndrome and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), is thought to be associated with spinal or meningeal inflammation [170, 171]. In the majority of NISP cases, the CSF protein was normal or slightly elevated, most often without pleocytosis, while in subacute monophasic cases, abnormal spinal fluid findings were restricted to the initial phase.

Serologic markers (antinuclear antibodies, extractable nuclear antigens, rheumatoid factor, and antineutrophil cytoplasmic antibodies) raise the possibility of specific connective tissue disorders. Many patients with Sjögren syndrome and NISP demonstrated seropositivity for extractable nuclear antigens such as ro (SS-A) and la (SS-B) [30]. Dalakas described four individuals with ataxic sensory findings suggesting NISP and paraproteinemia, three with IgM kappa and one with IgA kappa monoclonal proteins [154]. Windebank et al. reported one case each of IgM kappa and IgG kappa monoclonal paraproteinemia in their NISP cohort [31]. Patients with sensory polyganglionopathy and antineuronal nuclear antibodies type 1 either had previously known

malignancy or subsequently were found to have cancer [18, 103]. A few case reports have appeared which document antineuronal antibodies in patients with sensory ganglionopathies in whom no malignancy could be found in life and in some cases at autopsy [172, 173], although the guiding principle of prudent diagnosis is that ANNA-1 (anti-Hu) seropositivity in a patient with sensory polyganglionopathy is a compelling evidence for an underlying small cell carcinoma of the lung [93]. These occult cancers may elude diagnosis for a number of years.

Electrophysiologic Testing

The most common nerve conduction abnormality in NISP was absent or low-amplitude sensory nerve action potentials (SNAP) with normal or relatively preserved motor (compound muscle action potential) amplitudes. Needle electromyography (EMG) was typically normal, although occasionally demonstrated mild abnormalities, indicating minimal involvement of motor units. Auger et al. observed that the trigeminal "blink" reflex was abnormal in 20/43 subjects with NISP while being normal in 17/17 patients with MISP [142].

Of 41 patients in Windebank's series, all but one showed a decrease in the amplitude of SNAPs with only mild slowing of conduction velocity [31]. From the majority of nerves tested, no SNAP could be elicited. Only eight of these patients had sensory conduction velocities below the range of normal, five from the distal median nerve. Motor nerve conduction studies were abnormal much less often than sensory studies. Ten of the 41 patients had abnormal compound muscle action potential amplitudes or conduction velocities, most commonly in the median and peroneal (fibular) nerves. EMG was usually normal. Eleven of the patients had fibrillation potentials in intrinsic foot muscles, while an occasional patient demonstrated fibrillation potentials in a leg or intrinsic hand muscle. Motor unit potential changes were more prominent, with abnormalities in 18 patients.

In Griffin's series 13 patients showed absent SNAP in most of the clinically involved limbs; seven of the patients had absent SNAP in all nerves tested [30]. Motor conduction abnormalities were limited to mild alterations in compound muscle action potential amplitudes and motor conduction velocities. EMG showed only minimal evidence of denervation in isolated muscles.

Knazan et al. performed extensive electrophysiologic testing on a 19-year-old man who after a "flu-like" illness developed sudden onset of severe sensory ataxia with marked disturbances of proprioception and vibration sense, minimal involvement of cutaneous sensation, areflexia, and normal strength [161]. These workers found normal motor conductions in the median, ulnar, and posterior tibial nerves; absent SNAP stimulating the median, ulnar, or sural nerves; and normal EMG of upper and lower limb muscles. No H reflex could be elicited. Median and tibial somatosensory evoked potentials could be recorded, although the median N20 scalp response was prolonged and the tibial P40 waveform was either absent or markedly prolonged [161].

In a series of patients with gluten sensitivity Hadjivassiliou et al. noted that all had either absent or attenuated sensory potentials at the time of diagnosis. Ten of the seventeen individuals showed asymmetric sensory fiber involvement either in a non-length-dependent fashion or patchy nerve involvement. Three of the seventeen had unrecordable potentials from nerves in both upper and lower limbs. Four patients showed length-dependent sensory fiber involvement but had no motor fiber involvement, in support of the diagnosis of sensory ganglionopathy [174].

The absence of SNAPs argues for involvement at or distal to the level of the dorsal root ganglion. In isolated disease of spinal roots, such as in traumatic root avulsion or CISP, SNAP amplitudes remain normal [154, 162, 175].

Imaging Studies

Magnetic resonance imaging studies of the cervical spinal cord of patients with NISP have sometimes demonstrated regions of increased signal intensity on T2-weighted sequences [143, 163, 176].

Pathologic Studies

Morphologic study of the dorsal root ganglion cell has focused on the peripheral (sural) nerve with only a few reports of spinal ganglia or dorsal root alterations. Inflammatory infiltrates have been demonstrated in biopsy and autopsy material from a number of patients with clinical features of NISP. In the sural nerves of two patients, Dyck et al. found decreased myelinated fiber (MF) density (mean 4,247/mm^2, range 2,286–6,209) primarily affecting large MF, a low rate of axonal degeneration, and no interstitial or endoneurial inflammation [24]. These abnormal findings are consistent with but do not directly demonstrate disease of the spinal ganglia. Windebank et al. described pathologic studies of 22 sural nerves in NISP [31]. Although the mean MF density was significantly decreased at 4,327 MF/mm^2 (range 52–9,968) compared with the mean value from 58 controls at 8,451 MF/mm^2 (range 5,101–12,995), no significant difference was found in the median MF diameter (5.32 μm in patients vs. 5.20 μm in controls). When the area of axons and myelin was assessed separately, however, striking differences were found. The median axon area was 4.24 μm^2 (range 2.19–7.71) compared with 7.09 μm^2 (range 3.15–12.63) in controls. The median myelin area was 17.79 μm^2 (range 6.81–24.22) compared with 14.20 μm^2 (range 7.78–29.55) in controls. Teased fiber analysis showed that the average percent of normal fibers (condition A) was lower (58.6 %, range 0–92 vs. 89.4 %, range 62–100), the percent of fibers with de- and remyelination (conditions C, D, F, or G) was higher (11.1 %, range 0–54 vs. 1.6 %, range 0–11),

and the percent of teased fibers undergoing axonal degeneration (conditions E or H) was higher (29.2 %, range 0–98 vs. 8.5 %, range 0–27) than in normal controls. A small mononuclear cell perivascular infiltrate was found in only 1/22 sural biopsy specimens. When taken with clinical and electrophysiologic findings, Windebank's studies demonstrating axonal atrophy suggest a more proximal site of disease (e.g., the spinal ganglia).

Twelve of Griffin's thirteen patients underwent sural nerve biopsy [30]. Five of these were reported as having reduced or severely reduced MF density. The mean MF density of the other six was 3,263 MF/mm^2 (range 688–7,598). They found inflammatory cells around epineurial blood vessels in six sural nerve specimens. Griffin et al. documented the thoracic dorsal root and spinal ganglion biopsy findings in three individuals [30]. All three demonstrated fiber loss in the dorsal roots. Inflammation was present in all three cases, with perivascular infiltrates in two cases and scattered inflammatory cells in small numbers throughout the endoneurium. Prominent mononuclear inflammatory cell infiltrates were noted in the three dorsal root ganglia specimens, typically situated around individual somas. In one patient immunohistochemical staining showed most of the inflammatory cells to be T lymphocytes, with only occasional macrophages. Neuronal loss varied from case to case and appeared to relate to the presence of these two types of inflammatory cells. In another case of NISP associated with Sjögren syndrome, we observed similar findings in lumbar dorsal root ganglion biopsy (see Fig. 23.2); in addition the posterior root appeared to be relatively unaffected, but the sural nerve showed marked reduction in the density of myelinated fibers.

Spinal nerve root histology in one patient in the series of Hadjivassiliou showed patchy loss of myelin staining and inflammatory infiltrates of lymphocytes and macrophages. Dorsal root ganglia also showed a less pronounced, diffuse lymphocytic infiltrate with loss of occasional neurons. Sensory ganglioneuropathy in this case was therefore thought to be inflammatory in nature and in the context of more widespread inflammatory changes affecting central and peripheral nervous system [174].

Because of the potential complications involved and for technical reasons, perhaps spinal ganglion biopsy should be restricted to only a very select group of patients with severe disease in whom malignant involvement must be excluded [177]. This procedure should be done only in highly specialized medical institutions.

Treatment and Management

Although various forms of immunotherapy have been given to patients with NISP, trials of treatment have not been sufficiently rigorous to establish whether any of these therapies are effective. A number of patients have received corticosteroids or other immunosuppressant therapy, and some have undergone plasma exchange or IVIG treatment [30, 31, 154, 178, 179]. To date no convincing results demonstrate that any treatment is more efficacious than no treatment. In individual anecdotal cases or case series, however, stabilization in clinical course or improvement has been associated with corticosteroid treatment, plasma exchange, IVIG treatment, or infliximab, a TNF blocker [180]. In addition, some patients appear to improve spontaneously, and some success has been shown with a strict gluten-free diet in patients with celiac disease [174].

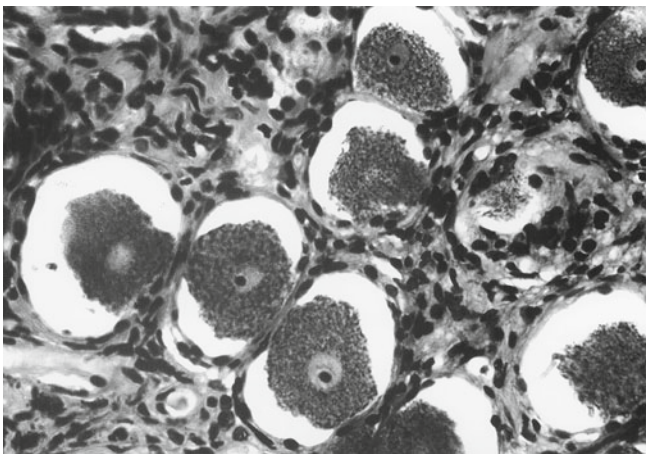

Fig 23.2 DRG pathology in NISP

Prognosis

Considering the two largest series of cases, the onset and pace of worsening are quite heterogeneous. Some patients present with a subacute or chronic progressive course, others have an explosive onset over hours. The disease course is most often chronic and progressive as reported in 20/38 patients by Windebank et al. [31] and in 8/13 patients by Griffin et al. [30]. In others the deficits remains unchanged – 10/38 [31] and 4/8 [30]. Still others had a chronic monophasic illness – 8/38 [31]. One of Griffin's patients followed a chronic relapsing course. Mean follow-up periods for these series were 98 months (range 12–324 months, Windebank's patients) and 41 months (range 5–190 months, Griffin's patients).

Toxic Polyganglionopathy

Many agents cause predominantly sensory symptoms and findings. These include drugs which alter microtubule structure such as vincristine and other vinca alkaloids; taxanes such as docetaxel, paclitaxel, thalidomide, lenalidomide, bortezomib, and ixabepilone [181, 182]; agents that interfere with axonal transport such as the hexacarbon solvents; and agents that disrupt axonal structure such as acrylamide and

ethylene oxide. In all these cases, the brunt of the injury appears to fall on the axon, with relative preservation of the neuron cell body. Without significant disease affecting the soma, there is the potential for recovery of function when the toxic source is removed.

For other agents, the major site of cellular damage is the neuronal perikaryon. This produces a distinctive clinical pattern with early proximal and distal sensory involvement, widespread hyporeflexia, and slow recovery after cessation of exposure. Cisplatin and vitamin B6 overuse fall in this category.

Cisplatin

Introduction

For *cis*-Diamminedichloroplatinum (II) (CDDP) which is a first-line agent for treating ovarian, testicular, and other neoplasms, neurotoxicity is dose limiting. The primary target is the dorsal root ganglion (DRG) neuron or its axon. Marrow depression and nephrotoxicity are significant adverse effects of CDDP therapy. Myelosuppression, which is common with prolonged usage, responds to erythropoietin. Nephrotoxicity has been reduced by saline diuresis [183]. The current primary dose-limiting side effects of CDDP are ototoxicity and neurotoxicity. Ototoxicity is common and thought to be due to a direct toxic effect on cochlear hair cells. Clinically apparent central neurotoxicity is rare [184, 185], although present if carefully sought with electrophysiological testing [186]. Significant peripheral neuropathy was reported soon after the drug was introduced [45, 46].

Etiology and Pathogenesis

Human studies have been limited. The reason for predominant sensory neuron toxicity may relate to drug access rather than selective neuronal vulnerability. CDDP does not cross the blood–brain barrier, and therefore, motor neurons and other central nervous system neurons are not directly exposed to toxic levels of drug. Because fenestrated capillaries supply the DRG, sensory neurons are exposed to serum levels of drug. This has been confirmed in human autopsy studies. Tissue platinum assays revealed the highest platinum concentration in tumor tissue (mean 3.3 μg/g), but similarly high concentrations were found in peripheral nervous tissue (3.5 μg/g in sural nerve and 3.8 μg/g in spinal ganglia). This compared with much lower concentrations in brain (0.17 μg/g) [187, 188]. Electrophysiological studies in cancer patients treated with CDDP confirm that large-diameter sensory axons are involved [189, 190]. Most studies have been interpreted as suggesting that the DRG neuron is the primary target [186, 191] which is compatible with findings in animals. It is not clear whether autonomic neurons, which are not protected by the blood–brain or blood-nerve barrier, are injured by cisplatin [192, 193]. Neuropathologic studies have shown loss of large myelinated fibers, most severe distally, and evidence of axonal degeneration [187, 194]. A single autopsy case in a child who had been treated with high-dose CDDP revealed severe loss of axons in both peripheral nerve and in the dorsal columns of the spinal cord [46].

Development of animal models for the study of CDDP neurotoxicity has been difficult because of the development of severe nephrotoxicity before neurotoxicity can be detected. In surviving animals, the possibility that neuropathy is due to renal failure rather than to CDDP has been difficult to ascertain. Behavioral studies which stress balance function have demonstrated a deficit in CDDP-treated mice [195] associated with biochemical abnormalities in DRG and slowing of tail nerve conduction. Several groups have demonstrated similar slowing of nerve conduction in rats [196–199]. Using similar doses, changes in DRG neurons of rats have been identified. These include neuronal shrinkage, nuclear abnormalities, and both decrease and increase of neurotransmitters [195, 199–202]. Examination of distal nerve segments has not generally provided additional information. Animal model studies have suggested that CDDP and related compounds have either facilitated access or preferential storage in the peripheral nervous system, particularly in DRG [203]. DNA-platinum adduct formation in rat DRG has been demonstrated in vivo [204].

Mechanistic studies of CDDP-induced neurotoxicity have been limited. CDDP binds to DNA of cancer cells and induces apoptosis. We have demonstrated that CDDP binds to neuronal DNA and induces apoptosis of DRG neurons in vitro and in vivo (Fig. 23.2). This is accompanied by upregulation of cellular markers associated with entry into the cell cycle. Apoptosis and entry into the cell cycle can be prevented by inhibitors of cyclin D1 and by agents such as nerve growth factor or insulin-like growth factor-1 that promote neuronal differentiation [205].

Clinical Presentation

The neuropathy is dose limiting and closely related to total cumulative drug dose [186, 188, 206, 207]. Neurotoxicity is apparent in the majority of adult patients who receive more than 400–500 mg/m^2 of CDDP [46, 187, 208]. The neuropathy is predominantly sensory with initial complaints of paresthesia in the distal extremities [187]. In some cases, symptoms begin proximally and may progress to severe sensory ataxia. Progression of neuropathy may continue for several months after cessation of CDDP [209], a phenomenon referred to as coasting. There have also been reports of symptoms developing 3–8 weeks after the last dose of chemotherapy [210]. Other platinum compounds produce similar toxicity. The experimental platinum analogs, ormaplatin [211] and oxaliplatin, cause similar neurotoxicity [212, 213]. Carboplatin is less neurotoxic [180]. In high doses, however, carboplatin does produce the same type of neuropathy as cisplatin [181, 214, 215].

Diagnosis

The diagnosis should be suspected in patients who develop sensory symptoms after two or more cycles of cisplatin treatment. Both *positive* (pain and paresthesia) and *negative* (numbness and ataxia) sensory symptoms may be present. The symptoms are usually symmetric and predominant in the lower limbs. This contrasts with malignant and nonmalignant sensory polyganglionopathies. In both of these disorders, symptoms often begin asymmetrically in the face and upper limbs [31, 93]. Nerve conduction studies typically show reduced or absent sensory nerve action potential amplitudes. In severe cases, somatosensory evoked potential amplitudes may also be reduced [186]. Other studies including examination of the cerebrospinal fluid are normal.

Treatment and Management

In 1992, Apfel demonstrated that cisplatin neurotoxicity might be prevented by nerve growth factor [195]. Nerve growth factor prevented cisplatin-induced alterations in behavior, electrophysiology, and DRG neuropeptides. This type of neuroprotection has been demonstrated for DRG [216, 217], sympathetic neurons [218, 219], PC12 cells [220], and in vitro [205]. In parallel studies, NT3 and NT4/5 have been shown to have neuroprotective effects for auditory system cells [221, 222] and DRG neurons [223]. All of the studies cited here have been empirical observations. In spite of this evidence, clinical trials have not been initiated. There is a fear that growth factors should not be used in patients with cancer because of the possibility of stimulating tumor growth. Better understanding of the mechanism of cell injury and protection will allow therapeutic trials to proceed.

Several other agents have been shown to have a protective effect against CDDP neurotoxicity in vitro and in vivo. Albers et al. [224] searched and selected quasi-randomized or randomized controlled trials in which participants received cisplatin (or related compounds) chemotherapy with or without a potential chemoprotectant (acetylcysteine, amifostine, ACTH, BNP7787, calcium and magnesium, diethyldithiocarbamate, glutathione, Org 2766, oxcarbazepine, or vitamin E) and were evaluated 0–6 months after completing chemotherapy using quantitative sensory testing (primary) or other measures including nerve conduction studies or neurological impairment rating using validated scales (secondary). One of four eligible amifostine trials [225–228] used quantitative sensory testing and demonstrated a favorable outcome in terms of amifostine neuroprotection, but the vibration perception threshold result was based on data from only 14 participants receiving amifostine who completed the posttreatment evaluation and should be regarded with caution. Of the six eligible glutathione trials [229–234], one used quantitative sensory testing but reported only qualitative analyses. Four eligible Org 2766 trials [235–238] employed quantitative sensory testing and reported disparate results; meta-analyses of three trials using comparable measures showed no significant vibration perception threshold neuroprotection. The remaining trial reported only descriptive analyses. The single eligible trials involving acetylcysteine [239], diethyldithiocarbamate [240], calcium and magnesium [241], and oxcarbazepine [242] and the two eligible trials involving vitamin E [243, 244] did not perform quantitative sensory testing. In all, data from 1,537 participants were included. The author concluded that at present, the data are insufficient to conclude that any of the purported chemoprotective agents (acetylcysteine, amifostine, calcium and magnesium, diethyldithiocarbamate, glutathione, Org 2766, oxcarbazepine, or vitamin E) prevent or limit the neurotoxicity of platin drugs among human patients.

Pyridoxine Abuse

Introduction

Vitamin B6 was recognized as an essential nutrient in the 1930s. The closely related compounds pyridoxal, pyridoxamine, and pyridoxine all function as active vitamins [245]. Neuropathy from vitamin B6 deficiency was initially described in swine fed with a pyridoxine-deficient diet [34, 246]. Neuropathy from vitamin B6 overuse was first described in a series of patients in 1983 [35]. The findings suggested a primary sensory ganglionopathy. It was caused by large doses of vitamin B6 which were being used as alternative therapy for premenstrual syndrome, schizophrenia, and carpal tunnel syndrome.

Etiology and Pathogenesis

Krinke and colleagues first demonstrated in dogs that high doses of pyridoxine in the diet caused progressive sensory ataxia associated with loss of DRG neurons and axons in peripheral nerve and dorsal columns [247]. This was subsequently confirmed in rats [36].

In two human studies, somatosensory evoked potential amplitudes were reduced suggesting involvement of central sensory pathways [35, 248]. A tissue culture study demonstrated that compounds which could be converted into active coenzyme were toxic to DRG, whereas inactive analogs were not [249]. This strongly suggested that the neurotoxicity was related to interference with the cellular action of the vitamin.

Clinical Presentation

Patients who developed sensory ataxia were taking 2–6 g of pyridoxine each day by mouth [35]. This compares to the minimum daily requirement of 2 mg/day. Progressive ataxia developed within weeks to months of starting the vitamin. In another report, two patients were accidentally given 132 and 183 g of pyridoxine intravenously over 3 days. They developed global sensory loss within several days which progressed to complete and permanent deafferentation

[250, 251]. At the other end of the spectrum, patients taking doses between 250 mg and 2 g developed numbness and paresthesia which subsided after discontinuing megavitamin use. Taken together with the animal studies, this strongly suggests that the polyganglionopathy is dose related. Clinical findings depend on severity. They include gait ataxia, loss of joint and position sense, and hyporeflexia with preserved muscle strength. Except in severe cases, recovery was the rule following discontinuation of the vitamin supplement.

Diagnosis

The diagnosis should be suspected in a patient with progressive, symmetric, large fiber predominant sensory loss. Patients need to be questioned carefully about holistic and alternative medicine treatments because this information may not be spontaneously volunteered. Nerve conduction studies show reduced or absent sensory nerve action potentials and reduced or delayed central sensory conduction [35, 248]. Other laboratory findings including cerebrospinal fluid examination are normal.

Treatment and Management

The molecular mechanisms responsible for the axonal degeneration are not fully understood, but pyridoxine-induced neuropathy in animals may be reversed by systemic administration of trophic factors, such as neurotrophin-3 or other compounds with NGF-like properties [252, 253]. Discontinuing pyridoxine supplementation resulted in resolution of symptoms and signs over weeks to months except in very severe cases [251]. In some subjects with good functional recovery, there were residual electrophysiological abnormalities. This suggests that part of the recovery resulted from peripheral sprouting or central adaptation, which would be compatible with a primary polyganglionopathy.

Central Sensory Syndrome

Introduction

The central sensory syndrome (CSS) is a group of rare disorders characterized by clinical abnormalities thought to be predominantly or purely limited to the central (posterior column) axon segment of the dorsal root ganglion cells involved.

Etiology and Pathogenesis

The disorders that have been linked to CSS to date include compressive posterior column myelopathy, myelopathy in HIV infection (gracile tract degeneration) [254], Holmes-Adie syndrome [255], subacute myelo-optic neuropathy (clioquinol intoxication) [256], tabes dorsalis [5, 6, 9], and, at least in experimental animals, vitamin E deficiency [43]. We could also include immune conditions such as CISP in this group [162] or even inherited disorders like spinocerebellar ataxia type 4 (Biemond ataxia) [257–262].

Clinical Presentation

Patients with the central sensory syndrome present with sensory loss, ataxia, and hyporeflexia. This may be present from birth in the case of Biemond ataxia, can be acquired by infection with HIV and subsequent myelopathy, or may occur late in life as a consequence of cervical spondylosis.

Diagnosis

The clinical and laboratory hallmarks of CSS, all three of which must be present for conclusive diagnosis, are: (1) abnormal sensation, typically involving dorsal column modalities such as vibration and joint position sense, often resulting in significant ataxia; (2) normal sensory and motor nerve conduction studies (as the lesion is proximal to the dorsal root ganglion cell body); and (3) either central abnormalities on somatosensory evoked potential testing and/or abnormal quantitative sensory testing.

Treatment and Management

The treatment of the central sensory syndrome depends on its etiology. Some cases of compressive CSS (for instance, due to a midline C3, 4 disks impinging on the posterior columns) may be entirely reversed with decompressive surgery. Other causes are not nearly as amenable to therapeutic intervention.

Prognosis

A detailed discussion of the prognosis of each of the varied causes of CSS is beyond the scope of this chapter.

Differential Diagnosis

The differential diagnosis involves separating MISP, NISP, and toxic polyganglionopathies from other sensory neuropathies. A variety of sensory polyneuropathies must first be considered. They include (1) metabolic, inflammatory demyelinating, toxic, deficiency, and other syndromes, beginning with sensory manifestations but at more advanced stages affecting other classes of neurons (axons), for example, motor and autonomic; (2) inherited neuropathies; (3) other cancer-related sensory neuropathies; (4) toxic syndromes; (5) deficiency states; and (6) infections.

Many polyneuropathies begin with sensory symptoms and findings, giving the sometimes false impression that there is no motor fiber involvement, only to be followed by motor symptoms and signs later. This is the pattern for the majority of polyneuropathies. The tendency for early distal sensory involvement occurs in polyneuropathies associated with metabolic conditions including diabetes mellitus [263],

hypothyroidism [264], primary biliary cirrhosis [265], and uremia [266]; in infectious polyneuropathies such as those described with diphtheria [6], human immunodeficiency virus (HIV) [169], leprosy [267], and Lyme disease [268]; in inflammatory-dysimmune diseases including dysproteinemias [30, 269], nonsystemic vasculitis [270], and Sjögren syndrome [29]; in inherited neuropathies such as Fabry disease [271], hereditary sensory and autonomic neuropathies (HSAN) type I [272], II [273], IV [274], and V [275], inherited amyloidosis [276], spinocerebellar degenerations [171, 260–262], and polymerase gamma (POLG)-related ataxic neuropathy [277–279]; and in toxic polyneuropathies such as those seen with exposure to arsenic [280], dichlorophenoxyacetic acid [281], dimethylaminopropionitrile [282], ethylene oxide [283], gold [284], hexacarbons [285], isoniazid [286], misonidazole [287], phenytoin [288], platinum [186], polychlorinated biphenyls [289], *N*-3-pyridylmethyl *N*′-*p*-nitrophenyl urea (PNU) [290], thallium [291], tainted L-tryptophan [292], and vincristine [293]. The reasons for early distal sensory predilection are usually explained by length-dependent dysfunction of peripheral nerve axons and the greater length of afferent versus efferent axons.

In evaluating a patient with symmetrical sensory symptoms and findings, perhaps the first matter that might be decided is whether the process seems likely to be inherited or not. If familial neuropathy can be excluded, the list of possibilities can be reduced substantially. The features which support the contention that a sensory neuropathy may be inherited might be summarized as age at onset, course, nature of symptoms, population of neurons (fibers) affected, type of pathologic alteration, pedigree information, and related laboratory findings. Indications of inherited sensory neuropathy may be present in the perinatal period (HSAN II-V) or develop during the second or later decades. Perhaps more typical than age of onset is the slowly insidious development of symptoms over many years which characterize HSAN I, spinocerebellar degeneration, POLG-related ataxic neuropathy, Fabry disease, and perhaps Tangier disease. In general, patients with inherited sensory neuropathies do not experience paresthesia as part of their neuropathies. The presence of prominent paresthesia (a "positive" sensory symptom) therefore favors an acquired sensory neuropathy. Sometimes in inherited neuropathy one class of neurons (fibers) is particularly vulnerable to being affected, whereas acquired sensory neuropathies tend to involve most classes. A history of a similar disorder among blood relatives or observing boney abnormalities or other physical findings (e.g., yellow-orange discoloration of the pharyngeal tonsils in Tangier disease or angiokeratosis of the buttock, scrotum, and perineum in Fabry disease) or laboratory abnormalities (e.g., hypocholesterolemia and abnormal serum lipoprotein electrophoresis in abeta- and hypobetalipoproteinemia, abnormal liver function tests in POLG ataxic neuropathy, or low leukocyte alpha galactosidase in Fabry disease) suggesting a specific variety of inherited neuropathy, though uncommonly encountered, obviously helps in identifying inherited neuropathy.

Having concluded that the patient's sensory symptoms are not likely to be inherited, the next step might be to decide whether the sensory symptoms are the onset of a more generalized polyneuropathy. Broad medical information about a patient often provides telltale clues. When sensory symptoms are associated with diabetes mellitus, uremia, hypothyroidism, acromegaly, hepatic failure, or severe hypoglycemic attacks, the correct diagnosis should come to mind. The course and pattern of the symptoms may suggest heavy metal intoxications, acute intermittent porphyria, vitamin B12 or copper deficiency, and a variety of other disorders. Clinical signs might also prove helpful, including microvascular or proliferative retinopathy (diabetes mellitus), macroglossia (amyloidosis, hypothyroidism), or sluggish deep tendon reflexes (hypothyroidism). Useful laboratory investigations include elevated fasting blood glucose and glycosylated hemoglobin (diabetes mellitus), increased thyroid stimulating hormone (hypothyroidism), elevated serum creatinine (uremia), or serum or urine monoclonal gammopathy (paraproteinemia, chronic ataxic neuropathy ophthalmoplegia IgM paraprotein cold agglutinins disialosyl antibodies (CANOMAD) [294], amyloidosis, or other blood dyscrasia).

The paraneoplastic or malignant inflammatory sensory polyganglionopathies (MISP), particularly the ones associated with small cell carcinoma of the lung, are not so readily distinguished from nonmalignant inflammatory sensory polyganglionopathy (NISP) on clinical ground alone. A history of smoking, constitutional symptoms (e.g., weight loss, fever, lymphadenopathy), or findings of malignancy suggest the paraneoplastic disorders. Particularly in persons 50 years and older, one may wish to obtain a chest radiograph, an X-ray metastatic bone survey; assess for monoclonal proteins in plasma and urine; and, if appropriate, obtain bone marrow, nerve, or other tissue to make a diagnosis of myeloma (multiple of osteosclerotic), amyloidosis (familial or acquired), or monoclonal gammopathy of undetermined significance.

Toxic syndromes may be suggested by their occurrence in clusters, exposure to putative toxins, distinctive physical findings (e.g., myokymia in gold intoxication, brawny induration of the limbs in eosinophilia-myalgia syndrome, palmoplantar cutaneous exfoliation in arsenic poisoning, or striate leukonychia (Mees lines) in metal intoxication), and suggestive laboratory abnormalities (e.g., peripheral eosinophilia in eosinophilia-myalgia syndrome associated with tainted L-tryptophan, peripheral basophilic stippling of erythrocytes in arsenical intoxication, or abnormal urine heavy metals in arsenic and thallium poisoning).

Deficiency syndromes such as vitamin B12 or copper deficiency can also present with combinations of characteristic

symptoms (unsteady gait, especially on uneven terrain and in the dark), physical findings (cognitive impairment, canities, limb and truncal ataxia, pseudoathetosis, and extensor plantar responses), and laboratory abnormalities (decreased cyanocobalamin or copper levels with megaloblastic anemia).

Infections such as tabes dorsalis, leprosy, and HIV infection might also be distinguished on the basis of symptoms and signs (e.g., tabetic "foot flapping" gait and Argyll-Robertson pupils, leonine facies with hypesthetic ears in Hansen disease, or anorexia, lymphadenopathy, and cutaneous findings in AIDS) and laboratory testing (positive syphilis serology, demonstration of mycobacteria on tissue biopsy, or positive HIV serology).

Other useful considerations include the size category of neurons (fibers) affected and the clinical pattern of neurological deficits. The specific sensory modalities involved may also prove helpful in establishing the diagnosis. Sensory neuropathies with prominent dysfunction or loss of large-diameter fiber modalities with examination findings such as kinesthesia and ataxia include hypothyroid polyneuropathy, uremic neuropathy, tabes dorsalis, vitamin B12 or copper deficiency, IgM paraproteinemic neuropathy, CANOMAD, spinocerebellar degenerations such as Friedreich ataxia, POLG ataxic neuropathy, toxic exposure to platinum or nitrous oxide, paraneoplastic sensory polyganglionopathies [17], toxic polyganglionopathies such as those associated with pyridoxine [35] and doxorubicin [295], infiltrative disease such as hematogenous metastasis to dorsal root ganglia sparing roots and nerves [296] and Sjögren syndrome [30], and idiopathic nonmalignant inflammatory sensory polyganglionopathies [31, 154]. Conditions with sensory neuropathies in which small-diameter fiber modalities may be prominently affected include amyloidosis, diabetes mellitus, Fabry disease, hereditary sensory and autonomic neuropathies, immune dysautonomias, Hansen disease, Tangier disease, and toxin exposures including gold, misonidazole, and tainted L-tryptophan. Other sensory neuropathies may involve both large- and small-diameter fiber modalities.

What is the differential diagnosis of diseases of the proximal sensory segments, the so-called polyganglioradiculoneuropathies? Even when armed with discriminating neurological history taking and examination skills as well as modern laboratory and electrophysiologic investigations, it is often difficult to sort out this group. The differential diagnosis of sensory polyganglioradiculoneuropathy rests on the exclusion of underlying malignancy. There is a female preponderance in NISP, while malignant inflammatory sensory polyganglionopathy affects the sexes similarly. In NISP clinical manifestations of Sjögren syndrome (e.g., dry eyes and mouth) may be present, while signs of severe systemic disease such as cachexia and weight loss (sometimes associated with cancers) are unusual. Magnetic resonance imaging can help to exclude structural intraspinal diseases. CSF for malignant cells can be useful. Although serologic testing such as for antinuclear and extractable nuclear antigens may be positive in NISP, antineuronal nuclear type 1 or anti-Purkinje cell antibodies have only rarely been described in these conditions. In MISP extractable nuclear antigen serologies are normal, and antineuronal nuclear 1 [103] or anti-Purkinje cell antibodies (personal communication, VA Lennon) are sometimes, though not invariably, demonstrated. As in the polyneuropathies, disorders which most commonly might be associated with both sensory and motor dysfunction on occasion may primarily affect the posterior roots, resulting in pure or relatively pure sensory polyradiculopathy. These include a pure sensory form of the Guillain-Barré syndrome [21], CISP [162], lympho- or plasmaproliferative disease [297], meningeal lymphomatosis [298], and meningeal carcinomatosis [299]. The pattern of deficits on neurologic examination may help distinguish polyganglioradiculoneuropathies from sensory polyneuropathies, but does not assist in dissecting out the specific causes of proximal sensory disease. Patients with sensory polyneuropathies have distal symmetric, "stocking-glove distribution" hypesthesia, absence or reduction of distal deep tendon reflexes, and normal muscle strength. Those with sensory polyradiculopathies and polyganglionopathies can demonstrate distal and proximal, symmetric or asymmetric sensory loss, widespread deep tendon hypo- to areflexia, and normal strength.

Part V

Neuromuscular Disorders: Peripheral Neuropathies

Approach to Peripheral Nerve Disorders

24

David N. Herrmann and Eric L. Logigian

Introduction

There are numerous causes of peripheral neuropathy. Advances in the understanding of the immune and genetic basis of a number of peripheral neuropathies have permitted more precise characterization and effective therapy for many of them. This has led to an array of investigative options, with variable specificity, making the diagnostic evaluation more complex. A structured approach is necessary to make an etiologic and cost-effective diagnosis of peripheral neuropathy (Table 24.1). The clinician identifies the presence of neuropathy by documenting symptoms and signs of a peripheral nervous system disorder. Characterization of the spatial and functional (motor, sensory, autonomic) pattern of nerve fiber involvement as well as the pathophysiology and temporal profile are essential to categorize neuropathies and limit the differential diagnosis. Consideration of medical comorbidity, medication and neurotoxin exposure, and the family history further narrows the list of possible etiologies. These steps are accomplished with a focused history and examination (often including family members), electrodiagnostic testing (nerve conduction studies and electromyography), and judicious laboratory testing. Cutaneous nerve or skin biopsy and specialized electrophysiological testing may be required in some instances. This approach allows an etiological diagnosis to be established in at least 76 % of cases [1, 2].

Does the Patient Have a Peripheral Nervous System Disorder?

The presence of a peripheral nervous system disorder is usually evident from the presenting signs and symptoms. No single clinical finding is definitive; rather, a combination of motor or sensory findings and their distribution permits the distinction between a central and a peripheral nervous system disorder. Reduced or absent deep tendon reflexes coupled with weakness, wasting, and fasciculations suggests dysfunction of lower motor neurons, nerve roots, or motor axons. Knowledge of the patterns of central sensory dysfunction (e.g., a "level" in spinal cord lesions) and peripheral sensory dysfunction (e.g., "stocking-glove," dermatomal, individual, or multiple sensory nerves) is also important in making this distinction. Central nervous system pathology may mimic a peripheral pattern of sensory dysfunction. Focal sensory symptoms, for example, hand numbness, may be seen with thalamic or parietal lesions; an apparent "stocking-glove distribution" of sensory loss may occur with cervical cord lesions, and posterior column dysfunction produces abnormalities in distal lower extremity proprioception and vibration sense and a positive Romberg test. Particular difficulty may arise with acute generalized weakness (e.g., Guillain–Barre syndrome (GBS) versus spinal shock), when there is peripheral and central nervous system involvement (e.g., vitamin B12 deficiency) or when symptoms predominate over signs (e.g., small fiber sensory neuropathies). The history, motor examination, sensory testing, and reflex abnormalities thus need to be considered collectively. Electrophysiologic testing or neuroimaging studies may occasionally be required to document or exclude involvement of the peripheral or central nervous system.

How Are the Findings Distributed in Space?

Peripheral nerve disorders should be characterized as being focal, multifocal, (asymmetric), or diffuse (symmetric) (Table 24.2). Focal disorders include radiculopathies (ventral

Table 24.1 Stepwise approach to the diagnosis of peripheral nervous system disorders

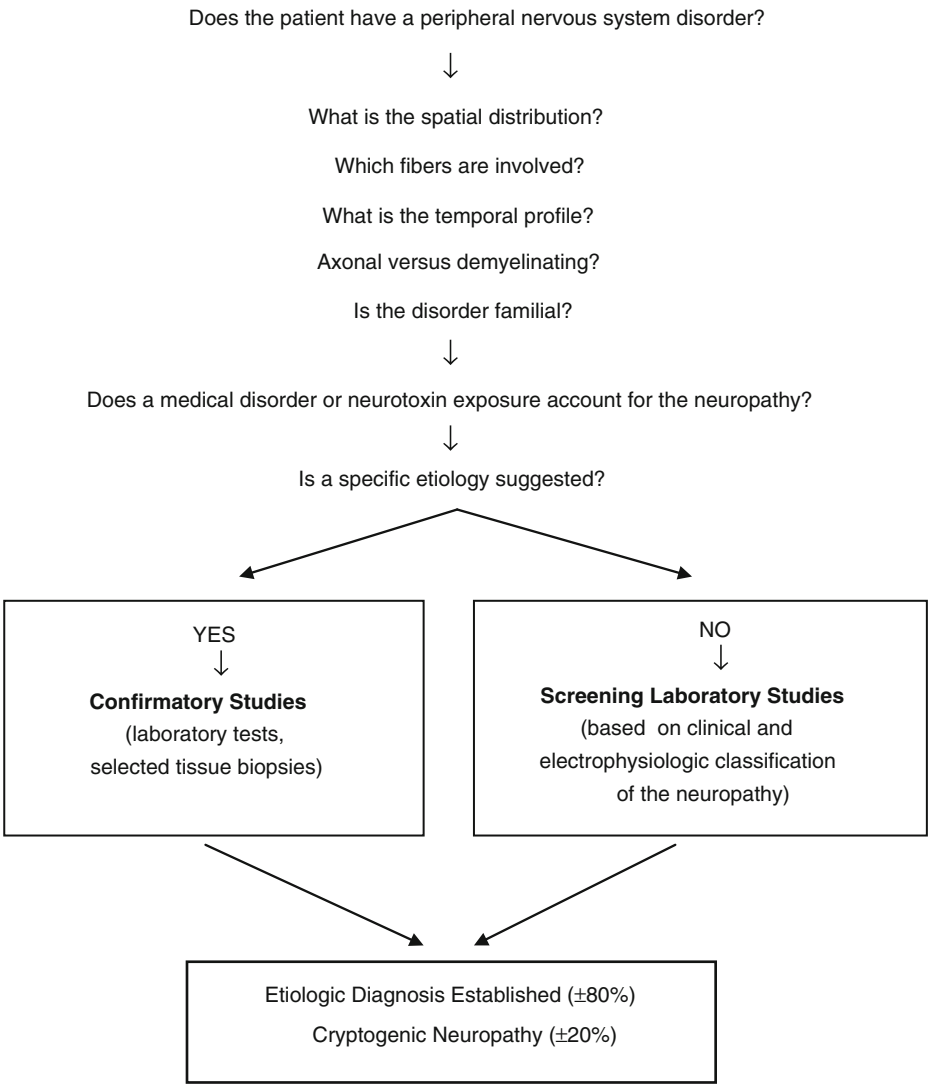

Table 24.2 Peripheral nervous system disorders: spatial patterns

Focal	Multifocal (asymmetric)	Diffuse (symmetric)
Mononeuropathy	Multiple mononeuropathies	Polyneuropathy
Monoradiculopathy	Polyradiculopathy	Dorsal root ganglionopathy
Brachial plexopathy	Motor neuropathy	Motor neuronopathy
Lumbosacral plexopathy	Motor neuronopathy	
Motor neuronopathy		
Dorsal root ganglionopathy		

or dorsal), plexopathies (brachial or lumbosacral), mononeuropathies (including cranial neuropathies), and rarely segmental neuronopathies. Multifocal patterns include polyradiculopathy and multiple mononeuropathies. This chapter will focus on the diagnostic approach to multifocal and diffuse disorders. Most acquired polyneuropathies evolve symmetrically, initially with a sensory disturbance in the feet which "ascends" to the knees, prior to involving the fingertips, forearms, anterior chest wall, and vertex. This is referred to as a length-dependent or "dying-back" neuropathy. Patients with symmetrical polyneuropathies may recall that sensory symptoms in one foot briefly preceded onset of identical symptoms on the other side, with subsequent symmetrical progression. This history should not dissuade the clinician from designating the neuropathy as symmetric [3]. Some symmetrical polyneuropathies are not length dependent. Patients with Guillain–Barre syndrome (GBS), chronic inflammatory demyelinating polyneuropathy (CIDP) [4–6], or porphyric neuropathy, for example, may have proximally accentuated weakness.

Neuropathy that begins in one leg or in the hands, for instance, usually indicates an asymmetric disorder. The history is vital in making this distinction since cumulative multifocal deficits may become confluent over time and appear on physical examination to be symmetrically or diffusely

Table 24.3a Differential diagnosis of neuropathy based on clinical and electrophysiologic classification: axonal and symmetric

Sensorimotor, axonal	**Predominantly motor axonal**
Acute	Acute
AMSAN syndrome	AMAN syndrome
Vasculitis	Porphyria
Alcohol/nutritional/toxic	Dapsone toxicity
Arsenic toxicity (rarely demyelinating)	Vincristine toxicity
Subacute/chronic	Critical illness polyneuropathy
Vitamin B12, B1 deficiency	Acute alcohol-related neuropathy
Gastric surgery	Subacute/chronic
Celiac sprue, Whipple's disease	Subacute motor neuronopathy (paraneoplastic)
Alcohol toxicity	CMTX, CMT2
Arsenic, thallium toxicity	Lead poisoning
N-Hexane toxicity	Vincristine
Acylamide,CS2 toxicity	Hypoglycemia (insulinoma)
Organophosphate toxicity	**Sensory only, axonal**
Ethylene oxide toxicity	Acute
Colchicine, chloroquine toxicity	Idiopathic sensory neuronopathy (onset often focal)
Disulfiram toxicity	Paraneoplastic
Metronidazole toxicity	Acute pyridoxine toxicity
Nitrofurantoin toxicity	Cis-platinum Paclitaxel
Phenytoin toxicity	Miller Fisher syndrome (often demyelinating)
HIV DSP	HIV infection
Lyme disease	Subacute/chronic
HTLV1	Paraneoplastic (Anti HU+ or Anti HU−) (onset may be asymmetric)
Paraneoplasia (solid organ tumors)	Paraprotein-associated Sjogren's syndrome (may be asymmetric)
MGUS-associated (IgA/IgG)	Mitochondrial cytopathy Thalidomide toxicity
Multiple myeloma	Dideoxycytidine toxicity
Amyloidosis	Didanosine toxicity
Diabetes	Pyridoxine toxicity
Hypothyroidism	Chronic inflammatory sensory neuropathy
Acromegaly	Primary biliary cirrhosis
COPD	Vitamin E deficiency
CTD (SLE, Sjogren's, MCTD)	Friedreich's ataxia
PNS vasculitis	Hereditary sensory neuropathy (type 1)
Sarcoidosis	
Benign, elderly

AIDP acute inflammatory demyelinating polyneuropathy, *GVHD* graft versus host disease

distributed when in fact they accrued asymmetrically. Nonetheless, clinical examination may be helpful in confirming inter or intra limb asymmetries in the degree of nerve involvement.

The syndrome of mononeuropathy multiplex is important to recognize as it has a limited differential diagnosis which includes several treatable forms of neuropathy [e.g., vasculitic neuropathy, leprosy, CIDP variants, and multifocal motor neuropathy with conduction block (MMN)] [7] (Tables 24.3a, 24.3b, and 24.3c).

Multifocal neuropathies may have characteristic distributions. The neuropathy of lepromatous leprosy, for example, has a temperature-dependent distribution affecting superficial, often unnamed, nerves from the coldest regions of the body (preferentially the earlobes, the nose, and the dorsal extremities) [8].

Nerve conduction testing and needle electromyography (EMG) can be used to confirm the spatial distribution of neuropathy and may identify asymmetry (particularly in sensory nerves) that is not apparent on clinical grounds, thus suggesting the presence of mononeuropathy multiplex.

Table 24.3c Differential diagnosis of neuropathy based on clinical and electrophysiologic classification: clinically asymmetric

Sensorimotor axonal	Demyelinating mixed motor and sensory
Acute	Acute
Vasculitis	AIDP (rarely asymmetrical)
Endocarditis	Subacute/chronic
Perineuritis	MADSAM
Lyme disease	Focal upper limb CIDP
Subacute/chronic	HNPP
Vasculitis, isolated PNS	Leprosy
Vasculitis, systemic	**Demyelinating, motor only**
vasculitis with connective tissue disease	Subacute/chronic
Vasculitis, paraneoplastic (rare)	Multifocal motor neuropathy
Vasculitis with infection (HIV, hepatitis B and C)	
Cryoglobulinemia	
Diabetes mellitus	
Sarcoidosis	
Perineuritis	

MADSAM multifocal acquired demyelinating sensory and motor neuropathy, *CIDP* chronic inflammatory demyelinating polyneuropathy, *HNPP* hereditary neuropathy with liability to pressure palsies

What Is the Pattern of Nerve Fiber Type Involvement?

The signs and symptoms of a peripheral neuropathy are determined by which fiber types (sensory, motor, and autonomic) are affected. A sensory greater than motor neuropathy is the commonest pattern; however, motor dysfunction may predominate (e.g., CIDP, GBS, Charcot–Marie–Tooth disease (CMT)). Pure sensory syndromes suggest a dorsal root ganglionopathy particularly when abnormalities are not length dependent. Similarly pure motor involvement raises the possibility of a motor neuron disorder. Autonomic dysfunction may go unrecognized when mild. Autonomic dysfunction can be seen in conjunction with sensory and motor involvement (e.g., diabetes mellitus) or may be the dominant feature (e.g., acute pandysautonomia). The pattern of nerve fiber involvement should also be considered from the point of view of whether large– or small-caliber nerve fibers are involved. From a practical standpoint, large-caliber nerve fibers include motor fibers and type A-α and A-β sensory afferents that subserve tendon reflexes, position, and vibration sense, while small-caliber A-δ and C fibers subserve autonomic function and mediate pain and temperature sensation [9]. Mixed large and small fiber neuropathies with sensory and motor involvement are the rule; however, at the onset, the only symptom of polyneuropathy may be positive sensory phenomena (pain, falling asleep sensation, pins and needles, prickling). Significant motor and autonomic fiber involvement may occur over time.

Table 24.4 Predominantly small fiber neuropathies

Acute	Chronic
Diabetes mellitus (e.g., insulin initiation)	Diabetes
Idiopathic small fiber sensory neuropathy	Marked hypertriglyceridemia
Acute pandysautonomia	
Dimethylaminopropionitrile toxicity	Sjögren's syndrome
	Primary amyloidosis
	Familial amyloidosis
	Fabry's disease
	Tangier's disease
	Hereditary sensory and autonomic neuropathies: (type I (some), III, IV, V)
	Chronic idiopathic small fiber sensory neuropathy

Preferential involvement of small-caliber nerve fibers on the other hand is only seen in a few conditions (Table 24.4). While the occurrence of neuropathic pain (burning, aching, stabbing, contact hyperalgesia) suggests involvement of sensory fibers, its presence is not specific for any pattern (small, large, or mixed caliber) of sensory fiber involvement [10]. Small fiber neuropathies, however, present with neuropathic pain and allodynia as the dominant feature or as dysautonomia or a combination of neuropathic pain and dysautonomia. Examination findings are often limited to contact hyperalgesia and a mild distal disturbance in sharp–dull discrimination with normal deep tendon reflexes (e.g., chronic distal idiopathic small fiber sensory neuropathy (ISFSN) or small fiber diabetic neuropathy). Bedside evaluation of the autonomic nervous system is usually limited to assessments of orthostatic hypotension, pupillary responses, and sudomotor abnormalities (e.g., anhidrotic skin).

By contrast, large fiber dysfunction is suggested by the finding of a lower motor neuron pattern of weakness, loss of deep tendon reflexes, impaired proprioception, an abnormal Romberg test, and impairments of gait and balance ("ataxic neuropathy"). Predominantly large fiber neuropathies suggest a differential diagnosis that includes dorsal root ganglionopathies (idiopathic, Sjogren's syndrome, paraneoplastic, or toxic), vitamin B12 deficiency, and predominantly sensory ataxic variants of CIDP and IgM MGUS-related neuropathies [11, 12] (Tables 24.3a, 24.3b, and 24.3c).

The pattern of nerve fiber involvement should be confirmed with ancillary testing. Standard nerve conduction studies and needle EMG are sensitive to large fiber sensory and motor dysfunction. Electrodiagnostic (EDX) testing may demonstrate both motor and sensory involvement, when the pattern appears to be one of a purely sensory or motor neuropathy clinically. Conversely it is diagnostically important to verify the pure sensory or motor nature of a disorder, when a neuronopathy (e.g., motor neuron disease or paraneoplastic sensory neuronopathy) is suspected.

Routine EDX studies are insensitive in the evaluation of small fiber sensory neuropathies. If cardiac dysautonomia is suggested clinically, this should be quantified with baroreceptor reflex testing (blood pressure response to the Valsalva maneuver), cardiovagal testing (heart rate variability with respiration), and heart rate and blood pressure responses to upright posture (tilt table evaluation) [13]. Commonly, as in chronic ISFSN ("burning feet syndrome"), cardiac autonomic dysfunction is not prominent, and such studies are less helpful. Rather, skin biopsy with quantitation of epidermal nerve fiber density, quantitative sudomotor axon reflex testing (QSART), and quantitative sensory testing (QST) are more sensitive [14–18].

What Is the Temporal Profile of the Disorder?

The temporal evolution of the neuropathy is diagnostically helpful and also directs the acuity of investigations and management. The history is most important in characterizing the tempo of the neuropathy, although the physical and electrophysiologic examinations do give some information about disease chronicity. The clinician should define the time from onset to nadir or from onset to the current state if the nadir has not been reached as being acute (days to weeks), subacute (6 weeks to 6 months), or chronic (6 months to years). The course should also be described as being (1) monophasic, (2) progressive (uniform or stepwise), or (3) relapsing, remitting. Acute sensorimotor neuropathy with a time to nadir of less than 6 weeks is caused by a limited number of disorders (Tables 24.3a and 24.3b). This temporal course is most commonly due to GBS; other considerations include porphyric neuropathy, rapidly progressive vasculitic neuropathies, some acute toxic neuropathies (e.g., large ingestion of thallium or arsenic), and critical illness polyneuropathy (CIP). Severe, subacute progressive or stepwise sensorimotor polyneuropathy with a time to nadir of 2–6 months has a broader differential diagnosis. The main treatable neuropathies in this category are CIDP, vasculitic neuropathy, and less commonly vitamin deficiencies (vitamins B1 and B12) and metabolic disturbances (e.g., hypothyroidism and renal failure) (Tables 24.3a, 24.3b, and 24.3c).

Chronic polyneuropathies may be either on an acquired or hereditary basis; however, very slow progression that occurs over decades strongly suggests an inherited disorder.

Is the Neuropathy Primarily Axonal or Demyelinating?

In reality, many neuropathies have overlapping pathological features; however, it is almost always possible to define the predominant pathophysiologic mechanism.

The causes of axonal neuropathies are abundant, while demyelinating polyneuropathy suggests just a few etiologies. Neuropathies should be characterized as being either primarily axonal or demyelinating and if demyelinating as either segmental (multifocal) or uniformly so. Multifocal or segmental demyelination is usually acquired, while uniform demyelination is typically on a hereditary basis [19]. An exception to this is hereditary predisposition to pressure palsies (HNNP), where nerve conduction studies show a nonuniform pattern of multifocal, distally predominant slowing of conduction velocities and conduction block at entrapment sites.

A limitation of the clinical examination is its inability to discriminate with any degree of certainty whether a neuropathy is primarily axonal or demyelinating. Weakness and loss of deep tendon reflexes out of proportion to muscle atrophy as well as palpably enlarged nerves suggest a demyelinating neuropathy, while prominent muscle atrophy along with weakness, fasciculations, and a distally dominant pattern suggests axonal loss.

Nerve conduction studies and needle EMG are required to clarify the pathophysiology in most instances. Exceptions include patients with typical presentations of diabetic neuropathy, HIV distal symmetrical polyneuropathy, and alcohol-related polyneuropathies where EDX studies may not be necessary [20].

Although pathophysiology is inferred rather than directly assessed with nerve conduction studies and needle EMG, the correlation with sural nerve biopsy is reasonably good, and currently employed electrophysiologic criteria for demyelination have good specificity but limited sensitivity [21, 22]. EDX studies evaluate the peripheral nervous system broadly at proximal and distal sites, which is important as sural nerve biopsy demonstrates only distal pathology. Sural biopsy commonly shows only axonal changes in patients with CIDP, for instance; more proximal nerve segments showing demyelination are not sampled.

Family History

Hereditary neuropathies account for about 40 % of patients with undiagnosed neuropathies who are intensively evaluated in a specialized setting [1]. The underrecognition of hereditary neuropathies can be attributed to several factors including a failure to elicit an adequate family history, the occurrence of de novo mutations (e.g., peripheral myelin protein-22 (PMP-22) gene duplication) as well as recessive and x-linked inheritance patterns, and the fact that the neuropathy may remain asymptomatic for decades. Such patients typically have signs of neuropathy on examination but are unaware of their neuropathy (or those of family members) because of its slow progression. Three features allow one to distinguish inherited from acquired cases in most instances. First, long-standing inherited neuropathies may produce characteristic deformities of the foot

(pes cavus) and of the spine (kyphoscoliosis). Second, in comparison to most acquired neuropathies, typical hereditary motor sensory neuropathy has little in the way of positive sensory symptoms. Third, clinical and EDX examination (nerve conduction studies) of family members even when asymptomatic may reveal polyneuropathy. Genetic tests are available for most demyelinating hereditary neuropathies (the most common types being Charcot–Marie–Tooth type 1A (CMTIA), CMT1B, CMTX, HNPP, and CMT4C) and approximately 30 % of axonal form of Charcot–Marie–Tooth disease [23, 24]. Genetic testing should be focused and guided by the clinical and electrophysiologic findings and inheritance pattern of the neuropathy (autosomal dominant, recessive, or X-linked) [23, 24]. Such testing can also be helpful to confirm a hereditary neuropathy among patients with an inherited neuropathy phenotype when a family history is lacking or when one is unable to examine family members, for atypical presentations raising the question of a treatable neuropathy such as CIDP and genetic counseling [23, 24].

Medical Comorbidity, Medications, and Toxins

Once the peripheral nerve disorder has been characterized as above, the clinician considers whether any medical disorder suggested by the review of systems and general examination accounts for the neurological picture. The review of systems should include inquiry about diabetes mellitus, connective tissue disease, underlying malignancy, infection, malnutrition, megavitaminosis (pyridoxine), and exposure to drugs, alcohol, or toxins at the workplace. Clues to a systemic disorder or toxic exposure associated with neuropathy are summarized in Table 24.5. The use of over-the-counter preparations (e.g., pyridoxine) is not often reported by patients unless specifically inquired about. Possible toxic exposures should coincide with the onset of the neuropathic symptoms. A peripheral neuropathy with a remote onset from the reported exposure or that progresses well years after termination of exposure is likely unrelated.

Putting It All Together

At this point, having characterized the neuropathy, one of three scenarios may exist: First, in a proportion of cases, a tentative etiologic diagnosis can been made (e.g., diabetic sensory polyneuropathy, GBS). Second, a number of clues from the medical and family history may direct specific investigations. Third, there may be no specific findings to direct further work-up. This latter scenario is common in the setting of chronic sensorimotor axonal polyneuropathies. Here laboratory testing is performed based on knowledge of

Table 24.5 Clues to a neuropathy associated with a systemic disorder or toxin exposure

Skin and appendages
Hyperpigmentation – POEMS syndrome, adrenomyeloneuropathy
Hypopigmentation – POEMS syndrome, leprosy
Vitiligo – vitamin B12 deficiency
Ichthyosis – Refsum's disease
Photosensitivity – SLE, porphyria
Angiokeratoma – Fabry's disease
Dupuytren's contracture – alcoholic liver disease, diabetes mellitus
Mees' lines – arsenic, thallium
Hair loss – thallium, hypothyroidism, SLE
Cheilosis/glossitis – vitamin B1–3, B6, B12, and folate deficiency
Macroglossia – amyloidosis
Erythema migrans – Lyme disease-associated peripheral neuropathy
Erythema nodosum – leprosy, sarcoidosis, inflammatory bowel disease
Purpura – vasculitis, cryoglobulinemia, amyloidosis
Pruritis – primary biliary cirrhosis
Hypertrichosis – POEMS syndrome
Renal
Fabry's disease
Systemic vasculitis
HIV infection
Diabetes mellitus
Connective tissue disorders
Gastrointestinal
Acute abdomen – porphyria, lead poisoning
Chronic diarrhea – malabsorption neuropathies, Whipple's disease, celiac disease
Rheumatologic
Raynaud's syndrome – cryoglobulinemia, connective tissue disease
Arthritis – Lyme neuropathy, SLE, rheumatoid arthritis, Sjogren's syndrome
Lymphoreticular
Lymphadenopathy – POEMS syndrome, Castleman syndrome, Waldenstrom's macroglobulinemia, lymphoma, HIV infection, paraneoplasia
Hepatosplenomegaly – POEMS syndrome, amyloidosis, plasma-cell dyscrasia
Orange tonsils – Tangier's disease
Pulmonary
Asthma – Churg–Strauss syndrome
Ophthalmologic
Cataracts – diabetes, Cockayne syndrome, myotonic dystrophy
Corneal Clouding – Fabry's disease
Retinitis pigmentosa – Refsum's disease, Cockayne syndrome, Bassen–Kornzweig disease
Microaneurysms – diabetes mellitus
"Beaded retinal vasculature" – vasculitis
Xerophthalmia – Sjogren's syndrome, sicca syndrome, sarcoidosis
Optic disc edema – POEMS syndrome, CIDP, AIDP
Auditory
Hearing loss – Refsum's disease, Cockayne syndrome, mitochondrial disorders, vasculitis

Table 24.6a Laboratory evaluation of undiagnosed neuropathies (axonal)*

Sensorimotor, axonal polyneuropathy	**Predominantly motor axonal**
Acute	Acute
Occasionally helpful	Essential
Lumbar puncture	Lumbar puncture (cytoalbuminemic dissociation)
24-h urine for heavy metals (arsenic, thallium)	Occasionally helpful
Urine/fecal porphyrins	Urine/stool for porphyrins
Red cell transketolase activity (thiamine deficiency)	Urine for toxins (e.g., acute arsenic intoxication)
Lyme serology (endemic areas)	Subacute/chronic
Subacute/chronic	Essential
Essential	SIEP/IFIX
Fasting glucose, HgA1c	Occasionally helpful
SIEP/IFIX	*GM1* ganglioside antibodies
HIV serology (if risk factors present)	Genetic testing (e.g., axonal CMT/distal hereditary motor neuropathy, if hereditary neuropathy phenotype)
Vitamin B12 level	Androgen receptor gene mutations (Kennedy's syndrome) SMN gene mutations (spinal muscular atrophy)
Occasionally helpful Oral glucose tolerance test	**Sensory only, axonal**
MMA levels	Acute
Thyroid function tests	Essential
Serum triglycerides, HDL (if pain is prominent)	ANA, anti Ro, anti La
ANA, anti Ro, anti La	Screening for occult malignancy
Genetic testing (axonal CMT if hereditary neuropathy phenotype)	Paraneoplastic antibodies
Rarely helpful	HIV serology (if risk factors present)
Peripheral nerve antibodies (e.g., antisulfatide antibodies)	Occasionally helpful
Predominantly small fiber neuropathy	GQ1B antibodies
Acute	Salivary gland biopsy (in some instances)
Essential	Subacute/chronic
Fasting blood glucose/HaA1c	Essential
Subacute/chronic	ANA, anti Ro, anti La Salivary gland biopsy (in some instances)
Essential	Screening for occult malignancy Paraneoplastic antibodies
Fasting blood glucose/HaA1c	HIV serology (if risk factors present)
Fasting triglycerides	Vitamin B12/
ANA, anti Ro, anti La	
Occasionally helpful Oral glucose tolerance test	Thyroid function studies
SIEP/IFIX (primary amyloidosis)	Occasionally helpful
Transthyretin mutations (familial amyloidosis)	Oral glucose tolerance test
Cholesterol, HDL (Tangier's disease)	Vitamin E levels
Leukocyte alpha-galactosidase (Fabry's disease)	MMA levels

*Laboratory testing should be selective and based on the clinical and electrophysiologic context

the differential diagnoses associated with the particular neuropathy syndrome (Tables 24.6a and 24.6b).

Role of Laboratory Testing

Laboratory studies may be helpful in documenting the presence of a systemic disease associated with neuropathy. In general, when the history and physical examination do not provide a clue to the presence of these diseases, the screening tests designed to detect their presence are usually negative. Most patients with peripheral neuropathy, whether acute or chronic, should have a complete blood count, serum electrolytes, renal and liver function studies, a serum B12 level, and screening for diabetes mellitus (fasting blood glucose (FBG) and HgA1c). A 75-g oral glucose tolerance test should be considered as an additional screening study for occult diabetes mellitus, in the setting of predominantly sensory or small fiber neuropathies, when a FBG and HgA1c are normal. Patients with chronic sensorimotor polyneuropathies should also be screened for paraproteinemia with serum immunofixation and immunoelectrophoresis as standard serum protein electrophoresis may not identify clinically important yet small monoclonal spikes.

Use of batteries of laboratory tests and "antibody panels" without regard for the characteristics of the neuropathy is discouraged and not cost-effective. The sensitivity, specificity, and impact upon care of a number of

Table 24.6b Laboratory evaluation of undiagnosed neuropathies (demyelinating)*

Demyelinating polyneuropathy (multifocal)	**Sensory and motor polyneuropathy with indeterminate electrophysiology**
Acute	Acute
Essential studies	Essential studies
Lumbar puncture (cytoalbuminemic dissociation)	Lumbar puncture (cytoalbuminemic dissociation)
HIV serology (if pleocytosis or risk factors)	Subacute/chronic
Lyme serology (if pleocytosis or risk factors)	Essential
Occasionally helpful	Fasting blood glucose/HgA1c
Urine for arsenic and porphyrins	Occasionally helpful
Viral hepatitis panel (B and C)	Lumbar puncture (cytoalbuminemic dissociation with CSF protein >150 mg/dl favors CIDP)
ANA, anti-dsDNA	**Demyelinating polyneuropathy (uniform)**
Subacute/chronic	Occasionally helpful
Essential	CMT1A, CMT1B, CMTX, CMT4C DNA studies
Lumbar puncture for cytoalbuminemic dissociation (CIDP)	Rarely helpful
HIV serology (if pleocytosis or risk factors)	(depends on clinical setting)
Lyme serology (if pleocytosis or risk factors)	Serum phytanic acid
Fasting blood glucose, HgA1c	Leukocyte arylsulfatase A
SIEP/IFIX/urine Bence-Jones protein	B-galactosidase, sphingomyelinase
Skeletal survey (if paraprotein present)	
Occasionally helpful	
CMT1B, CMTX DNA studies (if distinction between CMT and CIDP unclear)	
HNPP DNA studies	
GM1 ganglioside antibodies (if purely motor)	
MAG antibodies (if distal and predominantly sensory)	

SIEP/IFIX serum immunoelectrophoresis and immunofixation, *HgAlc* hemoglobin Alc, *ANA* antinuclear antibodies, *SMN* survival motor neuron, *MAG* myelin-associated glycoprotein, *MMA* methylmalonic acid, *CIDP* chronic inflammatory demyelinating polyneuropathy, *HNPP* hereditary neuropathy with predisposition to pressure palsies
*Laboratory testing should be selective and based on the clinical and electrophysiologic context

commercially available peripheral nerve antibody assays (e.g., antisulfatide antibodies in undiagnosed sensory neuropathies) are uncertain [18, 20, 25]. When no clinical clues to the etiology of a neuropathy are found, selective use of laboratory tests based on the neuropathy syndrome is preferred (see Tables 24.6a and 24.6b).

Role of Nerve and Skin Biopsy

Tissue biopsy is only required in a minority of patients with peripheral neuropathy [26–28]. Studies have indicated that sural *nerve biopsy* yields a diagnosis in about 27 % of cases and provides useful information in a further 37 % of instances [21, 26]. The nerves biopsied include the sural (most frequently), superficial peroneal, and radial sensory nerves (see Chap. 12). Selection of a moderately involved nerve (based on sensory nerve conduction studies) is preferable.

The primary indication for cutaneous nerve biopsy is to identify potentially treatable causes of neuropathy in undiagnosed progressive acute or subacute asymmetric and less commonly symmetrical sensorimotor polyneuropathies. In practice, this is usually to confirm a suspected diagnosis of peripheral nervous system vasculitis prior to initiation of therapy. Performance of a simultaneous muscle and nerve biopsy is advocated in the evaluation of PNS vasculitis and increases sensitivity by at least 25 % [27]. Nerve biopsy in this setting less commonly identifies carcinomatous or lymphomatous infiltration or granulomatous disease (e.g., sarcoidosis). A pattern of focal perineurial inflammation (perineuritis) may also be seen in this group of patients and, while often idiopathic, may be associated with underlying sarcoidosis, cryoglobulinemia, or occult malignancy.

Nerve biopsy may also be used to confirm a diagnosis of leprosy, if skin biopsy is not diagnostic. Nerve biopsy can be helpful in identifying amyloidosis (acquired or familial); however, skin and abdominal fat pad sampling is less invasive and can be biopsied initially. Nerve biopsy will occasionally reveal evidence of a demyelinating polyneuropathy (CIDP), in patients with indeterminate progressive sensorimotor polyneuropathies that do not meet electrodiagnostic criteria for acquired demyelination. A biopsy may also be of value in distinguishing hereditary from acquired demyelinating neuropathies, when the clinical, electrophysiologic, and genetic evaluation is inconclusive.

Assessment of epidermal innervation with *punch skin biopsy* using immunohistochemical techniques (antibodies to the axonal marker, protein gene product 9.5) is helpful in

documenting the presence of small fiber neuropathy in patients with burning feet syndrome, when nerve conduction studies are normal or equivocal (see Chap. 13). This method may have greater sensitivity than sural nerve biopsy and is minimally invasive but does not offer an etiological diagnosis [17, 18, 28, 29]. However, cutaneous nerve biopsies are of low diagnostic yield and questionable value in patients with indolent chronic sensorimotor or predominantly sensory axonal polyneuropathies [3].

Pitfalls in the Evaluation of Peripheral Neuropathy

Errors in the diagnosis of neuropathy are common if the approach is not systematic or if electrodiagnostic studies are of poor quality and performed without consideration of the clinical picture.

"False-Positive" Diagnosis of Peripheral Neuropathy: Lumbosacral Polyradiculopathy

Lumbosacral polyradiculopathy from spinal stenosis may be difficult to distinguish from polyneuropathy. Distal sensory loss, weakness, and ankle areflexia may be seen in both instances. The two disorders can be distinguished by the presence of pseudo-claudication or radicular back pain in spinal stenosis and distal "burning" pain in neuropathy [30]. Electrophysiologically, the finding of normal sensory nerve action potentials with needle EMG abnormalities in proximal leg and paraspinal muscles in lumbosacral polyradiculopathy contrasts with the low-amplitude sensory nerve action potentials and upper extremity abnormalities seen in polyneuropathies.

Not All Distal Weakness Is Due to Peripheral Neuropathy

Distal muscle wasting and weakness are seen in rare cases of distal myopathy (e.g., inclusion body myopathy, Welander syndrome) or spinal muscular atrophy [30].

Amyotrophic Lateral Sclerosis (ALS) May Be Misdiagnosed as Peripheral Neuropathy

There are occasional patients with a distal sensory disturbance in the feet who have in addition severe, progressive muscle wasting and weakness. Initially, such patients may be assumed to have a severe, predominantly motor polyneuropathy. Over time, the correct diagnosis of ALS with a coincidental minor sensory neuropathy becomes obvious [30].

Failure to Consider Age

Reduced vibration sense in the feet and ankle areflexia may be seen among the normal elderly population. Similarly lower extremity sensory nerve action potentials and to a lesser extent compound muscle action potentials are of significantly lower amplitudes or absent in patients over the age of 60 as compared to young adults [31]. Peripheral neuropathy may be erroneously diagnosed if the patients' symptoms are not carefully considered and if age-based normal values for nerve conduction studies are not applied.

Distinction Between Acute Central and Peripheral Nervous System Disorders

Acute mononeuropathies of the radial, proximal median, and peroneal nerves may initially be misdiagnosed as a stroke. Careful attention to the distribution of weakness (confined to a single nerve territory) resolves the uncertainty since small cortical infarcts do not usually exactly mimic mononeuropathies.

Erroneous Diagnosis of CIDP

It is not uncommon for the diagnosis of demyelinating neuropathy to be made based on a report of slowed nerve conduction velocities, despite a history and examination which are inconsistent with this electrodiagnosis. The discrepancy is clarified when repeat nerve conduction studies are normal and the patient indicates that the extremities were not warmed during the initial study. Overemphasis on slowing of nerve conduction velocities at common sites of entrapment, misdiagnosis of conduction block due to overstimulation of motor nerves at distal sites, or failure to appreciate the presence of normal anatomical variants (Martin–Gruber anastomosis) may erroneously be taken as evidence of a demyelinating neuropathy [32].

The Diagnosis of Peripheral Neuropathy Is Correct but the Cause Is Falsely Attributed

If a risk factor for peripheral neuropathy exists (e.g., diabetes mellitus), an association is often presumed. In general, this assumption will be correct. However, errors arise when care is not taken to ensure that the clinical and EDX features are consistent with this assumption. An example of this is the diabetic patient who presents with painless acute or subacute weakness on a background of chronic distal sensory findings. In this instance, EDX studies may show a chronic polyneuropathy with demyelinating features. While

Table 24.7 Neuropathies for which there is disease-modifying therapy

GBS/variants	GBS/variants	CIDP
HIV-associated GBS	HIV-associated GBS	Systemic vasculitis
CIDP	CIDP	MADSAM syndrome
MGUS neuropathy (some IGA/IGG)	MMN	Isolated PNS vasculitis
Refsum's disease	MGUS neuropathy	Sarcoidosis
	MADSAM syndrome	PNS vasculitis (CTD-associated)
Cytotoxics (e.g., cyclophosphamide)	**Endocrine treatment**	**Vitamin replacement**
Isolated PNS vasculitis	Hypothyroid neuropathy	B1
Systemic vasculitis	Acute diabetic small fiber neuropathy	B12
MMN	Acromegaly	E
CIDP		Copper
Rituximab	**Antimicrobials**	**Radiation/surgery**
Anti-MAG neuropathy?	Lyme disease	Osteosclerotic myeloma
IgM-associated demyelinating neuropathies?	Leprosy HIV DSP?	POEMS syndrome
	CMV	**Liver Transplantation**
		Familial amyloidosis

the EDX studies may be consistent with the patients known diabetic neuropathy, the prominent subacute painless weakness is atypical and suggests the possibility of superimposed CIDP.

False-Negative Diagnosis of Peripheral Neuropathy

This occurs most frequently in the setting of very mild sensory polyneuropathies or predominantly small fiber painful sensory neuropathies, as on examination findings are often minimal and routine nerve conduction studies normal or equivocal.

Approaches to the Management and Follow-Up of Patients with Peripheral Neuropathy

Therapeutic approaches consist of those that alter the natural history of the disease (Table 24.7) versus symptomatic pharmacotherapies and rehabilitative strategies to limit disability. The specific management approaches and algorithms for individual subtypes of neuropathy are described in subsequent chapters. Disease-modifying agents are variable in their degree of efficacy, cost, and side-effect profile. In only a few instances have therapies been subjected to prospective and randomized evaluation. These factors bear heavily on the decision to initiate or continue therapy. Multifocal motor neuropathy and peripheral nervous system vasculitis are cases in point. While intravenous immunoglobulin and cyclophosphamide in the case of multifocal motor neuropathy and corticosteroids and cyclophosphamide for PNS vasculitis have demonstrated efficacy, the optimal regimens and duration of therapy are less certain. In multifocal motor neuropathy, some patients may require periodic intravenous immunoglobulin indefinitely in order to avoid relapse. The modest efficacy of immunotherapy in some disorders is reflected in stabilization or slowing of progression over a period of years. The conventional period of follow-up over 1 to several months in order to guide management decisions may be too short to appreciate only slowing of progression, and therefore, serial follow-up over a longer period of time is often required.

The optimal outcome measures to assess progress or response to therapy are uncertain. Traditional approaches in the clinic rely on a combination of the patient's report of their progress, assessment of symptoms, and serial assessment of the degree of neurological impairment (neurological examination and a grading scale of strength). Nerve conduction studies and electromyography are commonly used as a marker to judge response to therapy. This approach has significant limitations. Neurological symptom scores (e.g., the neuropathy symptom score (NSS)) are weak indicators of severity and progression in, for instance, diabetic neuropathy [33, 34]. The Medical Research Council (MRC) grading scale for strength has good inter-rater reliability in a clinical trial setting but is nonlinear with the upper 50 % of strength represented by grades 4–5. It performs less well in assessing mild degrees of weakness and detecting mild changes in strength from one office visit to the next. Neurological impairment scores such as the MRC scale and the neurological disability scale correlate weakly with functional outcome measures such as the Rankin scale [34]. Nerve conduction studies often do not correlate well with clinical improvement, at least in part, because they assess a limited number of distal nerve segments that may or may not correspond to clinical symptoms and signs.

The clinician is best served by combining a focused and serial neurological examination of selected muscle or nerve distributions, with inquiry about a defined but individualized set of activities of daily living at each visit and serial functional assessments. In terms of the latter, we find it helpful to identify one or more simple bedside measurements or activities (e.g., grip dynamometry, arising from a chair, heel walking, Rombergism) that can be followed in the clinic.

Approach to Small Fiber Neuropathy

25

Giuseppe Lauria, Ingemar S.J. Merkies,
Stephen G. Waxman, and Catharina G. Faber

Introduction

The term "small fiber neuropathy" (SFN) commonly refers to a condition characterized by damage of small-caliber nerve fibers (thinly myelinated Aδ and unmyelinated C) with somatic functions, namely, peripheral axons carrying thermal and nociceptive sensation, and with autonomic functions. When there is an isolated or predominant impairment of the subgroup of these small fibers with autonomic function, the term "autonomic neuropathy" is used. In addition to symptoms and signs reflecting peripheral deafferentation (e.g., thermal and pinprick hypoesthesia), SFN includes neuropathic pain symptoms and signs (e.g., burning pain, allodynia, hyperalgesia) which often dominate the clinical picture and have contributed to inclusion of SFN within the more general class of painful neuropathies. Autonomic disturbances can occur but are usually limited and often underdiagnosed. In patients with pure SFN, clinical and neurophysiologic investigations do not show involvement of large myelinated nerve fiber, thus making the diagnosis of SFN challenging in clinical practice. However, patients complaining of symptoms suggesting SFN must be diagnosed for at least three main reasons. First, the definition of the diagnosis can lead to a focused screening of potential etiologies. Second, early disease-modifying or symptomatic treatments can be initiated. Third, awareness of the disease can increase patients' compliance, which is particularly important in the treatment of neuropathic pain.

Over the last 15 years, SFN has been the subject of intensive investigations prompted by the availability of skin biopsy, a novel tool that readily permits morphometric and qualitative evaluation of somatic unmyelinated C fibers innervating the epidermis. Skin biopsy has overcome the limitations of routine neurophysiologic tests to detect the damage of small nerve fibers. This approach has extended to the study of autonomic neuropathies and, through the analysis of dermal myelinated nerve fibers, of inherited and immune-mediated neuropathies.

Small Nerve Fibers

Thermosensory and Nociceptive Functions

Small-caliber nerve fibers encompass several functions which underlie both our ability to distinguish among different non-noxious and noxious thermal stimuli and the multiplicity and variability of symptoms in SFN. Aδ and C fibers include multiple groups of thermosensitive skin afferents, most of which have distinct response functions enabling them to encode the stimulus intensity. The identification of dedicated afferents to the transduction of warmth and cold sensation provides a basis for their classification as "cold" and "warm" fibers [1]. Moreover, skin nerve endings and resident cells express several members of the transient receptor potential (TRP) ion channel family, which operate over specific temperature ranges, providing a molecular basis for thermosensation [2, 3]. Based on their activity which depends

B. Katirji et al. (eds.), *Neuromuscular Disorders in Clinical Practice*,
DOI 10.1007/978-1-4614-6567-6_25, © Springer Science+Business Media New York 2014

on the temperature of their environment, human TRP have been grouped into six families, three of which (vanilloid channels [TRPV], melastatin channels [TRPM], ankyrin transmembrane protein channels [TRPA]) deserve particular interest as thermoreceptors [4].

Aδ fibers have a primary role in conveying cold sensation, as demonstrated by differential nerve block experiments [5]. They are activated by static innocuous cold stimuli in the range between 20 and 30 °C, and by menthol, which induces sensitization and increase of their discharge rate. Microneurographic studies have also identified subclasses of C fibers which respond to cold stimuli [6]. This observation was prompted by the evidence that menthol induces spontaneous burning pain, cold hyperalgesia, and flare reaction during A-fiber block that abolishes cold sensation [7]. This subclass of C fibers, known as "type 2," were found to have a distinct bimodal response to heating and cooling, with discharge rate at skin temperatures down to 0 °C and above 45 °C associated with a "hot burning" quality the perception. It has been suggested that their function is not to detect cold objects but rather to provide information about skin temperature for the purposes of unconscious thermoregulation, for which their high sensitivity would be appropriate. Their primarily role in innocuous cold nociception would provide a warning about potentially dangerous temperatures. Cold hyperalgesia and burning sensation to cold stimuli, in association with cold hypoesthesia, have been described in patients with neuropathy. These phenomena have been attributed to the disinhibition or the sensitization of this class of C fibers [6, 8]. Finally, some large myelinated fibers innervating Merkel and Ruffini pressure mechanoceptors also respond to cold stimuli down to 14.5 °C [9], likely explaining the illusionary perception that an object may appear heavier when it is cold rather than warm. The sensation of cold becomes painful when hairy and glabrous skin is exposed, respectively, to temperatures between 10 and 15 °C and 18 °C. Noxious cold stimuli induce different sensations such as pricking, burning, aching, and heat. Experimental studies demonstrated that both Aδ and C fibers are activated by these stimuli, explaining this pattern of sensation. Indeed, if Aδ fibers are blocked and C fibers remain active, a noxious cold stimulus is perceived as burning or heat. Recent studies showed that the Nav1.8, the sodium channel expressed in dorsal root ganglion (DRG) neurons and small-caliber nerve fibers, plays a critical role in the detection of noxious cold stimuli [10].

Cutaneous warm fibers are activated by static temperatures above 30 °C, with a maximal discharge rate at 40–43 °C. Like cold fibers, they adapt after repetitive stimuli. Differential fiber block studies have demonstrated that warm sensation is conveyed by C fibers [5]. Noxious heat stimuli induce an almost instantaneous sharp and pricking pain followed by a later dull and burning sensation. This phenomenon disappears if the stimulus is applied in the proximal sites of the body and is experienced in the hairy skin only [11]. This dual type of pain indicates that different fibers are activated. Studies with differential blocks have demonstrated that the fast pain is conveyed by Aδ fibers, whereas the long latency pain is mediated by C fibers. Aδ nociceptors involved in heat pain sensation have been classified into two groups. Type I fibers are present in glabrous and hairy skin and respond to short-lasting high temperatures (>53 °C), whereas they show a delayed activation upon long-lasting stimuli (30 s). After a burn injury, these fibers become sensitized to heat stimuli and mediate thermal hyperalgesia [12, 13]. Type II fibers have a lower threshold (47 °C) and are activated by long-lasting stimulation (53 °C for 30 s) with an adaptation during the response. They are not present in the glabrous skin, explaining the lack of first sharp pain after heat stimuli in the palm of the hand. Heat-responsive C fibers are estimated to be located at a depth between 20 and 600 μm in the epidermis and dermis [14]. Their range of activation is between 37 and 49 °C and is similar in glabrous and hairy skin. However, only those innervating the hairy skin sensitize after a burn injury.

Temperature perception depends on the balance between the input from skin thinly myelinated Aδ and unmyelinated C fibers, and the sensory experience is the result of the integration of their activity in the central nervous system. One demonstration came from studies comparing patients with complete or partial damage of non-noxious warm or cold pathways [15]. These experiments showed that when thermal sensations are disrupted, a noxious stimulus elicits a sensation of pricking pain with a higher threshold compared to healthy subjects. Conversely, when one thermal modality is preserved, both noxious and non-noxious stimuli acquire the characteristic of the intact modality, resulting in a paradoxical sensation. Therefore, innocuous cold stimuli are perceived as non-painful warm in the skin areas in which only warm sensation is intact, and vice versa. Moreover, in these areas, noxious cold and heat stimuli induce a sensation of heat pain. Therefore, lesions or diseases throughout these pathways are responsible for some of the neuropathic pain symptoms.

A further important role is that played by voltage-gated ion channels expressed in DRG neurons, sympathetic neurons, and small-caliber axons. Among them, sodium channels merit particular interest due to their critical role in the generation and conduction of action potentials in the nociceptive pathway. Indeed, ectopic spontaneous activity in primary afferent neurons and axons following nerve injury is matched by the increased expression of different sodium channel subunits, contributing to peripheral and central sensitization that reflects in the typical symptoms of neuropathic pain (e.g., burning, paroxysmal, and evoked pain). The Nav1.7, Nav1.8, and Nav1.9 are preferentially expressed within peripheral nervous system neurons and, along with Nav1.6, have been detected in intraepidermal nerve fibers (IENF) of rat paw [16]. Nav1.7, a tetrodotoxin-sensitive

subunit, acts as a threshold channel that amplifies subtle depolarizations such as generator potentials, bringing neurons to voltages that stimulate Nav1.8, a tetrodotoxin-resistant subunit, which contributes most the inward current responsible for the depolarizing phase of action potentials. Thus, Nav1.7 is poised as a molecular gatekeeper of pain detection at peripheral nociceptors [17]. Changes in the functional properties of Nav1.7 due to single amino acid substitutions have been linked to multiple pain syndromes, including inherited erythromelalgia (IEM), paroxysmal extreme pain disorder (PEPD), and, more recently, SFN [17, 18]. Studies in experimental models of neuropathic pain have also shown changes in levels of expression in multiple sodium channel subunits. Nav1.3 channels are overexpressed in nociceptors soon after nerve damage, such as within neuromas, contributing to the typical ectopic discharges [19, 20]. Nav1.8 is first downregulated then upregulated in uninjured adjacent axons hours after the damage, contributing to changes in excitability [21]. Nav1.8 is also essential to the excitability of cold sensing terminal axons, and its overexpression was recently found to be determinant to the cold hypersensitivity induced by oxaliplatin in an animal model, a feature typical of human neuropathy [22]. Nav1.9 channels are preferentially expressed in small-caliber non-peptidergic DRG, trigeminal, and myenteric neurons and have been found in nerve endings of skin and cornea [21]. Its expression is thought to contribute to the functional specialization of peptidergic (IB4+) and non-peptidergic (IB4−) neurons [23], though the role in neuropathic pain remains uncertain at the light of experimental studies showing either upregulation or downregulation in different pain states, and unchanged nociceptive behavior in null mice [24]. IENF express also the isoform type 2 of the sodium-calcium exchanger (NCX2) that under normal conditions contributes to calcium extrusion. Changes in persistent sodium influx following axon damage might reverse the sodium-calcium exchange and induce degeneration [16].

Features of Skin Nerve Fibers

Skin separates internal tissues from the external environment, creating a protective barrier that contributes to maintenance of body homeostasis and immunological defenses and provides a structural substrate for peripheral aspects of the transduction and transmission of sensory stimuli. The epidermis is the topmost living layer and is composed of four different layers of keratinocytes that differentiate as they progress from the basal layer to the stratum corneum, with a turnover of about 30 days. The other resident cells include Langerhans cells, melanocytes, and Merkel cells. The basement membrane (dermal-epidermal junction) separates the epidermis from the subpapillar dermis which is organized in papillae in which vascular plexus and periodic capillary loops reside. In the glabrous skin, the apexes of the papillae contain Meissner's mechanoreceptors. Their density in the fingertip is 33.0 ± 13.2 (standard deviation [SD]) *per* square millimeter [25, 26]. Pacini's and Ruffini's corpuscles reside deeply in the dermis and are commonly excluded from routine skin biopsy examination. The matrix of the superficial dermis also includes fibroblasts, hair follicles, arrector pilorum muscles, blood vessel, and sebaceous and sweat glands.

IENF are the endings of dorsal DRG small-diameter neurons and have exclusive somatic function as demonstrated by the degeneration only after axotomy or DRG destruction, but not after sympathectomy [27]. Intriguingly, IENF lose their Schwann cell ensheathment while crossing the dermal-epidermal junction, similar to large myelinated fibers when reaching the inner core of mechanoreceptors where the sensory stimulus is transduced [28]. No synaptic contact between IENF and epidermal cells has been described, and the presence of naked axons is likely to favor communication through paracrine pathways. IENF widely express TRPV1 [29], a channel crucial for thermal hyperalgesia induced by tissue inflammation [30]. Also keratinocytes and other nonneuronal cells (e.g., vascular smooth muscles, endothelium) express members of the TRP family which participate in the homeostasis of temperature sensations and play a role in the pathogenesis of mechanical hyperalgesia and inflammatory pain [26, 31, 32]. Moreover, keratinocytes secrete chemical substances (e.g., neurotrophins, ATP, β-endorphin, interleukins) which may influence DRG neuron excitability. Is has been also shown that mechanical stimulation of keratinocytes can affect DRG neurons through ATP and purinergic receptor signalling. On the other hand, peptidergic nerves (i.e., expressing CGPR and SP) influence keratinocyte maturation and the ability of Langerhans cells to present antigens to lymphocytes [33, 34]. Therefore, one current view is to consider the whole skin, and in particular the epidermis, as a huge polymodal receptor which functions are based on the relationship between resident cells and nerves [35].

Small Fiber Neuropathy

Definition

The criteria to diagnose SFN have been based for more than a decade on the different methods used to assess the selective damage of small fibers, including clinical examination, routine and nonconventional neurophysiological studies such as the cutaneous silent period examination [36], laser-evoked potentials (LEPs) [37], contact heat-evoked potentials (CHEPs) [38], quantitative sensory testing (QST) of thermal and pain thresholds [39], and morphometric assessment of IENF using skin biopsy [40]. This led to a nonhomogenous approach to the

diagnosis in clinical practice and research. Most recently, the NEURODIAB expert panel [41] has proposed a graded definition of SFN as follows: (1) *possible* – presence of length-dependent symptoms and/or clinical signs of small fiber damage; (2) *probable* – presence of length-dependent symptoms, clinical signs of small fiber damage, and normal sural nerve conduction study; and (3) *definite* – presence of length-dependent symptoms, clinical signs of small fiber damage, normal sural nerve conduction study, and altered IENF density at the ankle and/or abnormal QST thermal thresholds at the foot.

Epidemiology

There are no focused studies that provide definite epidemiological data on SFN. Before the availability of the current tools, the diagnostic criteria were not narrow enough to permit a retrospective analysis. On the other hand, the prevalence of SFN in more recent case series of sensory neuropathies is biased by the selection criteria of patients. Therefore, although supposed to be common, especially among patients with diabetes or metabolic syndrome and connective tissue diseases, the precise frequency of SFN is not known.

Symptom Presentation and Clinical Examination

SFN has been considered prototypical of painful neuropathy. This is not completely correct because mixed (large and small fiber) and even predominantly large fiber neuropathies can also present with severe neuropathic pain symptoms, at least over some periods of their course. However, the most common complaint of SFN is that of burning feet, although patients can show dysautonomic disturbances (e.g., abnormal sweating of leg and/or feet, xerostomia and/or xerophthalmia, dizziness, genitourinary disturbances), and about 15 % of them have calf cramps [42].

The quality of neuropathic pain can differ in different patients, though about 60 % of patients describe it as spontaneous, such as burning or like a sunburn, paroxysmal, pruritic, or deep. It is frequently worse at rest, particularly at night, interfering with sleep. Evoked pain more commonly presents with thermal (cold or warm) allodynia or dynamic mechanic (i.e., tactile) allodynia. Patients may complain that the feet are cold although they are warm at touch or feel as if their feet and legs are constricted, like in a skin that is too tight. Allodynia may make bedsheets intolerable or induce pain while wearing certain footwear or walking. Symptoms of restless legs syndrome can also coexist.

Neurological examination focused to feet and soles can detect thermal and/or pinprick hypoesthesia in up to 40 % of patients and disclose hyperalgesia or aftersensation in 10–20 % of patients [43]. Vibratory sensation, examined by the 64 Hz tuning fork and assessed referring to available normative values [44], should be normal at the toe. In pure SFN, there should be no muscle atrophy or weakness. Deep tendon reflexes should be normal. Various forms of autonomic dysfunction may be reported by the patients, though it is important to ask focused questions (e.g., reduced or excessive sweating, constipation or diarrhea, impotence, micturition disturbances, dry eyes and/or mouth, dizziness at postural variation). It has been reported that, in SFN patients, functions mediated by cholinergic and skin vasomotor fibers are more impaired than those mediated by systemic adrenergic fibers, reflecting in more frequent vascular deregulation in the lower limbs than cardiovascular autonomic impairment [45]. This observation was confirmed in a large group of pure SFN patients [43]. In most patients, SFN starts distally and shows a length-dependent course with proximal involvement of the legs and, later, of the hands. Some patients can present with diffuse symptoms involving feet, hands, low abdomen, and perioral region, such as in SFN caused by oxaliplatin neurotoxicity. In a small number of patients with SFN, discomfort may first be felt in the face or scalp [46]. In these cases, as well as in patients complaining of patchy or asymmetric sensory symptoms, sensory neuronopathy (i.e., ganglionopathy) should be considered and appropriate diagnostic work-up started in order to rule out paraneoplastic or immune-mediated diseases [47] even in patients with pure SFN [48].

Table 25.1 SFN symptom inventory questionnaire (atleast 2 are required)

Sensory	Autonomic
Peripheral pain (burning)	Sicca syndrome (dry mouth/eyes)
Paresthesia	Accommodation disturbances
Allodynia	Hyperhydrosis/hypohydrosis
Diminished temperature sensation	Micturation disturbances
Diminished pain sensation	Impotence/diminished lubrication
	Gastroparesis
	Diarrhea/constipation
	Facial flushing
	Orthostatic complaints
	Palpitations

Questionnaires and Scales

The only validated tool available is the SFN Symptom Inventory Questionnaire (SIQ) [49]. It includes 13 questions, each having 4 response options: 0 = never, 1 = sometimes, 2 = often, 3 = always (Table 25.1). It has been proposed to define the diagnosis of SFN in patients with at least 2 positive answers and evidence of IENF and/or thermal threshold QST abnormalities, after large fiber impairment is ruled out by clinical and nerve conduction examinations.

Table 25.2 Acquired and genetic diseases associated with pure and predominantly somatic SFN

Metabolic	Diabetes	Immune-mediated	Celiac disease
	Impaired glucose tolerance		Sarcoidosis
	Hypothyroidism		Sjögren syndrome
			Paraneoplastic syndrome
Drugs and toxics	Antiretroviral drugs		
	Metronidazole	Genetic	Fabry's disease
	Bortezomib		Sodium channel mutations (SCN9A)
	Chronic alcohol abuse		Familial burning feet syndrome
			Hemochromatosis

The clinical picture of SFN is dominated by neuropathic pain symptoms. Therefore, it is important to grade both spontaneous and evoked (allodynia and hyperalgesia) pain intensity in all the patients; this can be especially helpful in the evaluation of the efficacy of treatments at follow-up visits. The Neuropathic Pain Scale (NPS) or the Visual Analogue Pain Scale (VAS) can be used to score pain from 0 (no pain) to 10 (most intense pain imaginable).

Natural Course

In a cohort of pure SFN [43], a potential etiology was determined in 25 % of patients. In particular, diabetes or impaired glucose tolerance (IGT) accounted for about 35 % of cases, Sjögren syndrome for 7 %, and hypothyroidism for 5 %, whereas SFN remained idiopathic in about 40 % of patients. At 2 years follow-up, in 20 % of patients formerly diagnosed with idiopathic SFN, diabetes or IGT was found. About 10 % of patients diagnosed with SFN showed a progression to a mixed (large and small fiber) neuropathy. In most patients with SFN, the clinical picture did not change over time, though about 30 % of them experienced a worsening of neuropathic pain intensity. Some patients with SFN may complain of disproportionate generalized pain and fatigue [50]. Whether this is part of an underlying disorder or a problem of coping with the disease remains frequently unanswered.

Recovery from SFN has been described [51] as well as courses with continuous symptoms and with intermittent symptoms [52, 53]. It has been also reported that the improvement of the metabolic status in patients with IGT can be associated with the recovery of SFN and with a decrease of pain intensity [54].

Etiology and Pathogenesis

There are a number of conditions clearly associated with pure and predominantly somatic SFN (Table 25.2). Conversely, small nerve fibers are frequently impaired in a large number of mixed neuropathies. Two examples are amyloid and chemotherapy-associated neuropathy. Both conditions can present with early symptoms reflecting the damage of small fibers, but neurophysiologic tests almost invariably show, with the exception of bortezomib in a small percentage of patients, the involvement of large sensory fibers [55, 56].

SFN has been described in association with several acquired conditions and systemic diseases, including diabetes and prediabetes, hypothyroidism, hyperlipidemia, statin, antiretroviral, and metronidazole therapy [43, 57–64], immune-mediated and connective tissue disorders [48, 65–70], infectious diseases [71, 72], chemotherapy [73, 74], chronic alcohol abuse [75], and paraneoplastic syndromes [76]. Fabry and Tangier diseases are rare genetic syndromes in which early neurological manifestations can include SFN [77]. Patients with SFN have been described also in hereditary hemochromatosis [78]. The frequency of SFN in each of these conditions varies in different series and is not precisely known. Moreover, many reports are anecdotal, making a causal correlation rather doubtful. However, a thorough screening should be always performed. Finally, in a substantial proportion of patients, ranging from 25 to 90 % in the different case series, the etiology may remain unknown [43, 79–82].

About one decade after the first description of familial SFN cases [83, 84], screening of the gene SCN9A encoding for the Nav1.7 the sodium channel demonstrated single amino acid substitutions (mutations and polymorphisms) in this peripheral sodium channel in 30 % of patients with a diagnosis of idiopathic painful SFN [18]. This observation supports definition of a new syndrome of channelopathy-associated SFN. A further family with acromesomelia (small hands and small feet) and SFN carrying another missense mutation of Nav1.7 has been also described [85]. All these novel Nav1.7 variants produced hyperexcitability of DRG neurons, on the basis of different changes in channel function compared to those typically found in IEM and PEPD. However, it has not been possible thus far to define a correlation between phenotype, genotype, and cell electrophysiological changes for the SFN variants. Indeed, the same amino acid substitution has been found to be associated with three different phenotypes such as severe facial pain, hands and feet pain, and scalp discomfort in three patients, two of which are from a single family, demonstrating intra– and interfamily phenotypic diversity in pain syndromes produced by a

single gain-of-function variant of Nav1.7 [86]. The bases for this phenotypic diversity are not yet clear. They may include modifier loci and environmental or epigenetic factors.

Despite the association of SFN with multiple acquired and genetic conditions, the pathogenesis underlying the degeneration of small fibers remains unknown. For example, it has been shown that diabetes reduces the ability of small epidermal nerve fibers to regenerate after chemical denervation with topical capsaicin even in patients without neuropathy [87]. It may be therefore hypothesized that hyperglycemia affects the machinery of axonal transport, though there is no strong evidence in support of this view. Immune-mediated mechanisms have been advocated for SFN associated with sarcoidosis and Sjögren syndrome based on the response to immune-modulating or immune-suppressant treatments in single patients or small case series [88–90], but this mechanism has not been shown by serum transfection experiments in animal models. Even the evidence that mutations of Nav1.7 causes unequivocal functional changes of small DRG neurons, from which small nerve fibers arise, does not directly explain their degeneration. It is possible that sodium overload in neurons and small axons induces an increase of intracellular calcium due to the reverse (calcium-importing) sodium-calcium exchange since the sodium-calcium exchanger is colocalized with Nav1.7 in small-caliber peripheral axons [16], but this has not been proven yet. Moreover, voltage-gated channels have complex interactions, suggesting that changes can affect each other [91].

Investigations in Small Fiber Neuropathy

Laboratory Tests

SFN should be first considered as potential complication of a possible underlying systemic disease, and diagnostic work-up should be directed at discovering it. Since diabetes mellitus is one of the most common causes of SFN, fasting glucose, glycosylated hemoglobin, and an oral glucose tolerance test should be performed. In addition to routine blood chemistry, screening of serum and urine protein electrophoresis and immune electrophoresis, thyroid hormones, vitamin B12, folate, cuprum, and antinuclear antibodies (including SS-A and SS-B) should be performed. Celiac disease should be considered and ruled out when suspected. Among immune-mediated disorders, Sjögren syndrome and sarcoidosis should be always taken into account. Amyloidosis should be also suspected, though at the diagnosis, patients commonly present a mixed neuropathy with dysautonomia and cardiac and/or liver involvement. A panel of onconeural antibodies, especially anti-Hu, anti-CV2/CRMP-5, and antiganglionic acetylcholine receptor antibodies, should be screened to rule out a paraneoplastic form [92].

Genetic conditions, such as Fabry's disease, are rare and present with a syndromic picture. When suspected, protein assay and mutations in alpha-galactosidase gene should be searched. The recent definition of channelopathy-associated SFN suggests that it may be helpful to screen SCN9A for gain-of-function mutations in patients with idiopathic SFN, especially if they have an early onset and positive familial history.

Neurophysiologic Studies

Since large fibers are not affected in SFN by definition, nerve conduction studies should not show abnormalities in sural nerve action potential amplitude (SNAP) or conduction velocity. However, in some patients, plantar sensory nerves can be abnormal [93, 94] suggesting that the involvement of most distal large myelinated fibers may be demonstrable at least in some.

A painful electrical cutaneous stimulus can elicit a phase of electrical silence in the muscle during a maximal voluntary contraction by the inhibition of motoneurons. This nociceptive reflex, known as cutaneous silent period (CSP), is mediated by Aδ fibers and has been used in patients to detect small fiber damage [36, 95–98]. Further studies demonstrated that it is also partly mediated by Aβ fibers [99]. The CSP can be analyzed in terms of latency and duration, but its diagnostic value in SFN is questionable in the light of a poor specificity [100].

Microneurography is a minimally invasive method that allows single Aδ and C fiber activity recording [101]. It has been used to demonstrate C fiber dysfunction in erythromelalgia after capsaicin denervation and in painful neuropathies [102–105]. This technique has significantly contributed to knowledge on the physiology of nociceptors and mechanisms underlying their sensitization [6, 8, 106–108]. Nevertheless, it is time consuming and requires both an expert investigator and a collaborative patient, being unsuitable for the assessment of small fibers in routine clinical settings.

Laser-generated radiant heat pulses selectively excite free nerve endings in the superficial skin layers and are recorded from the scalp as late and ultralate laser-evoked potentials (LEPs) which are generated by Aδ and C fibers, respectively [109]. LEPs provide an accepted method of investigating nociceptive pathways and have been used to detect the damage of small fibers in painful neuropathies [37, 110–113]. However, LEPS are frequently absent both in SFN and mixed neuropathies [43, 114], making this technique nonspecific for diagnosis in individual patients.

Contact heat-evoked potential stimulators (CHEPs) provide a technique, more recently developed [115], that exploits an extremely rapid heat rising time to evoke Aδ– and C-fiber-related scalp components. Only a few studies on SFN

have been performed using this technique, mainly demonstrating a correlation with Aδ fiber damage and skin denervation [38, 114, 116–118].

Quantitative Sensory Testing

The most popular technique used to investigate the function of small fibers has been the determination of perception thresholds to warm, cold, and by pain quantitative sensory testing (QST) devices [39, 119, 120]. This is discussed in details in Chap. 11. Several reports demonstrated thermal threshold abnormalities in patients with SFN and neuropathic pain [43, 121, 122]. However, despite its widespread use, QST has some drawbacks that limit the reliability of results in clinical practice. Indeed, this approach has proved to be more useful in population studies than in individual patients [123, 124]. The expected correlation between cold and/or warm threshold, conveyed by Aδ and C fibers, respectively, and IENF density was found in some [125–129], but not all the studies [130–132].

QST was also used to investigate whether the individual pattern of signs and symptoms reflecting specific alteration in nociceptive processing allows stratification of patients based on their somatosensory profile rather than the underlying etiology, thus providing a mechanism-based classification of neuropathic pain. The analysis of 13 QST parameters including measurements of negative (e.g., hypoesthesia) and positive (e.g., hyperesthesia) sensory thresholds performed in a cohort of 1,236 patients of neuropathic pain patients did not confirm this hypothesis [133]. Indeed, there was a remarkable phenotypic heterogeneity across the major neuropathic pain syndromes that included an overlap between central and peripheral nervous system diseases. For example, polyneuropathy and central pain were both reported to have low rates of positive and high rates of negative sensory signs, with similar frequencies of paradoxical heat sensation.

A recent study investigated two groups of patient with nerve injury with and without neuropathic pain and did not find any difference in the thermal thresholds, with a higher frequency of evoked pain (light touch allodynia and reduced mechanical pain thresholds) in the pain group only [134]. Overall, the analysis of sensory thresholds by QST may provide information on the nociceptive pathway functions and be a valid complement to the bedside examination. However, it should be used in relation to the clinical context and in conjunction with other tests [123].

Skin Biopsy

This valuable diagnostic procedure is most commonly performed using a 3-mm disposable circular punch under sterile technique, after topical anesthesia with lidocaine. No suture is required. The specimen contains both the epidermis and the dermis. A skin specimen is commonly taken at the leg, 10 cm above the lateral malleolus, within the territory of the sural nerve. Healing occurs within 7–10 days. The procedure, including the immunohistochemical assay and the procedure for quantification of IENF, has been detailed in guidelines and is discussed comprehensively in Chap. 13 [135]. Skin biopsy is a safe technique, with an estimated frequency of side effects of 1.9:1,000, most commonly mild infection due to improper wound management, which recovers with topical antibiotic therapy, or excessive bleeding which does not require suturing. Normative reference values adjusted per age decade and gender (using bright-field immunohistochemistry) are available and provided the lower cutoff to define the quantification of IENF as normal or reduced in individual patients [136]. A novel method to measure dermal nerve length is also available [137]. It proved to correlate with IENF density and demonstrated a high performance in distinguishing SFN from healthy individuals. Further studies are warranted to establish age- and gender-matched normative reference values and the impact of dermal nerve quantification in symptomatic patients with normal IENF density, in asymptomatic patients at risk to develop neuropathy, and in patients with mixed (large and small) neuropathies.

Skin biopsy represent the most reliable technique to diagnose SFN [138]. It demonstrated the correlations between the loss of IENF and the clinical presentation in patients with diabetes, HIV, connective tissue disorders, and other conditions at risk for SFN [139]. The density of IENF correlates with the loss of pinprick sensation in patients with idiopathic SFN [140]. It correlates also with the number of symptoms of SFN and, inversely, with the quality of life of patients with SFN associated with sarcoidosis [49]. In patients with diabetic neuropathy, IENF density progressively declines over time and was not correlated with the degree of metabolic control, indirectly supporting the hypothesis that hyperglycemia may trigger mechanisms maintaining axonal damage. In HIV neuropathy, a baseline reduction of IENF density predicted the risk of developing neuropathy symptoms over a 2.9-year period, which was 14-fold higher in patients with a density lower than 10 IENF/mm [141]. This is in keeping with studies showing that morphological changes of IENF, mainly large axonal swellings, may predict the development of an overt neuropathy at 2 years follow-up [139, 142].

An even less invasive sampling method is the suction of the epidermis alone using the “blister technique” [143]. It does not cause bleeding and local anesthesia is not needed. A comparative analysis of IENF density between this technique and the punch biopsy did not show differences [144].

Treatments for Small Fiber Neuropathy

Causative therapies should be given whenever possible. However, there is no evidence of efficacy of disease-modifying treatments in SFN. Response to intravenous immunoglobulin or immune-suppressant drugs has been reported in single patients or small cases of patients with SFN associated with sarcoidosis and Sjögren syndrome [88–90]. In Fabry's disease, enzyme replacement therapy failed to induce the regeneration of IENF [145].

Most patients with SFN need treatments for neuropathic pain for which guidelines are available; outlined also in detail in Chap. 80 [146]. The available evidence is based on studies of painful neuropathies of different etiology, whereas no clinical trial has been focused on SFN.

Charcot-Marie-Tooth Diseases

26

Florian P. Thomas, Velina Guergueltcheva,
Francisco De Assis Aquino Gondim,
and Albena Jordanova

Introduction

Charcot-Marie-Tooth (CMT) disease (also called hereditary motor and sensory neuropathy; HMSN) is a heterogeneous group of hereditary diseases of peripheral nerve (Table 26.1). CMT disease is a common disorder affecting children and adults, which may lead to significant impairment. Modes of inheritance include autosomal dominant, autosomal recessive, and X linked.

Historical Perspective and Classification

The earliest identification of hereditary peripheral neuropathies dates back to clinical and clinicopathological reports by Virchow, Aran, Eichorst, Friedreich, Osler, and others [1]. The definitive descriptions by Tooth [2] and Charcot and Marie [3, 4] in 1886 led to the recognition of the condition as Charcot-Marie-Tooth disease (CMT). In 1889, a family with X-linked CMT was reported [5]. An early-onset, severe form was contributed by Dejerine and Sottas in Charcot's group at the Salpetrière Hospital in Paris, France [6]. The association with tremor was noted by Roussy in 1926 [7]. Different forms of inheritance were later categorized by Allan [8].

The advent of modern electroneuromyography (ENMG) in the 1960s permitted further classification of CMT into one with relatively normal nerve conduction velocities (NCV), axonal and preservation of the myelin sheath (CMT2 or HMSNII), and another with slow NCVs and histological features of hypertrophic demyelinating neuropathy with Schwann cell abnormalities and prominent onion bulb formation (CMT1 or HMSNI) [9–11]. The features of CMT1 and CMT2 were outlined in two landmark publications detailing the genetic and clinical characteristics of over 200 patients [12, 13]. CMT1 patients have median motor NCVs below 38 m/s. Slowing is uniform along individual nerves and between nerves; this distinguishes CMT1 from acute or chronic inflammatory demyelinating polyneuropathy [14, 15]. CMT2 patients have NCVs above 38 m/s. A separate intermediate NCV CMT subtype (DI-CMT) was also recognized [16–18]. The Dejerine-Sottas syndrome (DSS or CMT3 or HMSNIII) features NCVs of <10 m/s. Classification systems based on inheritance and clinical, electrophysiological, and histological features are being complemented by mutation analysis, since major phenotypic variations appear to be best explained by the impact of specific mutations on myelin and axonal functions and interactions. Furthermore, pedigrees in which young members have fairly normal NCVs, whereas older relatives have severe slowing, have been described [19]. In general, clinical deficits correlate better with progressive axonal degeneration than with slowed NCVs.

In the 1980s, genetic linkage studies demonstrated the first CMT loci on chromosome 1 [20] and chromosome 17 [21–23]. In 1991 CMT1A, the most common form of CMT, was associated

Table 26.1 CMT subtypes

Subtype	Gene	Chromosome	Distinctive features
CMT1A	*PMP22*	17p12	Most common subtype, onion bulbs nerve biopsy
CMT1B	*MPZ*	1q23.3	Often identical to CMT1A, late-onset axonal variant
CMT1C	*LITAF/SIMPLE*	16p13.13	No distinctive features
CMT1D	*EGR2*	10q21.3	Rare subtype, no distinctive features
CMT1E	*PMP22, MPZ, Cx32*, others		Association of CMT with deafness
CMT1F	*NEFL*	8p21.2	NEFL mutations also associated with CMT2E
HNPP	*PMP22*	17p12	Asymmetric recurrent neuropathy, tomacula
HNA	*SEPT9*	17q25	Recurrent painful brachial plexopathies, dysmorphic features
CMTX1	*Cx32*	Xq13.1	Common subtype, CNS involvement, variable NCVs
CMTX2	Unknown	Xp22.2	Infantile onset, mental retardation
CMTX3	Unknown	Xq26	Prominent paresthetic pain, women with high arches
CMTX4	Unknown	Xq24-q26.1	Severe, deafness and mental retardation in males
CMTX5	*PRPS1*	Xq22.3	Axonal neuropathy, deafness, optic neuropathy
CMTX6	*PDK2*	Xp22.11	Axonal polyneuropathy
DI-CMTA	Unknown	10q24.1-q25.1	Second decade onset
DI-CMTB	*DNM2*	19p13.2	Mild–moderate, neutropenia, cataract, onion bulbs
DI-CMTC	*YARS*	1p35.1	Variable onset
DI-CMTD	*MPZ*	1q23.3	Variable distal wasting, weakness and sensory loss
DI-CMTE	*INF2*	14q32.33	Second decade onset, legs > arms, kidney disease, hearing loss
CMT2A1	*KIF1B*	1p36.2	Rare
CMT2A2	*MFN2*	1p36.2	Common subtype, variable onset and severity
CMT2B	*RAB7*	3q21.3	Most sensory, foot ulcerations, occasional onion bulbs
CMT2B1	*LMNA*	1q22	Second decade onset
CMT2B2	*MED25*	19q13.33	Minimally reduced NCVs
CMT2C	*TRPV4*	12q24.11	First decade onset, vocal fold dysfunction
CMT2D	*GARS*	7p14.3	Worse hand than leg weakness, slow progression
CMT2E	*NEFL*	8p21.2	Variable onset age and severity
CMT2F	*HSPB1*	7q11.23	Slow progression
CMT2G	Unknown	12q12-q13.3	Slow progression of foot deformity, conduction velocities may be normal
CMT2H/K	*GDAP1*	8q21.11	Variable onset and severity, some with pyramidal signs
CMT2I	*MPZ*	1q23.3	Asymptomatic or cramps with foot deformities
CMT2J	*MPZ*	1q23.3	Fourth to sixth decade onset, deafness, sensory and autonomic dysfunction
CMT2L	*HSPB8*	12q24.23	Also linked to dHMN2A
CMT2M	*DNM2*	19p13.2	Prominent gait ataxia
CMT2N	*AARS*	16q22.1	Onset first to sixth decade, asymptomatic or distal weakness/sensory loss/deafness
CMT2O	*DYNC1H1*	14q32.31	Early onset and delayed milestones
CMT2P/AR-CMT2	*LRSAM1*	9q33	Second or third decade onset, distal weakness, mild sensory changes
DSS	*PMP22, EGR2, MPZ, PRX*		Onset in infancy or early childhood, hypertrophic nerves
CHN	*PMP22, EGR2, MPZ*		Neonatal hypotonia, areflexia and arthrogryposis
CMT4A	*GDAP1*	8q21.11	Infancy onset, severe, vocal cord paralysis, onion bulbs
CMT4B1	*MTMR2*	11q21	Infancy onset, severe, focally folded myelin sheaths
CMT4B2	*SBF2*	11p15.4	First to second decade onset, glaucoma, myelin outfoldings
CMT4C	*SH3TC2*	5q32	Prominent scoliosis; early loss of ambulation; heterozygotes: mildly affected
CMT4D Lom	*NDRG1*	8q24.22	First decade onset, gait difficulty, skeletal deformities, hearing loss
CMT4E	*EGR2*	10q21.3	Cranial nerve involvement, arthrogryposis, and respiratory failure
CMT4F	*PRX*	19q13.2	First decade onset, gait ataxia, onion bulbs
CMT4G Russe	*HK1*	10q22.1	Severe disability, prominent sensory loss, intermediate motor NCVs
CMT4H	*FGD4*	12p11.21	Early onset, scoliosis, hypomyelination, redundant myelin sheaths
CMT4J	*FIG 4*	6q21	Severe phenotype, childhood onset, motor dominant
CMT RIA	*GDAP1*	8q21.11	Variable severity
CMT RIB	*KARS*	16q23.1	Self-abusive behavior and dysmorphic features
GAN	*Gigaxonin*	16q23.2	Early onset, mental retardation, tightly curled hair

with a 1.5-Mb duplication within chromosome 17p11.2, which contains the myelin gene *PMP22* [24, 25]. Mutations in *PMP22* were linked also to demyelinating neuropathies in Trembler and Trembler-J mice [26, 27] and to CMT1A and DSS [28–30]. Transgenic mice and rats that overexpress *PMP22* were found to develop neuropathies resembling CMT1 [31–33]. CMT1A also occurs with partial or complete trisomy of the short arm of chromosome 17, as part of a phenotype with developmental and growth delay, craniofacial and skeletal anomalies, and heart defects [34, 35].

The second most common subtype, X-linked recessive CMTX1, was found to result from mutations in the gap junction protein beta 1/connexin-32 (*GJB1/Cx32*) on chromosome Xq13.1 [36]. Other loci and two more genes have been identified for subtypes CMTX2, CMTX3, CMTX4, CMTX5, and CMTX6 (see below) [37].

The 1990s also saw the identification of other CMT genes. CMT1B and some cases of DSS were found to be associated with mutations in the myelin protein zero gene (*MPZ*), located on chromosome 1q23.3 [38–40]. Mutations in the zinc-finger-domain-containing transcription factor early growth response two gene (*EGR2* or *Krox20*) on chromosome 10q21.3 were linked to congenital DSS, hypomyelinating neuropathy (CHN), and CMT1D [41]. Deletion of *PMP22* was associated with hereditary neuropathy with liability to pressure palsies (HNPP) and several other phenotypes [42]. Recent studies identified numerous nonrecurrent genomic rearrangements of atypical size on the 17p12 chromosome, encompassing the *PMP22* gene, in patients with either CMT1A or HNPP, further underscoring the fact that either altered dosage or dysregulation of this gene is the major cause for the CMT1A and HNPP phenotypes [43]. An HNPP-like condition, hereditary neuralgic amyotrophy (HNA), was mapped to chromosome 17q25 [44, 45]. Mutations of all of these genes have been associated with several overlapping clinical phenotypes. For instance, DSS occurs with *PMP22*, *Cx32*, *MPZ,* and other mutations [19, 41, 46–48]. Some 50 genes have been associated with different CMT subtypes, and their number continues to increase [49].

CMT disease genes can be categorized by cell biological criteria. Some play a role in signal transduction or the cell cycle (*GDAP1, MTMR2, SBF2, SPTLC1, NDRG1*), others are associated with the cytoskeleton (*NEFL, DYNC1H1, INF2, gigaxonin, LMNA, MFN2, RAB7, PRX, KIF1Bβ), and* some with Schwann cell membranes (*MPZ, Cx32, PMP22*), yet others are transcription factors (*EGR2, SOX10*) or are involved in protein degradation (*LITAF/SIMPLE, LRSAM1*). Mutations in aminoacyl tRNA synthetases which catalyze the esterification of an amino acid to its cognate tRNA have been identified (*AARS, GARS, KARS*, and *YARS*) in several subtypes; they may be pathogenic by way of other cellular roles than protein synthesis. The various CMT genes do not act in isolation; for instance, *PMP22* and *MPZ* co-localize and may interact in the myelin sheath [50]. In the Trembler mouse, Schwann cells are deficient in neural growth factors; this could lead to impaired axonal and myelin maintenance [51]. In rodents, *PMP22* overexpression upregulates the *CXCL14* gene which modulates expression of myelin genes and alters cell proliferation, and is expressed exclusively by sciatic nerve Schwann cells [52]. And *EGR2* regulates the transcription of several myelin genes.

This chapter gives greater emphasis to the more common CMT subtypes such as CMT1A, CMTX, CMT1B, CMT2, and HNPP than others. Rare mutations are discussed in some detail when they are associated with unique phenotypes or specifically contribute to understanding of normal and abnormal nerve physiology. Hereditary motor (HMN), sensory and autonomic (HSAN), and sensory (HSN) neuropathies; neuropathies with multiorgan disturbance or prominent central nervous system (CNS) involvement are reviewed briefly.

Epidemiology

CMT is found worldwide in people of all races and ethnic groups. It is among the most common heritable neurologic disorders, but estimates of its frequency vary. An exhaustive study from Norway indicated a prevalence of 3.6 per 10,000 people [53], whereas a worldwide meta-analysis estimated a prevalence of 1 in 10,000 people [54]. A Japanese epidemiologic study demonstrated a prevalence of 10.8 per 100,000 people [55]. In the USA, CMT affects approximately 150,000 people. It may be less common among African Americans; this may represent a lower frequency of specific mutations or protection from disease manifestation through unknown disease-modifying mechanisms.

Estimates of the frequency of CMT subtypes vary [54]. CMT1 accounts for about 50 % of CMT, CMT2, and CMTX for 10–15 % each. DI-CMT forms are rare. CMT1A accounts for 70–80 % of CMT1, CMT1B for about 10 %. CMT2A2 accounts for about 20 % of CMT2. CMTX1 accounts for 90 % of all CMTX. A Finnish study of 435,000 individuals found a prevalence of 16/100,000 people for HNPP and 20/100,000 people for CMT in general [56].

The autosomal-recessive forms are rare (less than 10 % of CMT in general) in the Western societies. Given the small size of sibships, many may remain unrecognized and be considered sporadic. Several have been described only in a small number of families with some being restricted to specific ethnic groups, for example, CMT4D Lom and CMT4G Russe. However, in populations with a high degree of consanguinity, for example, in North Africa, the Middle East, or in European Gypsies, autosomal-recessive forms likely account for 30–50 % of all CMT [57].

Clinical Presentation

Symptom Onset

Subjective and objective age of onset may vary with subtype, penetrance, familial phenotype, perceptiveness, and ascertainment bias. One of the authors' (FPT) patients reported symptom onset in his 50s; however, his family had been aware of his steppage gait 30 years prior. Asymptomatic individuals may be detected during mutation screening of families after a relative has been diagnosed. As a noteworthy caveat, a family history may be unrecognized due to oligo- or asymptomatic relatives, lack of perceptiveness of symptoms, nonpaternity, and late onset or early death of relatives; furthermore, de novo mutations with a truly negative family history must be considered, as well as autosomal-recessive inheritance. CMT1A has one of the highest de novo mutation rates, similar to neurofibromatosis type 1. Some families notice delayed walking in affected offspring. One of the authors' (FPT) patients was able to accurately diagnose CMT in children of her family by watching their feet point down when sitting on the ground. Other complaints include thin lower legs, clumsiness, and difficulty running. Onset in the first decade is common, but some patients date disease onset into young or mid or even late adulthood. Exceptions are more severe phenotypes such as DSS and CHN. Most CMT1A patients develop clinical evidence of disease before age 20 [58].

Fig. 26.1 Severe limb weakness and gait impairment in CMT4D Lom

Patient Complaints

Motor symptoms typically predominate over sensory. Often patients experience weakness and muscle wasting, foot deformities, loss of balance, and tripping over objects due to foot drop. Manipulating small objects such as forks, zippers, or pencils may be difficult. Parents or teachers of a child may notice a delay in motor milestones, clumsiness, frequent falls, or toe walking. Ankle sprains and fractures are frequent. Paresthesias, in contrast to acquired neuropathies, are typically less severe and rarely a presenting symptom; however, they may be acknowledged upon questioning. On the other hand, patients may deny sensory symptoms despite marked loss of sensation on examination. In CMT1 radicular pain may result from enlarged nerve roots (sometimes visible by MRI) because of ongoing demyelination and remyelination with connective tissue proliferation. Complaints of cold feet often associated with hair loss or leg edema occur. Non-neuropathic pain can be caused by pressure or strain of various structures associated with bones, joints, and tendons and abnormal posture at the knees, hips, and back, which results from foot weakness and fixed-foot deformities such as Achilles tendon shortening. Because of hammertoes and high arches, patients experience painful calluses and have difficulty finding shoes. Kyphoscoliosis and abnormal gait can lead to back pain. Patients complain of lower and upper limb cramps, often worse with fatigue.

Physical Findings

In some forms of CMT (e.g., HNPP and HNA), focal asymmetric features predominate; in others (e.g., certain *PMP22* mutations, HMSNP, HNA, and others), proximal weakness predominates. But typically, a predilection exists for distal limbs as the site of disease onset and for more severe symptoms and signs, and weakness and muscle atrophy affect the legs more and earlier than the arms (Fig. 26.1). Distal limb muscles atrophy over time and may produce the classic "inverted champagne bottle" or "champagne glass" appearance (Fig. 26.2). In young children, the exam may be entirely normal or limited to impaired heel gait. Proximal weakness is rare except in the most severely affected, in certain subtypes, and in hereditary focal neuropathies. Therefore, most patients with marked distal weakness are

Fig. 26.2 Distal leg atrophy in DI-CMTC. Inverted champagne bottle appearance of distal leg atrophy in a family with DI-CMTC. *Left* to *right*: the first, fourth, fifth, sixth, and tenth individuals have CMT; the second, third, seventh, eighth, and nineth are unaffected blood relatives

able to walk, albeit often with ankle foot orthoses. Severely affected patients may lose their ability to walk without assistance (Fig. 26.2). Sensation may be normal until adulthood, but distal, mild, and pansensory loss is common. Reflexes are absent or depressed. Foot deformities (including high arches or flat feet, hammer toes, and shortened Achilles tendons with fixed foot drop), while stigmata of CMT are nonspecific, as they can occur in chronic acquired neuropathies (Fig. 26.3). They become more prevalent with age and contribute to unequal wearing of shoes. Gait is compromised by poor proprioception, distal weakness, and foot drop due to weakness and later due to Achilles tendon shortening resulting in steppage gait. Enlarged and excessively firm nerves may be present in CMT1, sometimes visible in the superficial cervical nerves and palpable along peripheral nerves of the arms. Postural tremor occurs in up to 25 % of patients. Whether it is incidental or part of the syndrome remains controversial [7, 59, 60]. CMT may have a more severe phenotype in men, possibly because of environmental (nerve trauma) or X-linked modifying factors; evidence for CMT gene regulation by androgens and progesterone derivatives suggests a genetic influence for this gender difference [61, 62]. Gender differences may be superseded by the great phenotypic variability among and within families. Some CMT subtypes are notable for relatively isolated motor, sensory, and autonomic dysfunction. Discrete and subtle CNS involvement has been described occasionally [63–65]. Cranial neuropathies are rare, but various pupillary abnormalities [66–75] and laryngeal dysfunction with aspiration and dysarthria [76] occur, and sensorineural deafness has been described with multiple specific mutations [67–85].

Fig. 26.3 Achilles tendon shortening with fixed foot drop and high arches in DI-CMTC. Achilles tendon shortening is often preventable if addressed early on with daily stretch exercises and foot bracing. Given the advanced stage shown here, this individual underwent surgery to improve gait and discomfort and to reduce likelihood of secondary damage to more proximal joints

Clinical Course

Slow progression of disability is typical. Therefore, any sudden deterioration requires consideration of superimposed acquired, for example, diabetic, autoimmune, or possibly independently inherited forms of neuromuscular diseases [86–90]. Severity varies widely between genetic subtypes, but also between families in a mutation-dependent fashion, and also within families [91]. Some adults require ankle foot orthoses only in the sixth decade, while children may already have foot drop, proximal leg weakness, and clawing of the fingers. A study of 43 CMT2 patients documented slow progression of weakness and disability, but most patients remained ambulatory [92]. During pregnancy, some patients experience more rapid deterioration from which they usually, but not always, recover [93, 94]. During medical procedures, prolonged immobilization of the body and limbs in fixed positions can result in nerve compression. Patients must inform their physicians of their CMT and request extra padding during procedures. Achilles tendon shortening is often preventable if addressed early on with daily stretch exercises and foot bracing. Different AFOs are appropriate for daytime versus nighttime use. Sometimes surgery is indicated for severe skeletal deformities to improve gait and discomfort and to reduce likelihood of ensuing damage to the knees, hips, and spine. Some patients find wider shoes a more comfortable fit for their high arches and hammertoes; wider shoes may also lessen local nerve compression. Sleep, upper airway, and pulmonary disorders result from pharyngeal, laryngeal, and phrenic nerve involvement with obstructive sleep apnea and vocal cord and diaphragmatic dysfunction and from restless leg syndrome (RLS) and periodic leg movement of sleep; some are more common in certain subtypes [70, 76, 82, 95]. Individuals with CMT1 suffer emotional stress that is similar to patients with comparable disability due to a stroke [96], with 44 % endorsing significant disability and 18 % depression; in this study, high disability predicted attitude about procreation, and 36 % of individuals opted against childbearing.

Diagnostic Evaluation

The purpose of investigative assessment in patients with a possible inherited neuropathy is to confirm or refute the working diagnosis and to determine whether a treatable neuropathy might exist as the sole condition or be superimposed on an inherited condition. The evaluation should include tests that address causes of neuropathies such as endocrinological, infectious, and immunological abnormalities, vitamin and nutritional deficiencies, and nerve compression.

Cerebrospinal fluid (CSF) analysis is rarely necessary but may be helpful in confusing clinical situations in which an acquired immune neuropathy is being considered. In CMT, CSF protein is usually normal but may be elevated above 100 mg/dl, in contrast, CSF protein is elevated in nearly all patients with DSS [97]. Elevated protein occurs in HNPP with recurrent polyradiculoneuropathy [98]. In a comparison of CMT1A, CMT1B, and CMTX, CSF protein (and CK) elevations were more common with *MPZ* mutations [99].

Establishing inheritance patterns can narrow the differential diagnosis and eliminate the need for some genetic tests. For practical purposes, CMTX forms need not be considered with well documented male-to-male disease transmission. On the other hand, the absence of a family history cannot be used to rule out a hereditary disorder because of the possibility of difficulties in ascertainment, variable penetrance and expressivity, nonpaternity, and de novo or recessive mutations.

Molecular genetic testing should be discussed as an option, when the clinical phenotype, family history, and ENMG suggest an inherited neuropathy. Clinical exam and ENMG often cannot definitively establish a diagnosis due to the overlap among clinical syndromes and the significant variability among family members with an identical genotype. Genetic verification permits sound family and prognostic counseling and advances the scientific understanding of phenotypes and pathomechanisms. In the current clinical practice, genetic testing often does not happen due to its cost. The importance of genetic evaluation is exemplified by a report of two sisters with severe CMT1 and healthy parents, for whom autosomal-recessive inheritance had been presumed until a low-level somatic and germline mosaicism of an *MPZ* mutation was identified in the unaffected mother with transmission to her affected daughters [100]. Patients may be difficult to persuade to undergo testing, because for many subtypes, genetic tests are not available yet, and thus, even with an extensive testing panel, all tests may return normal. With advancements in sequencing technologies, screening for all known CMT genes in a single assessment is an attractive opportunity that will significantly facilitate molecular diagnosis in the very near future. Although routinely fresh blood is required for DNA analysis, alternative sources of biological material are also applicable. For example, *PMP22* mutations have been diagnosed in 12-year-old, highly degraded DNA from sural nerve biopsies [101].

Genotyping does not exclude mutations with 100 % certainty. Laboratory errors such as mislabeling occur. DNA can degrade in transit. If results are counterintuitive, the test should be repeated. Point mutation analysis is largely limited to the protein-coding sequences but does not include the promoter, enhancer, silencer, deep intronic, or other non-translated sequences. Search for copy number variants, apart from *PMP22* duplication/deletion, is not performed on a routine basis. Mutations in more than one CMT gene in a patient (digenic inheritance) cannot be currently excluded. And genetic tests are not commercially available for many CMT genes.

Early ENMG studies showed slowed NCVs in patients with peroneal muscular atrophy [9–18]. Median motor NCVs are below 38 m/s in CMT1 and above 38 m/s in CMT2, though some studies have proposed a cutoff of 42 m/s. The distinction is not always clear: Relatively normal NCVs were found in younger members of a family with a particular *MPZ* mutation, whereas older relatives had severely slowed NCVs [67]. Conduction values are symmetric, and differences between proximal and distal nerve segments are rare. While exceptions exist, the concept of uniform slowing suggests that in CMT1, all myelinated fibers are affected along the entire nerve, in contrast to disorders such as CIDP, characterized by patchy involvement of different nerve segments, conduction block, and temporal dispersion [14]. Nerves often are refractory to stimulation or require higher intensity and prolonged stimulation. CMAP amplitudes may be reduced or absent (especially in the distal lower limbs due to complete denervation of small foot muscles), as may be sural nerve sensory action potential (SNAP) amplitudes. EMG may be normal in proximal muscles but show distal changes with increased duration CMAPs. Signs of active denervation such as increased insertional activity and fibrillation potentials are not prominent in muscles unaffected by weakness. Phrenic nerve CMAP also shows reduced amplitudes.

Although demyelination is the histopathological hallmark of CMT1, the clinical hallmarks, weakness and sensory loss, are probably produced by axonal degeneration and not demyelination. Children with CMT1A, for example, have conduction slowing prior to the onset of symptoms, and the NCVs do not change appreciably as the disease progresses, suggesting that demyelination is not sufficient to cause neurologic manifestations. In addition, CMAP amplitudes, not NCVs, correlate best with weakness in CMT1A [102]: In a study of 42 patients with CMT1A, weakness correlated with axonal loss measured by reduced CMAP amplitudes, but not with NCV slowing, suggesting that disability results from loss or damage to large-caliber motor and sensory axons.

In CMT1A, NCVs range from 10 to 42 m/s, again illustrating that the distinction of CMT1 and CMT2 cannot rest on NCVs alone [58]. Sensory NCVs are similarly reduced, when obtainable, but are often absent. Sensory loss correlates with median sensory NCVs and CMAP amplitudes [103]. In a study of 80 children, ENMG changes were documented as young as age two, and motor NCV slowing progressed throughout the first 6 years of life; CMAP amplitudes were decreased early in the disease, and the normal CMAP increase with age was attenuated [104]. In addition, axonal excitability is altered in CMT1A [105]: Stimulation thresholds were above normal, and the threshold electrotonus was markedly abnormal, suggesting altered cable properties consistent with demyelination and exposure or spread of K^+ channels normally sequestered under the myelin. In a *Pmp22* transgenic mouse model, the degree of weakness correlated with the number of functional motoneurons, but not the number of myelinated fibers or myelin thickness [106]. Anatomical evidence exists of progressive length-dependent axonal loss in CMT1A [82, 107] and in mice overexpressing *PMP22*.

Depending on the specific genetic defect and (in some families) age-related changes, neuropathies associated with MPZ mutations can present as demyelinating (CMT1B), pure axonal (CMT2), or intermediate (DI-CMTD) forms [67, 99, 108].

In HNPP diffuse sensory conduction slowing independent of nerve entrapment was reported consistent with a background demyelinative distal polyneuropathy; slowed motor NCVs were less common, although DMLs and F-wave latencies were frequently prolonged consistent with a distal motor polyneuropathy, similar to that seen in IgM monoclonal gammopathy against myelin-associated glycoprotein or sulfated glucuronyl paragloboside [109]. Others found that slowing correlated with the exposure to entrapment [110]. EMG is normal in proximal muscles but may show distal changes with increased CMAP duration. Signs of active denervation such as increased insertional activity and fibrillation potentials are not prominent in muscles unaffected by weakness. ENMG can lead to a HNPP diagnosis, even when the clinical features do not suggest it. On the other hand, bilaterally normal median DMLs and sensory NCVs at the wrist appear to exclude HNPP. ENMGs were similar in oligosymptomatic and asymptomatic patients and became characteristic as early as the second decade [111]. The variability within families may be considerable. Diagnostic criteria for the disorder have been proposed including slowed median sensory NCVs at the wrist, bilaterally delayed median DMLs, prolonged DMLs, and motor NCV slowing in the peroneal nerves [112, 113].

In DSS, the original description found absent electrical responses in the legs only in some cases and complete absence in the most severe cases [6]; NCVs are below 12 m/s in the arms with uniform slowing and marked dispersion [9].

Neuroimaging

Imaging studies may show enlarged spinal roots, limb, and cranial nerves [97, 114–119]. Homozygosity for *PMP22* mutations enhances root hypertrophy [97]. Areas of demyelination may be identified in the CNS, which should be imaged in the presence of symptoms or signs not attributable to the PNS [63, 64, 72–75, 119]. In CMT1A, MRI may reveal early restricted involvement of intrinsic foot muscles with atrophy, fatty infiltration, edema, and contrast enhancement; with advanced disease, proximal leg distal muscles may be affected [115]. In a comparison study, CMT1A was characterized by peroneal nerve innervated muscle involvement, whereas CMT2A MRI showed fatty infiltration of superficial posterior

compartment muscles [116]. MRI in CMT2M showed calf muscle infiltration, often in a length-dependent fashion [117]. In CMT1B, ultrasound showed median and vagus nerve enlargement; cranial nerve size did not differ between patients with and without cranial neuropathies [118].

Clinical and Genetic Subtypes

CMT1

PMP22 Duplication and Mutations (CMT1A)

A1.5-Mb duplication on chromosome 17p12 that includes the *PMP22* gene is the cause of most cases of CMT1A with the remainder resulting from point mutations in this gene (www.molgen.ua.ac.be/CMTMutations/). The *PMP22* genomic region is flanked by homologous repetitive palindromic sequences, which serve as substrates for a non-equal crossover resulting in a duplication in the case of CMT1A or a deletion in the case of HNPP. The duplication has been detected in many ethnic groups and accounts for 70–80 % of CMT1 cases [46]. Ninety percent of patients with sporadic CMT1 have a de novo 17p11.2-12 duplication. Duplications of paternal origin comprise nearly 90 % and are caused by unequal meiotic crossover between both chromosome 17 homologues, whereas the much rarer maternal duplications (and deletions) result from an intrachromosomal process [120].

Phenotypic Variations and Genotype-Phenotype Correlations

While most patients with *PMP22* duplication have a typical course, unusual phenotypes occur, in particular with point mutations. Tremor (Roussy-Levy syndrome) can be associated with CMT1A [59]. Occasional patients will present with radiculopathies due to enlarged nerve roots. Early hand involvement, which is frequently unrecognized, was documented by dynamometry, 9-hole peg test, and disease-related manifestations in a study of 84 children with CMT1A [121]. A Guillain-Barré-like presentation with rapid progression over 1 day and 17p11.2-12 duplication has been described [122]. A family with *PMP22* duplication presented with slow progression and predominantly proximal upper limb weakness and wasting [123]. In a family with *PMP22* duplication the severity of sleep apnea and neuropathy were correlated, possibly due to pharyngeal involvement [95]. Two sisters with neuropathy due to *PMP22* duplication had prominent sensory complaints, tremor, and episodes of acute paralysis [124]. CMT1A with deafness has been associated with several specific mutations [77–80]; this sometimes referred to as CMT1E. A *PMP22* mutation in the fourth transmembrane domain leading to a premature stop codon (Cys109stop) causes a phenotype ranging from asymptomatic to severely affected [125]. A father with adult-onset CMT1A and a 3-year-old child with congenital pes cavus, both with *PMP22* duplication, illustrate the diversity of the phenotype and the appearance of anticipation [126]. Atypical phenotypes can also result from the coexistence of CMT with inflammatory neuropathy, which may reflect a greater propensity of peripheral nerves in CMT to suffer inflammatory injury [127–129]. CMT1A has also been associated with prolonged QT syndrome [130].

Pathogenesis

PMP22 is a 160 amino acid protein with four membrane-spanning domains that are highly conserved in evolution. The protein is most highly expressed in Schwann cells, where it localizes to compact myelin but also is found in the brainstem and spinal motor neurons. Structural analysis indicates both a pore and a cell adhesion function.

Analysis of sural nerve RNA from patients with CMT1A due to duplication suggests that *PMP22* mRNA and protein overexpression causes the dysmyelination [131]. The exact pathogenetic mechanism is unknown; however, in vitro, *PMP22* overexpression disturbs the Schwann-cell cell cycle and causes apoptosis, whereas downregulation accelerates cell proliferation [132]. In Schwann cells of CMT1A patients, the overexpression of ErbB2 and B3, the Schwann cell receptors for neuregulins, an axonal growth factor family, might inhibit myelination and cause recurrent demyelination and axonal damage [133].

PMP22 point mutations likely cause neuropathy by a mechanism other than gene dosage. *PMP22* mutations in Trembler and Trembler J mice, also found in some CMT1A patients [29], inhibit transport of normal and mutant proteins from the endoplasmic reticulum and Golgi complex to the cell surface and cause *PMP22* accumulation in the Schwann cell bodies [134]. This results in a reduction in the amount of *PMP22* protein available for myelination, implying at least in part a loss of function disease mechanism. Trembler mice are much more severely affected than mice carrying a single copy of *Pmp22* [135]. Trembler mice have less myelin than *Pmp22+/−* animals, and the steady-state levels of their myelin-specific mRNAs are dramatically reduced [136]. This additional effect of mutated *PMP22* is probably caused by the interactions of the mutated *PMP22* with other cellular constituents (a toxic gain of function mechanism).

Neuropathology

Most nerve biopsies from CMT1 demonstrate a hypertrophic demyelinating neuropathy with onion bulbs indicating chronic remyelination and loss of myelinated fibers, preferentially those with large diameter. Biopsies from CMT1A patients with *PMP22* duplication reveal normal epi- and perineurium; increased fascicular area, endoneurial collagen, and numbers of Schwann cell nuclei; and loss of large myelinated fibers that correlates with age and clinical severity. *PMP22* expression in nerve biopsies is increased [137]. Most teased fibers are abnormal with widespread segmental demyelination and frequent paranodal loss of myelin. Internode

length is decreased and variable with numerous short internodes. In contrast to *PMP22* duplication, cases of *PMP22* missense mutations presenting as CMT1A or DSS show hypomyelination and resemble Trembler mice. A family with a mutation affecting the splice acceptor site of intron two presented with a typical clinical CMT1A phenotype; the nerve biopsy revealed a demyelinating neuropathy without classical onion bulbs or tomacula [138]. Skin biopsy, a less invasive alternative, showed myelin abnormalities; *PMP22* mRNA and protein levels are increased in CMT1A and decreased in HNPP [139].

PMP22 Deletion and Mutations (HNPP)

Onset of neuropathies associated with *PMP22* deletions typically occurs between age 30 and 40 but ranges from the first to the eighth decade; nerve palsy may be present at birth [140]. Presentations vary remarkably. For example, a 2-year-old child presented with toe-walking, pain, stiffness, asymmetric weakness, and bilateral upper motor neuron findings, and by age seven episodic numbness and weakness in the arms and borderline NCV were identified, and HNPP was then diagnosed [141]. Due to its insidious onset, many patients are unaware of the disability or seek medical attention only late in life. Some are asymptomatic. Of about 1,000 individuals with CMT at single US center, 6 % were found to have HNPP [142]. The condition may occasionally be identified when individuals develop an acquired neuropathy and seek evaluation.

In typical HNPP, motor symptoms predominate over sensory. After resting a limb in an awkward position, patients may report dysesthesias and weakness lasting weeks to months, rather than seconds to minutes. Slight nerve compression and repeated local exercise leads to episodes of weakness with decreased perception to touch and pain. Most attacks are sudden and initially followed by recovery. Most present with a single nerve involvement, sometimes upon awakening. Precipitating trauma, such as carrying heavy loads or playing musical instruments, may be minimal and unavoidable. One of the authors (FPT) evaluated a 15-year-old girl who would develop numb fingers when holding a pen, and once, after sitting on her cousin's shoulders, both legs became weak for some 20 min. In another personally evaluated family, an affected father and son develop recurrent symptoms of a greater occipital neuropathy when lying supine on the floor during yoga exercises. The father's cousin developed brachial plexus neuropathy during deer hunting season due the recoil of the rifle and greater occipital neuropathy when working on pipes lying on his back in the crawlspace under his house [143]. Between episodes of palsy, the exam may be normal or mildly abnormal. There may be distal and mild pansensory loss. Reflexes are normal in over 60 %. In one study, ankle jerks were absent in close to 40 % of patients, and areflexia occurred in slightly more than 10 % [113]. There is typically no neuropathic pain. In a series of 17 patients, most had transient focal weakness or sensory loss related to activities that may compress nerves [144]. HNPP can present as familial carpal tunnel syndrome without nerve palsy [145].

Sites of compression are often those of anatomic vulnerability: the fibular neck for the peroneal nerve, the cubital tunnel for the ulnar nerve, the spiral groove of the humerus for the radial nerve, and the carpal tunnel for the median nerve. Rare sites of involvement include the surgical head of the humerus for the anterior branch of the axillary nerve [146]. In a study of 70 patients, the average number of nerve palsies over a lifetime was about two [111]; the most commonly affected structure was the peroneal nerve, followed by the ulnar, the brachial plexus, and the radial and median nerves; and weakness persisted for more than 3 months in 15 % of patients. In three members of one family, brachial plexus palsies were the only manifestation [147]. Brachial plexopathy in HNPP may be recurrent, isolated, or part of other multiple mononeuropathies and is painless, in contrast to HNA [148–150]. While typically the disability is mild, progressive polyneuropathy with recurrent episodes of palsy may result in significant disability.

Phenotypic Variation

While HNPP is the most common manifestation of *PMP22* deletions, other phenotypes have been identified [111, 140, 151–153]. In one study, 41 % of participants with HNPP were unaware of their condition, and a quarter were essentially without symptoms [152]. In oligo- or asymptomatic individuals, the exam may reveal subtle abnormalities such as distal hyporeflexia or Tinel signs: In one report, a girl had a steroid responsive peroneal neuropathy; significantly slowed motor and sensory NCVs were recorded in the clinically unaffected monozygotic twin and their father [154]. The second most frequent presentation may be largely symmetric, slowly progressive polyneuropathy with high arches and hammertoes [111, 151, 152]. Some patients have recurrent, sensory symptoms lasting minutes to hours triggered by limb position or nerve compression. Others present with a chronic sensory polyneuropathy. Not surprisingly, patients may evolve from one phenotype to another, and different phenotypes may coexist in a family. Rarely, patients present with subacute recurrent or confluent demyelinating multiple mononeuropathies and are misdiagnosed as acute (AIDP) or chronic inflammatory demyelinating polyneuropathy (CIDP) [98, 151, 155]. Cranial neuropathies, including deafness [81], are infrequent and may sometimes represent chance events. Other rare associations include CNS manifestations [63–65], moving toes and myoclonus [65], fulminant 4-limb weakness possibly related to nerve compression [156], and sciatic neuropathy as the initial presentation [157]. Subclinical CNS involvement may manifest as abnormal blink and jaw-opening reflexes and acoustic evoked potentials [64]. The co-occurrence of schwannomas in the median and medial plantar nerves and HNPP has led to speculations about a possible common genetic basis [158].

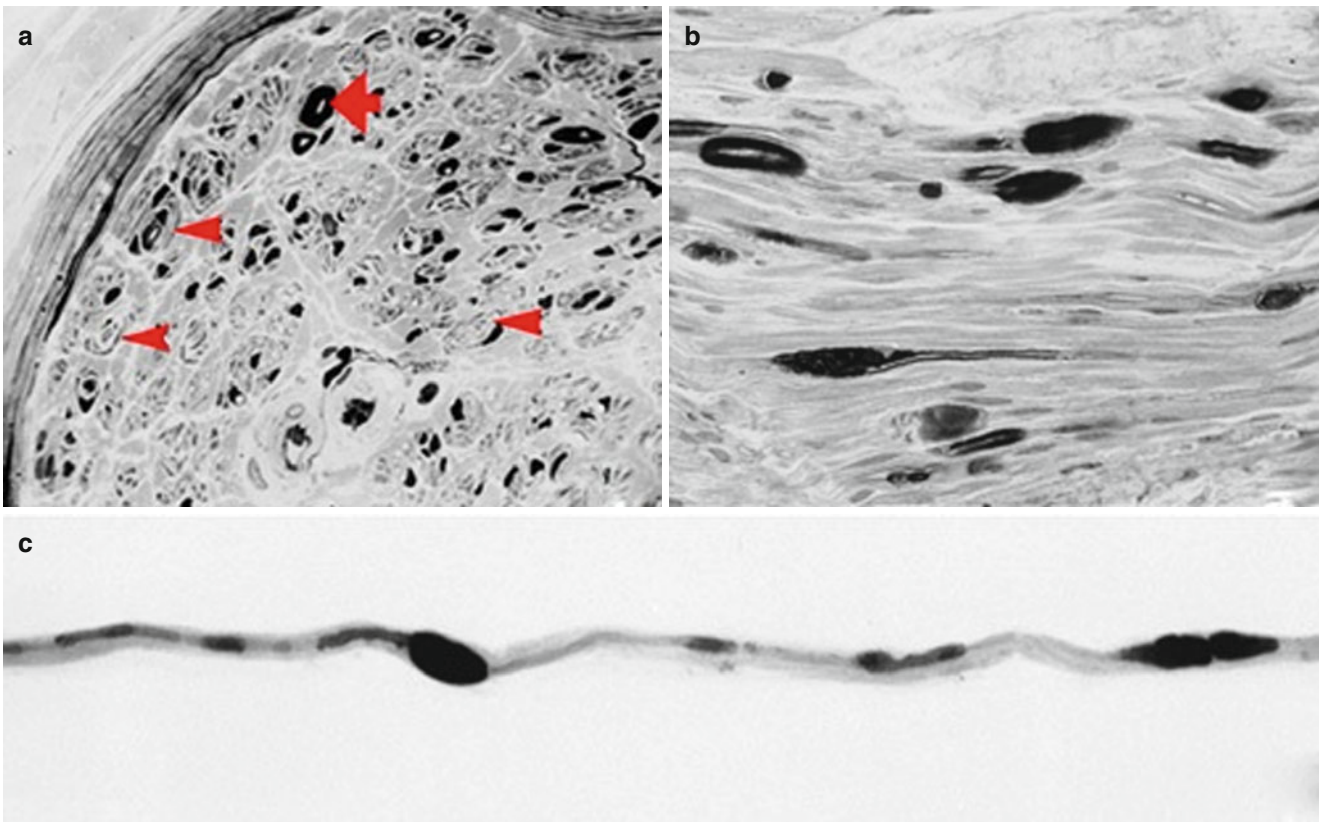

Fig. 26.4 Sural nerve biopsy in CMT1B showing tomacula. (**a**) Semithin cross section shows a marked depletion of myelinated nerve fibers. Scattered onion bulbs consist of concentrically arranged Schwann cell processes (*arrow heads*), some without a central myelinated fiber. Several myelinated fibers have a thick myelin sheath and an irregular contour, suggesting that they are tomacula (*large arrow*). (**b**) Semithin longitudinal section demonstrating tomacula in continuity with myelinated fibers. The myelin sheath is inappropriately thin, probably as a result of segmental remyelination or hypomyelination. (**c**) Teased myelinated nerve fiber containing tomacula that consists of globular expansions of myelin measuring 30–50 μm in length. Segments of the myelin sheaths between tomacula vary in thickness, and many of them are abnormally thin

Besides by *PMP22* deletion, HNPP can result from other *PMP22* mutations. Several HNPP patients with frameshift, nonsense, or splice-site mutations had typical phenotypes, likely because the mutations resulted in a functional deletion [159–161]. A mild phenotype resulted from a 3' splice-site mutation, preceding coding exon 3 [162]. Atypical phenotypes may also result from a combination of mutations in different CMT-causing genes. In one family, *PMP22* and *LMNA* mutations co-segregated, leading to a severe phenotype with unusual axonal involvement in addition to a typical myelinopathy [88].

Undiagnosed HNPP in an oligosymptomatic patient may complicate the treatment and diagnosis of an acquired neuromuscular disease later in life. For instance, a person with the disorder might develop diabetic amyotrophy or CIDP, and the ensuing clinical and electrical presentation and treatment responses might difficult to understand. HNPP has been diagnosed associated with ALS [89] and oculopharyngeal muscular dystrophy [90].

Pathogenesis

The fact that both *PMP22* deletions and frameshift or nonsense mutations are associated with HNPP suggests a loss of function mechanism. This notion is supported by the finding of *PMP22* underexpression in HNPP patient and transgenic mouse nerve tissue and of a similar clinical and histological phenotype in humans and animal models [135, 163, 164]. Homozygous *PMP22*-deficient animals have delayed myelination and weakness at 2 weeks, frequent tomacula at 3 weeks, severe nerve conduction slowing, onion bulbs and other signs of demyelination or remyelination when older than 2 months, and axonal atrophy at 12 months [164].

Neuropathology

Both motor and sensory fibers in most nerves show segmental demyelination and remyelination; variable, secondary, and axonal loss; and focal thickening of the myelin sheath or tomacula (Figs. 26.4 and 26.5) [165–168]. Outside of the tomacula the ratio of axon and fiber diameter (g ratio) is normal.

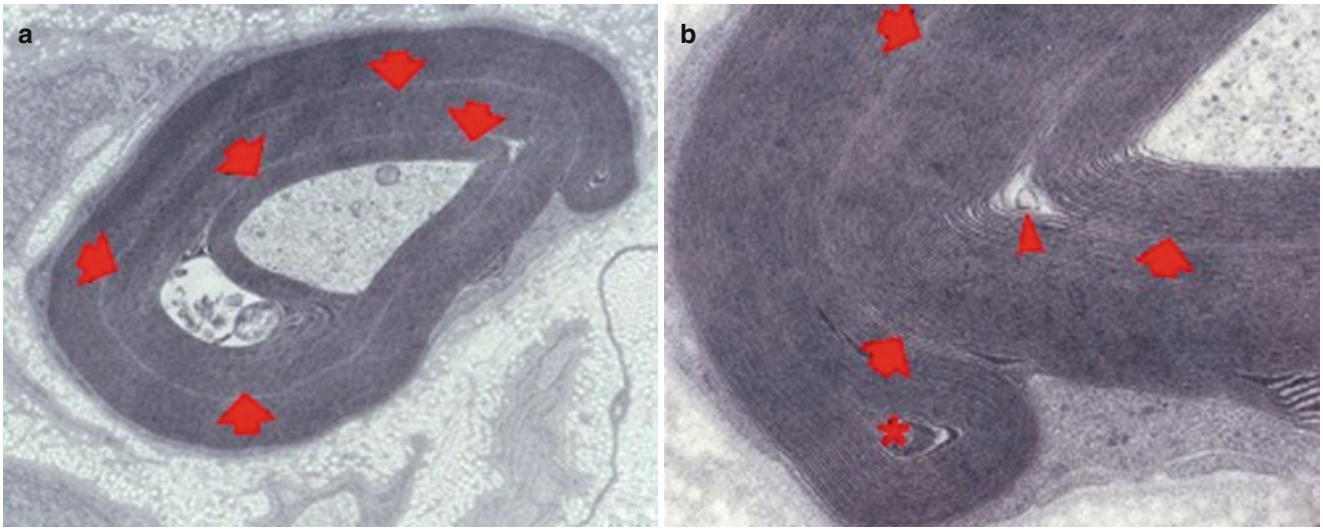

Fig. 26.5 Ultrastructure of a representative tomaculum. A redundant fold of myelin is wrapped nearly twice around the axon. The membranes of this fold are compacted about the original myelin sheath (19 lamellae) to form a hypermyelinated structure that is 97 lamellae thick along most of its circumference. The radial periodicity of these myelin lamellae is normal (14–15 nm). Where the extracellular surfaces of the original myelin sheath and the redundant fold fuse, a thin zone of reduced staining is formed (*large arrows*), which is about three myelin lamellae thick. The altered staining is mostly accounted for by the seam and the two adjacent intraperiod lines that are more lucent than elsewhere. The seam follows each turn of the redundant loop to form a giant spiral that ends in the ab-axonal Schwann cell cytoplasm. The paired membranes of these intermediate lines become indistinct within the cytoplasm, obscuring their connection with the surface membrane of the cell. Compaction of the internal surfaces of the redundant fold forms a second seam that is less distinct than the first one. It is formed by the line of fusion of the cytoplasmic surfaces of the Schwann cell membrane, thus producing an additional major dense line for each turn of the myelin fold. At the terminus of this seam, a small pocket of cytoplasm marks the site where the membrane of the fold loops back on itself (*asterisk* and *arrow head*). This remnant of cytoplasm is derived from the ad-axonal Schwann cell cytoplasm **A** × 13,000; **B** × 39,000

Onion bulb formation and increase in endoneurial connective tissue are limited. Tomacula are more often perinodal than internodal. Nodes of Ranvier are often obscured, probably by the transnodal myelin. There may be branching and duplication of the mesaxons, and more than one Schwann cell may participate in myelination [166]. In HNPP, the genetic defect disturbs adhesion of the myelin lamellae and may make them susceptible to displacement [167]. Ultrastructurally, the tomacula appear as redundant myelin loops, both external and internal, with intramyelinic folds. In a large teased-fiber study, a quarter of fibers were normal; half showed evidence of demyelination or remyelination, and half of fibers had tomacula [168]. Tomacula are not unique to HNPP but occur to various degrees with CMT1B and other CMT disorders, immune mediated, and other neuropathies [168–174].

CMT1B

This form of CMT results from mutations in the *MPZ* gene on chromosome 1q23.3 which codes for a membrane protein exclusively expressed by Schwann cells and constituting over 50 % of compact myelin. *MPZ* is a member of the immunoglobulin supergene family. The mature protein contains three major domains: an extracellular domain (amino acids [aa] 1–124), a transmembrane domain (aa 125–150), and a cytoplasmic domain (aa 151–219) [175].

Phenotypic Variations and Genotype-Phenotype Correlation

Typical clinical presentations are identical to CMT1A. Whether disability is greater in CMT1B or CMT1A is not clear [176]. CNS expression of mutated protein may be responsible for rare features such as dysphagia and deafness. Some 100 *MPZ* mutations have been identified. Over half are missense; the rest are nonsense, frameshift, deletion, or insertion mutations. They cluster in exons 2 and 3 encoding the extracellular domain, and in this way, they can disturb myelin compaction. Others are in the transmembrane (exon 4) or cytoplasmic (exons 5 and 6) domains or its margins. In rare cases, increased *MPZ* gene dosage is associated with CMT neuropathy [177].

Based on the age of onset and clinical and pathological features, most *MPZ* mutations are separable into two groups: one causing a severe, early-onset, demyelinating neuropathy and a second, causing a late-onset neuropathy with prominent axonal loss [178]. Patients with early onset usually have severe neuropathies with very slow NCVs. Many patients with late onset developed symptoms around or after age 40 and have relatively normal or only slightly slowed NCVs; nerve biopsies show prominent axonal loss with mild

demyelination. Insertion of a charged amino acid, altering a cysteine residue in the extracellular domain, and truncation of the cytoplasmic domain cause severe early-onset neuropathy, possibly due to disruption of the tertiary structure of MPZ and the MPZ-mediated adhesion and myelin compaction. Late-onset forms are usually caused by mutations that more subtly alter myelin structure but disrupt Schwann cell-axonal interactions and thereby lead to axonal degeneration.

Unusual phenotypes reflect the impact of specific mutations: Mild phenotypes with recurrent symptoms due to acute nerve compression in patients with demyelinating neuropathy have been associated with heterozygous nonsense mutation (Tyr145Stop) which leads to formation of an extracellularly truncated protein [179]. A combination of distal sensorimotor symptoms, cramps, restless legs syndrome, neuropathic pain, and carpal tunnel syndrome has been reported in a family with a missense Asp234Tyr mutation [180]. Chronic cough is described with the Thr124Met mutation [181]. A phenotype with tonic pupils and conduction block was described [182]. A mild late-onset phenotype with NCVs of 32 m/s resulted from an Asp122Glu substitution, which eliminates a crucial N-glycosylation site [68]. Tremor (Roussy-Levy syndrome) is associated with a heterozygous Asn131Lys substitution in the extracellular domain [60]. CMT1B responsive to immune modulation has been reported with some mutations [180, 183]. Mild recurrent CMT1B with an exon 3 Glu71stop mutation that may reduce MPZ expression was associated with sensitivity to intense manual work, demyelination and remyelination, myelin uncompaction, and axonal loss [184]. A double mutation with a de novo extracellular Val42 deletion and an intracellular Ala221Thr substitution was found in a 25-year-old woman with a progressive neuropathy since age 2. Her father had two normal alleles, and her mother had the Ala221Thr substitution [185]. A mixed demyelinating and axonal neuropathy, pes cavus, and pupillary light-near dissociation were associated with mutations His81Arg and Val113Phe lying on the same allele [69]; the phenotype was less severe than in two instances of isolated His81Arg mutations [186, 187]. A His39Pro extracellular domain mutation was linked to hearing loss and restless leg syndrome [82]. Significant intrafamilial variation was found in several families with a Thr124Met mutation initially classified as CMT2 with late-onset weakness and marked sensory abnormalities which also displayed deafness and pupillary abnormalities: Most patients had at least 1 NCV >38 m/s, and while demyelinating features were found in biopsies, axonal degeneration was also prominent, as were tomacula [67]. In another family, the same mutation was associated with respiratory and autonomic involvement including bladder, sudomotor, papillary manifestations, and neuropathic pain [70].

Pathogenesis

As a homophilic tetrameric adhesion molecule, the extracellular domains of four MPZ molecules form a doughnut-like structure which in turn interacts with the MPZ tetramer of the adjacent myelin membrane [188]. Co-localization studies of MPZ and *PMP22* suggest that they may interact. MPZ is also involved in cell-signaling processes and functions in intracellular and extracellular myelin compaction. Whether MPZ mutations cause predominantly axonal or demyelinating phenotypes may reflect their location in domains involved in myelin-axon or intra-myelin interactions [99]. In part, the effect of a heterozygous *MPZ* mutation may result from a 50 % reduction in functional gene dosage. The clinical, electrophysiological, and histological consequences of different mutations may also reflect the interaction of abnormal with normal MPZ units and with other cellular proteins. Abnormal MPZ can exert a dominant negative effect, thus reducing the amount of functional protein to less than 50 % and causing a more severe phenotype. Without this dominant negative effect, a milder form of CMT1B would result. In experimental system co-expression of wild-type and mutated MPZ confirms that some mutations inactivate wild-type protein, whereas others do not. In Schwann cell cultures, glucocorticoids stimulate the expression of MPZ and *PMP22*; this may explain the benefit of steroids in some cases of CMT1 [183, 189]. Schwann cells from *Mpz* knockout mice downregulate *PMP22* and upregulate myelin associated glycoprotein and proteolipid protein; mistargeting of these and other proteins to inappropriate cellular compartments and dysregulation of other adhesion molecules also occur [190].

Neuropathology

Nerve biopsy usually reveals hypertrophic demyelinating features with onion bulbs and loss of myelinated fibers. An autopsy study described hypertrophy and endoneurial fibrosis in peripheral and spinal nerves [191], while autopsy of another patient with His10Pro mutation showed prominent axonal pathology including focal axonal enlargements and thin myelin but no segmental demyelination [192]. Two biopsies from a family with a Lys96Glu mutation demonstrated prominent tomacula [172] (Figs. 26.4 and 26.5). Tomacula, focally folded myelin, and other specific myelin abnormalities have been reported in extracellular domain mutations such as Ser49Leu, Lys96Glu, Lys101Arg, Lys130Arg, lle135Leu, Ile106Leu, Asp109Asn, Ser34 deletion, Arg69Cys, Arg69His, and Arg69Cys; uncompacted myelin is found in a quarter to two-thirds of nerve fibers with mutations that include Thr4Ile, Arg69Cys, Arg69His, Asn131Lys, and Ser34 deletion [193–199]. Patients with mutations in the intracellular domain (exons 5 and 6) and in the exon 4 transmembrane domain (Gln186stop) or its margins showed

severe myelin uncompaction and hypomyelination. Not only typical demyelination and remyelination but also intracellular myelin uncompaction at the major dense line was associated with the Arg98Cys mutation in the extracellular domain in a patient with delayed motor development, typical CMT as an adult, and NCVs <10 m/s [200]; the same mutation was detected in a severely affected infant who died at 22 months [193]. Mutational introduction of cysteine residues is likely to compromise the correct disulfide bond and thus protein structure.

CMT1C

This subtype has no distinguishing clinical features versus other forms of CMT. Onset age is variable. ENMG and biopsies are indicative of chronic demyelination. Several mutations in the *LITAF* (*SIMPLE*) gene on chromosome 16p13.13 have been identified. This gene appears to have a role in protein degradation [201]; it is highly expressed in Schwann cells. Mutated, it may be pathogenic through both loss and toxic gain-of-function mechanisms [202].

CMT1D

This rare subtype presents with little phenotypic differences compared with CMT1A or B. It results from dominant specific mutations in the zinc-finger binding domain of the early growth response gene 2 (*EGR2* or *Krox20*) on chromosome 10q21.3. Other *EGR2* mutations have been associated with DSS and both recessive and dominant CHN [203]. EGR2 regulates transcription of *PMP22*, *MPZ,* and other myelin genes and plays a role in cellular proliferation and myelin maintenance. Homozygous Egr2 knockout mice show peripheral hypomyelination [41].

CMT1E

CMT1E denotes the association of *PMP22* or *MPZ* mutations with deafness [77–80, 82].

CMT1F

While mutations in the *NEFL* gene more often cause an axonal phenotype (CMT2E, see below), a demyelinating subtype has been described [204, 205].

CMTX

CMTX is an X-linked dominant neuropathy, where milder clinical manifestations are found in heterozygous woman compared to hemizygous men.

CMTX1 accounts for up to 20 % of all instances of CMT, making it the second most common CMT1 subtype after CMT1A. CMTX1 is associated with mutations in the gene encoding the gap junction protein connexin32 (*Cx32* or *GJB1*) on chromosome Xq13.1 [36]. The protein is expressed in Schwann cells and forms tunnel-forming gap junctions between the myelin lamellae. Over 160 different mutations have been described, scattered along the entire coding and cis-regulatory regions of *Cx32*. These include point mutations, deletions and insertions, and rarely deletions of the entire coding region. Some mutations may not affect the open reading frame but the promoter, splice sites, or untranslated portions of the mRNA. In distinction from the significant mutation-dependent variations in CMT1A and B phenotypes, patients harboring different *Cx32* mutations are similarly affected, consistent with a loss-of-function effect.

Phenotypic Variation

Symptoms commonly develop in the first decade but may appear before the age five or in the third decade [206]. Compared to CMT1A and B, paresthesias, sensory loss, and atrophy, especially of hand muscles, may be more prominent [207, 208]. Onset is later in women, in whom the condition is usually milder. In some cases, the severity in women may approach that observed in men [209], likely due to unequal inactivation of the X chromosome (lyonization) resulting in predominant expression of the abnormal *Cx32* allele in nerves. In men, CMTX1 tends to be more severe than CMT1A. Variable pes cavus deformity is present in those affected [210–212]. Median motor NCVs in men are usually <38 m/s, whereas in women they range from the demyelinating range to normal [213]. Women may be asymptomatic but have an abnormal ENMG. The CNS may be affected in CMTX1 and present with extensor plantar responses [71], dystonia [72], paresis, aphasia, dysarthria, cranial nerve palsies [73], sensorineural deafness and delayed brainstem auditory evoked potentials [83], and cerebellar pathology [74]. CNS manifestations may be precipitated by febrile illness, hyperventilation, or moving to higher altitudes. CNS signs and symptoms are usually transient, but persistent abnormalities have also been reported [75]. In some cases MRI shows reversible white matter lesions [73].

Pathogenesis

Cx32 localizes to regions of non-compact myelin, that is, Schmidt-Lanterman incisures and the paranodes of myelinating Schwann cells, where it forms gap junctions between adjacent myelin lamellae. The resulting cytoplasmic continuity accelerates the transport of metabolites, ions, and second messenger molecules between the ad-axonal and perinuclear regions of Schwann cells compared to the circumferential path along the Schwann cell cytoplasm [214]. *Cx32* mutations may interrupt this pathway or have other toxic effects, thereby injuring myelinating Schwann cells and their axons.

Different *Cx32* mutations have different effects on the ability of the mutant protein to form functional gap junctions; some mutant proteins cannot be detected within the cell; some accumulate within the cell but do not reach the cell membrane, while other mutants do reach the cell membrane and some of these form functional gap junctions.

Other CMTX neuropathies have broader nervous system manifestations. CMTX2 maps to chromosome Xp22.2 and is characterized by infantile onset, neuropathy, and mental retardation [215]. CMTX3 maps to chromosome Xq26 and presents with prominent paresthetic pain [216]; women may be asymptomatic but have high arches and weak foot dorsiflexion. CMTX4 maps to chromosome Xq24-q26.1. Men have a severe axonal neuropathy with muscle weakness from infancy, and most have associated deafness or mental retardation or both, while women are asymptomatic [84, 217]. CMTX5 with mostly axonal neuropathy, deafness, and optic neuropathy is due to mutations in the phosphoribosylpyro-phosphate synthetase (*PRPS1*) gene on chromosome Xq22.3 [85].

CMT2

As with other forms of CMT disease, phenotypic variation is common among and within CMT2 families. Some reports suggest that CMT2 has a later onset. One family with 50-year anticipation between generations has been reported [218]. Patients may have greater atrophy and distal leg weakness with relatively less hand weakness. Areflexia, pes cavus, and hammer toes may be less common than in CMT1. Nerve hypertrophy is absent, but it is variable in CMT1 as well. CMT2 often presents a diagnostic dilemma because characteristic features such as enlarged nerves and near-pathognomonic neurophysiologic findings are absent. With later onset, the condition may be difficult to differentiate from a late-life-acquired neuropathy when the family history is unclear. Thus, prevalence assessments are of uncertain validity, though estimates suggest that there is one case of CMT2 for every two cases of CMT1. CMT2 and CMT1 can rarely be differentiated by history and examination findings alone. Sural nerve pathology usually reveals reduced numbers of myelinated axons, especially of larger diameter. Rare myelin defects can be observed.

CMT2A1 and CMT2A2

The clinical onset of CMT2A can vary from childhood to old age. Affected members of a large southern Italian pedigree had distal weakness, wasting, hyporeflexia, and mild panmodal sensory loss [219]. Biopsies revealed loss of myelinated fibers, rare onion bulb formations, and mitochondrial abnormalities [219–221]. Mutations in the *MFN2* gene cause CMT2A2 [222, 223]. MFN2 protein (mitochondrial GTPase mitofusin 2) is a large dynamin-like GTPase located on the outer mitochondrial membrane. CMT2A was also linked to a loss-of-function mutation in the *KIF1Bβ* gene on chromosome 1p36.2; this subtype has been categorized as CMT2A1 [224]. KIF1B beta is a motor protein involved in the anterograde transport of mitochondria. *MFN2* mutations are far more common than *KIF1B* in CMT2A. CMT2A2 is clinically indistinguishable from CMT2A1, CMT2E, and CMT2F. *MFN2* mutations account for 20–33 % of CMT2; thus, CMT2A is the most common form of CMT2 and second in frequency only to CMT1A [221]. Some patients have optic atrophy or sensorineural hearing loss; this also referred to as HMSNVI [222]. There are two major forms of CMT2A: severe with early onset and mild with late onset [119, 221]. Some patients develop minor CNS changes; foot deformities occurred in all patients in a large Korean series [119]. Some patients have low-penetrance *MFN2* mutations with normal nerve conduction and minor neuromuscular changes on examination, but most CMT2A patients have an early-onset and severe phenotype; CMT2A accounts for 91 % of the severe phenotypes of CMT2 [225]. Of note, *MFN2* genetic defects have predominantly dominant inheritance; however, homozygous or compound heterozygous mutations are also reported in early-onset CMT2. Twenty MFN2 gene missense mutations were identified among 150 individuals with clinically diverse HSMN, dominant and recessive inheritance, and motor NCVs of 25 m/s or greater [226].

CMT2B

CMT2B is a predominantly sensory neuropathy, which has lead to a debate to its classification with hereditary motor and sensory neuropathy versus hereditary sensory and autonomic neuropathy. Patients may have foot ulcerations and even amputations, but no clinical weakness. High arches, hammertoes, and hyporeflexia are also present. Although neurophysiologic abnormalities are established early in life, clinical onset may be much later. Decreased CMAP amplitudes and denervation are characteristic. CMT2B biopsies reveal evidence of degeneration and regeneration, with the presence of occasional onion bulbs. CMT2B maps to chromosome 3q21.3 and is caused by mutations in the small guanosine triphosphatase (GTPase) late endosomal protein RAB7, a member of the RAS-associated GTP-binding proteins [227, 228]. RAB7 is ubiquitously expressed in sensory and motor neurons and serves to regulate linkage of vesicles and other membranes to the cytoskeleton and plays a role in lysosomal degradation.

CMT2B1

Onset of CMT2B1, an autosomal-recessive condition, in a Moroccan family is in the second decade. Features include distal and (less often) proximal weakness and pes cavus. Motor NCV are near normal. Linkage was found to chromosome 1q22 [229]; in a similar family a homozygous mutation in the

LMNA gene, which encodes the intermediate filaments lamin A and C, a component of the nuclear envelope, was detected [230]. In *LMNA* knockout mice, the authors found reduced axon density, axonal enlargement, and non-myelinated axons. This same gene is mutated in limb-girdle muscular dystrophy type 1B, autosomal-dominant Emery-Dreifuss muscular dystrophy, dilated cardiomyopathy type 1A, mandibuloacral dysplasia, and autosomal-dominant partial lipodystrophy. Co-occurrence of *LMNA* and *PMP22* mutations causes an unusual phenotype [88].

CMT2B2

A second form of autosomal-recessive axonal CMT has been mapped to chromosome 19q13.33 in a Costa Rican family. Patients have a sensorimotor polyneuropathy with distal arm and leg weakness and wasting, hyporeflexia, and sensory loss with normal or minimally reduced NCVs [231]. A missense mutation in the *MED25* gene, a transcriptional regulator, was identified in affected family members, which likely causes a loss of protein function [232].

CMT2C

CMT2C onset varies from congenital to late adulthood. Mild sensory loss is combined with weakness especially in the hands but also in the proximal legs, diaphragm, and intercostal muscles. Worsening hand weakness in the cold, neurogenic bladder and hearing loss are common. Vocal fold dysfunction can lead to early death. Other patients have scapuloperoneal spinal muscular atrophy or congenital distal spinal muscular atrophy. Mutations in the transient receptor potential vanilloid four (*TRPV4*) gene on chromosome 12q24.11 were found in several families [233–235]. TRPV4 is a nonselective cation channel. Gain of function mutations in *TRPV4* cause also various skeletal dysplasia syndromes including spondylometaphyseal dysplasia, brachyolmia, and metatropic dysplasia. Patients with both neuropathy and skeletal abnormalities have been described, underscoring that TRPV4-associated channelopathies are spectrum disorders. All neuropathy-causing mutations cluster around the ankyrin-repeat domain of the protein [235].

CMT2D

CMT2D patients often have worse hand than leg weakness and slow progression [236, 237]. Onset is typically in the second to third decades but rarely in infancy [238]. Tendon reflexes are usually absent in the arms and decreased in the legs. CMT2D is allelic disorder with distal spinal muscular atrophy type V [239], and both phenotypes can occur in the same family. They are caused by mutations of the *GARS* gene-encoding glycyl-tRNA synthetase on chromosome 7p14.3 [237]. Studies in *Gars* mice models suggest that the neuropathy is caused by a gain of toxic function of the mutant protein, rather than loss of aminoacylation properties; however, the exact pathomechanism is unknown [240].

CMT2E

CMT2E can be difficult to distinguish from CMT1A, CMT1B, or CMT2A, though more severe clinical phenotypes occur [205]. Onset age ranges from the first to third decades [205, 241, 242]. Multiple dominantly inherited mutations in different protein domains are reported in the neurofilament light chain gene (*NEFL*) on chromosome 8p21.2. NEFL is a major component of neurofilaments, the neuron-specific intermediate filaments maintaining neuronal cytoskeleton and determining axonal caliber [243]. *NEFL* mutations disrupt both self-assembly and co-assembly with medium and heavy chain neurofilaments. This impacts axonal transport of neurofilament building blocks and affects the anterograde and retrograde transport of other cell components, particularly of mitochondria, resulting in progressive degeneration and loss of neuronal viability. In contrast, the only recessive Glu210X mutation reported to date causes loss of NEFL protein. In affected persons homozygous for this mutation, this leads to lack of neurofilaments and progressive axonal loss [244]. ENMG indicates axonal involvement with demyelinating features and prolonged DMLs disproportionate to the conduction slowing, similar to findings in anti-MAG-associated neuropathy [245]. In some cases, NCVs are severely slowed, and for these a classification as CMT1F (see above) has been proposed [204, 205]. One nerve biopsy revealed axonal degenerative and regenerative features as well as onion bulbs [205]. This highlights the marked variability of clinical patterns with specific CMT gene mutations. Thus, strict genotype-phenotype correlations are difficult to establish.

CMT2F

CMT2F patients exhibit slow progression and primarily distal weakness. In a six-generation Russian family with autosomal-dominant inheritance, onset ranged from age 15 to 25 [246]. Patients had early hyporeflexia and symmetric, slowly progressive weakness and leg atrophy with foot drop, whereas upper limb weakness and wasting ensued years later. Sensory impairment was mild to moderate. Mutations in the small heat-shock 27-kDa protein 1 (*HSPB1*) gene on chromosome 7q11.23 were detected in the Russian [247] and subsequently in multiple families. This gene is also mutated in distal hereditary motor neuropathy type 2B (dHMN2B). *HSPB1* mutations may act by disrupting the intermediate filament or tubular networks, enhanced binding of client proteins, aggregate formation, or other mechanisms.

CMT2G

CMT2G was first described in ten relatives from a three-generational Spanish family [248]. The mean age at onset was 29 but with a broad range of 9–76 years. Patients had slowly progressive foot deformity, difficulty walking, hypo- or areflexia, and mild stocking hypesthesia. NCVs were normal

in some and mildly slowed in others. Biopsy showed regenerating fibers, fiber loss, and atrophy. A disease-associated locus on chromosome 12q12-q13.3 has been identified; however, the causal mutation is unknown [249].

CMT2H/K

This subtype denotes CMT linked to a locus at chromosome 8q21.11 [250] where dominant mutations in the ganglioside-induced differentiation-associated protein 1 (*GDAP1*) gene have been found. GDAP1, located in the outer mitochondrial membrane of neurons and Schwann cells, appears to function in mitochondrial fission pathways. Both autosomal-recessive and dominant forms are associated with defects in *GDAP1* [251]; the latter are often milder. Patient with dominant GDAP1 mutations present with axonal ENMG findings (i.e., moderately slowed NCVs >38 m/s and decreased CMAP amplitudes), onset age ranging from childhood to late adulthood, and generally slow progression without loss of ambulation [251]. Severity ranges from asymptomatic to wheelchair dependency at age 60. GDAP1 mutations are also associated with CMT4A (see below).

CMT2I

Several MPZ mutations have been associated with an autosomal-dominant, adult onset axonal CMT phenotype. Carriers may be asymptomatic or present with cramps, foot numbness, and deformities [77, 252–254]. One patient had normal NCVs at age 15, while older relatives had variable slowing into the CMT1 range, suggesting progressive NCV slowing with age [255].

CMT2J

Several families and isolated patients with CMT2 and onset in the fourth to sixth decade with marked sensory abnormalities, weakness, deafness, chronic cough, and autonomic dysfunction including pupillary abnormalities have been reported. NCVs ranged from below 38 m/s to normal. Biopsies showed axonal changes. Several MPZ mutations were identified [67, 181, 256, 257].

CMT2L

CMT2L denotes an axonal, autosomal-dominant subtype with linkage to chromosome 12q24.23 and mutations in the heat shock 22-KD protein 8 (*HSPB8*) gene. The encoded protein has chaperone and transport functions and is also implicated in distal hereditary motor neuropathy type 2A (dHMN2A) [258].

CMT2M

CMT2M is linked to mutations in the dynamin 2 (*DNM2*) gene on chromosome 19p13.2 [259–261]. Patients present with a sensorimotor neuropathy, prominent gait ataxia. NCVs are near normal and nerve biopsy reveals loss of large diameter fibers and rare onion bulb formation. *DNM2* mutations are also associated with autosomal-dominant centronuclear myopathy I and dominant DI-CMT B [261] (see below). Dynamins contain a GTPase domain and scaffolding proteins with a role in membrane trafficking.

CMT2N

CMT2N has a variable phenotype with onset ranging from the first to the sixth decade and from absence of symptoms to distal weakness and sensory loss, and deafness; NCVs range from 32 m/s to normal [262, 263]. It has been associated with Asn71Tyr and Arg329His mutations in the alanyl-tRNA synthetase (*AARS*) gene on chromosome 16q22.1. The mutation reduces aminoacylation activity of the protein [262].

CMT2O

A 4-generation 23-member family with early-onset sensorimotor neuropathy and delayed milestones has been described. NCVs were normal and nerve biopsies showed evidence of axonal degeneration. A missense mutation in the cytoplasmic dynein heavy chain 1 (*DYNC1H1*) gene on chromosome 14q32.31 [264] was identified. The protein is involved in cargo binding and axonal transport along microtubules.

CMT2P

This subtype with autosomal-dominant or autosomal-recessive inheritance is linked to homozygous or heterozygous mutations in an ubiquitin ligase encoded by the leucine-rich repeat-and-sterile alpha motif-containing one gene (*LRSAM1*) on chromosome 9q33 [265, 266]. Like the LITAF/SIMPLE implicated in CMT1C, LRSAM1 plays a role in protein degradation pathways. Affected individuals with a heterozygous frameshift mutation present in the second or third decade with progressive distal muscle weakness and mild distal sensory disturbances. ENMG revealed severe axonal changes confirmed by biopsy in one individual [265], whereas a mild axonal distal neuropathy with onset in early adulthood and NCVs >38 m/s was associated with a homozygous splice acceptor mutation [266].

DSS (HMSN3 or CMT3)

Originally described in 1893 as a hypertrophic polyneuropathy with onset in infancy or early childhood in patients born from unaffected parents, DSS is characterized by distal sensory loss with ataxia, pes cavus, distal weakness with proximal progression, palpable hypertrophied nerves, and Argyll-Robertson pupils [4, 6]. Lightning pain, described in the original two cases, is uncommon. In 1906 Marie reported a variant of DSS with distal atrophy, nerve hypertrophy, areflexia, intention tremor, and dysarthria but without sensory ataxia or Argyll-Robertson pupils [4]. Common features include early

onset, delayed motor milestones, severe gait disturbance, ataxia, variable nerve hypertrophy and thickened spinal roots, increased CSF protein, and very slow NCVs [9, 267]. Although a slowly progressive length-dependent sensorimotor deficit is typical, a relapsing-remitting course occurs [267].

Neuropathology

Hallmarks include extensive nerve and root hypertrophy due to demyelination-remyelination, decreased fiber density, segmental demyelination, onion bulbs, and sometimes giant whorls of cell processes [9]. In young patients, teased fibers reveal thinly myelinated internodes, irregularity of myelin sheath thickness, and segmental demyelination [267].

Pathogenesis

Mutations in *MPZ*, *PMP22*, *EGR2*, and *PRX* [28, 38, 47, 267, 268], and linkage to chromosomes 8q23-24 [269] have been described. The possible existence of milder and unrecognized hereditary neuropathies in one or both parents must be considered. Autosomal-recessive forms are discussed in the CMT4 subgroup below.

Congenital Hypomyelination Neuropathy (CHN)

Patients present with neonatal hypotonia, areflexia, distal weakness, slow NCVs, and at times, contractures or arthrogryposis [91, 270]. It may result from dominant *MPZ*, *PMP22*, or *EGR2* mutations, as well as from homozygous states when parents are heterozygous for the same or different mutations or when one mutation inherited from one parent is combined with a de novo mutation in the same or another gene [47, 203, 271].

Neuropathology

There is severe hypomyelination, demyelination, and axonal loss. Absence of active myelin breakdown and rare onion bulbs points to CHN, whereas demyelination or remyelination and abundant organized onion bulbs are common in DSS. CHN results from a congenital impairment in myelin formation, whereas DSS results from aberrant demyelination and subsequent remyelination of the peripheral nerve.

Hereditary Neuralgic Amyotrophy (HNA)

HNA has also been referred to as neuritis with brachial predilection, hereditary brachial plexus neuropathy, hereditary neuralgic amyotrophy with predilection for the brachial plexus, and idiopathic brachial plexus neuropathy. HNA is an autosomal-dominant form of recurrent focal painful neuropathy with predilection for arm involvement. An early report described a woman with three episodes of painful arm weakness, whose sister had experienced seven such attacks [272]. Some 200 families worldwide have been identified [273, 274].

Patients experience episodic weakness, atrophy, and sensory disturbances, usually preceded by severe pain in the affected arm. Onset is between 10 and 30 years of age, though rarely earlier. Near complete recovery begins within weeks to months after onset. Recurrences may affect either arm. Right arm involvement has been described most frequently. The lower cranial nerves; the lumbosacral plexus; the phrenic, long thoracic, and recurrent laryngeal nerves; and the sympathetic nervous system may be affected. As in the sporadic forms, attacks may follow infections or immunization [273]. Some patients follow a relapsing-remitting course and others a chronic undulating course [275]. While the frequency of attacks diminishes with age, patients accumulate deficits. ENMG reveals signs of denervation and reinnervation in weak muscles. Biopsies show decreased myelinated fiber density in individual nerve fascicles. Treatment focuses on pain control and rehabilitation; there is limited support for the use of corticosteroids and IVIG [276]. Common dysmorphic features include hypotelorism, short stature, cleft palate, partial syndactylism, unusual skin folds, and creases in the neck or scalp referred to as cutis verticis gyrata [45, 277]. Linkage to chromosome 17q25 was found in some families [45, 275, 278], and mutations in the *SEPT9* gene which plays a role in the cytoskeleton, cell division, and tumorigenesis have been identified [278].

CMT4

CMT4 describes autosomal-recessive forms of demyelinating CMT. In its most severe forms, there is overlap with DSS/CMT3. The classification represents distinct clinical and histological subtypes, of which several occur only among specific ethnic groups. Axonal autosomal-recessive subtypes include CMT2B.

CMT4A

CMT4A manifests in early infancy with delayed motor development, muscle atrophy, weakness, and occasionally, scoliosis. Vocal fold paralysis may develop. The disease may progress to severe motor weakness [279–281]. NCVs are in the demyelinating range, CMAP and SNAP amplitudes are reduced or absent. Pathologic hallmarks include hypomyelination with onion bulbs, though mixed features of demyelination and axonopathy histologically and by ENMG can exist and are referred to as CMT-RIA [280, 282, 283]. The axonal form is associated with vocal cord and diaphragmatic paralysis with midlife onset [283, 284]. Linkage to mutations in the ganglioside-induced differentiation-associated protein-1 (*GDAP1*) gene on chromosome 8q21.11 has been established [280, 281, 285, 286] (see also under CMT2H/K [250, 251]).

CMT4B1

CMT4B1 is a nonhypertrophic, severe, sensorimotor neuropathy with onset in infancy [174, 287]. As weakness progresses, some patients become wheelchair bound. A histological hallmark is the presence of focally folded myelin sheaths [288]. Linkage to chromosome 11q21 was established, where several homozygous or compound heterozygous mutations in a myotubularin-related protein 2 (*MTMR2*) result in premature translation termination or frameshift [289]. Such loss of function mutations could result in constitutive phosphorylation of an unknown substrate, with Schwann cell proliferation and myelin overgrowth.

CMT4B2

The CMT4B2 subtype is characterized by sensorimotor neuropathy, with onset in the first or second decade, and early-onset glaucoma. It has been identified in consanguineous families from Tunisia, Morocco, Brazil, and Japan. Motor NCVs are severely reduced, and nerve biopsies showed myelin outfoldings. Early visual deficiencies and later blindness result from congenital glaucoma with buphthalmos, megalocornea, and increased intraocular pressure [290]. Mutations were found in the gene for SET-binding factor 2 (*SBF2*) on chromosome 11p15.4, a pseudophosphatase- and myotubularin-related protein that may be involved in phosphoinositide-mediated signaling events controlling myelination [290, 291].

CMT4C

CMT4C manifestations are variable but include prominent scoliosis, early loss of ambulation, and respiratory problems; onset varies from infancy to age 12. Hearing loss and facial paresis may occur. NCVs are typically in the demyelinating range but may be intermediate [292, 293]. Nerve biopsies revealed axonal loss and abnormal Schwann cell processes with increased basal lamina production [294]. Linkage to chromosome 5q32 was found [292, 295], where multiple truncating and missense mutations in the *SH3TC2* gene (also known as *KIAA1985*) which codes for the SH3 domain and tetratricopeptide repeats-containing protein 2 have been found [292, 293]. The protein, localized to plasma membranes of Schwann and other neural cells, appears to play a role in myelin maintenance and axon-myelin interactions. Certain heterozygous mutations are associated with mild axonal polyneuropathy and/or carpal tunnel syndrome [296].

CMT4D or HMSN-Lom

CMT4D was first described in gypsies living in Bulgaria and later on in affected individuals from this ethnic group across Europe [297]. This variant is characterized by gait difficulties in the first decade, skeletal deformities, hearing loss, and severe sensorimotor deficits (Fig. 26.1). NCVs are less than 15 m/s, with unobtainable sensory responses. Biopsies reveal demyelination or remyelination and severe progressive axonal loss [298]. Onion bulb formations were more conspicuous in younger than older individuals. Hypomyelination and uncompacted myelin were observed together with intraaxonal accumulation of irregular curvilinear material. A private nonsense mutation in the N-myc downstream-regulated gene 1 (*NDRG1*) on chromosome 8q24.22 was reported [297]. A splice-site mutation in a non-Gypsy patient is also reported [299]. Ubiquitously expressed, but particularly in Schwann cells, NDRG1 may play a role in growth arrest and cell differentiation, possibly as a signaling protein shuttling between the cytoplasm and the nucleus. The protein may mediate Schwann cell signaling necessary for axonal maintenance.

CMT4E

CMT4E has a severe phenotype with cranial nerve involvement, arthrogryposis, and respiratory failure; some patients may walk with aid of a walker [300]. NCVs are below 10 m/s. Biopsies reveal near absence of myelin, occasional onion bulbs, and axonal loss. This CMT form is caused by autosomal-recessive mutations in the *EGR2* gene on chromosome 10q21.3 Less-severe EGR2 mutations with autosomal-dominant inheritance are classified as CMT1D and DSS [41] (see above).

CMT4F

CMT4F was first identified in a Lebanese family. Patients present with a disabling ataxic neuropathy with onset before age 10 with delayed developmental milestones, distal atrophy and weakness, pain, and prominent large fiber involvement resembling DSS. Motor and sensory responses are difficult to evoke in most individuals [268, 301]. Onion bulbs, loss of axons, and hypertrophied myelin sheaths are seen in biopsies. Several mutations in the periaxin (*PRX*) gene on chromosome 19q13.2 have been identified [268, 301–303]. PRX codes for L and S periaxin, which interact both with plasma membrane and cytoskeletal proteins and play a role in the assembly of signaling complexes at sites of cell-cell contact.

CMT4G Russe

CMT4G Russe is described in Gypsies residing in Bulgaria, Spain, Romania, and France [304, 305]. Patients have severe disability with prominent sensory loss, intermediate motor NCVs, and a high threshold for electrical nerve stimulation. It results from a mutation in an alternative untranslated exon of hexokinase 1 (*HK1*) on chromosome 10q22.1 [306].

CMT4H

CMT4H is an early-onset neuropathy with delayed milestones, distal weakness and atrophy, sensory impairment, and scoliosis described in two Lebanese and Algerian

families [307]. NCVS are below 15 m/s, and biopsies reveal axonal loss, hypomyelination, and eccentric folding of redundant myelin sheaths. Mutations in the *Frabin/FGD4* gene on chromosome 12p11.21 were found in the original and several other families of different ethnicities [308]. The protein is involved in Schwann cell shape, possibly by affecting Rho GTPase signaling pathways [309]. There is considerable clinical heterogeneity and variable functional impairment [309]. A less severe phenotype with slowly progressive polyneuropathy is also described where patients remain ambulatory to middle age [310].

CMT4J

CMT4J denotes a severe phenotype with variable but often childhood onset resulting from compound heterozygous mutations on chromosome 6q21 in the *FIG 4* gene which encodes the $PI(3,5)P_2$ 5 lipid phosphatase [311]. Patients have proximal and distal and asymmetric muscle weakness with rapid progression and only mild sensory loss. The phenotype resembles motor neuron disease, and indeed, some mutations in the same gene are associated with motor neuron disease subtype 11 with normal NCVs. ENMG reveals denervation in proximal and distal muscles and variable NCVs [312]. Neuropathologic findings include large fiber loss, thinly myelinated fibers, and small onion bulbs.

GAN

Autosomal-recessive giant axonal neuropathy presents in childhood and is associated with short stature, tightly curled hair, prominent CNS involvement including mental retardation and optic atrophy, severe disability, and MRI white matter hyperintensities. Missense, nonsense, and frameshift mutations in the gigaxonin gene on chromosome 16q23.2 lead to neurofilament accumulation and segmental axonal swelling [313].

Dominant Intermediate CMT (DI-CMT)

Individuals and families with NCVs atypical for both CMT1 and CMT2 have long been recognized. Before the advent of genetic testing, Bradley, Davis, and Madrid proposed a CMT classification that included an intermediate group, characterized by median motor nerve NCVs of 25–45 m/s and intermediate pathological changes compared to the hypertrophic neuropathy group [16–18]. The growing number of genetically and phenotypically characterized CMT families indicated that based on ENMG and pathological criteria, specific mutations in several genes indeed lead to intermediate phenotypes. These genes encode for MPZ [67, 108, 178], Cx32 [77, 212, 213, 314], NEFL [242, 315, 316], and GDAP1 [280, 282, 283]. Supporting the genetic heterogeneity of the intermediate CMT category, additional loci have been identified segregating in large families with dominant inheritance: DI-CMTA, DI-CMTB, DI-CMTC, and DI-CMTE.

DI-CMTA

DI-CMTA, originally reported in 1985 [317], is clinically characterized by second-decade onset, when patients develop leg weakness, difficulty running, and muscle cramps. Motor difficulties with exposure to cold occur. By the fifth decade, patients have severe weakness and distal limb atrophy, steppage gait, pes cavus, areflexia, and mild distal sensory loss. Later, the course stabilizes and elderly patients are typically not wheelchair bound. NCVs are 25–45 m/s. By biopsy, features of demyelination and remyelination (onion bulb formation and uncompacted enlarged myelin lamellae) and chronic axonopathy (large fiber loss and clusters of regenerated axons) coexist [317–320]. Linkage has been assigned to chromosome 10q24.1-q25.1 [320]; however, the causal gene is still unknown.

DI-CMTB

Patients with DI-CMTB are mildly to moderately affected; some have neutropenia or cataracts. NCVs range from 26 m/s to normal and CMAP amplitudes from severely reduced to normal. Nerve biopsies reveal predominantly axonal degeneration and loss of large diameter fibers; segmental demyelination and remyelination with onion bulb formation are rare [321, 322]. DI-CMTB is associated with mutations in the dynamin 2 (*DNM2)* gene on chromosome 19p13.2 [260, 261, 321–323], which is also implicated in CMT2M [259] (see above) and centronuclear myopathy.

DI-CMTC

The DI-CMTC subtype presents with typical moderate severity sensorimotor features (Figs. 26.2 and 26.3) and was first described in one US and one Bulgarian family with onset in childhood in the former and in young adulthood in the latter. Median motor NCVs were in the range of 24–58 m/s. Sural nerve biopsies revealed age-dependent morphological changes of axonal degeneration, absence of onion bulbs, and <10 % fibers with segmental remyelination [324] (Fig. 26.6). DI-CMTC is linked to chromosome 1p35.3 and is caused by mutations in the *YARS* gene encoding tyrosyl-tRNA synthetase (TyrRS) [325, 326]. So far, only three disease-causing *YARS* mutations have been described. The Bulgarian DI-CMTC patients carry an E196K mutation, while the US patients are heterozygous for a G41R substitution. A de novo in-frame deletion (153-158delVKQV) was identified in a single Belgian patient. In vitro and transgenic Drosophila studies suggest a gain-of-toxic-function neurodegenerative effect of the mutations [326, 327].

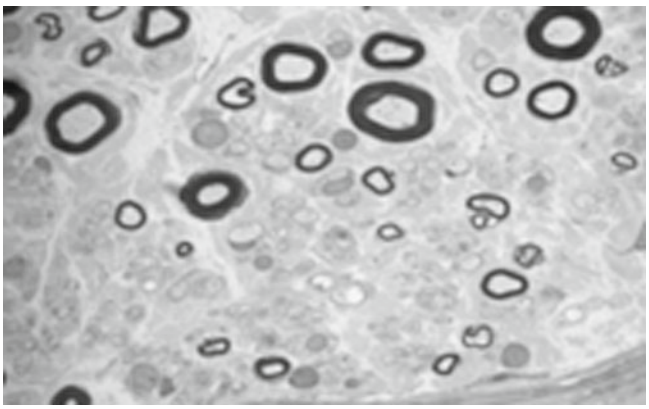

Fig. 26.6 Sural nerve biopsy in DI-CMTC. Semithin toluidine blue-stained cross section shows marked depletion of myelinated nerve fibers. Many remaining fibers have thin myelin sheaths

DI-CMTD

A four-generation family with autosomal-dominant CMT, variable distal wasting, weakness, and sensory loss (worse in the legs) was reported [108]. Motor NCVs range from 24 to 41 m/s. Biopsies revealed axonal changes, segmental demyelination and remyelination, but no onion bulbs. An Asp6Tyr mutation in the extracellular domain of MPZ was found.

DI-CMTE represents a sensorimotor neuropathy with onset in the second decade affecting the legs more than the arms, of variable severity associated with a kidney disorder ranging in severity from proteinuria to end-stage renal disease. Some patients have hearing loss. NCVs were in the intermediate range, and nerve biopsies revealed axonal loss and onion bulb formation. Renal biopsies showed focal segmental glomerulosclerosis. The condition results from a mutation in exons 2 or 3 of the inverted Formin 2 (*INF2*) gene on chromosome 14q32 [328]. Mutations of INF2 are also known to cause autosomal-dominant kidney disease without neuropathy. INF2 is involved in actin and microtubule maintenance in both Schwann cell myelin and glomerular podocytes, two cell types with a large surface area.

RI-CMTB

Recessive intermediate CMT (CMT RIB) has been described in a patient who also had developmental delay, self-abusive behavior, dysmorphic features and vestibular Schwannoma, and NCVs 39.5 and 30.6 m/s in the median and ulnar nerves. RI-CMTB results from mutations in the *KARS* gene encoding lysyl-tRNA synthetase on chromosome 16q23.1 [329].

Management

With the exception of CHN, a person's lifespan is not altered in most instances of CMT. Disability is highly variable and difficult to predict in young individuals, even among siblings [72, 96], but quality of life is generally lowered [330]. In the majority, CMT is slowly progressive. If progression accelerates, other causes, such as acquired neuropathies or other inherited neuromuscular conditions, should be sought [86–89, 331]. For children, a disability measure, CMT Pediatric Scale, has been validated [332]. Dealing with a life of initially mild but progressive disability can increase the risk of depression and lead to further disability. Referrals to mental health professionals may be indicated. Genetic counseling is indicated, in particular when affected or unaffected individuals with an affected child contemplate procreation. When both parents have symptomatic or asymptomatic CMT, they may have homozygous or compound heterozygous offspring with DSS or CHN.

Education can help patients and their families cope with the progression of disability and reduce the likelihood of avoidable nerve damage, for example, exposure to drugs and neurotoxins, such as alcohol. Internet resources are available from the Charcot-Marie-Tooth Association (www.CMTAUSA.org), the National Organization for Rare Diseases (www.RareDiseases.org), and many others. Patients should be familiar with disability rights regulations and entitlements to "reasonable accommodations" at work and in school.

Primary prevention is not a practical option at present. As CMT rarely affects life span, intellect, or independent living, most patients have children. Prenatal screening raises ethical issues; it is available in Bulgaria for high-risk Gypsy communities [333–335].

As no medical therapy can slow the progression of CMT, secondary prevention focuses on awareness and avoidance of intercurrent conditions or interventions that can exacerbate physical disability or lead to systemic or focal neuropathies, such as diabetes mellitus, vitamin deficiencies, hypothyroidism, neurotoxic agents, and prolonged immobilization during surgery. Awareness of the CMT diagnosis on the part of the patient and health care providers is essential: For example, malignancies may present indications for neurotoxic drugs such as platinum compounds or vincristine [336, 337]. At times alternative treatments with less neurotoxicity may be equally effective.

Patients should maintain a well-balanced diet and avoid obesity and impaired glucose tolerance which can foster back pain, acquired systemic and focal neuropathies including meralgia paresthetica, and spinal root disease. Limiting alcohol use is important given the lack of evidence re safe amounts. Nerves in HNPP in particular are sensitive to prolonged compression for which intoxication in general is a risk factor. Avoiding a sedentary lifestyle within the confines of any functional needs is important. Exhaustion of weak muscles may be undesirable, given the evidence for overuse weakness in CMT [338]. Individuals with HNPP should minimize work and recreational activities that can compress or injure nerves. Sleep disorders and laryngeal and

pulmonary involvement require evaluation and consideration of therapeutic options [76].

Pain may result from joint deformities or compensatory overuse of certain muscle groups. Abnormal gait and scoliosis can lead to back pain. Some types of pain may respond to nonsteroidal anti-inflammatory drugs. Dysesthetic pain may occur but is typically mild except in certain subtypes. It responds to the same drugs as in acquired neuropathies. Sometimes muscle cramps require treatment.

Depending on the degree of foot deformities, patients may benefit from Achilles tendon lengthening, tendon transfers, hammertoe correction, and release of the plantar fascia. However, such surgeries can often be prevented by conservative measures and lifelong follow-up with physical therapists.

Referrals to physical therapists and prosthetics or orthotics specialists are often required to prevent and treat joint deformities. AFOs can facilitate ambulation, prevent falls and injuries, and prevent Achilles tendon shortening, but if weakness spreads to proximal limbs, ambulation can be impaired even with AFOs. Special AFOs can be worn at night. With mild foot drop, boots can delay the need for AFOs. For moderate foot drop, lighter AFOs may be more appropriate. Thick-handle tools and cutlery can render certain activities of daily living easier.

While no adverse reactions to anesthetics including succinylcholine were identified in one study; succinylcholine may still be inadvisable [339]. As nitrous oxide (N_2O) may contribute to B12 deficiency, B12 levels should be assayed and deficiency be treated prior to N_2O anesthesia. Prolonged body and limb positions can result in nerve compression, especially in HNPP. Regional anesthesia is relatively contraindicated in CMT.

Inherited Metabolic Neuropathies

27

Perry K. Richardson and Scott T. Demarest

Inherited Metabolic Neuropathies

The inherited metabolic neuropathies are a complex, heterogeneous group of disorders. In some, peripheral nerve dysfunction is one feature of a multisystem disease; in others neuropathy is the predominant manifestation of an underlying genetic mutation. These diseases were originally described based on clinical and pathologic characteristics and carry the names of their discoverer. With time, biochemical and later molecular genetic discoveries prompted classification by enzyme deficiency or genotyping. These major disorders are listed in their traditional classification in Table 27.1.

As understanding of the pathogenesis and molecular causes of the inherited disorders has improved, so have treatments. While many of these diseases remain ultimately fatal, some have improved life expectancy resulting from better supportive care and in some cases correction of a metabolic defect. A key development resulting from progress in genotyping is the recognition that some diseases have a wider phenotypic spectrum than initially thought. Mild or atypical presentations are increasingly identified, thus changing the expected course and outcome. The last decade has seen tremendous advances in gene therapies, enzyme replacement, and transplantation, including hematopoietic stem cell transplantation. While these treatments are still in their infancy, they are likely the future of treatment of some inherited metabolic neuropathies.

Several online resources are updated frequently, providing information on the most recent research, testing, gene discoveries, and genotype-phenotype correlations. Gene Reviews and OMIM (Online Mendelian Inheritance in Man), accessed at www.genetests.org, are two of the best and most user-friendly resources for this rapidly evolving science.

Familial Amyloid Polyneuropathy

Familial amyloid polyneuropathy (FAP) is an autosomal dominant potentially fatal disorder of variable penetrance manifested by multiorgan dysfunction. The principal targets for symptomatic amyloid deposition are the peripheral nerves, the heart, the eye, and sometimes the kidneys, leptomeninges, and brain. The characteristic neuropathy is a progressive length-dependent painful sensorimotor polyneuropathy with autonomic dysfunction, although focal neuropathies, especially carpal tunnel syndrome, may occur. The characteristic pathogenic feature is transformation of the constituent mutated protein into β-pleated sheets of amyloid that are deposited in the target organs. The best described subtype is transthyretin (TTR) amyloid neuropathy, wherein mutated TTR monomers are produced in the liver. Recent data from long-term follow-up studies show that if performed early, liver transplantation can significantly prolong life expectancy. Therapy aimed at stabilizing TTR tetramers to reduce amyloid fibril formation has shown promise in early trials.

Classification

Before the emergence of molecular genetics, hereditary amyloidoses were classified by phenotype and ethnic origin, but currently FAP is classified by the amyloid fibril protein and genotype. A variety of phenotypes are described. Those with relevance to neuromuscular disease are included in

Table 27.2 with their phenotypes and representative genotype. Apolipoprotein-A1 and gelsolin amyloidosis, named for their precursor proteins, are less common and present differently.

Epidemiology

Andrade first described FAP in 1952 in northern Portugal, where the gene carrier frequency is 1/538 and the disease prevalence is 1/1,000 [1]. The disease was later reported in Japan (1968), Sweden (1976), France, Brazil, and elsewhere. Penetrance varies by country of origin. Symptoms begin in the mid-30s in northern Portuguese patients, more often men, but the onset ranges from 17 to 78. Genetic anticipation is described. In endemic areas of Japan, men and women are equally affected with a high penetrance. In northern Sweden, the disease has a late onset (55–60 years) with lower penetrance [2, 3]. The Ile84Ser mutation in an Indiana/Swiss kindred shows essentially 100 % penetrance by age 50. About 1/100,000 US Caucasians carry the disease, although about 3 % of African Americans and 5 % of West Africans have a non-neuropathic familial amyloid cardiomyopathy associated with the Val122Ile mutation.

Transthyretin-Related Amyloidosis

Costa et al. discovered TTR (formerly prealbumin) to be the constituent protein of this most common cause of FAP [4]. The Val30Met mutation accounts for the majority of cases [5]. Clinical features can be divided into neurological and non-neurological manifestations. The earliest symptoms are burning pain, paresthesias, and sometimes painless ulcers and injuries to the feet and legs that spread to the arms in a relatively short time. Autonomic involvement in this subtype is early and includes GI dysfunction (constipation alternating with diarrhea, recurrent vomiting, weight loss), erectile dysfunction, orthostatic intolerance, and blurred vision. Clinical signs include loss of thermal and pinprick sensation in the feet that may extend above the ankles in as little as a few months after onset. Dissociated sensory loss with sparing of large fiber modalities (vibration, proprioception) is the hallmark of this neuropathy [6]. Neurogenic orthostatic hypotension manifested by marked drop in blood pressure on standing with a fixed pulse is often found along with scalloped pupils. Motor weakness begins later in the legs with a steppage gait and may spread to the hands with generalized hyporeflexia on exam. There may be upper limb involvement with median nerve compression from amyloid deposition in the carpal tunnel in many TTR amyloidosis subtypes. The Indiana/Swiss and Maryland/German subtypes present with early-onset carpal tunnel syndrome followed by lower limb neuropathy. Patients may develop Charcot joints and are ultimately wheelchair-bound or bedridden, with death from infection, malnutrition, or fatal cardiac arrhythmia.

Electromyography (EMG) is consistent with an axonal neuropathy, although it may be normal early on if pathology is limited to small fibers. Needle EMG shows evidence of acute and chronic denervation with distal limb predominance [7].

The heart is a major target organ for amyloid deposition in TTR amyloidosis. ECG shows arrhythmia or various types of heart block, leading to pacemaker insertion in as many as 31 % of patients [8]. The characteristic echocardiographic abnormality is one of refractile echoes giving a "granular sparkling appearance" [9]. TTR is also produced in the vitreous and the choroid plexus. Ocular involvement includes vitreous opacities and open-angle glaucoma that may be the presenting sign as described in Swedish patients. Less commonly, CNS involvement is heralded by dementia and lobar and subarachnoid hemorrhages from brain amyloidosis and amyloid angiopathy. Brain MRI may show meningeal enhancement in the oculoleptomeningeal subtype of amyloidosis (OLMA) associated with rare TTR mutations [10]. Other organs variably affected include the kidneys (especially in apolipoprotein-A1 amyloidosis), gastrointestinal tract, the skin, and the lungs.

Table 27.2 Phenotypes associated with familial transthyretin amyloidosis

Phenotype		
Type	Features	Representative genotype
TTR amyloid neuropathy (formerly familial amyloid polyneuropathy type I [Portuguese-Swedish-Japanese type])	*Early* Sensorimotor polyneuropathy of the legs Carpal tunnel syndrome Autonomic dysfunction Constipation/diarrhea Impotence *Late* Cardiomyopathy Vitreous opacities Nephropathy	Val30Met
TTR amyloid neuropathy (formerly familial amyloid polyneuropathy type II [Indiana/Swiss; Maryland/German type])	*Early* Carpal tunnel syndrome *Late* Sensorimotor polyneuropathy of extremities Autonomic dysfunction Constipation/diarrhea Impotence Cardiomyopathy Vitreous opacities Nephropathy	Ile84Ser
TTR cardiac amyloidosis (familial amyloid cardiomyopathy)	Cardiomegaly Conduction block Arrhythmia Anginal pain Congestive heart failure Sudden death	Val122Ile
TTR leptomeningeal/CNS amyloidosis	Dementia Ataxia Spasticity Seizures Hemorrhage (intracerebral and/or subarachnoid) Psychosis Hydrocephalus	Asp18Gly

Pathogenesis

The characteristic neuropathy of FAP affects nerve fibers in a sequential manner histologically and clinically. There is loss of unmyelinated sensory fibers accounting for the pain, temperature loss, and dysautonomia. This is followed by small and then larger myelinated fiber loss. Amyloid is demonstrated typically by Congo red staining and visualization of an apple-green birefringence with polarized light microscopy. These deposits are widespread, affecting nerve trunks, spinal roots, and sensory ganglia, characteristically found in the endoneurium and around vasa nervorum but also in the epineurium and perineurium [11, 12]. On teased fiber preparations, segmental demyelination may be found along with evidence of Wallerian degeneration. On electron microscopy, Schwann cell degeneration is seen in association with amyloid (Fig. 27.1). At high resolution the fibrillar amyloid is seen to be comprised of unbranched fibrils measuring 10 mm with parallel dense borders (Fig. 27.2). Amyloid deposits are found in almost every organ, and abdominal fat, sural nerve, rectal mucosa, or peritendinous fat specimens obtained at carpal tunnel surgery are the common accessible sites for diagnostic biopsy. The sensitivity of GI mucosal biopsy is 85 %, but sural nerve pathology may be more patchy and therefore less sensitive for diagnosis [13].

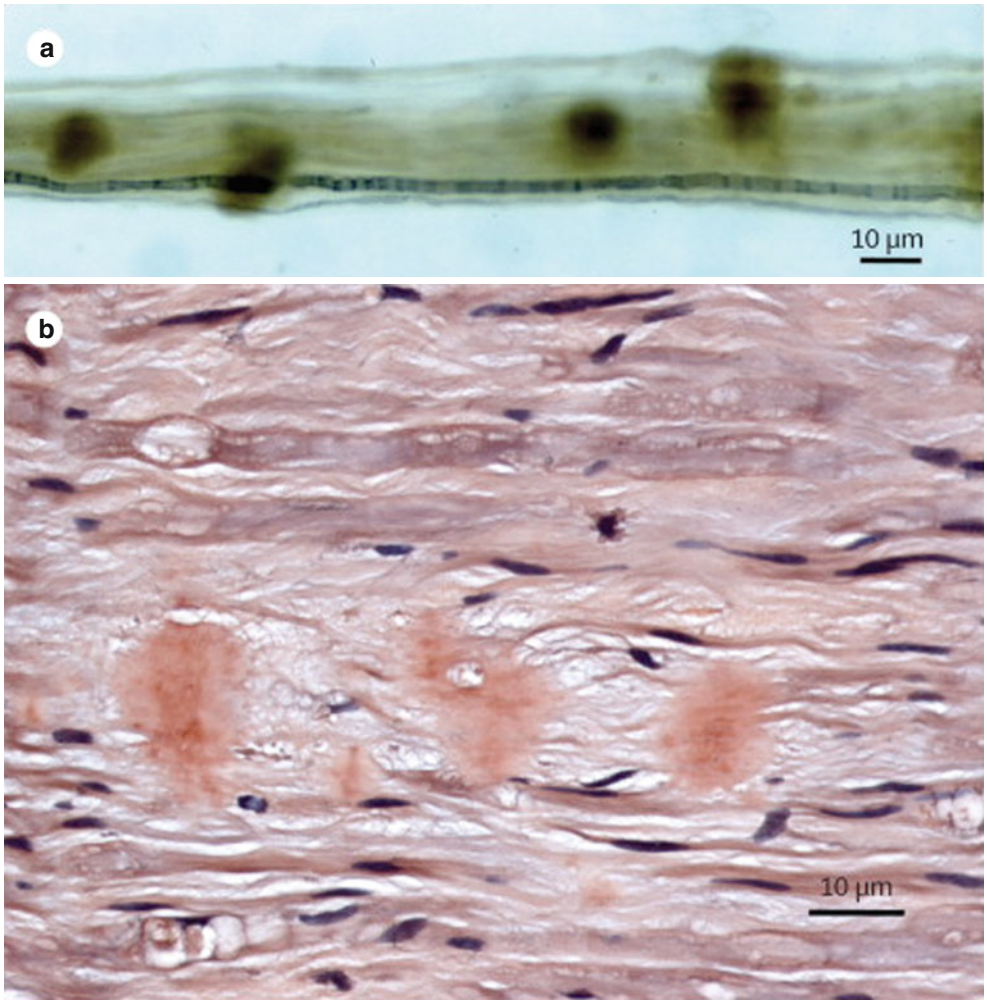

Fig. 27.1 Amyloid deposits in the endoneurium in transthyretin familial amyloid polyneuropathy. (**a**) Teased preparation of the endoneurial content of a nerve biopsy specimen from a 30-year-old man carrying the transthyretin Val30Met mutation. Balls of amyloid deposits can be seen scattered in the endoneurium. Osmium tetroxide stain was used. (**b**) Longitudinal section of a paraffin-embedded nerve biopsy specimen from a different 30-year-old man carrying the Val30Met mutation. Congo red-stained amyloid deposits can be seen (From Plante-Bordeneuve and Said [195]. Used by permission)

The TTR gene resides on chromosome 18 (18q11.2-q12.1) and contains four exons. There have been over 100 point mutations identified and one trinucleotide deletion. The soluble protein is a 55 kD tetramer composed of four identical monomers, each having an extensive β-pleated structure with eight β-pleated sheets arranged in two parallel plates. Under normal conditions, TTR transports thyroxine (T4) and retinol. Mutations cause the tetramer to dissociate into monomers that aggregate and form insoluble amyloid fibrils in the extracellular tissue [14]. In the heart, amyloid deposits have been shown to consist of both mutated and wild-type TTR [15]. The majority of patients are heterozygous for the TTR mutation, but compound heterozygotes and homozygosity have been described. Homozygous mutations do not appear to cause anticipation or a worse course, and some mutations are associated with a relatively more benign course, suggesting there is variable resistance to tetramer dissociation [16].

The ultimate cause of the neuropathy remains unknown. Nerve ischemia and nerve compression theories are postulated but lack evidence and justification. TTR fibrils may bind to the receptor for advanced glycation end products (RAGE) on specific cell targets and induce endoplasmic reticulum (ER) stress via MAP kinase signaling that may result in nerve dysfunction [14]. Based on accumulating biochemical studies, the hypothesized mechanisms of TTR neurotoxicity are summarized in Fig. 27.3. Since the variant TTR circulates from birth, amyloid deposition may also depend on unknown age-related mechanisms that promote amyloid fibrillogenesis. A transgenic mouse model exists but does not demonstrate nerve pathology [17].

Diagnosis

The diagnosis of FAP should be suspected in any patient with symptoms and signs of small fiber peripheral neuropathy, especially with a family history of FAP. Because of the variable penetrance of this disease, patients without a family history but with the phenotype should also be considered for evaluation. If the familial mutation is known, targeted mutation analysis will suffice. If the age of onset is later and a family

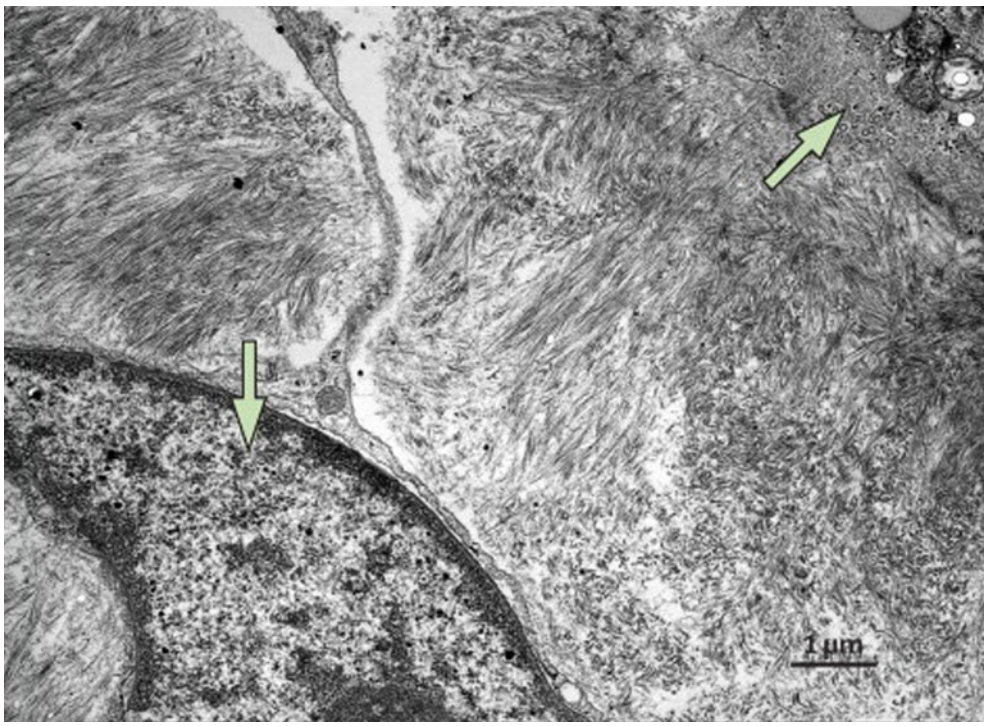

Fig. 27.2 Schwann cell degeneration in contact with endoneurial amyloid deposit in transthyretin familial amyloid polyneuropathy. Electron micrograph of a sural nerve biopsy specimen from a 34-year-old man carrying the transthyretin Val30Met mutation. The fibrillary structure of amyloid and the destruction of endoneurial cells can be seen. At the right upper corner of the photograph, a Schwann cell is degenerating (*arrow*), while at the left lower corner, a fibroblast can still be identified (*arrow*). Sample was stained with uranyl acetate and lead citrate (From Plante-Bordeneuve and Said [195]. Used by permission)

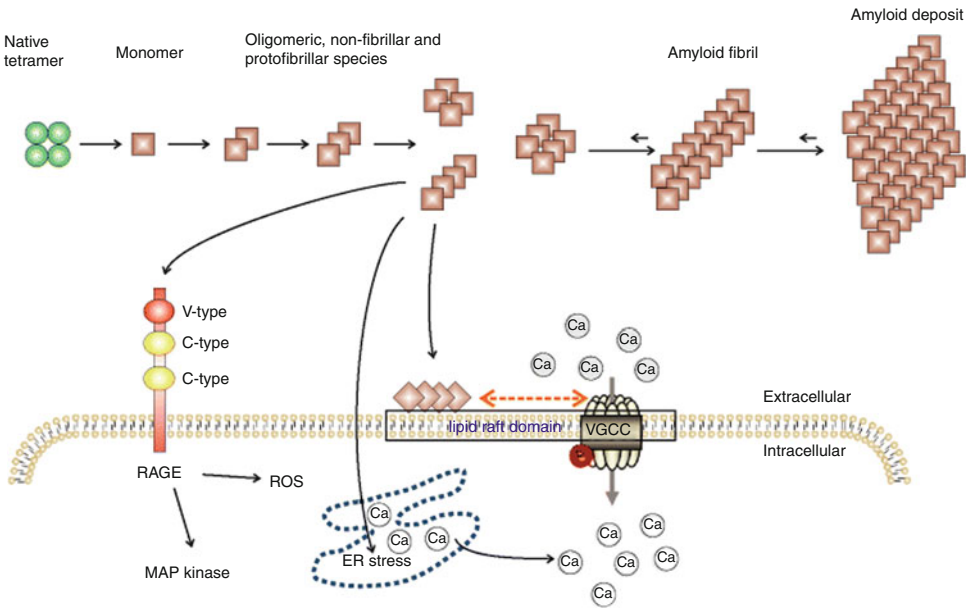

Fig. 27.3 Hypothetical mechanism illustrating how TTR may cause neuronal dysfunction. In this model, mutations in TTR destabilize the native tetramer leading to dissociation into a monomer, which can aggregate. Monomers, low-molecular-mass nuclei, oligomers or protofibrils are the major toxic species. Studies show that these low-molecular-mass diffusible species can bind to lipid membranes. In the model, binding to the lipid membrane disrupts the structure of the lipid rafts, thereby inducing changes in the membrane, which lead to activation and calcium entry through voltage-gated calcium channels (*VGCC*). Alternatively, TTR may bind to a receptor for advanced glycation endproducts (*RAGE*) to affect MAP kinase signaling and induce ER stress, with release of calcium from intracellular stores. ER stress is potentially cytodestructive, and RAGE receptors are known to regulate cascades that are involved in mitogenesis, cellular injury, death, and apoptosis. In contrast with the low-molecular-mass diffusible aggregates, larger amyloid deposits are less toxic than the low-molecular-mass diffusible species but may provide a local pool of TTR which can dissociate into toxic species. ROS, reactive oxygen species; V-type, V-type binding domain on RAGE; C-type, C-type binding domain on RAGE (From Hou et al. [14]. Used by permission)

history is negative, then diagnosis depends on clinical features, biopsy material, and DNA analysis. Blood tests may show an increased concentration of variant TTR in plasma. Confirmation of FAP requires immunolabeling of the amyloid type (TTR, apolipoprotein-A1, or gelsolin), differentiation from AL amyloidosis (serum light chain testing), and DNA testing to identify the specific mutation. Assessment should also include staging of the disease through tests of cardiac, ocular, renal, and brain disease. Autonomic evaluation should be considered, especially if liver transplantation surgery is planned. Prenatal and preimplantation genetic diagnosis is available to families undergoing genetic counseling.

Treatment and Prognosis

Treatment of TTR amyloidosis can be divided into symptomatic therapy and attempts to reduce the formation or pathogenicity of amyloid. Neuropathic pain may respond to appropriate anticonvulsants (gabapentin) or antidepressants that are serotonin-norepinephrine reuptake inhibitors (SNRI) such as duloxetine. Opioids and tramadol are other options [18]. Tricyclic antidepressants should be used with caution as they can worsen orthostatic hypotension and cardiac arrhythmias. Orthostatic hypotension can be particularly dangerous and contributes to mortality in the perioperative period. Strategies include correcting dehydration, liberalizing salt intake, fludrocortisone, midodrine, and elastic stockings. Gastroparesis and vomiting can be treated with small meals, hypomotility agents, and ondansetron. Diarrhea may respond to opioids or subcutaneous octreotide. Urinary catheterization may be necessary to reduce UTI and numerous drugs can reduce incontinence. Carpal tunnel syndrome tends to be more severe in FAP patients, and surgical carpal tunnel release should therefore be considered. Cardiac disease is treated with the appropriate drugs or insertion of a cardiac pacemaker or defibrillator. Vitreous disease is treated with vitrectomy or trabeculectomy if needed. Renal failure may require dialysis or transplantation.

Approximately 90 % of TTR is produced in the liver; thus, orthotopic liver transplantation has been used to treat TTR amyloidosis. First reported in Sweden, follow-up evaluation demonstrated reduced amyloid load by scintigraphy, diminished variant TTR in plasma, and purported clinical improvement, albeit with little effect on the neuropathy [19]. As experience with transplantation has grown, long-term natural history data is accumulating, with some reports of prolonged survival and stabilization or improvement of peripheral neuropathy. Evidence suggests that cardiac and eye disease generally persists and may be even accelerated after liver transplantation [15, 20]. This concern has led to combined liver and heart or liver and kidney transplantation. Since penetrance is variable, orthotopic liver transplantation is not recommended for asymptomatic carriers. Although the liver is the main source of TTR production, it does not develop significant amyloid deposition and therefore can be used for transplantation into patients without TTR amyloidosis, but reports of the development of amyloidosis after domino liver transplant have surfaced [21].

The FAP World Transplant Registry (www.fapwtr.org) in Sweden monitors the results of reported transplant patients. As of 2011, over 1,500 liver transplants have been included, over 80 % of which carry the Val30Met mutation. The postoperative 5-year survival rate was 77 %. Factors associated with improved survival were (1) symptoms less than 7 years (79 % vs. 60 %), (2) modified body mass index 600 or greater (82 % vs. 57 %), and (3) patients with the Val30Met mutation (79 % vs. 56 %). About a third of patients reported clinical improvement, especially gastrointestinal manifestations [22]. The 16-year experience at the Karolinska Institute indicated a 5-year survival of 92 %. Most symptoms stabilized though few improved with the polyneuropathy disability score being stable or improved in 78 %. Age at onset over 40, duration over 7 years and mBMI less than 600 were found to be negative prognostic factors by multivariate analysis [23]. In a Japanese cohort, the estimated probability of survival at 10 years in the subgroup of patients with FAP onset before the age of 50 who underwent liver transplant was 100 %, compared to 73 % in nontransplanted patients [24]. Other reports show progression of the neuropathy after transplantation [25]. This may be due to continued deposition of amyloid derived from wild-type TTR into the amyloid nidus present in peripheral nerve tissue similar to that found in patients with cardiomyopathy after liver transplant [26]. It is also hypothesized that continued deposition of mutated TTR into peripheral nerve can occur by transmission through CSF pathways from the choroid plexus to the nerve by via the subarachnoid space [27].

A number of reports show progression of cardiac arrhythmias necessitating pacemaker insertion [28] and cardiomyopathy [29], sometimes rapidly, after liver transplantation. A long-term follow-up study of 34 transplanted patients focusing on ocular, cardiac, and renal outcomes noted progression of ocular symptoms in 50 %, cardiac amyloidosis in 29 %, and reduced estimated glomerular filtration rate [20].

Other treatment strategies with varying success in TTR amyloidosis include (1) reducing the concentration of variant TTR, (2) inhibiting its synthesis, (3) stabilizing the tetramer, (4) inhibiting aggregation of amyloidogenic intermediates, (5) disrupting amyloid fibril formation, and (6) gene replacement with the normal TTR gene [30]. Plasmapheresis and immunoadsorption are ineffective. Tafamidis meglumine and diflunisal are two drugs that were found to stabilize TTR tetramers with the aim of reducing amyloid fibril formation. A phase II/III clinical trial of tafamidis showed favorable effect on neuropathy progression, quality of life, and mBMI [31]. NSAIDS can inhibit amyloid fibril formation. A phase

III study of diflunisal is underway, with excellent tolerability thus far. Gene therapy using ribozymes [32], small interfering RNAs [33], and antisense oligonucleotides [34] to degrade variant TTR RNA shows promise in vitro, but there are no clinical data.

Survival in those with FAP without liver transplant is approximately 9–13 years, with cardiac death in up to 30 % and infection, malnutrition, and severe autonomic failure contributing to mortality [35]. There is ethnic and mutation-related variation in survival [22]. It seems clear that orthotopic liver transplantation in appropriate patients can significantly prolong survival to over 20 years. Subgroup analysis indicates that patients under 50 with a shorter course of symptoms restricted to the peripheral nervous system have better outcomes [36]. Combined liver and heart or liver and kidney transplants should be considered in the presence of combined organ involvement, as cardiac complications are not halted otherwise.

Apolipoprotein-A1 Amyloidosis

Van Allen first described a family with onset in their fourth decade of progressive renal failure, gastric ulcers, and peripheral neuropathy similar to that found in TTR amyloidosis, although with less prominent autonomic neuropathy [37]. The amyloidogenic protein, apolipoprotein-A1, is a 28 kD plasma protein synthesized in the liver and small intestine. The Gly26Arg mutation is more prominently associated with peripheral neuropathy [38]. Pathology shows amyloid deposition in multiple areas of the peripheral nervous system.

Treatment is similar to that for TTR amyloidosis, with attention to renal function, eventual dialysis, antacids, or surgery for GI ulcers. Experience with liver or combined liver and kidney transplantation is sparse. Success in reducing plasma variant apoA1 levels by 50 % and improvement in neuropathy was reported after hepatorenal transplantation in one case [39].

Gelsolin Amyloidosis

Meretoja first reported patients with slowly progressive neurological and ocular dysfunction in Finland in 1969 [40]. The genetic defect is a mutation of nucleotide 654A on chromosome 9. The responsible protein was found to be gelsolin, a calcium-dependent regulatory protein, which regulates actin filament dynamics in the cytoplasm and binds and clears actin from plasma. Gelsolin is present in the skin, cornea, and nerve tissue. The characteristic clinical features include corneal lattice dystrophy, various cranial neuropathies, and abnormal skin laxity. The cranial nerves most affected are the upper branch of CN VII, CN XII, IX, XI, or V. A relatively mild mixed axonal and demyelinating sensory polyneuropathy is found. Cardiac conduction defects may necessitate pacemaker insertion and renal failure may ensue. Central nervous system complications include cerebral hemorrhage from amyloid angiopathy.

Treatment includes proper eye care and surgery for facial laxity. Gelsolin is not produced in the liver; therefore, transplantation is not indicated. The prognosis is more favorable than TTR amyloidosis with advances in renal transplantation and relatively little dysautonomia; however, chronic immunosuppression after renal transplant increases the risk of infection.

Porphyria

The porphyrias are a heterogeneous group of disorders resulting from the interruption of heme biosynthesis and are rare causes of peripheral neuropathy. Though the most important sites for heme synthesis are the bone marrow and liver, neuropathy is only seen in the hepatic porphyrias. Disturbances in heme biosynthesis result in the accumulation of porphyrins with acute attacks being precipitated by stress, drugs, and hormones. Neuropathy is described in the four hepatic porphyrias: acute intermittent porphyria (AIP), variegate porphyria (VP), hereditary coproporphyria (HCP), and aminolevulinic acid (ALA) dehydrase deficiency.

Clinical Presentation

The cardinal features of neuropathy, central nervous system manifestations, and abdominal involvement characteristic of an acute attack of porphyria are similar in all of the hepatic porphyrias. Classically acute attacks of porphyria are characterized by severe abdominal pain that is often concerning for an acute abdomen and may be accompanied by nausea, vomiting, constipation, diarrhea, distention, or ileus, but 5 % of patients may present without abdominal complaints. Brain involvement manifests as almost any acute psychiatric symptom most commonly agitation and nightmares, which may progress to florid psychosis and, eventually, to seizures and coma that may be exacerbated by hyponatremia. A peripheral neuropathy that is diffuse, sometimes asymmetric and often rapidly progressive resembling Guillain-Barré syndrome, develops a few days after the onset of symptoms. Limb pain may be the first feature followed by motor involvement. In contrast to the generalized hyporeflexia of Guillain-Barré syndrome, reflex loss is patchy in proportion to the degree of muscle weakness [41]. Isolated mononeuropathies may occur, e.g., bilateral wrist drop [42]. Overall, 40 % of patients with porphyria develop a neuropathy, even between attacks [43]. Cranial nerves are often involved as is the autonomic

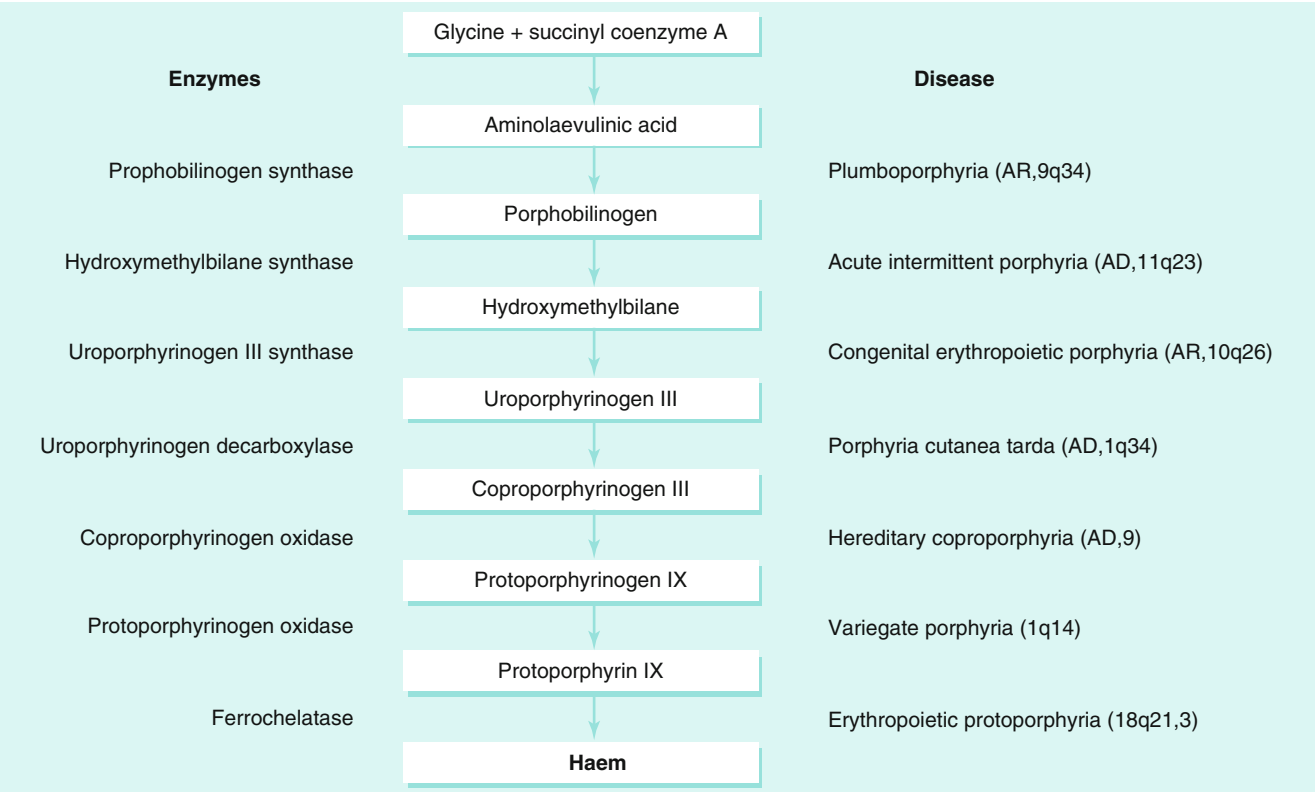

Fig. 27.4 The heme biosynthesis pathway with the enzymes that catalyze each step and the corresponding disease associated with dysfunction of those enzymes (From Thadani et al. [196]. Used by permission)

nervous system. Bulbar manifestations can be severe and paralysis of the respiratory muscles may necessitate intubation and ventilation. Urine will appear red to reddish-brown during an acute attack. The clinical history should seek to identify typical triggers of acute attacks, e.g., drugs or hormones that induce the hepatic microsomal cytochrome P450 system [44], although fasting, alcohol, stress, and infection are also known triggers. Acute attacks are about five times more common in women than men presumably due to hormonal influences. Blisters and skin fragility may occur in HCP and VP.

Pathology and Pathogenesis

Axonal degeneration of peripheral nerves and central chromatolysis are the pathological features described in porphyria, although detailed pathological studies have rarely been undertaken [45]. Patchy demyelination is also described. The pathogenic mechanisms leading to the peripheral neuropathy in porphyria are not completely understood, but two main theories are considered. One is that excess ALA is neurotoxic [46] and the other posits heme deficiency could lead to decreased levels of cytochromes, with detrimental metabolic effects on nervous tissue [47], perhaps through oxidative stress and free radical formation. A recent study showed evidence of Na/K pump dysfunction in the peripheral nerves of patients during an acute attack that may be related to decreased energy supply and reduced heme availability [48].

Etiology

There are eight enzymes involved in heme synthesis. Deficiency of any of these enzymes results in decreased heme production and accumulation of porphyrin precursors and porphyrins in various tissues (Fig. 27.4). Table 27.3 summarizes the distribution of the resulting byproducts.

The estimated prevalence of acute porphyria in most Western countries is 1–2 per 100,000, most of whom have *acute intermittent porphyria (AIP)*. In Sweden the gene frequency is higher at 1 per 10,000 [49]. AIP is an autosomal dominant disorder caused by a partial deficiency of porphobilinogen (PBG) deaminase. This disease is characterized by incomplete penetrance with 90 % of individuals being clinically latent. The *HMBS* gene for PBG deaminase is on the short arm of chromosome 11. Two distinct mRNAs are produced from this gene by alternative transcription and splicing resulting in two forms of PBG deaminase, one of which is erythrocyte specific. Over 100 different mutations are described in the PBG deaminase gene including single-base

Table 27.3 The differential accumulation of heme synthesis substrates in the blood and urine as well as ALAD activity

	Urinary excretion			Stool excretion				
Disorder	ALA	PBG	Copro-porphyrin	Copro-porphyrin	Proto-porphyrin	ALAD activity	Neurovisceral attacks	Photocutaneous symptoms
AIP	↑	↑	Normal or ↑	Normal	Normal or ↑	Normal	+	–
Hereditary coproporphyria (HCP)	↑	↑	↑	↑	Normal	Normal	+	+
Variegate porphyria (VP)	↑	↑	Normal or often ↑	Normal or often ↑	↑	Normal	+	+
ALAD porphyria (ADP)	↑	Normal or slightly increased	↑	Unknown	Unknown	↓	+	–
Hereditary tyrosinemia type 1	↑	Normal	Normal	Normal	Normal	↓	+	–

From genereviews.org
Hereditary tyrosinemia type 1, although not a porphyria, has been included as well for clinical comparison

substitutions, small insertions, and deletions. Partial deficiency of PBG deaminase gives rise to elevated PBG and ALA in the urine and in the serum during acute attacks, with decreased PBG deaminase activity in erythrocytes (except in those patients where the erythrocyte-specific enzyme is normal).

Variegate porphyria (VP) is also autosomal dominant, caused by a partial deficiency in protoporphyrinogen (PPG) oxidase. In the UK, this form of porphyria is about one-third as common as AIP, but the highest prevalence of 3 per 1,000 occurs in South Africa [50]. During acute attacks of VP, urinary ALA, PBG, and coproporphyrin are increased and fecal protoporphyrin and coproporphyrin are elevated. PPG oxidase activity in leukocytes is decreased.

Hereditary coproporphyria (HCP), an autosomal dominant disorder due to partial deficiency of coproporphyrinogen (CPG) oxidase, is much less frequent than AIP or VP. During acute attacks, urinary and fecal coproporphyrin are elevated as well as urinary ALA, PBG, and uroporphyrin. CPG oxidase activity is reduced in leukocytes.

Aminolevulinic acid (ALA) dehydrase deficiency is an extremely rare autosomal recessive disorder due to a homozygous deficiency of the enzyme ALA dehydrase on chromosome 9. This causes a markedly elevated urinary ALA and a minimally elevated urinary porphobilinogen (PBG) with a profound reduction in serum ALA dehydrase activity. Note that in hereditary tyrosinemia, type I dysfunction of fumaryl acetoacetate hydrolase leads to accumulation of 4,6-dioxoheptanoic acid, a potent inhibitor of ALA dehydrase, and thus mimics ALA dehydrase deficiency.

Diagnosis

The main clinical differential diagnosis for porphyric neuropathy is Guillain-Barré syndrome, but abdominal symptoms are more severe in porphyria. A history of urine color change, brain involvement, and electromyographic findings of an axonal polyneuropathy also helps distinguish porphyria from Guillain-Barré syndrome. Previous skin involvement or photosensitivity raises the possibility of VP and HCP. Arsenic, thallium, or lead poisoning may cause a similar presentation with abdominal and neuropathic symptoms, and heavy metal intoxications may also cause a rise in urinary coproporphyrins.

When an acute porphyric attack is suspected, a rapid screening test for urinary porphobilinogen (PBG) should be performed using the Watson-Schwartz [51]. If positive, the diagnosis should be confirmed by specific quantitative assays of urinary PBG and measurement of fecal and plasma porphyrins (PBG and ALA), which will also characterize the type of acute porphyria. Although PBG excretion is usually increased in AIP in the asymptomatic phase, PBG excretion in HCP and VP usually returns to normal. All of the hepatic porphyrias cause an elevated urine ALA and this can be measured where clinically indicated.

Electromyography and nerve conduction studies reveal a predominantly motor axonal neuropathy, with relatively persevered sensory nerve action potentials, H-reflexes, and F-waves [52]. Genetic testing should be undertaken for any new diagnosis of porphyria, and family members should be tested where appropriate.

Treatment

Care of the acute attack often requires hospitalization. The most important first step is to withdraw potentially exacerbating drugs. Relief of pain and vomiting may be required. In mild cases, hydration and glucose are adequate treatment. The most effective therapy is now accepted to be the intravenous administration of heme, particularly in severe attacks. Heme arginate is said to be preferable to hematin as it is

more stable and has less side effects [53]. Patients may require nasogastric feeding to obtain adequate calorie intake during the acute phase. Assisted ventilation may be necessary. During an acute attack, plasma PBG levels have been shown to be the most reliable marker of improvement [54]. Treatment of confusion and seizures may be difficult because of the limited number of drugs that are safe, e.g., gabapentin [55]. Menses-related attacks can be difficult to manage since hormones may exacerbate porphyria.

There have been recent trials of recombinant human porphobilinogen deaminase in patients with AIP. Although this therapy is still in early stage evaluation, results suggest safety and evidence of improved enzymatic activity [56]. The mainstay of treatment of porphyria is the prevention of attacks. A current drug list should be consulted before any drug is prescribed to a patient with porphyria (www.drugs-porphyria.org). Mortality is now less than 10 % and decreasing with growing awareness [57]. Although the abdominal and central nervous system complications improve, recovery from the neuropathy may be incomplete. Repeated acute attacks may lead to chronic renal failure.

Leukodystrophies

Metachromatic Leukodystrophy

The leukodystrophies are lysosomal storage disorders (lipidoses) affecting myelin. The metachromatic leukodystrophies (MLD) are a heterogeneous group of disorders characterized by demyelination in the central and peripheral nervous system and accumulation of galactosyl sulfatide (cerebroside sulfate) in glia, Schwann cells, and macrophages. The inheritance pattern is autosomal recessive. The *ARSA* gene resides on chromosome 22q13.33 and codes for arylsulfatase A.

The finding of metachromatic lipid deposits in nervous system tissue is pathognomonic for MLD. Metachromasia refers to the staining properties of the abnormal tissue. When frozen tissue is stained with acidified cresyl violet (Hirsch-Peiffer stain) or with toluidine blue or thionine, sulfatide-rich storage deposits stain a golden brown. Fixing the tissue with lipid solvents like alcohol before staining abolishes the metachromatic reaction. Urinary sediment may also show metachromatic material.

Late-infantile, juvenile, and adult-onset forms are recognized; most cases are due to a deficiency of arylsulfatase A, which results in the accumulation of sulfatide in many tissues, particularly in the nervous system and kidneys. The AB variant, where arylsulfatase activity is normal, is due to a deficiency of the sphingolipid activator protein B. Multiple sulfatase deficiency, a genetically distinct condition, has features of both late-infantile MLD and mucopolysaccharidosis.

Clinically, the late-infantile form of the disease (50–60 % of cases) begins by age 30 months with preceding normal development. The disease evolves rapidly over 2–3 years from a predominantly hypotonic neuropathic form to one in which central nervous system dysfunction predominates. The disease usually starts with hypotonia and walking, sitting, or crawling difficulty progressing to inability to stand without support. At this stage, the reflexes are often absent with motor weakness in the feet. Slowed nerve conduction velocity is a common finding [58]. Regression of mental development may begin. As the disease progresses, ataxia becomes more prominent and spasticity develops accompanied by limb pain, dementia, and dysarthria. In the terminal stages, the child develops quadriplegia or decerebrate rigidity, blindness, deafness, seizures, and myoclonic jerks or opisthotonus. Juvenile MLD (20–30 % of cases) presents between the ages 3 and 20 years. Symptoms include reduced school performance, clumsiness, dysarthria, seizures, and behavioral problems. Survival from 10 to 20 years is common. Adult-onset MLD (15–20 % of cases) can present at any age beyond puberty, often with a behavior change suggesting psychosis, with poor job performance, alcoholism, and emotional instability [59]. A mild peripheral neuropathy is often found, with reduced motor nerve conduction velocity. Ataxia and spasticity generally supervene and inexorable progression occurs with disabling speech, vision, and UMN signs.

Many variations to the clinical types described above have been reported. Childhood-onset peripheral neuropathy without central manifestations [60], hypotonia suggestive of spinal muscular atrophy or myopathy [61], adult-onset isolated demyelinating neuropathy [62], multifocal nonuniform slowing [63], mirroring chronic inflammatory demyelinating neuropathy [64, 65] may all be encountered within MLD.

The gene frequency is about 1/40,000; however, from 13.7 to 17 % of normal individuals may have reduced level of arylsulfatase A without disease. These pseudoarylsulfatase deficiency states may cause confusion when screening with enzyme levels for genetic counseling or disease detection; thus, DNA analysis is the recommended method for prenatal and preimplantation detection. An immune-based assay of blood spot samples can differentiate MLD and pseudodeficiency and offer the possibility of effective newborn screening [66]. Because there are alleles that result in either no enzyme (O allele) or residual enzyme (R allele) activity, genotype-phenotype correlations exist. Late-infantile disease is associated with the presence of two O alleles, adult-onset MLD with two R alleles, and juvenile cases one of each.

Pathologically, there is degeneration of myelinated fibers in the brain and peripheral nerves. Brain MRI shows white matter abnormalities that may be confluent. CSF protein is elevated. Segmental demyelination-remyelination and small onion bulbs may be found [67]. On light microscopy, lipid

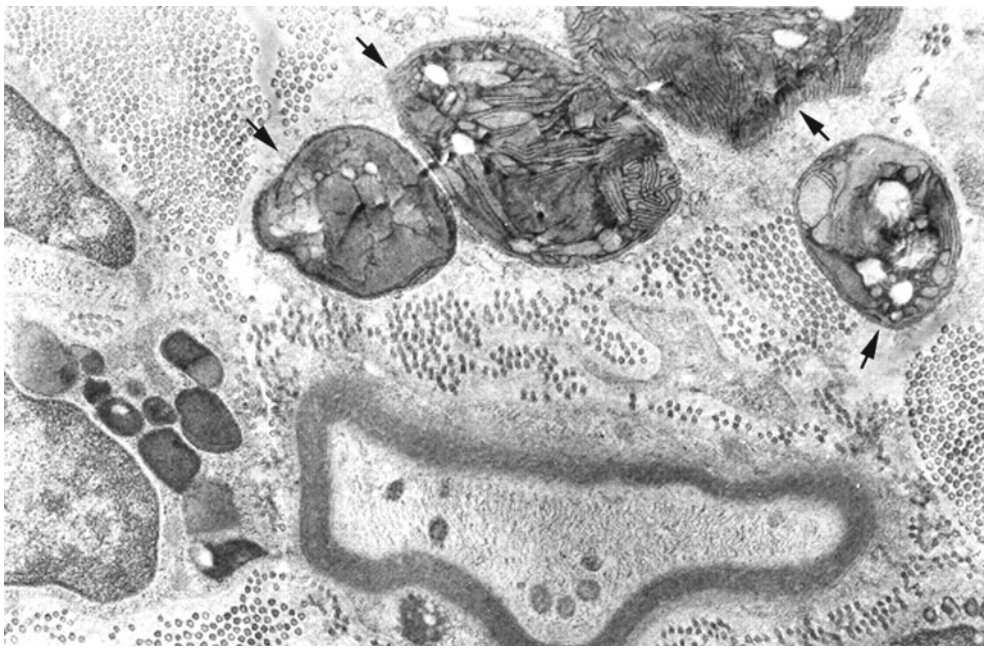

Fig. 27.5 Electron micrograph showing tuff stone inclusion bodies composed of stacks of lamellar discs and plates (*arrows*) enclosed within a membrane in the endoneurium. Original magnification, ×10,000 (From Bindu et al. [197]. Used by permission)

accumulation with metachromatic granules is found in glia, macrophages, and Schwann cells and viscera, especially the kidney and gall bladder [68]. Ultrastructurally, the metachromatic granules are found in relation to Schwann cell nuclei along with inclusions of various types, some of which are thought to be specific to this disease. The earliest reported are membrane-bound concentric lamellated figures exhibiting a periodicity of 5.6–5.8 nm [69]. Myelin figures have a periodicity of 8 nm between their major dense lines. Tuffstone bodies, prismatic stacks, and zebra bodies are also seen (Fig. 27.5) [70]. These inclusions are not derived from myelin breakdown, as they are present in Schwann cells associated with unmyelinated axons and in fetal nerves before demyelination is evident. Inclusions are found less in the juvenile and adult-onset forms. Mouse models show accumulation of sulfatides but not significant peripheral nerve demyelination.

The pathogenesis of the demyelination is uncertain. Sulfatides comprise about 5 % of myelin lipids, and their accumulation may interfere with normal oligodendrocyte and Schwann cell function [71], attract toxic cations or other metabolites [72], or contribute to temperature-dependent myelin instability [73].

Reduced arylsulfatase A levels are found in serum, but diagnosis requires either molecular genetic analysis or demonstration of abnormal urinary sulfatide excretion or of metachromatic lipid deposits in nervous tissue. Brain MRI may suggest a leukodystrophy. Motor nerve conduction velocity as low as 10–20 m/s and reduced or absent sensory action potentials [61] may precede symptoms [74, 75], but these may be less obvious in the adult-onset MLD.

The prognosis is poor in untreated late-infantile MLD, with death usually by age six. Bone marrow transplantation is the only treatment that influences the neurologic progression of the disease [76]. Later age of onset and minimal clinical involvement before transplantation are the best prognostic factors [77]. NAA levels by magnetic resonance spectroscopy correlate with function and can be used to monitor disease progression [78].

Efforts underway to improve bone marrow transplant include using autologous stem cells, combined therapy with bone marrow and mesenchymal stem cell transplant, or ARSA genetically engineered to cross the blood–brain barrier. Gene therapy has not yet reached human subjects, but potential strategies are reviewed by Biffi [79] and Gieselmann and Krageloh-Mann [80].

Multiple Sulfatase Deficiency (O Variant)

Multiple sulfatase deficiency was described in 1973 [81] and is caused by a defect in formylglycine-generating enzyme (FGE), responsible for activating most sulfatases. Patients have deficiencies of arylsulfatases A, B, and C and iduronate sulfatase (Hunter type) and have features of both late-infantile MLD and mucopolysaccharidosis, with earlier onset and death usually by age 12 years. Dementia and spasticity with reduced tendon reflexes are combined with ichthyosis, coarse facial features, and skeletal changes (flared ribs, broad phalanges) in classic cases. A demyelinating neuropathy similar to MLD is found and nerve biopsy shows metachromatic inclusions. Urine and tissue show accumulation of both sulfatides and mucopolysaccharides.

Saposin B Deficiency (AB Variant)

Another variant of MLD is described with normal activity of arylsulfatase A and B but with a deficiency of the cerebroside sulfate activator protein, saposin B (AB variant) [82].

The gene is on chromosome 10q21-23. The age of onset is variable but clinically and pathologically, this variant is indistinguishable from MLD. The diagnosis of activator deficiency is suspected in a child who appears to have MLD but with normal ARSA activity and evidence of excess urinary sulfatide excretion and/or tissue storage.

Globoid-Cell Leukodystrophy (Krabbe's Disease)

Globoid-cell leukodystrophy is an autosomal recessive disease caused by a deficiency of galactocerebrosidase-β-galactosidase (aka galactosylceramide-β-galactosidase-GALC). This leads to nervous system damage by accumulation of psychosine and galactocerebroside in oligodendrocytes and Schwann cells, demyelination, and variable axon loss. The pathologic hallmark in brain tissue is multinucleated globoid cells of macrophage origin, containing prismatic and tubular inclusions found around small blood vessels. In peripheral nerve, macrophages and endoneurial Schwann cells contain similar inclusions, but frank globoid cells are rare. The gene is on chromosome 14q31.3 and many mutations are known.

In the era of molecular diagnosis the stereotypical presentation of this disease as one of early infancy is being reconfigured, with late-infantile, juvenile, and even adult-onset cases now described. In the classical form, onset is usually between 3 and 6 months, with the child developing irritability and motor and intellectual delay. Spasticity, opisthotonus, nystagmus, optic atrophy, deafness, tonic seizures, and intermittent fevers develop. Deep tendon reflexes are reduced after about 6 months as neuropathy develops, though Babinski signs are present. Death usually occurs by age 2 years.

Later onset comprises 10–15 % of patients. These patients have intellectual regression, visual difficulty, and spastic paraparesis but with variable peripheral neuropathic features. Several reviews detail the clinical and biochemical features of cases across the age spectrum [83–85]. Neuropathy may be the presenting feature [86].

Laboratory testing reveals MRI evidence of symmetric white matter changes or sometimes calcifications in the brain. Enhancement of cranial nerves [87] or roots [88] may be found. EMG shows uniform slowing of motor NCV consistent with an inherited demyelinating neuropathy [89–91]. Sural nerve biopsy is diagnostic but rarely needed today as the diagnosis is made by assay of GALC activity in leukocytes, serum, or cultured fibroblasts.

Pathologically, the brain has myelin loss with globoid cells with characteristic inclusions described below. Peripheral nerves show thinning of myelin sheaths or segmental demyelination, and dense material may be seen near blood vessels. Ultrastructurally, the pathognomonic inclusions are seen in Schwann cells and macrophages as nonoriented straight or curved, prismatic or tubular structures. Depending on their plane of section, they may appear as empty clefts [92].

In a natural animal model of the disease, the "twitcher" mouse, hematopoietic stem cell transplantation can reduce globoid cells and induce remyelination [93]. Nerve conduction was shown to improve in humans treated with hematopoietic stem cell transplantation [94]. Clinical improvement after donor umbilical cord blood transfusion suggests this may be a breakthrough therapy for this disorder [95].

Adrenoleukodystrophy/ Adrenomyeloneuropathy

Diseases affecting peroxisomal function include those that interfere with peroxisome biogenesis (neonatal adrenoleukodystrophy, infantile Refsum disease) or disorders with deficiency of single peroxisomal enzymes or proteins. The latter category is associated more often with peripheral neuropathy and includes adrenoleukodystrophy and classical Refsum disease.

Adrenoleukodystrophy (ALD) is an X-linked recessive disorder that affects primarily the nervous system myelin, the adrenal cortex, and the Leydig cells of the testes. The associated gene, *ABCD1*, is on chromosome Xq28 near the color vision gene, and its product is not actually an enzyme but a membrane transport protein in the ATP-binding cassette subfamily (ALDP) [96]. The pathologic substance, very long-chain fatty acids (VLCF), can be detected in several organs, plasma, and cultured skin fibroblasts. Adrenomyeloneuropathy (AMN) is a variant of later onset with peripheral neuropathy.

This disease has marked phenotypic heterogeneity even in families with the same mutation and between monozygotic twins, suggesting environmental modifiers [97]. Families have been described harboring both ALD and AMN patients with identical haplotypes [98]. There are many de novo mutations. Heterozygous females may develop symptoms later in life to a milder degree than males and pass on the disease to each male offspring. If both hemizygote and heterozygotes are included, it is estimated to occur in 1:16,400 live births [99].

Schilder (1913) described the pathology of a case originally published by Haberfeld and Spieler (1910) under the title "encephalitis periaxialis diffusa." Griffin and Schaumburg (1977) are credited with distinguishing adrenomyeloneuropathy (AMN) as a distinctive phenotype [100]. Hugo Moser, a preeminent scientist of this disease, described seven phenotypes [101], but for simplicity, three main symptom sets will be described here. The classic ALD patient is a boy developing attention deficit disorder-like behavior changes and regressing school performance between ages 4 and 8 years, with rapidly progressing spasticity, visual difficulty, dementia, pseudobulbar palsy, seizures, and adrenal insufficiency

with its associated skin hyperpigmentation. Untreated, the boy becomes bedridden with death ensuing over the next 1–2 years. This is estimated to occur in about 35 % of affected individuals.

Adrenomyeloneuropathy (AMN), caused by the same mutation, occurs in about 40–45 % of patients and generally presents in the third decade with slowly progressive spastic paraparesis, peripheral neuropathy, and sexual dysfunction with hypogonadism. There may be antecedent adrenal dysfunction, recognized by pigmentation, nausea, vomiting, weakness, and hypotensive episodes in about 70 % of men. On exam, the AMN patient may have hypotension, bronzed skin, gait stiffness with mild spasticity early on, but reduced deep tendon reflexes. Reduced vibration and proprioception, indicative of large myelinated peripheral nerve fiber dysfunction, is often found. On electromyographic testing, slowed motor nerve conduction velocities, indicating a demyelinating neuropathy, are most common, but mixed axonal and demyelinating or predominantly axonal changes have been reported. Brain MRI is generally normal, but van Geel found that about 20 % of patients with AMN had radiographically apparent cerebral demyelination [102]. The prognosis is one of slowly progressive spasticity that may require assistive devices for ambulation, social and emotional support, and treatment of libido and erectile dysfunction. Truncation of the initial 65 amino acids of the ALD protein has been correlated with the AMN phenotype [103].

Female carriers are heterozygous and may develop slowly progressive spastic paraparesis and sphincter dysfunction in adulthood; adrenal insufficiency is much less common. Peripheral neuropathy could be detected electrodiagnostically in about two-thirds of women and close to 90 % of men, showing mixed multifocal demyelination and axon loss [104].

The pathogenesis of these subtypes is similar, though different in degree, for unclear reasons. The transport protein facilitates β-oxidation of long-chain fatty acids. The defect leads to accumulation of lipid material consisting of unbranched saturated fatty acids with a chain length of 24–30 carbons, especially hexacosanoate (C26:), in many cells. Detection of elevated levels of these VLCF is the basis for diagnosis. The pathophysiologic link between these findings and the cellular damage is uncertain. Loss of microglia in regions of the brain with intact myelin has been observed and suggests that VLCF accumulation causes microglia apoptosis early, then leading to demyelination [105]. VLCF are apparently toxic to oligodendrocytes and to mitochondrial function in vitro [106].

Pathologically, massive myelin degeneration is found in the brain with sudanophilic staining and pockets of inflammatory infiltrates. The most common finding on microscopy is lipid-laden macrophages and gliosis. The ultrastructural changes are nonspecific to this disease, but include lamellar cytoplasmic inclusions ("zebra bodies") in central nervous system white matter, adrenals, and Schwann cells [107]. Atrophic changes and inclusions are also found in the adrenal cortex and testes. Sural nerve biopsies show loss of both myelinated and unmyelinated axons, increased endoneurial collagen, and small onion bulbs without inflammation. Teased fiber preparations may show demyelination with remyelination [108]. Mitochondria in dorsal root ganglion neurons show lipid inclusions [109]. These changes have been difficult to recapitulate in knockout mouse models. Oligodendrocyte and myelin damage can be ameliorated with IGF-1 and NT-3 introduced via a viral vector [110].

The diagnosis is made by demonstrating elevated levels of C26 fatty acid or elevated C26:C22 ratios in plasma or skin fibroblasts. Prenatal testing via amniocentesis is available. In heterozygotes, plasma levels are normal in 15 %, and thus, genotyping with DNA analysis may be tried next. ALD should be considered in boys with progressive cognitive or behavioral problems associated with visual loss and UMN signs. AMN should be suspected in young or middle-aged men and women with progressive gait and sphincter dysfunction, especially with hypoadrenalism. In classic cases, brain MRI is abnormal with often dramatic white matter damage. CSF protein may be elevated. Evaluation should include measurements of electrolytes, serum testosterone, and cortisol.

For ALD, a three-pronged treatment is currently recommended: early dietary adjustment, adrenal hormone replacement, and hematopoietic stem cell transplantation if MRI abnormalities develop. Corticosteroid and mineralocorticoid therapy is essential for those patients with adrenal insufficiency. Physical therapy, bladder relaxants, drugs for erectile dysfunction, and testosterone therapy may be helpful.

Variable but sometimes significant success has been reported with bone marrow transplantation, hematopoietic stem cell transplantation, and, in asymptomatic patients, dietary strategies ("Lorenzo's oil"). Because of phenotypic heterogeneity, there is no one treatment recommended for all, and the timing of marrow and stem cell transplantation is controversial. Some individuals with ALD remain asymptomatic until middle age or later.

Bone marrow transplant is recommended for boys in early stages of classic ALD, ideally with minimal intellectual and motor deficit (e.g., performance IQ >80) [111]. Hematopoietic stem cell transplantation can restore intact ALD protein in tissues [112], and a 5-year survival rate of 56 % was reported [113]. Bone marrow transplant is not recommended for AMN as this can be a slowly progressive disorder.

Dietary restriction of long-chain fatty acids alone is not effective. Lorenzo's oil is a mixture of oleic acid and erucic acid. Incorporated with a low-fat diet, it was hoped that this treatment could stabilize or improve the disease, but trials in symptomatic patients have not shown success [114, 115]. An open trial using Lorenzo's oil in asymptomatic boys with normal brain MRI showed reduction in plasma C26:0 levels and reduced risk of developing MRI lesions. The amount of

C26:0 reduction correlated with reduction of risk [116]. The treatment is still considered investigational. Gene therapy may be considered in those patients without suitable donors for hematopoietic stem cell transplantation [117].

A separate disease, neonatal ALD, has autosomal recessive inheritance and is due to abnormalities of peroxisomal biogenesis or assembly rather than a single enzyme defect. Clinically, neonatal ALD is characterized by seizures, hypotonia, facial dysmorphism, blindness, deafness, hepatomegaly, and diffuse amyotrophy. Tendon reflexes may range from absent to brisk. Slow nerve conduction velocity and denervation may occur. Nerve biopsy shows decreased density of myelin sheaths without inclusions. Disease onset is in infancy with rapid progression due to white matter degeneration in the brain. Adrenal insufficiency does not occur. Plasma shows elevations in VLCF and, occasionally, phytanic acid [118].

Tangier Disease

Tangier disease (TD) is a rare disorder of lipid metabolism caused by mutations in the *ABCA1* gene. ATP-binding cassette A1 (ABCA1) normally is a transmembrane protein that transports free cholesterol from cells into the circulation to bind with apoliporotein-A1 and become high-density lipoprotein (HDL). Peripheral neuropathy occurs in half of patients with variable features, though upper body sensorimotor dysfunction is a clinical clue to diagnosis.

The disease was first described in 1960 when enlarged tonsils containing cholesterol-laden macrophages were removed from a boy living on Tangier Island, off the Virginia coast [119]. This finding was linked to markedly low serum HDL levels, and the gene defect was discovered in 1998. A related disorder, familial HDL deficiency, is seen in patients with one mutant allele but does not lead to peripheral neuropathy.

There is no typical clinical presentation, family history may be lacking, and errors in diagnosis are common. Hand or face weakness and numbness may lead patients to seek medical attention. Loss of pain and temperature sensation is common, with motor weakness evident in some, either with a distal predominance in the feet or hands or with bilateral facial weakness, causing patients to sleep with eyes partially open [120]. Transient ptosis and diplopia may occur. Pain is not a common feature, and there is no significant autonomic dysfunction.

When sensory manifestations are confined to the arms and face, a syringomyelia-like pattern is suggested, but MRI of the spinal cord is normal [121]. An asymmetric or multifocal pattern of deficit may cause confusion with the Lewis-Sumner syndrome [122]. A relapsing-remitting clinical course occurs and contributes to diagnostic inaccuracy.

Nerve conduction studies typically show no recordable SNAPs in the arms and legs, consistent with the hypothesized pathology of dorsal root ganglia damage with secondary axonal degeneration. Motor nerve conduction are often markedly slow, with prolonged distal motor latencies and occasional conduction block resembling that found in chronic progressive demyelinating neuropathy [123].

Other clinical findings represent cholesterol deposition and include enlarged yellow-orange tonsils, xanthomas, corneal clouding, hepatosplenomegaly, lymphadenopathy, and coronary and carotid artery disease, with a sixfold increased risk of myocardial infarction [124].

The *ABCA1* gene resides on chromosome 9q31. The defect leads to impaired removal of cellular cholesterol. Lipoproteins render lipids soluble in the circulation for transport. They are composed of cholesterol, phospholipids, triglycerides, and apolipoproteins. The latter are responsible for targeting the hydrophobic lipid to the appropriate cellular receptor or enzyme. Apolipoprotein-A1 is the major structural component of high-density lipoproteins. Point mutations, deletions, and compound heterozygosity have been reported in the *ABCA1* gene leading to reduced levels of apolipoprotein-A1. A defect in the reverse cholesterol transport pathway prevents transfer of cholesterol via the ABCA1 transporter to high-density lipoprotein leading to elimination of lipid-poor high-density lipoproteins by the kidneys [125].

Nerve pathology shows loss of small myelinated and unmyelinated axons. There are prominent lipid vacuoles in Schwann cells but not in neurons [126, 127]. Demyelination and remyelination is seen in the subtype with relapsing-remitting multifocal neuropathy. The precise pathogenesis of the neuropathy is unknown, but cholesterol deposition in Schwann cells is theorized to cause paranodal dysfunction and tomacula are described [128]. Lipid-laden macrophages are found in the bone marrow, liver, tonsils, and other organs.

It is suggested that lipid profiles be included in patients with neuropathy resembling those described above in order to detect the characteristic reduced high-density lipoprotein (<5 mg/dL) and cholesterol (usually <150 mg/dL, but may be normal) levels and increased triglyceride (>300 mg/dL) levels of Tangier disease. The diagnosis is secured by demonstrating reduced or absent apolipoprotein-A1 levels (<5 mg/dL) and a relevant gene mutation by DNA analysis. Reduced HDL levels may also be seen in chronic infection and lymphoproliferative disease, but finding reduced HDL levels in family members (who are obligate heterozygotes) strengthens the likelihood of TD. There is no specific treatment, and dietary management of lipids is the mainstay of therapy.

Bassen-Kornzweig Disease (Abetalipoproteinemia)

Abetalipoproteinemia is a rare autosomal recessive disorder that presents in infancy or childhood with hyporeflexia, ataxia, sensory peripheral neuropathy, and acanthocytosis.

The disorder was first clinically described in 1950 and in 1993 mutations in the gene on chromosome 4q23 encoding the microsomal triglyceride transport protein (MTP) identified [129]. The basic biological defect is an inability of the body to synthesize the proteins of cell membranes because of the impaired absorption of fat and fat-soluble vitamins through the mucosa of the small intestine. This results in markedly reduced concentrations of the apolipoprotein-B (ApoB)-containing lipoproteins (very low-density lipoproteins, low-density lipoproteins), with decreased levels of chylomicrons, cholesterol, and triglycerides. Serum HDL is normal in this disease. Vitamin E deficiency likely contributes to the pathology.

The disease has a heterogeneous clinical presentation with the fat malabsorption syndrome causing steatorrhea and failure to thrive. Neurological manifestations occur in infancy in about a third of patients with visual deterioration from retinal and macular degeneration associated with reduced tendon reflexes and progressive ataxia with features of both large fiber sensory loss and cerebellar ataxia. The child may be unable to stand or walk in adolescence, and many patients are confined to a wheelchair by age 30 [130]. In addition to impaired vibration and proprioception, titubation, dysarthria, muscle weakness, and oculomotor abnormalities, extensor plantar reflexes, pes cavus, and scoliosis reminiscent of Friedreich's ataxia occur. Sensory nerve action potentials are reduced in amplitude or absent, and motor nerve conduction velocity is normal or mildly slowed, reflecting a predominantly axonal sensorimotor neuropathy [131]. Other clinical findings in some include anemia, cardiomyopathy with congestive heart failure, mild clotting dysfunction due to vitamin K deficiency, and mild mental retardation.

Blood smears reveal acanthocytes, the characteristic spiky erythrocytes caused in this case by a defective lipid layer of the red cell membrane. Foamy vacuoles are seen in cells of the intestinal mucosa. Loss of myelinated fibers in the sural nerve and degeneration of the posterior columns and cerebellar Purkinje and granule cells is observed. Anterior horn cells, retinal ganglion cells, muscle fibers, and myocardium show degenerative changes.

The diagnosis should be suspected in a child presenting with progressive ataxia and acanthocytes on peripheral blood smear and is supported by finding markedly low levels of very low- and low-density lipoproteins in the serum. Treatment with high-dose vitamins E, A, and K (if warranted) may stabilize the disease or reverse symptoms if given early [132]. Dietary restriction of very long-chain fatty acids can reduce steatorrhea. The prognosis is poor in untreated patients, and most are bedridden by early adulthood.

Familial hypobetalipoproteinemia is another disorder of the ApoB-containing lipoproteins with the same serum profile as abetalipoproteinemia. Its inheritance is autosomal dominant. Homozygotes are clinically similar to abetalipoproteinemia. Some patients have mutations in the ApoB gene, most of which cause ApoB truncations, or PCSK9 mutations [133]. Dietary fat restriction and vitamin E supplementation may stabilize deterioration.

Anderson's disease (chylomicron retention disease) is another rare autosomal recessive ApoB-deficient disease. Chylomicrons in plasma after fat ingestion are absent due to an inability to secrete ApoB-containing chylomicrons from the intestine. Neurologic manifestations and acanthocytosis occur in some patients. MTP is normal, but mutations of the SARA2 gene are reported [133].

Fabry's Disease

Fabry's disease is a lysosomal storage disorder caused by mutations in the α-galactosidase-A (*GLA*) gene on chromosome Xq22. The enzymatic defect results in deposition of glycosphingolipids including globotriaosylceramide (Gb3) in cells throughout the body, especially affecting vascular endothelial and perineurial cells. Phenotypic diversity is noteworthy, with the classic phenotype of most neurologic interest, but there are variant phenotypes affecting cardiac and renal function that may be misdiagnosed. The classic clinical features include acroparesthesias, angiokeratomas, hypohidrosis, corneal and lens opacities, and progressive renal failure. Although classically affected males have almost no GLA, others with over 1 % GLA function may have cardiac or renal variant phenotypes, and heterozygous females may be variably symptomatic (Table 27.4). Enzyme replacement therapy is safe and effective in reducing symptoms, and gene therapy is successful in reducing storage in knockout mice.

The first patients were reported independently by Anderson and Fabry in 1898 [134]. Neurological manifestations predominate in the classic form, with intense burning pain in the distal arms and legs beginning often in childhood, reflecting a small fiber peripheral neuropathy. Hypohidrosis is linked to deposition of storage material in sweat glands, as there is little evidence of autonomic failure despite small fiber involvement. EMG studies may be normal, but thermal threshold testing [135] and intraepidermal nerve fiber density [136] are abnormal. Angiokeratomas, small telangiectasias with keratin and epidermal cell proliferation, can be widespread or limited to the lower "bathing trunk" area of the body (Fig. 27.6). They are found in two-thirds of men and about one-third of women, and their presence correlates with disease severity [137]. Proteinuria may be detected early, and renal failure may ensue if untreated. Cerebrovascular disease may be a presenting feature or a variant of the disease. A *GLA* mutation was found in 5 % of men and half that percentage of women with cryptogenic stroke under age 55 [138].

Death is caused by cardiac or renal disease with median survival in men of about 50 years. Stroke occurs in up to a

Table 27.4 Major manifestations in classic and atypical Fabry's disease

Manifestation	Classic	Renal variant	Cardiac variant

LVH-left ventricular hypertrophy
TIA-transient ischemic attack

From genereviews.org

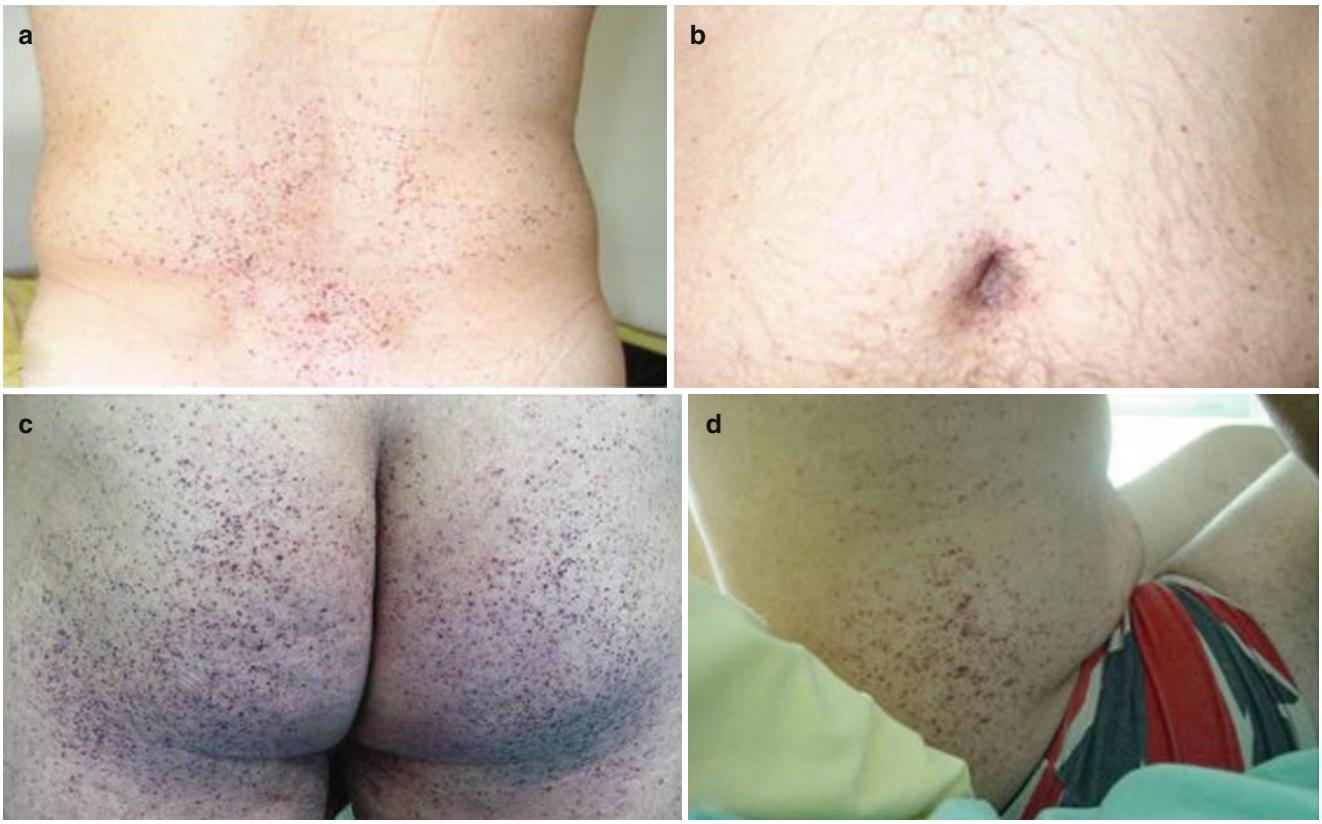

Fig. 27.6 Fabry's disease Angiokeratoma: the angiokeratoma are small, raised, dark-red spots that increase in number and size with age and can occur singly or in clusters. They are typically found on the lower back (**a**), buttocks (**c**), groin, flanks (**d**), and upper thighs, but their distribution may be restricted to a limited area, such as the umbilicus (**b**) (This is an Open Access article distributed under the terms of the Creative Commons Attribution License (http://creativecommons.org/licenses/by/2.0), which permits unrestricted use, distribution, and reproduction in any medium, provided the original work is properly cited)

quarter of patients [139], and increased cerebral vessel tortuosity and basilar artery dilatation was found on MRA in nearly 90 % of patients [140]. End-stage renal disease usually occurs by the third to fifth decade, and hemodialysis and renal transplantation have improved survival. Hearing loss, corneal dystrophic changes (cornea verticillata), cataracts, early myocardial infarction, and left ventricular hypertrophy are also common. Heterozygous women often develop similar

but milder manifestations as men, with later onset and less severe renal disease, about 10 % requiring dialysis or transplantation [141].

The genetic defect is on Xp22 with over 300 mutations described. Missense mutations correlate with the lowest enzyme levels, but nonsense, frame shift, and splice site defects have all been described. Variation in the endothelial nitric oxide synthase gene (*NOS3*) may also have a role in determining the phenotype [142].

Among men diagnosis is confirmed by deficiency of GLA activity in plasma or leukocytes, and DNA analysis for one of the reported *GLA* mutations provides additional confirmation. Women demonstrate markedly decreased GLA activity, which confirms a carrier state; however, enzyme activity may be normal, in which case molecular genetic testing is necessary to clarify the genetic status. Prenatal diagnosis and preimplantation genetic diagnosis are available but require prior identification of the responsible mutation in the family.

The incidence of Fabry's disease is estimated to be 1:50,000 male births and occurs among all ethnic and racial groups [143]. Atypical forms of the disease present in later life with hypertrophic cardiomyopathy or renal failure and may be misdiagnosed as idiopathic cardiac disease, atherosclerotic disease, or chronic glomerulonephritis [144]. A newborn screening study of GLA activity in Italy showed an incidence of 1:3,100. Molecular modeling studies and in vitro mutant enzyme activity yielded a ratio of 11:1 of individuals with the later onset: classic phenotype [145].

Pathologically, lipid may be seen in multiple organs and skin on light microscopy, with more characteristic findings seen on ultrastructural examination. PAS and acid phosphatase-positive storage material consists of Gb3 and is found deposited mainly in arterial endothelium, vascular smooth muscle, cardiac muscle, skin, and variably in neurons, muscle, liver, and sinusoidal histiocytes of lymph nodes. The kidney shows mesangial widening and glomerular endothelium and tubules contain foam cells. In the peripheral nervous system, glycolipid granules and concentric laminated cytoplasmic inclusions termed zebra bodies are seen under EM in ganglion cells and perineurium, with loss of small myelinated and unmyelinated nerve fibers [146, 147]. Punch biopsy of skin can demonstrate reduced intraepidermal nerve fiber density. Proliferation of vascular smooth muscle cells in the brain and a prothrombotic state contribute to cerebral infarction [148]. Evaluation should include renal and cardiac function studies, hearing, eye, and neurological examinations. Current or potential treatment strategies include symptom management and hemodialysis, enzyme replacement therapy, chaperone therapy, gene replacement therapy, and substrate reduction therapy.

Gabapentin, carbamazepine, and phenytoin may reduce pain. For hypertension, angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers are preferred for their renal protection. Enzyme replacement therapy currently consists of two drugs: agalsidase β and α. They markedly reduce Gb3 in tissues and urine sediment, and clinical trials successfully achieved their hope for outcome endpoints of reduction of neuropathic pain and improvement in cardiac and renal function [149, 150]. Enzyme replacement therapy improves peripheral nerve and sweating function [151] although intraepidermal nerve fiber density is less likely to improve in patients with impaired renal function [152]. Enzyme replacement therapy should be initiated early in all men with Fabry's disease and in female carriers with significant disease [153, 154]. It is also recommended to start enzyme replacement therapy in asymptomatic boys at age 12–13. Its role in long-term prophylaxis of clinical symptoms, especially stroke, is unproven.

Gene replacement using viral vectors or bone marrow transplantation shows promise in a mouse model of Fabry's disease, but there is no human data [155]. Chaperone therapy, using drugs such as 1-deoxygalactonorijimycin, DGJ, to enhance GLA activity is now in clinical trials in humans after success in the mouse model [156]. A modified enzyme (α-N-acetylgalactosaminidase, NAGA) with GLA-like effect was shown to cleave accumulated Gb3 in a patient's fibroblasts and improve pathology in Fabry mice, implying potential therapeutic application to humans [157].

The Fabry Outcome Survey [158] and the Fabry Registry [159] are sources of updates on the disease, and a Prognostic Index has been developed [160].

Cerebrotendinous Xanthomatosis (Cholestanolosis)

Cerebrotendinous xanthomatosis is a rare autosomal recessive disorder manifest by late-infantile diarrhea, childhood cataracts, and later characteristic tendon xanthomas and progressive neurological dysfunction. The gene defect on chromosome 2q35 causes a defect in sterol 27-hydroxylase, leading to impaired bile acid synthesis with accumulation of cholestanol in tissues. The neurological features include neuropsychiatric symptoms, dementia, pseudobulbar palsy, ataxic or spastic gait, and a mild distal peripheral neuropathy [161].

Nerve biopsy shows a reduction in large myelinated fibers, and although demyelination is described, other reports suggest primarily an axonopathy [162, 163]. The diagnosis is suggested by the clinical signs and by finding a high plasma cholestanol with normal cholesterol. Genetic analysis of the *CYP27A1* gene allows an accurate diagnosis. Without treatment, patients die in the fourth decade. Early diagnosis is important, because therapy with oral chenodeoxycholic acid results in clinical improvement [164].

Refsum Disease

Classical Refsum disease is an autosomal recessive disease characterized by accumulation of phytanic acid in serum and tissue and is recognized by the clinical triad of retinitis pigmentosa, peripheral neuropathy, and cerebellar ataxia plus a raised cerebrospinal fluid protein. Patients usually present between age 10 and 30 years although both younger and older onset patients occur. The earliest manifestation is usually night blindness due to the retinitis pigmentosa. A sensorimotor demyelinating polyneuropathy affecting all aspects of the peripheral nervous system including the autonomic system will eventually develop and is associated with palpably thickened peripheral nerves, atrophy, and areflexia in the late stages. Nerve hypertrophy may not be clinically evident as it is most severe in the brachial and lumbosacral plexus. These manifestations are progressive but can be episodic in the earlier stages of the disease. Sudden increases in dietary phytanic acid, rapid weight loss, or illness may temporarily worsen the symptoms. Other abnormalities may include sensorineural deafness, anosmia, ichthyosis, skeletal deformities, and cardiac abnormalities that can lead to sudden death.

In Refsum disease, the branched-chain fatty acid phytanic acid accumulates because of a deficiency of the chromosome 10 encoded peroxisomal enzyme phytanoyl-CoA hydroxylase (*PHYH*) gene, which catalyzes the first step in the α-oxidation of phytanic acid to pristanic acid [165, 166]. This in turn prevents adequate fatty acid catabolism via β-oxidation. The mechanism by which accumulation of phytanic acid leads to the phenotype of Refsum disease is unclear. Rat and mouse models suggest the pathogenesis is a combination of oxidative stress, release of intracellular calcium stores, and mitochondrial respiratory chain dysfunction [167]. Accumulation of phytanic acid has also been shown to lead directly to Purkinje cell death [168]. There are recent reports of *PEX 7* mutations resulting in a disorder phenotypically indistinguishable from Refsum disease [169].

The finding of raised serum phytanic acid and defective α-oxidation in cultured skin fibroblasts with the appropriate clinical picture is highly suggestive of Refsum disease, but these biochemical alterations are not specific and may be found in disorders of peroxisomal biogenesis, including infantile Refsum disease and in some isolated peroxisomal β-oxidation defects [170]. Mutational analysis of the *PHYH* or *PEX7* genes is the best way to confirm the diagnosis. Nerve conduction studies show a sensorimotor demyelinating polyneuropathy. Segmental demyelination, depletion of myelinated fibers, and onion bulbs are described. Nonspecific Schwann cell inclusions (osmiophilic bodies and crystalline bodies) are reported [171].

The treatment of Refsum disease is well established. Phytanic acid is derived exclusively from external sources, e.g., ruminant products, cod, and some nuts, so dietary adjustment is key [172]. Plasma exchange or extracorporeal lipid apheresis can reduce serum phytanic acid levels more quickly in acute situations if necessary [173]. Before treatment was available, 50 % of patients died by the age of 30. In vitro phytanic acid can be catabolized by omega-oxidation via enzymes expressed in some human cells. Significant research has been done to push Refsum disease patients enzymatically into omega-oxidation through manipulation of CYP-450 and other mechanisms [174].

Infantile Refsum disease is a disease of abnormal peroxisomal biogenesis. The patients have mental retardation, sensorineural deafness, pigmentary retinopathy, dysmorphic features, and hepatomegaly, and some have peripheral neuropathy. Nerve conduction studies confirm a sensorimotor neuropathy with moderately reduced motor conduction velocities. Nerve biopsy is reported to show loss of myelinated nerve fibers without hypertrophic changes [175]. Another peroxisomal disorder, methylacyl-CoA racemase deficiency, is associated with pristanic acid dysregulation and causes an adult-onset sensorimotor neuropathy that may be either demyelinating or axonal [176].

Niemann-Pick Disease (Sphingomyelin Lipidoses)

Historically four types of autosomal recessive Niemann-Pick disease (NPD) are described (types A–D). The first two types (A,B) are due to mutations in the *SMPD1* gene on chromosome 11, with a deficiency of sphingomyelinase (ASM) causing accumulation of sphingomyelin in a variety of tissues. However, types C and D have normal ASM activity and result from mutations in *NPC1* and, more rarely, *NPC2* genes, causing abnormalities in cholesterol transport with accumulation of sphingomyelin and cholesterol in lysosomes [177]. Since these are different disorders albeit causing lipid storage, the classification system will need revision [178].

Type A NPD is a fatal disorder of infancy characterized by hepatosplenomegaly, retinal cherry red spots, severe developmental delay, occasional seizures, and rarely a peripheral neuropathy. The peripheral neuropathy is characterized by reduced motor nerve conduction velocities with pathological findings of segmental demyelination and remyelination, Schwann cell and axon lipid inclusions, and endothelial foam cells [179, 180]. Type B NPD, classically referred to as the non-neurologic form, presents in childhood with hepatosplenomegaly and demonstrates a wide phenotypic variation. A review of 64 patients reported that about a third of type B patients had neurologic involvement, 22 % mild and nonprogressive, but 8 % with severe and progressive involvement. All severe progressive patients were found to have the Gln294Lys mutation and onset between the ages of 5 and 7 years [181].

Types C and D NPD are allelic and usually present in childhood with hepatosplenomegaly, ataxia, vertical gaze palsy, and motor and intellectual decline. There are case reports with a mild demyelinating peripheral neuropathy though this is not a main feature [182].

Markedly deficient ASM activity in leukocytes or cultured fibroblasts confirms the diagnosis of types A and B and reduction of cholesterol esterification for *NPC1/2*. Enzymatic and molecular analysis may also be used on cultured amniocytes and chorionic villi for prenatal diagnosis. Although new mutations are being described frequently, there are targeted DNA tests available based on the patient's origins (e.g., Ashkenazi Jew or North African).

There is no curative treatment for NPD. In type A death usually occurs by age 2 or 3 years, whereas patients with type B frequently survive into adulthood. Orthotopic liver transplant and amniotic cell transplant have not been effective therapy. Hematopoietic stem cell therapy on the other hand has shown some benefits but does not seem to help with neurological deficits [183]. Recombinant Hsp70 has been shown to stabilize lysosomes and may be therapeutic for *SMPD1* patients [184]. Preliminary data using the glycosphingolipid inhibitor miglustat show evidence of stabilization or benefit in some individuals with NPD-C [185]. Studies of neurosteroid replacement therapies are underway [186].

Disorders with Defective DNA Repair

Xeroderma Pigmentosum

Xeroderma pigmentosum (XP) is a rare autosomal recessive disease characterized by an increased frequency of sunlight-induced skin cancers as a result of defects in DNA repair or replication after damage by ultraviolet irradiation or various chemical carcinogens. Eight genes have now been linked to XP. Seven are involved in nucleotide excision repair (XPA-XPG) and one, yet to be cloned (XP variant), in replication of damaged DNA.

Patients usually present between age 1 and 2 years with increased sensitivity to sunlight. XP may be divided into non-neurological and neurological forms. Patients with the non-neurological forms (XPC, E, and F) have a 2,000-fold increase in skin cancer occurrence for individuals under the age of 20 years. The neurological forms (XPA, B, D, and G) manifest with mental retardation, microcephaly, spasticity, seizures, sensorineural hearing loss, cerebellar ataxia, and dystonia. An axonal or mixed neuropathy may be present as evidenced by absent tendon reflexes and reduced amplitude or loss of sensory nerve action potentials [187]. Overall, 25 % of patients with XP have neurologic manifestations [188]. The severe form is historically referred to as De Sanctis-Cacchione syndrome; however, the neurologic manifestations may be limited to isolated hyporeflexia. XP has significant genetic and phenotypic overlap with Cockayne syndrome.

Pathologically, there is a loss of myelinated and unmyelinated axons with sensory fibers being affected to a greater extent than motor. Autopsies have demonstrated axonal degeneration and secondary demyelination [189]. The diagnosis can be made by laboratory testing of UV sensitivity of fibroblasts and excision repair; however, this is not universally available. Genetic tests are currently commercially available for XP types A, C, D, E, and G. There is a 30-year estimated reduction in life span, mainly due to neoplasia, but also related to neurologic complications. Life expectancy is 29 years with neurologic manifestations compared to 37 years without. Treatment is aimed at early diagnosis, genetic counseling, and skin care including protection from sunlight and monitoring and treatment of skin cancers.

Cockayne Syndrome

Cockayne syndrome (CS) is a rare disorder mainly characterized by sun sensitivity, short stature, and neurological dysfunction without increased frequency of skin cancer. There are three forms of CS (although other classifications schemes have been used): types I and II exist on a spectrum with type I typically presenting around age two with survival into the second decade, associated with mutations of *ERCC8* (25 % of CS patients). Type II is characterized by failure to thrive and meet neurologic milestones from birth and is associated with mutations in *ERCC6* (75 % of CS). Of note there is significant overlap with XP discussed above. *ERCC6* mutations are also associated with the De Sanctis-Cacchione form of XP. Type III is a milder form with little or late-onset neurologic symptoms. There is also an XP-CS combination disease with skin lesions and some of the neurologic disease of CS.

Patients with CS usually present early with sun sensitivity. Other clinical features include growth retardation, progeria, mental retardation, microcephaly, normal pressure hydrocephalus, deafness, pigmentary retinopathy, and ataxia. A demyelinating polyneuropathy is a common finding with hyporeflexia, reduced motor conduction velocities, and segmental demyelination on sural nerve biopsy [190]. Primary demyelination is also seen in the CNS. The diagnosis may be made by the demonstration of hypersensitivity of cultured CS cells to killing by UV light and by delayed recovery of DNA and RNA synthesis following UV radiation. Genetic testing is commercially available for both *ERCC6* and *ERCC8.* It is reasonable to start testing with *ERCC6,* as this represents 75 % of CS patients. Treatment is supportive.

Ataxia-Telangiectasia

Ataxia-telangiectasia (AT) is an autosomal recessive disorder characterized by neurological symptoms, oculocutaneous telangiectasia, and immunologic deficiency and, at the cellular level, by radiosensitivity, chromosomal instability, and impaired induction of ionizing radiation-induced cell cycle controls. The gene for AT (*ATM*) is localized to chromosome 11q22-23. The ATM protein is a member of the chemical family that phosphorylates key substrates involved in DNA repair.

Patients usually present in early childhood with a slowly progressive cerebellar ataxia, oculomotor apraxia, and oculocutaneous telangiectasia. Other neurological manifestations appear with time and include choreoathetosis and neuropathy, as evidenced by hyporeflexia, distal sensory loss, and distal motor weakness [191]. A variant presenting as adult-onset spinal muscular atrophy is reported [192]. Nerve conduction studies show reduced SNAP amplitudes and a slight reduction of motor conduction velocities. The pathology is a loss of large myelinated fibers. Endocrine abnormalities may occur and include growth retardation, delayed sexual maturity, and glucose intolerance. There is evidence of impaired humoral and cellular immunity with an increased incidence of infections and lymphoreticular malignancies. Lymphocytes and fibroblasts have increased sensitivity to ultraviolet, gamma, and x-irradiation.

The diagnosis is suggested by the clinical features, cerebellar atrophy on MRI, and high levels of circulating α-fetoprotein (>10 ng/ml). Lymphocytes and fibroblasts may be tested for irradiation sensitivity or ATM levels by immunoblot. Ninety percent of patients with AT have no detectable ATM and about 10 % have trace amounts; less than 1 % have normal ATM. Although *ATM* gene sequencing is available, it is less sensitive for AT than immunoblotting for ATM levels as only 90 % of patients have an identifiable *ATM* gene mutation. 7,14 translocation is present in 5–15 % of patients and should be checked with high-resolution karyotyping. There is no effective specific treatment. Pulmonary disease secondary to immunodeficiency and recurrent aspiration are common causes of death. Replacement IVIg may be necessary for frequent infections. Betamesthasone was shown to provide some neurologic improvement [193, 194]. Patients should avoid radiation therapy and high-dose radiologic exams as they have reduced ability to recover from the effects of radiation.

Guillain-Barré Syndrome and Related Disorders

28

Ezequiel Agustin Piccione, Karim Salame, and Bashar Katirji

Introduction

Guillain-Barré syndrome (GBS), also known as Landry-Guillain-Barré-Strohl syndrome, was described in 1916 [1, 2]. GBS is usually a predominantly motor disorder with areflexia and subjective more than objective sensory symptoms. GBS is the most common cause of acute flaccid paralysis worldwide, particularly with the almost complete eradication of poliomyelitis. Its incidence in North America and Europe ranges from 0.8 to 1.9 cases per 100,000 population. GBS affects individuals of all races and ages, but is more common in subjects above 50-year-old [3, 4], and the incidence increases by 20 % for every 10-year increase in age [5]. The annual incidence of GBS increased with age from 1.7/100,000 before 50 years to 3.3/100,000 after 50 years. The annual incidence in children less than 15 years old is between 0.34 and 1.34 per 100,000 population [4]. GBS affects males more than females with a male to female ratio of 1.78.

For many years since its original description, GBS was considered to be a single disorder and interchangeably named acute inflammatory demyelinating polyradiculoneuropathy (AIDP), based on evidence of acute immune attack on myelin and resemblance to experimental allergic neuritis. In addition, criteria for the published diagnosis of GBS have been based on AIDP clinical and electrophysiological features (Table 28.1).

Table 28.1 Diagnostic features of the typical form of Guillain-Barré syndrome, acute inflammatory demyelinating polyradiculoneuropathy (AIDP)

Clinical features
Required for the diagnosis:
Progressive weakness in both arms and legs
Areflexia or hyporeflexia (generalized or in weak limbs)
Strongly supporting the diagnosis:
Progression of symptoms over days to 4 weeks
Relative symmetry of symptoms
Mild sensory symptoms or signs
Cranial nerve involvement, especially facial diplegia
Recovery beginning 2–4 weeks after progression ceases
Autonomic dysfunction
A preceding upper respiratory or gastrointestinal illness
Absence of fever at the outset
Making the diagnosis doubtful:
Well-demarcated sensory level
Marked, persistent asymmetry of symptoms or signs
Severe and persistent bladder or bowel dysfunction
Excluding the diagnosis:
Diagnosis of botulism, myasthenia gravis, poliomyelitis, or toxic neuropathy
Abnormal porphyrin metabolism
Recent diphtheria
Meningeal carcinomatosis or lymphomatosis
Laboratory criteria
Elevated CSF protein concentration with no pleocytosis or fewer than 10 cell/mm^3
Electrophysiological criteria (any 3 of 4 criteria)
Reduction in conduction velocity of 2 or more motor nerves <80 % lower limit of normal (LLN) if amplitude >80 % of LLN; <70 % of LLN if amplitude <80 % of LLN
Prolonged distal latencies in 2 or more motor nerves >125 % of the upper limit of normal (ULN) if amplitude >80 % of LLN; >150 % of ULN if amplitude <80 %
Absent or prolonged minimum F-waves in 2 or more motor nerves, >120 % of ULN if amplitude >80 % of LLN; >150 % of ULN if amplitude is <80 % of LLN
Conduction block or abnormal temporal dispersion (>20 % drop in amplitude or >15 % change in duration between proximal and distal sites) in 1 or more motor nerves

Table 28.2 Classification of Guillain-Barré syndrome

GBS types
Acute inflammatory demyelinating polyradiculoneuropathy (AIDP)
Acute motor-sensory axonal neuropathy (AMSAN)
Acute motor axonal neuropathy (AMAN)
GBS variants
Miller Fisher syndrome
Ataxic variant (acute ataxic neuropathy)
Pharyngeal-cervical-brachial variant
Multiple cranial neuropathy variant
Facial diplegia with paresthesias
Paraparetic variant
Acute pandysautonomia (acute autonomic neuropathy)
Others

More recently, it has become clear that AIDP represent only the prototype of GBS, and other related immune polyneuropathies that cause acute generalized weakness but with different etiologies and pathophysiologies have been grouped together and called GBS. These GBS types comprise most commonly the axonal subtypes of GBS, in which the primary pathology is axonal degeneration and not segmental demyelination, including acute motor axonal neuropathy (AMAN), a pure motor disorder, and acute motor-sensory axonal neuropathy (AMSAN), an acute mixed sensorimotor axonopathy (Table 28.2).

In addition to these three major subtypes of GBS, several GBS variants have been described. These variants deviate significantly from the flaccid weakness and areflexia of typical GBS. Their link to GBS is supported by preceding infectious episodes, diminished reflexes, elevated CSF protein levels, and a presumed immune-mediated origin. Of these, Miller Fisher syndrome is the most widely known, but others include facial diplegia with paresthesias, pure sensory or ataxic forms, a pharyngeal-cervical-brachial regional form, and an acute dysautonomia (see Table 28.2).

Etiology

Although the topography, pathological features, pathophysiology, prognostic features and, more recently, immunopathogenesis of GBS are well understood, the etiology of the disease remains uncertain. There are no genetic factors that are known to predispose individuals to develop GBS, nor is there evidence that GBS is communicable. There have been reports of clusters of cases without an obvious source, but these have been thought to represent random variations [7].

The association of GBS with vaccinations has been suspected and debated for more than four decades. Reports of a definite association of GBS and conventional influenza, hepatitis B, and Gardasil vaccines have been published [8–10]. An "epidemic" of GBS, more accurately, an approximately fivefold increase in the incidence of cases over the estimated natural occurrence, was reported following the swine influenza vaccination program in 1976 [11]. However, lack of clarity in case ascertainment still generates controversy regarding the validity of this association [12–14]. Nonetheless, the risk of developing GBS is one to two additional GBS cases per one million vaccinated persons. The incidence of GBS was higher among conventional influenza vaccinees that were younger than 65 years, but the morbidity was higher among those older than 65 years [10]. Following the recent pandemic swine flu in 2009, another specially designed H1N1-influenza vaccine was introduced. Though epidemiological studies from North America and Europe did not find an increase in incidence of typical GBS among contemporary H1N1-influenza vaccinees [15, 16], atypical GBS cases and cases with GBS variants were recently reported [17].

An upper respiratory tract viral illness, diarrhea, or other infectious illness occurs 1–4 weeks before the onset of GBS in approximately two-thirds of patients (Table 28.3) [2, 18].

Table 28.3 Antecedent illnesses associated with Guillain-Barré syndrome

Viral infections
Cytomegalovirus
Influenza
Parainfluenza
Epstein-Barr virus
Cocksackie
Echo
Measles
Mumps
Rubella
Herpes simplex virus
Herpes Zoster virus
Hepatitis A and B virus
Human immunodeficiency virus
Bacterial and other infections
Campylobacter jejuni
Mycoplasma pneumoniae
Typhoid
Shigella
Legionella pneumonia
Cyclospora
Systemic illnesses
Hodgkin's lymphoma
Thyroid disease
Addison's disease
Leukemia
Paraproteinemia
Solid tumors (lung cancer)
Sarcoidosis
Systemic lupus erythematosus
Surgery
Trauma
Vaccination
Pregnancy

In any individual case, the relationship between an antecedent illness and GBS may be less certain. Respiratory or gastrointestinal syndromes are the most common antecedent illnesses. In most patients, the infection resolves by the time the neurological condition develops.

Campylobacter jejuni (*C. jejuni*) is the most frequently identified bacterial infection preceding GBS. In addition to its peculiarity of being a bacterial rather than a viral infection, it is implicated in up to 30 % of GBS cases studied prospectively with serological studies [19, 20]. Patients with *C. jejuni* enteritis develop fever, watery diarrhea, and abdominal cramping with GBS typically developing days later. However, a substantial number of patients have only serological evidence of recent *C. jejuni* infection without enteritis [19]. *C. jejuni*-related GBS has more severe axonal loss on electrodiagnostic (EDX) studies, elevated anti-GM1 antibodies, and a more protracted recovery compared to cases without the infection (see Sect. "Acute Motor Axonal Neuropathy" below) [19, 21]. The immunologic implications of *C. jejuni* as a triggering agent for GBS are of great interest because this sequence of events supports postinfectious nerve inflammation as a pathogenetic theory. Certain strains of *C. jejuni* are the cause of enteritis in a disproportionate number of GBS patients [22]. The lipopolysaccharides of these organisms share ganglioside-like epitopes with peripheral nerves (such as GM1, GQ1b, and GalNAc-GD1a) and are thought to induce a form of molecular mimicry in which the immune system, in its efforts to eradicate *C. jejuni,* elaborates antibodies against neural antigens and secondarily produces GBS [21, 23].

The most commonly identified viral infection is *cytomegalovirus* (CMV), with serological evidence of preceding infection in 10–15 % of cases [18, 24]. In some instances, the only indication that CMV is the preceding infectious agent may be an elevation in liver enzymes concomitant with the onset of GBS symptoms. GBS triggered by CMV infection tends to occur in younger individuals and to produce a more severe course with respiratory failure, prominent sensory loss, more frequent cranial nerve involvement, and raised antibodies directed against the ganglioside GM2 [18, 25]. Similarly, judging by serological studies, Epstein-Barr virus infection precedes GBS in approximately 10 % of patients, and the infectious clinical syndrome varies from mononucleosis to pharyngitis or hepatitis [18]. The relationship between GBS and other viruses reported to precede the condition, such as respiratory syncytial virus, parainfluenza virus, echovirus, coxsackie virus, measles, mumps, rubella, herpes zoster and simplex virus, influenza, and hepatitis A and B, is less certain (see Table 28.3). GBS may occur soon after seroconversion with human immunodeficiency virus (HIV) [26]. There are no clinical or EMG features that distinguish these patients from non-HIV-related forms of GBS, except for a prominent lymphocytic pleocytosis in the spinal fluid of patients with HIV, which may therefore complicate the CSF formula in GBS [26]. GBS has also been reported following immune reconstitution from highly active retroviral immunotherapy [27].

Among other bacteria, *Mycoplasma pneumoniae* (*M. pneumoniae*) has been reported to precede GBS in approximately 5 % of cases and should be considered when weakness develops after a prodromal illness characterized by fever, headache, and severe dry cough [18]. Infection with *M. pneumoniae* is supported by the presence of cold agglutinin antibodies in the serum and is confirmed by complement-fixing antibody tests. Lyme disease is a bacterial illness caused by a spirochete, *Borrelia burgdorferi* in the United States and *Borrelia afzelii* in Europe. It is transmitted by infected hard ticks belonging to a few species of the genus Ixodes. Lyme disease may cause a chronic axonal sensorimotor polyneuropathy, a painful polyradiculitis (Bannwarth's syndrome), or acute facial diplegia [28, 29]. This may mimic GBS, but the presence of a true postinfectious polyneuritis with Lyme is still somewhat uncertain. As with HIV, a lymphocytic pleocytosis in the spinal fluid may distinguish these patients from typical cases of GBS [28, 29]. Shigella, salmonella, typhoid, brucella, cyclospora, and yersinia enterocolitica also have preceded GBS during epidemics or in single cases [30].

Several systemic illnesses also have been tenuously linked to acute GBS, but most of these are implicated more often with CIDP. For example, a GBS-like syndrome has been described in patients with Hodgkin's disease, lung cancer, thyroid disease, systemic lupus erythematosus, paraproteinemia, and sarcoidosis in single case reports or small series [31, 32]. It is difficult to be certain that these are anything more than chance associations.

Many GBS series have included a small proportion of cases that occurred after surgery, and only few cases genuinely appear to have been triggered by an operation. It is now considered that some of these patients who develop weakness after being admitted to the intensive care unit have a "critical illness polyneuropathy" rather than GBS as a consequence of multiorgan failure and sepsis or other factors associated with a prolonged postoperative course in an intensive care unit (see Chap. 76). It is also unlikely that the axonal loss and prognosis in GBS patients worsen after admission to the intensive care unit due to concomitant critical illness polyneuropathy [33]. Trauma has rarely been reported as a precipitant to GBS, and we have seen several such cases, but the association remains uncertain. In one study reported in 2006, 16 patients receiving tumor necrosis factor-alpha antagonist therapy developed GBS and were reported to the US Food and Drug Administration [34]. Other medications, drugs of abuse, bone marrow transplantation, and spinal epidural anesthesia all have been reported to precede GBS, but these connections also remain unproven. GBS may occur at any time during pregnancy, but the risk is maximal during the first 2 weeks after delivery [35].

Pathogenesis

A number of immune mechanisms involving humoral and cellular immunity, complement deposition, proinflammatory cytokines, and other inflammatory mediators are theorized to be involved in the pathogenesis of GBS [36]. Many of these purported mechanisms have been gleaned from studies in an experimental model of the disease—experimental autoimmune neuritis (EAN) that represents a fair version of the human disease. The extent to which each of these immune processes is related to various clinical and electrophysiological patterns, and the implications for treatment and prognosis, is of great interest but has not been fully studied. In EAN, rabbits, guinea pigs, or rats are immunized with autologous peripheral nerve tissue and Freund's adjuvant (a nonspecific stimulator of immune reactions). After a latency of several days, they develop a rapidly progressive paralytic illness with the pathologic features of endoneurial inflammation and demyelination, identical to the clinical and pathological manifestations of GBS [37]. This inflammatory response is mediated by T cells that are directed against epitopes on peripheral nerve myelin including PO, P2, and PMP 22, and by implication, this immune attack leads to macrophage invasion and demyelination [38].

In classical pathological studies of GBS, demyelination was most prominent adjacent to regions of intense perivenular inflammation [39, 40]. Pathological material from patients with GBS shows a similar accumulation of lymphocytes and macrophages in a perivascular distribution scattered throughout the peripheral nervous system with a predilection for spinal roots [39–41]. Macrophages and T cells express major histocompatibility (MHC) class II antigens which are upregulated on Schwann cells in the region of inflammatory lesions in patients with GBS. One hypothetical sequence that has been offered is that activated T cells, stimulated by a preceding infection and by an interaction with antigen presenting cells that express MHC class II antigens, disrupt the blood nerve barrier, attack endoneurial antigens, and release inflammatory cytokines such as interleukin-2 and tumor necrosis factor (TNF) [36]. In keeping with this hypothesis, several investigators have demonstrated elevated levels of TNF and soluble TNF receptor in the serum of patients with acute GBS [42, 43]. These cytokines attract macrophages that are capable of producing nerve demyelination and damage Schwann cells and axons [36, 42, 43].

There is also evidence that humoral factors are central to the development of GBS. Passive transfer studies have shown that sera from GBS patients injected into the nerves of animals induces local demyelination. Furthermore, the observed clinical recovery following removal or neutralization of autoantibodies (or other pathogenic humoral factors) by plasmapheresis or intravenous immune globulin (IVIG) supports a role for B-cell-mediated processes in the pathogenesis of GBS [44]. Koski et al. demonstrated that elevated serum levels of complement-fixing anti-myelin antibodies correlated with disease activity in patients with GBS [45, 46]. Recent autopsy studies revealed that local complement activation occurs at the site of nerve lesion, such as the axolemma in patients with AMAN and the Schwann cell membrane in patients with AIDP [47, 48]. There is now evidence, using high-resolution immunocytochemistry, of early complement activation and deposition of activated complement components along the outer surface of the Schwann cell. The presence of terminal complement complex is associated with vesiculation of the outermost myelin lamellae. This occurs before and within 1 week of invasion of macrophages [48]. In patients with AMAN associated with axonal loss, the complement activation product binds to the axolemma of motor fibers and, in severe cases, immunoglobulin and activated complement within the periaxonal space of myelinated internodes [47].

Numerous studies have demonstrated the presence of anti-neural antibodies directed against acidic glycoconjugates in the serum of patients with GBS. These peripheral nerve antigens are usually gangliosides (GM1, GD1a, GQ1b, and GT1a) which differ with regard to the position and number of their sialic acid. There is solid indication that *anti-ganglioside antibodies* play a pathogenic role in the pathophysiology of GBS [49]. In clinical practice, these antibodies are found in only a minority of patients since autoantigens have not been well identified in AIDP. The anatomic distribution of the gangliosides within the peripheral nervous system may explain some of the observed clinical variants of GBS [36, 49]. For example, GQ1b is strongly expressed in the oculomotor, trochlear and abducens nerves, as well as the muscle spindles in the limbs, which explain the distinct Miller Fisher syndrome (ophthalmoplegia, ataxia, and areflexia), frequently associated with anti-GQ1b antibody [50–52]. There is also strong evidence currently that the axonal subtypes of GBS, particularly AMAN and less commonly AMSAN, are associated with antibodies directed against GM1 and GD1a at the axolemma. This eventually attracts macrophages invading the nodes of Ranvier and inserting between the axon and the axolemma, resulting in axonal degeneration. In AMAN, the myelin sheath also remains intact, and there is no lymphocytic inflammation [53]. In AMAN, only the axons of the ventral roots are involved, while in AMSAN, both the dorsal and ventral roots are affected [38, 41].

Increasing evidence supports that *molecular mimicry* plays an important role in the pathogenesis of GBS. It is likely that genetic polymorphism in various strains of *C. jejuni* determines the specificity of the antiganglioside antibodies and the associated variant of GBS. Lipooligosaccharide, a major component of the outer membrane of *C. jejuni*, has ganglioside-like products; sensitization with GM1-like

lipooligosaccharide by injecting it, rabbits induced a neuropathy resembling AMAN [54]. *C. jejuni* bacterial isolates from patients with AMAN have GM1-like and GD1a-like lipopolysaccharides, whereas bacterial isolates from patients with the Miller Fisher syndrome usually express GQ1b-like lipopolysaccharides [55, 56]. It is now evident that *C. jejuni* is composed of several classes that have diverse lipooligosaccharide biosynthesis genes. *C. jejuni* is now grouped into several classes based on the organization of these genes. A specific class carrying a sialyltransferase gene (cst-II) is associated with the development of GBS. Patients infected with a specific strain (Thr51), which expressed both GM1-like and GD1a-like lipooligosaccharides, had anti-GM1 or anti-GD1a IgG antibodies and present with typical GBS manifestations including limb weakness. In contrast, patients infected with another strain (Asn51), which expresses GT1a-like or GD1c-like lipooligosaccharides, have anti-GQ1b IgG antibodies and present with the Miller Fisher syndrome including ophthalmoplegia and ataxia [55–58]. On the basis of the above findings, one may conclude that *C. jejuni*-associated/GM1-related GBS represents at least true instance of a molecular-mimicry-related disease.

Clinical Features

GBS in its typical form is a predominantly motor neuropathy, although acral paresthesias are almost always present at the onset of the illness (Table 28.4). Tingling, prickling, or pins and needles sensations are usually followed within hours or days by symmetrical leg weakness and trouble walking. The presence of acral paresthesias increases the probability of the correct diagnosis of GBS [2]. Difficulty climbing stairs or arising from a chair or commode is typical. Weakness of the upper limbs, ocular, oropharyngeal, and facial muscles develops with variable frequency and severity.

The *weakness* is often bilateral but some degree of asymmetry is common. Rarely, the weakness begins in one limb hours or a day before involving the contralateral limb. Proximal weakness is more frequent than distal and often more severe. In contrast to diseases that affect the muscle or neuromuscular junction, weakness rarely remains restricted to the shoulder or hip girdle muscles; some degree of hand or distal leg weakness develops after the proximal muscles. The weakness often moves to the upper limbs resulting in an *ascending paralysis*. Weakness that remains limited to the legs or, alternatively, weakness that begins in the hands or shoulder girdle and involves the legs may occur as the condition advances. A pattern of *descending paralysis* occurs in 10–15 % of cases, with symptoms beginning in the cranial nerves or arms and spreading to the legs. Approximately one-third of fully developed cases have a degree of weakness that is similar in the arms and legs. Fasciculations or myokymia are observed in a small number of patients.

Table 28.4 Frequency of clinical features in Guillain-Barré syndrome

	Initially	In fully developed Illness
Paresthesias	70	85
Weakness		98
Legs > arms	54	
Arms > legs	14	
Approximately equal	32	
Ophthalmoparesis	5	15
Facial weakness	35	50
Bulbar weakness	25	50
Respiratory failure	10	30
Ataxia	10	15
Sphincter dysfunction	15	5
Areflexia	75	95
Pain	25	30
Sensory loss	40	85

The second hallmark sign of GBS is *reduced or absent deep tendon reflexes*, presumably reflecting desynchronization or dispersion of impulses carried by myelinated fibers in the afferent arm of the reflex arc. Approximately 70 % of patients have absent deep tendon reflexes at the time they are first examined. Reflexes occasionally remain elicitable until weakness or large fiber sensory loss advances. Reflexes are almost always unobtainable in limbs that are too weak to resist gravity. Yuki et al. found that the myotatic reflexes were normal or exaggerated during the entire clinical course in approximately 10 % of GBS patients, more commonly in patients with AMAN than AIDP [60]. However, the diagnosis of GBS must remain questionable in this group, and upper motor neuron causes of weakness should be excluded.

More than half of GBS patients experience *paresthesias* of the distal extremities as the initial symptom. Most patients complain of "pins and needles," "prickling," or "tingling" feelings, likened to an "asleep feeling" in an arm or leg following compression of the limb. In contrast to most length-dependent axonal polyneuropathies, patients with GBS often develop paresthesias in the fingertips soon after the feet are affected and sometimes beforehand. The sensory symptoms are symmetric and often precede weakness by a few days, ascending to the ankles and wrists as the illness progresses. Paresthesias of the trunk or face are infrequent. Patients may also describe an acral numb, heavy, or dead sensation as the disease evolves. Some experience sensory loss over the trunk, and a well-demarcated sensory level simulating spinal cord disease has been described, but only to the extent of a noticeable change in sensation, not analgesia below the level. The detection of a genuine thoracic sensory level should prompt further evaluation with an MRI of the spinal cord to exclude a myelopathy including transverse myelitis. Reduced

vibration sense and proprioception in the distal limbs are the most common findings. A substantial number have sensory ataxia that is soon obscured by weakness. Pinprick sensation may also be impaired in distal parts in severely affected patients.

Pain is a common but underappreciated symptom in GBS. Pain may precede the onset of weakness by 2 weeks in 1/3 of patients [61], and about 2/3 of patients have modest discomfort early in the illness [62]. Pain, when not severe, may be overlooked by medical staff who are preoccupied with more pressing medical complications, and intubated patients often are unable to convey their discomfort. The discomfort in GBS has been described as (1) aching, usually confined to muscles of the back, hips, or upper legs (the most common type); (2) shooting or stabbing, radicular pain radiating from the back to one or both legs; or (3) chronic and unrelenting, burning, dysesthetic feelings in the distal limbs [61–63]. Rarely, back and radicular pain can precede weakness and paresthesias and be attributed to sciatica or a spinal condition [63]. At 1-year follow-up, pain is reported in 38 % of patients, and the pain intensity was highest in patients with typical GBS and in those with sensory disturbances and with higher level of weakness and disability [61].

Approximately one-half of GBS patients will have *cranial nerve involvement* at some time in the course. The facial nerve is most commonly affected, and facial weakness typically occurs when there is substantial limb weakness. Conversely, lack of facial weakness in a patient with severe generalized paralysis should at least raise concerns about the accuracy of the diagnosis. As with limb weakness, facial paralysis is often bilateral, but occasionally asymmetrical, and rarely unilateral. Weakness of the ocular muscles arises in 10–20 % of patients, the abducens nerve being most commonly affected. Impaired abduction is usually bilateral and occasionally asymmetrical. Oropharyngeal weakness occurs in up to one-half of patients during the course of the illness and presents great problems in terms of aspiration. In severely affected patients, there may be paralysis of all the cranial muscles, ventilatory failure, and flaccid paralysis of all the limbs, simulating the "locked-in" state [64].

Weakness of the diaphragm that leads to *respiratory failure* and a requirement for ventilator support occurs in approximately 20–30 % of patients with GBS [65–67]. Most such patients are quadriparetic, although patients with a bibrachial pattern of weakness may also have pronounced oropharyngeal and respiratory muscle involvement (see Sect. "Guillain-Barré Syndrome Variants"). Weakness of the neck muscles, tongue, and palate tends to parallel involvement of the diaphragm and respiratory muscles. Diaphragmatic weakness, which causes reduced vital capacity, inspiratory force, and tidal volume, invariably causes atelectasis. Coughing and clearing of oral secretions are then impaired, generating progressive atelectasis, arteriovenous shunting, and mild hypoxia. These changes further aggravate ventilatory failure by causing tachypnea and an increased work of breathing. As the respiratory rate increases, levels of carbon dioxide actually may be reduced in the early stages of respiratory compromise. However, as the diaphragm, intercostal, and accessory muscles become further exhausted, hypercapnea ensues and patients may rapidly deteriorate with hypercarbia and respiratory arrest. If diaphragmatic and respiratory muscle weakness have not occurred 2 weeks into the course of the illness, assisted ventilation should not be necessary unless other pulmonary or medical complications ensue. The main predictors of mechanical ventilation include shorter days between onset of weakness and admission, higher Medical Research Council (MRC) sum score, and presence of facial and/or bulbar weakness (see Sect. "Prognosis") [65]. Patients with GBS who require ventilator support have a less favorable prognosis for neurologic recovery, longer hospitalization, and higher mortality.

Dysautonomia is a less common but well-recognized feature in patients with fully developed GBS, occurring up to 65 % of cases [68, 69]. This number is certainly overestimated if one considers only changes of clinical significance. Autonomic nervous system complications tend to occur more frequently in those with severe paralysis and ventilatory difficulties, but rarely may develop in otherwise mild cases. The most common cardiac manifestations include sinus tachycardia, sinus bradycardia, sinus arrest and other supraventricular arrhythmias, paroxysmal hypertension, hypotension (especially postural hypotension), and so-called vagal spells that consist of bronchorrhea, bradycardia, and hypotension. Infection, hypoxia, pulmonary embolus, and other medical complications should be excluded before attributing cardiovascular disturbances to dysautonomia. Because of the potential for complete heart block, sinus arrest or other life-threatening cardiac arrhythmias (e.g., ventricular tachycardia), and the risk of rapidly progressive respiratory failure, most patients with GBS require monitoring in an intensive care setting early in the illness (see Sect. Supportive Care in under the Sect. Treatment and Management). Other features of autonomic instability include ileus, urinary retention (surprisingly common—seen in one-quarter of patients and suggesting a myelopathy), and inappropriate antidiuretic hormone secretion leading to hyponatremia [70]. Many patients have minor aspects of dysautonomia that are clinically insignificant, such as altered sweating, mild orthostatic hypotension, and acral cyanosis from vasomotor instability.

GBS can have sometimes unusual features such hearing loss, meningeal signs, vocal cord paralysis, papilledema, and mental status changes [71]. Recently, cases of GBS has been associated with posterior reversible encephalopathy syndrome (PRES) [72]. One explanation for the PRES is that the cytokines, produced in the context of GBS, may increase the permeability of the blood–brain barrier.

Guillain-Barré Syndrome Subtypes

For many years, the term AIDP was interchangeably used with GBS. It is now well recognized, particularly during the last two decades, that axonal forms of GBS exist and these are distinguished from AIDP using electrophysiological and pathological characteristics. These disorders, AMAN and AMSAN, remain under the same umbrella term of GBS because they share many of the clinical findings, including flaccid weakness and areflexia, preceding infectious episode, and a presumed immune-mediated origin (see Table 28.2). These disorders are also often preceded by infections, but may be occasionally associated with connective tissue disorders [73, 74]. Also, these disorders may be difficult to distinguish on early electrodiagnostic studies since the nerve conduction changes may overlap and sequential studies are often necessary.

Acute Inflammatory Demyelinating Polyradiculoneuropathy (AIDP)

AIDP is the prototype of GBS and characterized by peripheral nerve and spinal root demyelination. This disorder accounts for up to 90 % of GBS cases in North America and Europe [75] but only 22–46 % of cases in China, Japan, India, Southeast Asia, and Mexico [76, 77]. This disorder is characterized by vesicular degeneration of myelin triggered by membrane-attack complex formation on the outer surface of Schwann cells. AIDP has not been strongly associated with antiganglioside antibodies [78].

Acute Motor Axonal Neuropathy (AMAN)

McKhann, Griffin, and colleagues described an acute paralytic syndrome in patients from regions of northern China and coined the term acute motor axonal neuropathy (AMAN) [79–81]. It is now clear that this disorder is as common as AIDP in Mexico, China, Japan, India, and Southeast Asia, accounting for 30–65 % of cases [76, 77]. In contrast, AMAN is rare in North America and Europe, probably accounting for less than 10 % of cases [75].

The disorder primarily afflicts children and young adults [79, 82] and causes symmetrical limb weakness, areflexia, facial diplegia, and oropharyngeal and respiratory muscle weakness that evolves over several weeks. The extraocular muscles are spared. There are no sensory features although mild changes in sensory nerves may occur [83]. The condition occurs as an annual epidemic during summer months. Most cases are preceded by a gastrointestinal illness with abdominal pain, cramps, and diarrhea and elevated antibody titers to Campylobacter jejuni, anti-GM1, and anti-GD1a [84–86]. The spinal fluid protein concentration is usually slightly elevated after several days of the illness, but EDX studies show reduced or absent compound muscle action potential amplitudes with normal conduction velocities, no conduction blocks, normal sensory potentials, and early active denervation, thus implicating a process similar or identical to AMSAN, with the exception of the normal sensory potentials (see below) [79–81].

Autopsy findings have confirmed widespread axonal degeneration with little demyelination or inflammation [48, 81]. Pathologic studies using electron microscopy have demonstrated the presence of macrophages in the periaxonal space of myelinated internodes [48, 53, 87]. The pathogenesis of AMAN has not been fully elucidated, but there is convincing evidence for an antibody- and complement-mediated process directed primarily at motor axons. There is evidence to suggest that IgG anti-GM1 or anti-GD1a antibodies bind to the axolemma at the node of Ranvier leading to membrane-attack complex formation. This results in the loss of voltage-gated sodium channels and leads to conduction failure. These rapidly reversible immune-mediated changes at the nodes of Ranvier may explain the puzzling speedy recovery that occurs in some patients with AMAN, a rate that is comparable to patients with AIDP. Another explanation for the rapid recovery is selective degeneration and subsequent quick regeneration of intramuscular motor nerve terminals in AMAN [86, 88, 89].

Acute Motor-Sensory Axonal Neuropathy (AMSAN)

In 1986, Feasby and coworkers described an axonal form of GBS, challenging the existent notion of GBS being a primarily demyelinating disease. These patients developed rapidly progressive paralysis, areflexia, and distal sensory loss [90, 91]. All of their patients required assisted ventilation and recovery was poor. The spinal fluid protein level was increased, but in contrast to the demyelinating features of typical GBS, EDX evaluation showed numerous inexcitable nerves, widespread active denervation, and no evidence of demyelination. An autopsy in one case showed axonal degeneration without inflammation or primary demyelination in the spinal roots and peripheral nerves. Since then, several studies have suggested that this syndrome, now termed acute motor-sensory axonal neuropathy (AMSAN), represents a variant of GBS that is clinically indistinguishable from typical, albeit very acute, cases but in which axons are the targets of the immune reaction. Virtually all patients become quadriplegic within days and require ventilator support and most have substantial residual weakness after recovery from the acute illness; some remain ventilator dependent for prolonged periods. Nerve conduction studies indicate an acute and widespread axonal sensory and motor neuropathy without demyelinating features.

It has also been argued that complete, distal conduction block and reversible conduction failure can simulate the finding of nerve inexcitability that is at the core of the diagnosis [92]. Subsequent pathological material from a few cases has shown axonal degeneration in the motor nerves

with macrophages insinuated in the periaxonal space of internodes; some patients also had axonal loss in the spinal roots [41].

Recent evidence suggests that AMAN and AMSAN share a common immunological profile and represent a continuum within the spectrum of axonal GBS [41]. Anti-GM1, anti-GM1b, and anti-GD1a, immunological markers for AMAN, are seen in high percentage of patients with AMSAN [93]. Also, sensory fiber involvement which distinguishes AMSAN from AMAN has been shown to be often involved subclinically in AMAN patients [83].

Evaluation and Diagnosis

Electrodiagnostic Studies

Electrodiagnostic (EDX) studies are very important in the diagnosis of GBS. Abnormalities on nerve conduction studies (NCS) are seen in up to 95 % of cases, and these findings are diagnostic in large number of GBS patients at some time during the course of the illness [94–96]. Unfortunately, NCS may be normal or show only modest nondiagnostic changes early in the course of GBS, at a time when treatment decisions have to be made. Repeat studies are often necessary, particularly when initial NCS findings are not specific [94]. The nature of the abnormalities detected by NCS depends upon the timing of the study in relation to disease onset and the number of nerves studied. Extensive testing of multiple nerves and multiple nerve segments in multiple limbs including evaluation of F-waves, H-reflexes, and blink reflexes is essential. The aim of NCS is to show evidence of *multifocal acquired nerve demyelination,* the hallmarks of AIDP, which represents the majority of patients with GBS in the Western World [75].

Abnormal Electrodiagnostic Parameters in GBS

The EDX studies in GBS include a variety of NCS parameters which may become abnormal during the course of illness. These include motor distal latencies, motor conduction velocities, CMAP amplitude and waveform configuration, sensory studies, late responses, and needle EMG. Although these EDX abnormalities are common in GBS, they vary in specificity which renders some of them less useful than others. The following are the most common abnormalities seen in GBS, with varying degree of specificity:

Abnormal H-Reflex

The tibial H-reflex is a sensitive test for detecting abnormalities of the S1 nerve root and early polyneuropathy and correlates fairly well with the Achilles reflex [97]. Absent H-reflexes correlate well with the areflexia in the lower extremities of GBS patients. The H-reflexes are absent bilaterally in almost all patients with GBS, including in 95–100 % of patients during the first 1–2 weeks of illness [98–100]. Hence, the H-reflex is the most sensitive EDX test. However, absent H-reflexes are not specific for GBS since it a common finding in the elderly and occurs in the majority of large fiber sensory and sensorimotor peripheral polyneuropathy such as diabetic and critical illness polyneuropathies, as well as S1 radiculopathies, cauda equina, and conus medullaris lesions.

Abnormal F-Waves

Multifocal acquired nerve demyelination, the hallmark of GBS [6], preferentially affects proximal and distal portions of the peripheral nerves [101]. Therefore, a common finding in early GBS is prolonged F-waves [94–96]. Prolonged or absent F-responses have been reported in as many as 40–80 % of GBS patients early in the illness [100, 102]. It may be the sole electrodiagnostic abnormality in about one-fourth of patients [101, 102]. The yield of F-wave studies improves by assessment of additional multiple F-wave parameters, including chronodispersion, mean latency, and mean amplitude [101]. However, these parameters are difficult to quantitate and are subject to variability.

Multiple and Complex A-Waves

A-waves are reproducible intermediate-to-late responses that are distinguished from F-waves and H-reflexes and usually seen during routine F-wave studies. A-waves may be recorded in normal individuals of the foot muscles while stimulating the tibial nerve. A-waves are commonly seen in multiple nerves and often with complex morphology in about 2/3 of patients with GBS [103, 104]. Their precise mechanism is not known, but they may be due to ephaptic transmission between axons or proximal re-excitation of the axon. Although prevalent in GBS, A-waves are not specific for GBS since they may be seen in other acquired and inherited demyelinating polyneuropathies (such as chronic inflammatory demyelinating polyneuropathy and Charcot-Marie-Tooth disease type I) and, less often, in axonal polyneuropathies, radiculopathies and motor neuron disease [103].

Motor Conduction Blocks

This is defined as a reduction (usually >20–50%) in the amplitude and area of the compound motor action potential (CMAP) following proximal nerve stimulation (Fig. 28.1). To be more specific and to avoid confusing GBS with polyneuropathies associated with compressive mononeuropathies, the conduction blocks in GBS should be located at non-entrapment sites (Fig. 28.2). This is a highly specific finding but is found in only about one-third of patients with GBS, dependent on the number of nerves and nerve segments studied [95, 98, 100]. Conduction block is often a sign of segmental demyelination, but transient conduction and block may be seen as the early manifestations of axonal loss such during the early stages of AMAN [105, 106]. Sequential studies are necessarily before a final diagnosis of axonal loss

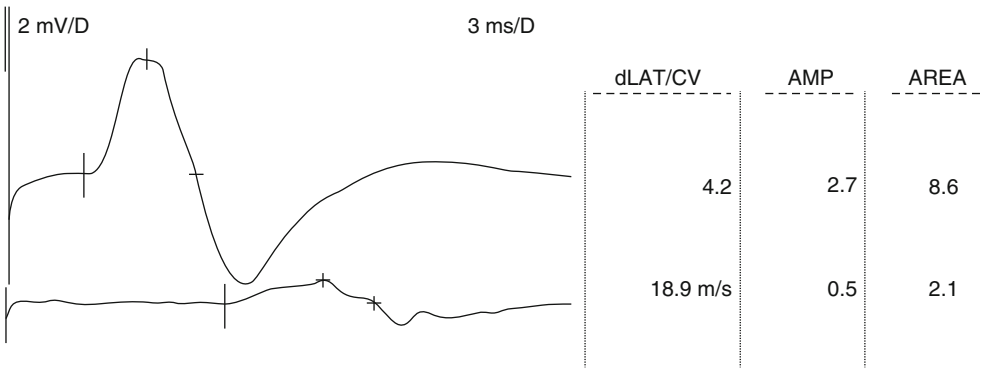

Fig. 28.1 Median motor nerve conduction study in a 35 year old patient with GBS examined at week 2 of illness. Note the forearm conduction block as evidenced by the significant drop in CMAP amplitude (80 %) and area (76 %) when CMAP obtained with distal stimulation at the wrist (*upper tracing*) is compared to proximal stimulation at the elbow (*lower tracing*). There is also marked slowing of forearm conduction velocity (18.9 m/s). *dLAT/CV* distal latency/conduction velocity, *AMP* amplitude

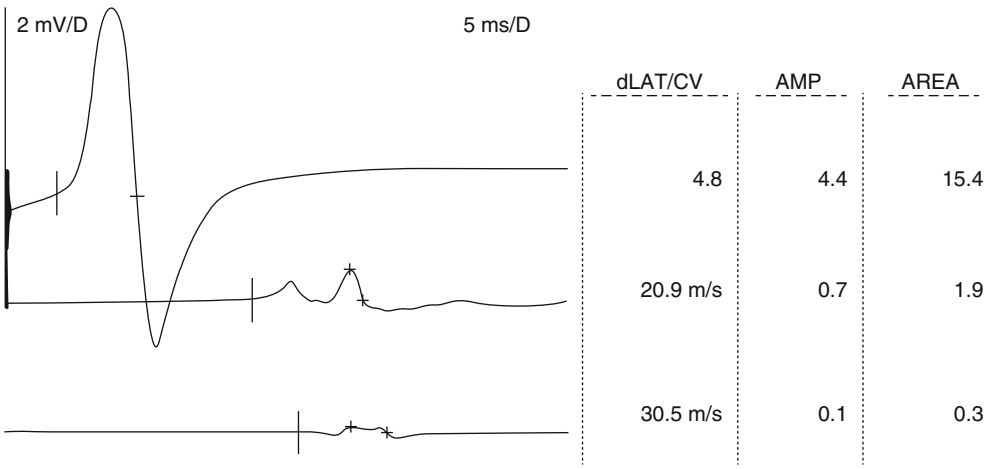

Fig. 28.2 Peroneal motor nerve conduction study in a 55 year old patient with GBS examined at week 4 of illness. Note the significant drop in CMAP amplitude (84 %) and area (88 %), with CMAP dispersion, when CMAP obtained with distal stimulation at the ankle (*upper tracing*) is compared to proximal stimulation below fibular neck (*middle tracing*) and popliteal fossa (*lower tracing*). The conduction block is distal to the fibular neck, not at a common entrapment site (i.e., fibular tunnel). *dLAT/CV* distal latency/conduction velocity, *AMP* amplitude

is made. Also, low distal CMAPs may be due to distal demyelination with distal conduction block and often mimic axonal loss. Rapid recovery of low distal CMAPs and SNAPs on sequential studies is a necessary confirmatory sign of distal demyelination [106].

Nerve Conduction Velocities Slowing

Significant slowing of nerve conduction velocities was first reported by Lambert and Mulder who reported in 60 % of their patients with GBS. During the early stage of disease, however, 80–90 % of patients with AIDP have normal conduction velocities [95]. It is now clear that prominent slowing of nerve conduction velocities is uncommon and is detected in only approximately 25 % of cases [98, 100]. Slowing is particularly uncommon during the first 2 weeks of illness in AIDP, and conduction velocities become paradoxically slower between 3 and 6 weeks from onset and during the recovery phase, presumably due to nerve fiber remyelination [95]. Additionally, controversies remain regarding the exact cutoff of conduction velocity that distinguishes primary demyelination from axonal loss, particularly in the presence of low CMAP amplitude. These values have varied from 60 to 80 % of the lower limits of the normal conduction velocity values [94, 95, 107].

Distal Latency Slowing

Since multifocal acquired nerve demyelination in GBS preferentially affects proximal and distal portions of the peripheral nerves, common findings in early GBS are prolonged distal motor latencies [94, 95]. Although this finding is common, it lacks specificity except when the latencies are significantly delayed and are within the demyelinating ranges. Similar to velocities, these ranges have also been controversial since demyelinating ranges have varied from 120 to 150 % of the upper limit of normal values [107–110].

Compound Muscle Action Potentials (CMAPs) Dispersion

The CMAP duration may be prolonged in GBS, and this is attributed to varying degrees of conduction slowing in demyelinated motor nerve fibers. Dispersion of the CMAP has only been considered as a criterion of demyelination in one study [108, 109]. Adding this fairly specific finding to other EDX parameters improved the sensitivity of EDX studies without worsening its specificity [111]. Distal CMAP durations of median, ulnar, peroneal, or tibial nerves measuring more than 8.5 ms are strong evidence for the presence of demyelination [111, 112].

Abnormal Sensory Nerve Action Potentials (SNAPs)

Earlier EDX criteria of GBS overlooked sensory nerve conduction studies by emphasizing abnormalities of motor NCS, such as conduction block, CMAP dispersion, abnormal F-waves, and slowing of latencies and velocities. It is now clear that SNAPs abnormalities are common and sometimes specific for AIDP. SNAP are abnormal in about 75 % of patients sometimes during the illness [94, 95, 100, 102]. The most common findings are reduced SNAPs amplitudes. This may reflects axon loss but is more likely caused by conduction block and phase cancellation. Slowing of sensory nerve conduction velocities is detected less frequently because the SNAP potential usually drops out before severe slowing is found.

Sensory NCS is now recognized to be important in providing EDX evidence that might distinguish primary demyelinating from axonal polyneuropathy. A *sural-sparing pattern*, also known as a "normal sural-abnormal median" pattern, is now recognized to be a common and specific finding in GBS and in particular AIDP [94, 100, 113, 114]. In contrast to the majority of length-dependent axonal polyneuropathies, the median and ulnar SNAPs are frequently reduced or absent when the sural nerve is normal ("sural sparing"), presumably as a consequence of random, multifocal demyelination. This pattern is the most specific sensory abnormality in AIDP and is present in about 50 % of patients during the first 2 weeks of illness [98, 100].

There are several limitations of the sural-sparing pattern which affects its sensitivity and specificity in the diagnosis of GBS. First, the sural SNAP may be either low in amplitude or absent in elderly patients and in those with underlying diabetic polyneuropathy [98]. Second, technical considerations in hospitalized or critically ill patients or those on mechanical ventilation render it difficult to study the sural SNAP. Third, the median sensory study may be abnormal in patients with preexisting carpal tunnel syndrome. Hence, sural sparing is better defined by preservation of sural SNAP in the presence of normal or near normal median *and* ulnar SNAPs in the upper extremity [98, 100].

Comparing several SNAP amplitudes in the upper and lower extremities is a useful exercise, particularly in elderly where the sural may be unobtainable. Among them, a sensory ratio (sural + radial SNAPs/median + ulnar SNAPs) is a good substitute for sural-sparing pattern. Patients with AIDP are 12 times more likely to have an elevated sensory ratio (>1) compared to patients with axonal polyneuropathies such as diabetic or critical illness polyneuropathies [115]. It is not known whether another lower limb SNAP, such as the superficial peroneal, could substitute for the sural.

Needle Electromyography (EMG)

Needle EMG is the least helpful EDX tool in the evaluation of patients with GBS, mostly since the EDX studies are often done early in the disease before signs of axonal degeneration are apparent on needle EMG. The initial finding in patients with GBS is reduced recruitment with the degree of abnormality proportional to the degree of muscle weakness. Early on, the combination of normal or virtually normal motor unit action potentials (MUAPs), reduced MUAP recruitment, and absent fibrillation potentials detected by needle EMG is characteristic. However, similar needle EMG findings are also seen in other acute axonal nerve lesions. The detection of abnormal spontaneous activity (fibrillation potentials) indicates axonal damage and occurs in 20–60 % of GBS patients in the first 4 weeks of the illness [95, 107]. This is seen in the demyelinating and axonal subtypes of GBS and signifies a variable element of axonal loss in all patients. Abnormal spontaneous activity is found more often during follow-up studies, 2–4 months after onset, and may be observed in proximal and distal muscles, consistent with multifocal nerve degeneration [95]. MUAP morphology changes start to occur after the fourth week of illness with an increased percentage of polyphasic MUAPs as the early change. Myokymia may be found in limb or facial muscles in some GBS patients, usually early in the course of the disease [94].

Electrodiagnostic Criteria in GBS

Various sets of EDX criteria for the detection of demyelination have been developed. These were mostly made by consensus or as part of the methods utilized in GBS studies [94, 95, 107, 109, 110]. However, most of these criteria were not subjected to vigorous scrutiny or applied to other neuropathies, and their specificities in GBS diagnosis were not well tested. For example, classic published diagnostic criteria of AIDP in GBS are fulfilled in 20–70 % of the cases based on the specific criteria utilized [99, 116]. This variation depends on how strict these criteria are in excluding patients with equivocal EDX findings.

Although it is intuitive to conclude that EDX studies are sensitive in confirming demyelination, EDX studies often reveal abnormalities that are not specific of primary demyelinating polyneuropathy during the early phases of the disease. Common abnormalities seen during the first few weeks of illness include absent or delayed H-reflexes, F-responses or blink reflexes, "sural sensory sparing," distal CMAP temporal dispersion, or frequent A-waves [95, 98–100]. During the first 4 days of weakness GBS, about 1/2 of the patients have normal NCSs (except for absent H-reflex in the majority of

Table 28.5 Diagnostic power of nerve conduction studies findings in the first 2 weeks of patients with AIDP

	Abnormalities	Sensitivity (%)	Specificity (%)
1. Nondiagnostic	Nonspecific abnormalities that are not specific for GBS, including absent H-reflexes, borderline or low CMAPs and/or SNAPs, minimal slowing of latencies or velocities	–	19
2. Suggestive	Upper extremity sensory sparing pattern *or* Absent or prolonged minimal F-wave latencies in at least 2 motor nerves with absent H-responses	26	86
3. Highly suggestive	Upper extremity sensory sparing pattern *and* Absent or prolonged minimal F-wave latencies in at least 2 motor nerves with absent H-responses	29	96
4. Definite	Signs of multifocal demyelination including: 1. Marked slowing of motor conduction velocity, distal latency and temporal dispersion 2. Conduction blocks in at least 2 motor nerves 3. Absent or prolonged minimal F-wave latencies in at least 2 motor nerves with absent H-responses	35	100
Highly suggestive or definite findings	3 and/or 4	64	96–100

SNAP sensory nerve action potential, *CMAP* compound muscle action potential

them), while only about 10 % of them have normal studies by the first week of illness [98]. Another 5–10 % have only nonspecific nerve conduction abnormalities, such as mild slowing, absent and/or prolonged H-reflexes or F-waves (due to spinal root demyelination), or low-amplitude CMAPs (due to intramuscular motor nerve terminals involvement).

We recommend using EDX criteria that include these different variables and have increasing levels of certainty in confirming the diagnosis of demyelination in AIDP [100] (Table 28.5). These criteria are designed to grade the level of confidence of the EDX studies, ranging from normal study to definite findings of acquired multifocal demyelination. Using these criteria, about 2/3 of patients with GBS meet the highly suggestive or definite criteria for AIDP during the first two weeks of illness with a very high specificity of 96–100 %. The remainder likely includes patients with the axonal subtypes of GBS, AMAN, and AMSAN, who do not have evidence of demyelination.

Electrodiagnostic Studies in GBS Subtypes

The EDX studies in GBS and its subtype may be confusing at the early stage of the disease when it is often difficult to determine the subtype classification of the disease (axonal vs. demyelinating) [105]. AIDP, AMAN, and AMSAN may have similar findings during the first weeks of illness. As outlined above, sensory conduction abnormalities are seen in patients with AMAN, making the distinction with AMSAN sometimes difficult [83]. Also, transient conduction slowing and block may be encountered during the early stages of AMAN, leading to incorrect diagnosis of AIDP [106, 117]. Similarly, some patients initially classified as "axonal" by nerve conduction studies have distal conduction block, and follow-up studies demonstrate rapid recovery of motor and/or sensory amplitudes typical of distal demyelination as seen in AIDP [92]. A useful diagnostic clue is the time course of EDX abnormalities. The nadir of conduction slowing in AIDP is 3–6 weeks after onset of symptoms, and this corresponds with the beginning of the clinical improvement [95]. In contrast, when conduction slowing or block is present in AMAN, it is evident early during the first 3 weeks of illness and rapidly resolves in parallel with clinical improvement [106, 117].

Prognosis of GBS Using Electrodiagnostic Studies

It has been long known that this presence of axonal damage in GBS is generally associated with worse outcome. In contrast, there is no association between slowing of nerve conduction velocities or F-wave latencies and clinical recovery. Early studies indicated a relationship between the detection of fibrillation potentials and poor outcome [118], but others have failed to confirm this finding as fibrillation potentials may occur when minimal amount of axonal loss has occurred [75, 107]. Also, fibrillation potentials may take several weeks to appear which renders needle EMG findings less useful.

Reduced CMAP amplitude is the most important predictor of outcome in GBS. Reduced mean CMAP amplitude (<20 % of the lower limit of normal) or absent CMAPs are strongly associated with a poor prognosis [66, 75, 119]. Hadden and colleagues demonstrated that 42 % of patients with an axonal loss pattern, on follow-up studies, were nonambulatory after 48 weeks [75]. On individual basis, one should be careful in making definite prognostic implications based on EDX studies only during the first 2–3 weeks of illness for several reasons: (1) Patients with axonal GBS studied early may show normal CMAP amplitude before the onset and completion of Wallerian degeneration [120]; (2) EDX evidence of conduction block when the site of stimulation is

advanced proximally does not always imply segmental demyelination since primary axonal degeneration may manifest with conduction block before the completion of Wallerian degeneration [121]; and (3) although low distal CMAP amplitudes imply almost always axonal loss, a severe distal demyelinative conduction block may mimic axonal degeneration and shows improvement of CMAP over a short period of time with good prognosis [94].

Serial EDX studies are extremely useful in GBS for the accurate diagnosis and prognosis of GBS. The disorder often evolves over several days to weeks, and a single early EDX study and before the illness reaches its nadir may be misleading. This lone study may miss the pathological changes that may have not been completed including Wallerian degeneration and sometimes rapid remyelination. Also, signs of segmental demyelination are most evident during the third and fourth weeks of illness [95]. These serial EDX studies are also mandatory for proper diagnosis and classification of GBS subtypes (AIDP, AMAN, and AMSAN). In many cases, the relative contributions of primary demyelination and axonal degeneration, or a combination of the two, cannot be determined with any certainty except if EDX studies are performed many weeks after the onset of disease and corroborated by the outcome.

Cerebrospinal Fluid Studies

Typically, the CSF protein level is elevated in the majority of patients at some time during the course of the illness. The protein concentration is elevated in only 50 % of patients during the first week of illness and is elevated in 75 % by the third week [2]. Usually, the protein level peaks in the second or third weeks of the illness followed by a slow decline towards normal that may take several months. The cause of increased CSF protein is not known but presumably results from abnormalities in the blood-CSF barrier due to inflammation at the level of the spinal nerve roots. Patients with GBS and exceptionally high protein levels (e.g., 1,500 mg/dL) may develop papilledema and symptoms of pseudotumor cerebri. Patients with AMAN and AMSAN also tend to have elevated CSF protein levels, but the frequency of this finding and the protein concentration is usually lower compared to patients with AIDP; normal values are not unusual. There is also correlation between the presence of demyelination on EDX studies and the CSF protein concentration during the first 2 weeks of illness [100]. There is no apparent correlation between the CSF protein level and clinical findings or outcome.

The increase in CSF protein is not usually associated with a cellular response. This "cyto-albuminologic dissociation" was observed first by Guillain-Barré and Strohl in their first cases and made the disease credible by differentiating it from a number of febrile paralytic disorders, particularly poliomyelitis [1]. However, in most large series, minorities, usually less than 10 %, of patients have a slight lymphocytic CSF pleocytosis greater than 10 cells/mm. GBS that follows Lyme or HIV infection often has a more prominent pleocytosis that reflects a concurrent meningeal reaction [26, 122]. Therefore, the presence of cells in the CSF certainly does not exclude the diagnosis, but other infectious disorders, such as Lyme and HIV [26, 122], or malignant conditions, such as lymphoma [32], should be excluded.

Antiganglioside Antibodies

Gangliosides are a large family of glycosphingolipids, predominantly distributed on the cell-surface membrane. Although antibodies against many of these gangliosides have been detected in sera of GBS patients, including LM1, GM1, GM1b, GM2, GD1a, GalNAc-GD1a, GD1b, GD2, GD3, GT1a, and GQ1b, the pathological significance of some of these antibodies is not known. In addition, most of these antibodies are found in subgroups of GBS patients. Antibodies to GD3, GT1a, and GQ1b are often seen in high percentage of patients with GBS associated with ophthalmoplegia, and antibodies to GQ1b are detected in 95 % of patients with MFS [123]. Antibodies to GM1, GM1b, GD1a, or GalNAc-GD1a are associated with about 50 % of patients with AMAN or axonal variants of GBS [78]. When strict criteria for GBS subtypes are used, IgG autoantibodies against GM1 or GD1a are associated with AMAN, AMSAN, and acute motor-conduction-block neuropathy (see below), but not with AIDP. No specific ganglioside antibody appears to be associated with AIDP, the prototypical and most common form of GBS in North America and Europe. This explains why these ganglioside antibodies are not clinically useful in clinical practice in these countries.

Imaging Studies

Magnetic resonance imaging (MRI) is most useful in excluding central nervous system disorders which may mimic GBS in their presentations. This includes MRI of the brain to rule out brainstem pathology and MRI of the cervical and thoracic spine to exclude cord compression or transverse myelitis. MRI of the lumbar spine, however, is often abnormal and shows nerve root enhancement of the cauda equina with gadolinium. This occurs in up to 80–90 % of patients particularly in children and in patients with severe weakness and severe leg and back pain (Fig. 28.3) [124, 125]. Occasionally, the facial nerves may also enhance with gadolinium in GBS patients with facial palsies [126].

Other Laboratory Studies

Routine laboratory studies are usually normal in patients with GBS. The erythrocyte sedimentation rate or liver function studies are infrequently elevated, although these

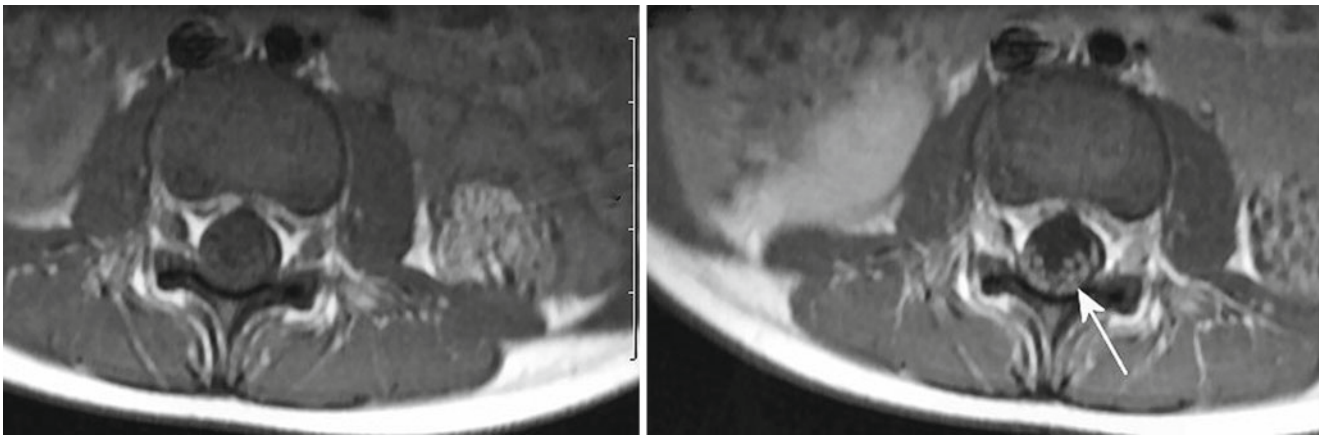

Fig. 28.3 MRI of lumbar spine in a 4 year old with GBS showing enhancement of cauda equina. T1 weighted image (*left panel*) is normal while T1 weighted image following contrast shows enhancement of nerve roots (*white arrow*, *right panel*)

findings most likely reflect a recent, preceding infectious illness and have little diagnostic utility. Viral antibody titers, particularly EBV and CMV, may be increased and thus help to identify the triggering infectious agent in individual cases. Prior infection with C. *jejuni* may be confirmed by detecting elevated serum IgM antibodies or culturing the bacteria from the stool [19].

An HIV titer should be obtained in patients with GBS who have CSF pleocytosis, risk factors for HIV or reside in geographic regions where AIDS is prevalent. Urine porphyrin screen, heavy metal testing, and Lyme titer may be indicated in selected cases but are rarely necessary. Stool culture and serum titers for *C. botulinum* and anti-acetylcholine receptor antibodies are helpful in patients when the ocular-pharyngeal-brachial variant is considered or when electrophysiological studies are consistent with a disorder of neuromuscular transmission. Creatine kinase (CK) may be slightly elevated, particularly in patients with muscle pain and tenderness [63]. A very high serum CK level distinguishes GBS from rhabdomyolysis or acute myopathies. Severe electrolyte imbalance may cause generalized weakness that rarely mimics GBS, and levels of magnesium, phosphorus, and potassium should be checked.

Differential Diagnosis

Acute GBS is easily recognized in typical cases, but unusual presentations expand the differential diagnosis to many other central nervous system and neuromuscular diseases (Table 28.6). With several subtypes and variant syndromes (see below), GBS may mimic a variety of neurological disorders [127]. Careful history and examination, coupled with cautious interpretation of diagnostic testing, is often necessary for accurate diagnosis. The first step is to establish that the clinical features are a consequence of a peripheral nerve condition.

Table 28.6 Differential diagnosis of Guillain-Barré syndrome

Peripheral neuropathies
Toxic neuropathies
Heavy metals—arsenic, lead, thallium, gold
Medications—vincristine, disulfiram, nitrofurantoin, isoniazid
Organophosphate poisoning
Hexacarbon (glue-sniffer's neuropathy)
Acute intermittent porphyria
Vasculitic neuropathy
Poliomyelitis
Diphtheria
Tick paralysis
Lyme disease
Critical illness polyneuropathy
Polyradiculopathies and ganglionopathies
Carcinomatous or lymphomatous meningitis
Acute sensory neuronopathy syndrome
Disorders of neuromuscular transmission
Botulism
Myasthenia gravis
Hypermagnesemia
Antibiotic-induced paralysis
Snake envenomations
Myopathies
Polymyositis
Other acute myopathies, e.g., drug induced
Metabolic abnormalities
Hypokalemia
Hypophosphatemia
Central nervous system disorders
Basilar artery thrombosis with brainstem infarction
Locked-in syndrome
Brainstem encephalomyelitis
Transverse myelitis
Acute necrotic myelopathy
Cervical cord or foramen magnum neoplastic compression
Hysteria
Malingering

Acute Peripheral Neuropathies and Poliomyelitis

Apart for GBS, the majority of acute peripheral neuropathies are toxic in nature. Acute toxic neuropathies are axonal and evolve in a subacute or chronic fashion. There are numerous environmental, industrial (heavy metals), and occupational toxins that cause a neuropathy, resembling GBS, following an acute exposure, including if a history of ingestion is lacking. Acute arsenic poisoning may have a presentation that is indistinguishable from GBS and AIDP. The EDX studies may show findings of acquired demyelinating polyneuropathy, which when repeated, convert to a dying-back neuropathy [128]. Thallium, lead, n-hexane (glue-sniffers neuropathy), and organophosphate poisoning are other examples of acute toxic neuropathies. In most instances, intoxication is heralded by gastrointestinal symptoms, and usually there is involvement of other organ systems, skin lesions, alopecia, and encephalopathy, coma, or other features of central nervous system toxicity. Acute toxic neuropathies are distinguished from GBS by the history of preceding toxic ingestion and by detecting suspected toxins in the serum or urine. Acute demyelinating neuropathies mimicking GBS have been linked to certain medications, such as amiodarone, perhexiline, and gold therapy for rheumatoid arthritis. An acute, rapidly progressive neuropathy, similar to GBS, has been described in alcoholics [129, 130]. These patients invariably have a long-standing history of alcohol abuse prior to onset of the acute neuropathy. Most develop progressive generalized weakness, severe distal sensory loss, and areflexia over days to weeks. The condition is distinguished from GBS by a normal CSF protein concentration and axonal features on EDX studies.

Patients with acute intermittent porphyria (AIP) may develop a neuropathy that resembles GBS [131–133]. A variety of medications or infections may trigger an acute attack. Initial symptoms include vomiting, constipation, and abdominal pain. Seizures occur in 10–20 % of cases and delirium or other psychiatric symptoms occur in most. The weakness is symmetric and begins in proximal muscles of the arms, but widespread weakness develops in most as the syndrome progresses. Hypertension, arrhythmias, or other features of dysautonomia are common. The cranial nerves are typically spared. EMG shows an axonopathy rather than demyelination, thus differentiating this condition from typical GBS. Increased urinary excretion of delta-aminolevulinic acid and porphobilinogen during an acute attack of AIP establishes the diagnosis.

Neuropathy is a common complication of systemic vasculitis and usually evolves in a subacute fashion; rarely, acute mononeuritis multiplex may have a fulminant course that simulates an acute polyneuropathy. Polyarteritis nodosa, and hepatitis B or C-associated vasculitis Churg-Strauss syndrome are the vasculitides most likely to cause a rapidly progressive polyneuropathy [134]. Focal or multifocal onset, severe pain, lack of diaphragmatic weakness or cranial nerve involvement, and electrophysiological features of a multifocal axonopathy distinguish acute vasculitic neuropathy from GBS in most cases. Furthermore, the CSF protein level is normal in the former condition. The diagnosis is established by pathologic evidence of vasculitis on biopsy material. Nonsystemic vasculitic neuropathy is generally an indolent condition that is rarely mistaken for GBS.

Lyme disease, a tick-borne illness, may be a consideration in cases of GBS presenting with facial diplegia or when there is a CSF pleocytosis. However, as already noted, most cases of Lyme neuropathy are characterized by chronic, slowly progressive, distal sensory loss or an asymmetric, painful polyradiculopathy.

Poliomyelitis, once the most common cause of acute paralysis in the world, is now a rarity except in few underdeveloped countries (see Chap. 19). The condition is most commonly contracted by non-vaccinated individuals after exposure to infants who recently were vaccinated against the poliovirus. A number of other viruses, typically the enteroviruses such as the West Nile virus, may produce an identical poliomyelitis syndrome and are a more common cause of acute motor neuronopathy simulating GBS. Affected individuals have a febrile illness, usually a gastroenteritis, followed by a paralytic phase 7–14 days later. The neurologic syndrome begins with fever, headache, and neck stiffness, followed by muscle pain, asymmetric flaccid limb paralysis, and fasciculations, and reaches a nadir within 4 weeks. Mild confusion may occur early in the illness. Diaphragmatic and oropharyngeal weakness are common but the extraocular muscles and sensory functions are spared. The CSF shows a lymphocytic pleocytosis and a normal or mildly elevated protein concentration, in contrast to GBS. Similarly, nerve conduction studies in poliomyelitis show reduced or absent motor amplitudes with normal conduction velocities and no conduction block. Sensory potentials are normal. Fibrillations are prominent in weak muscles early in poliomyelitis. Culture of the poliovirus from the pharynx or stool or detection of elevated antibodies directed against poliovirus with acute and convalescent sera establishes the diagnosis.

During the West Nile encephalitis epidemic in North America in the late 1990s and early 2000s, many patients with weakness were diagnosed mistakenly as GBS. Upon further studies, it was clear that these were cases of West Nile-induced poliomyelitis with evidence of anterior horn cell damage [135, 136]. When motor weakness occurs in West Nile, it may be asymmetric with paralysis of one limb (monoparesis) or fairly symmetric affecting four limbs (quadriparesis), with or without brainstem involvement and respiratory failure. EDX studies also reveal normal SNAPs, low-amplitude CMAPs recorded from weak muscles, signs

of diffuse active denervation (including the paraspinal muscles), and generalized or focal loss of motor units [137]. The pathology is consistent with poliomyelitis with identified neuronal loss, perivascular chronic inflammation, and microglial proliferation in the ventral horns of the spinal cord, especially in the cervical and lumbar segments [138].

Diphtheria is also a rare cause of acute polyneuropathy in developed countries because of effective vaccination programs. It is also reported in closed communities in countries where diphtheria remains endemic despite prior vaccination [139]. Infection with *Corynebacterium* diphtheria produces a febrile syndrome with severe pharyngitis, followed by palatal weakness and descending paralysis that develops weeks later. A membranous exudate over the tonsils and pharynx is present in most cases, and cervical adenopathy may be prominent. Bulbar weakness is present in the majority of patients. Over half the patients develop paralysis of accommodation. Symmetric limb weakness may be mild or severe with a predilection for proximal muscles. There is generalized areflexia, minimal sensory loss, and no dysautonomia. The course is slower than GBS, with maximal paralysis developing as long as 3 months after the onset of palatal weakness. The CSF profile demonstrates a cyto-albuminologic dissociation, similar to GBS, and EDX studies show an acute demyelinating neuropathy. Differentiation from GBS may be impossible if the early facial involvement is not recognized, but the low prevalence of diphtheria in developed countries makes GBS a more likely cause of acute, generalized, areflexic paralysis.

Critical illness polyneuropathy (CIP) was once frequently mistaken for GBS in the intensive care setting (see Chap. 76). It is now recognized as a common cause of limb weakness and failure to wean in ventilated patients in intensive care units (ICU). CIP is encountered most often in patients who have had sepsis and multiorgan failure [140–142]. Flaccid limb weakness, muscle atrophy, and generalized hypo- or areflexia are found in most patients. A small minority have facial weakness or ophthalmoparesis. Accurate sensory examination may be difficult in ventilated ICU patients, but most patients appear to have distal loss of all sensory modalities. Dysautonomia does not occur. The CSF protein concentration is normal and EDX studies demonstrate axonal loss with diffuse denervation without demyelination. Critical illness myopathy and prolonged exposure to neuromuscular blocking agents are other conditions that may simulate GBS in the ICU.

Disorders of the Neuromuscular Junction

Botulism is a rare condition that begins with cranial nerve dysfunction followed by generalized paralysis and can be confused with the oropharyngeal or ophthalmoparetic regional variants of GBS (see Chap. 50). Food-borne botulism usually begins hours to days after the ingestion of the neurotoxin produced by *Clostridium botulinum* types A, B, or E by way of contaminated food. Nausea and vomiting are followed by constipation and neurological symptoms. Blurred vision is an early complaint. Initial findings include dilated pupils in most patients, with paralysis of accommodation, ptosis, and oropharyngeal weakness. Diaphragmatic weakness with ventilatory failure is common and may be more severe than limb weakness. In contrast to GBS, the deep tendon reflexes are usually preserved. EDX studies show reduced amplitudes of the motor potentials with an incremental increase of the amplitude (usually >100 % above baseline) following high-frequency repetitive nerve stimulation, indicating a presynaptic neuromuscular junction abnormality. The CSF is normal. Detection of botulinum toxin in the serum, contaminated food source, or culture of *Clostridium botulinum* from the stool confirms the diagnosis.

In myasthenia gravis (MG), the slow onset of weakness, prominent fluctuation, fatigue, and the regional pattern of involvement usually poses little difficulty distinguishing these cases from GBS, but rarely patients with MG have a fulminant course with rapidly progressive limb and respiratory muscle weakness resembling an ocular-pharyngeal-brachial variant of GBS (see below) [143]. Although ptosis occurs in a minority of patients with GBS and may be transiently responsive to edrophonium, though it does not fatigue. Similarly, oropharyngeal weakness, nasal speech, and hypophonia do not fluctuate in GBS patients. Preserved deep tendon reflexes and lack of sensory symptoms or signs, dysautonomia, or an elevated CSF protein level are other features that differentiate MG from variant patterns of GBS. Patients with MG usually have transient improvement in strength following administration of edrophonium. EDX studies easily differentiate the two conditions; in MG, nerve conduction studies are normal and low-frequency repetitive nerve stimulation recording from a clinically affected muscle demonstrates a decrement (>10 %) of the amplitude characteristic of a postsynaptic neuromuscular junction abnormality.

Tick paralysis causes rapidly progressive paralysis that perhaps simulates GBS more closely than any other condition [144]. The illness is rare and affects mostly children in the northwestern United States in the spring and summer. A short prodrome characterized by fatigue, paresthesias, and ataxia is followed by generalized, areflexic weakness that occurs 3–5 days after attachment of the tick. The CSF is normal throughout the illness. The EDX studies show reduced motor amplitudes without demyelinating features; sensory studies are normal. The diagnosis is established by finding the tick, usually located at the hairline, and removal is followed by rapid recovery.

Central Nervous System Disorders

Occlusion of the basilar artery with pontine infarction may produce flaccid quadriparesis with ocular and bulbar findings. The symptoms usually begin suddenly and often there is a history of preceding transient ischemic attacks. Deep tendon reflexes may be reduced at the initial evaluation although hyperreflexia develops after a few days or weeks. Babinski signs are usually present. Vertical eye movements are preserved and other cranial nerve findings may be present but are usually asymmetrical. Most patients with brainstem stroke are somnolent or comatose because of involvement of the ascending reticular activating system.

Acute cervical transverse myelitis may cause a rapidly progressive quadriparesis. The detection of a spinal sensory level on the trunk and upper motor neuron findings (hyperreflexia, extensor plantar responses) differentiates this condition from GBS, but in the spinal shock stage of an acute myelopathy, flaccid limb weakness and areflexia simulate a lower motor neuron condition. In the acute inflammatory myelopathies (multiple sclerosis, neuromyelitis optica, or acute disseminated encephalomyelitis), weakness is often asymmetric, bowel and bladder dysfunction is an early and prominent finding, and the cranial nerves are normal. There is usually an inflammatory response with lymphocytes in the spinal fluid. Increased signal abnormalities on T2-weighted MRI or gadolinium enhancement of the cervical or thoracic cord establish the diagnosis.

Anxiety or a panic attack may be considered early in the illness when paresthesias are the only symptom of emerging GBS and deep tendon reflexes may be preserved. These patients may be labeled as "anxious" with symptoms attributed to hyperventilation and are often discharged from the emergency room, only to return later with generalized and diaphragmatic weakness.

Treatment and Management

Supportive Care

Most patients with GBS require admission to an intensive care unit (ICU) under the care of physicians who are familiar with the medical complications that develop in paralyzed ICU patients (Table 28.7) [146, 147]. The timely and skillful management of medical problems is as important as immune therapy in the outcome of patients with GBS.

Ventilatory failure is a central issue and should be anticipated in any GBS patient with progressive limb or oropharyngeal weakness. About 15–30 % of patients with GBS will need ventilatory support [65, 147]. Atelectasis develops early and leads to mild hypoxemia. Hypercarbia and hypoxemia is a later finding as ventilatory failure advances; therefore, arterial blood gases are not as helpful as respiratory mechanics in monitoring the evolution of diaphragmatic weakness in GBS patients. Vital capacity (VC), tidal volume, and negative inspiratory force are reasonably sensitive reflections of diaphragmatic power, and progressive decline in these values indicates impending mechanical respiratory failure and the need for ventilatory support (Fig. 28.4) [146]. These measures should be obtained early on in the course and repeated as frequently as dictated by the clinical state (up to every 4–6 h). Bulbar dysfunction including swallowing problems with difficulty in clearing secretions increases the odds of needing ventilator support. In general, if the forced vital capacity is less than 15–20 mL/kg, the maximum expiratory pressure is less than 30 cmH_2O and the maximum inspiratory pressure is less than 30 cmH_2O, impending respiratory arrest is present and intubation should be performed [148]. Also, PCO_2 above 48 mmHg or PO_2 less than 56 mmHg on room air are definite indications for intubation [2, 149].

Prediction for respiratory failure in patients with GBS is important in order to improve outcome and reduce mortality. Several studies have recently tried to answer this question. Walgaard et al. found that patients who required ventilatory support had facial and/or bulbar weakness, shorter days between onset of weakness and admission, and more limb weakness (higher Medical Research Council sum score) [65]. Sharshar et al. proposed that patients should be monitored in ICU setting if at least one of the following predictors of respiratory failure is present: (1) time from onset to admission of <7 days, (2) inability to cough, (3) inability to

Table 28.7 Guidelines for the general management of patients with Guillain-Barré syndrome

Measure vital capacity as indicated by rapidity of deterioration:
Vital capacity 12–15 mL/kg: intubate
Vital capacity 15–19 mL/kg: intubate if bulbar paralysis
Incentive spirometry to prevent atelectasis
Bronchial clearing and assisted coughing
Chest X-ray examination weekly, or more often
Biweekly serum albumin, sodium, BUN, calcium measurements
Urinalysis weekly
Pulmonary embolism prophylaxis: 5,000 U heparin every 12 h subcutaneously
Peristalsis checked
Gastrointestinal bleeding prophylaxis: magnesium-containing antacid 30–120 mL or sucralfate
Decubitus prophylaxis: frequent position changes; air-floating bed or water mattress and skin care
No antibiotic prophylaxis; urine and pulmonary infections treated with antibiotics after bacterial sensitivities available, unless septic
Tube feeding when swallowing is impaired (start with continuously administered fiber-enriched mixtures)
Inquiries daily concerning pain, sleep, and hallucinosis; administration of adequate pain treatment
Limitation of antecubital phlebotomy if plasma exchange anticipated

Reprinted with permission from Ropper et al. [145]

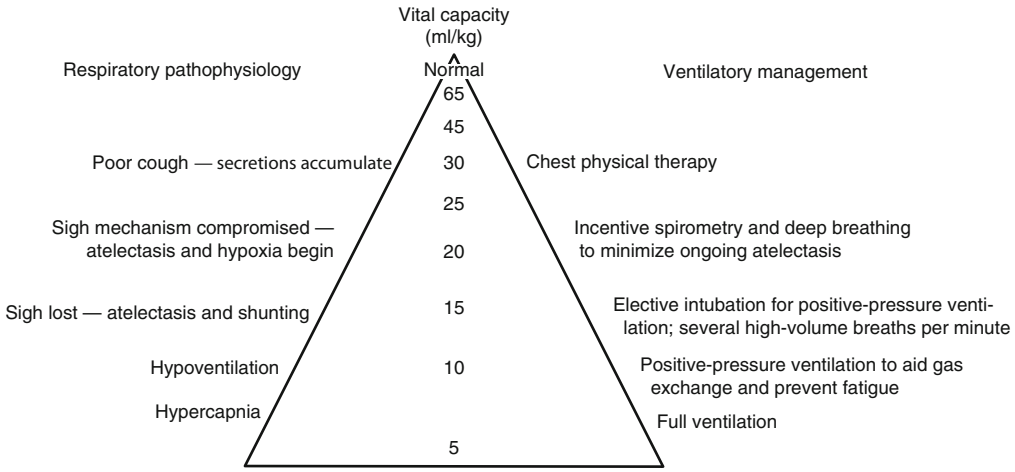

Fig. 28.4 Schematic diagram of pathophysiologic events in patients with ventilatory failure and Guillain-Barré syndrome, with corresponding suggested management (Reprinted with permission from Ropper AH [190])

stand, (4) inability to lift the elbows, (5) inability to lift or head, or (6) vital capacity <60 % of predicted. More than 85 % of patients with 4 out of these 6 predictors were intubated [150]. Moreover, Durand et al. found that the EDX is a predictor for mechanical ventilation. They found that the risk of respiratory failure was very low in GBS patients with less than 55.6 % conduction block of the common peroneal nerve [151].

Incentive spirometry is useful in the early stages of the illness to prevent atelectasis. Frequent suctioning and chest physiotherapy minimize the accumulation of secretions and prevent aspiration and bronchopneumonia, but patients with moderate oropharyngeal weakness (e.g., those who cannot safely swallow liquids) will probably require intubation for protection of the airway. Most patients with severe, ventilator-dependent GBS who have no improvement after 2 weeks require tracheostomy to secure long-term airway management, avoid tracheal stenosis, facilitate suctioning, and maximize patient comfort. However, tracheostomy can be deferred for another week if pulmonary function tests show any significant improvement form baseline. Older patients with preexisting pulmonary disease are more likely to require tracheostomy [152].

Autonomic dysfunction is a well-recognized feature of GBS and a significant source of mortality. It is present in 70 % of patients, but serious and potentially fatal dysautonomia occurs in 20 % of patients. Severe autonomic disturbances affect mainly patients with severe weakness and those with respiratory failure. Many of the features of autonomic dysfunction are self-limited and require no intervention. For example, resting tachycardia is common in GBS patients and does not require treatment except in those with active coronary artery disease and acute myocardial ischemia. Hypertension often develops as a consequence of a procedure (e.g., suctioning or catheter placement) but is usually transient and does not require therapy. Sustained high blood pressure (e.g., >180/95) may be managed with angiotensin-converting enzyme inhibitors or beta-blocking agents. Short-acting intravenous medications, such as nitroprusside or esmolol, are preferred for patients who have severe, labile hypertension and require immediate therapy. Conversely, postural hypotension, often precipitated by only minor position changes, can be effectively treated with a bolus of intravenous saline or by placing the patient in the supine position. Norepinephrine and other sympathomimetic agents generally should be avoided because of the risk of rebound hypertension, but vasopressors may be necessary for those with persistent supine hypotension. Invasive procedures or cholinergic medications may trigger excessive vagal discharges ("vagal spells") and precipitate bradycardia, asystole, or other vagally mediated arrhythmias [153, 154]. These episodes are usually transient, but anti-arrhythmic medications (atropine) or cardiac pacing may be necessary [154]. Micturitional disturbances are common and can be managed with intermittent catheterization or an indwelling catheter [147, 155].

Nosocomial infections are probably the most common medical complication that develops in GBS patients in the ICU with pulmonary infections predominating [156]. Other infections include urinary tract infections and central venous catheters sepsis. Tracheitis and sinusitis are other considerations in intubated patients who have a persistent fever and no apparent source of infection. Every effort should be made to identify the organism to guide appropriate antibiotic therapy. Routine monitoring of the chest X-ray and sputum and urine cultures are useful. However, bacterial colonization occurs frequently, and patients should receive antibiotic therapy only when there is clinical evidence of an infection; inappropriate treatment only increases the risk of infection with resistant pathogens. Although indwelling urinary catheters are often necessary in GBS patients, the risk of colonization and infection increases after several days.

Immobilization that is associated with GBS predisposes to deep venous thrombosis and pulmonary embolism. Subcutaneous heparin or intermittent pneumatic compression

boots should be used routinely, and chronic anticoagulation with warfarin may be considered for those who are bedbound or ventilator dependent for long periods. Low molecular weight heparin has become popular, but the value of neither the old nor new type of heparin has been established by a trial; they are presumed from experiences in general medicine to be helpful. Although mucous plugging is probably the most common cause of acute respiratory decompensation in ventilated patients with GBS, any unexplained episode of acute oxygen desaturation requires evaluation for pulmonary embolism.

Patients who are intubated or have dysphagia due to oropharyngeal weakness require nasogastric tube feedings to maintain long-term nutritional support. A gastrostomy tube can be placed at the time of tracheostomy in patients with prolonged recovery. Hyperalimentation may be necessary in patients with an ileus. Neostigmine or erythromycin can be effective to treat ileus [147]. Moreover, daily abdominal auscultation and monitoring of opioid administration should be performed. Judicious intravenous hydration is essential because insensible fluid losses may be substantial, leading to dehydration and exacerbating autonomic instability. Hyponatremia may develop, usually as a consequence of inappropriate antidiuretic hormone secretion. Hyponatremia is an independent indicator of poor prognosis [70].

Pain is a common symptom in patients with GBS and is often underappreciated by the medical staff [61, 63]. Narcotics are almost always needed to manage pain, and the use of nonnarcotic, chronic analgesics often provides additional relief. Carbamazepine and gabapentin are usually successful in alleviating pain during the acute phase of GBS and may be used for long-term management of neuropathic pain [147]. An excellent alternative for severe pain in the back or legs is epidural analgesia [157]. Most patients benefit from early physical and occupational therapy [158]. For example, passive range of motion of paralyzed joints prevents contractures, foot boards minimize the risk of foot drop and shortening of the Achilles tendon, and frequent turning and air mattresses reduce the risk of skin breakdown and development of decubitus ulcers. Symptoms of anxiety and depression are also common, occur at all stages of the illness, and should not be overlooked. Those who are paralyzed, intubated, and unable to communicate with their caregivers are most likely to experience fear and helplessness. Communication boards allow patients to maintain a connection with their families, nurses, and medical staff. Facilitating contact with recovered GBS patients provides additional psychological support.

Immunotherapy

Several large, randomized, controlled trials have demonstrated the benefits of *plasma exchange* when performed within the first 2 weeks of the illness. The North American study involved 245 patients randomized to receive plasma exchange, 200–250 mL/kg over five sessions within 2 weeks, or supportive care [159]. Treated patients improved more rapidly and regained the ability to walk earlier (an average of 53 days for the plasma exchange group vs. 85 days in untreated patients). Furthermore, those who required ventilator assistance and were treated with plasma exchange weaned sooner than controls (24 vs. 48 days). Similar findings were reported from French and Swedish trials [160, 161]. Severely affected patients with features that are associated with a poor prognosis (see below) also benefited from treatment, but probably less so than others. The efficacy of plasma exchange is reduced if therapy is initiated after 3 weeks from the onset of symptoms [159, 162]. Plasma exchange is most effective when started within the first 2 weeks of symptom onset [159], but benefits are still seen if started within 30 days of symptom onset [163]. Improvement may occur after as few as two exchanges in patients with mild GBS, but four exchanges, performed approximately on alternate days, appear necessary in those with moderate or severe forms of the illness [164]. Adding more exchanges is not indicated, since six exchanges are not superior to four in severe GBS [163, 164]. A recent report of the therapeutics and technology assessment subcommittee of the American Academy of Neurology found that plasmapheresis is effective for the treatment of moderate and severe GBS (class I studies, level A) and probably effective in mild disease (level B) [165].

Patients treated with plasma exchange generally experience few serious adverse effects. Treatment-related complications include pneumothorax at the time of placement of central venous catheters, line infection with bacteremia or sepsis, cardiac arrhythmias, hypotension from rapid fluid shifts, and excessive bleeding. In some patients, generally large men, the high volume of exchange necessary may be accomplished through antecubital veins, thus obviating the risk of a central venous catheter. Plasma exchange is difficult to conduct in young children and patients with severe dysautonomia, especially those with hypotension, or with active cardiac disease, coagulopathy, or hepatic failure. Plasma exchange is safe to perform in children and pregnant women.

Intravenous immune globulin was introduced as an alternative to plasma exchange because of its efficacy in other immune-mediated disorders, its relative safety, and ease of administration. A randomized trial comparing IVIG (400 mg/kg/day for 5 days) to plasma exchange in 150 patients with GBS established that (1) IVIG is an effective therapy for GBS, (2) the efficacy is comparable to plasma exchange, and (3) there was a low frequency of adverse effects [166]. A larger, international, randomized, multicenter, controlled trial of 379 patients with GBS (the "Sandoglobulin trial") subsequently compared IVIG (400 mg/kg/day for 5 days),

plasma exchange (50 mL/kg exchanges over 8–13 days), and combined therapy. It established that IVIG and plasma exchange had equivalent efficacy and that plasma exchange followed by IVIG provided no additional benefit [167]. There was no difference in functional disability scores at 4 and 48 weeks between IVIG, plasma exchange, and combined therapy, nor was there any difference in secondary outcome measures (time required to wean from mechanical ventilation, number of days to recover ambulation, and the proportion of patients unable to walk after 48 weeks). These findings were subsequently confirmed by several studies and meta-analysis, despite the lack of placebo studies in IVIG [163, 168, 169]. A recent report of the therapeutics and technology assessment subcommittee of the American Academy of Neurology concurred also that there is strong evidence (level A) to support the use of IVIG in GBS which should be initiated during the first 2 weeks of disease onset [169]. Also, the analysis concluded that the combination of plasmapheresis and IVIG is probably not better than either treatment alone.

The beneficial immunomodulator effects of IVIG are complex and not completely understood, but probably include neutralization of proinflammatory cytokines (especially tumor necrosis factor-alpha and interleukin-1 beta), downregulation of pathogenic antibodies, modulation of Fc-receptor-mediated phagocytosis, inhibition of complement deposition, and promotion of remyelination [36, 44].

Headache is probably the most common side effect of IVIG occurring in up to 16 % of patients [169]. It may be prevented by premedication with analgesics or corticosteroids and by slowing the rate of infusion. Other minor complications include transient fever, chills, and transient hypertension. Serious adverse effects are currently rare and occur in less than 5 % of patients. These include serum sickness reaction, aseptic meningitis, acute renal tubular necrosis (possibly due to a high osmotic load), and a hypercoagulable state with risk of deep vein thrombosis, especially in nonambulatory patients, and myocardial infarction or stroke, especially in patients with risk factors for cardiovascular disease. IVIG should not be administered to patients with known IgA deficiency, a rare genetic trait, because of a high risk of developing an anaphylactic reaction. Transmission of HIV has not been reported, and infection with hepatitis C virus has been reported during the 1990s but not since. Recent improvement of IVIG manufacturing using nanofiltration or caprylate (a saturated medium-chain fatty acid) has essentially eliminated the risk of viral transmission. IVIG can be administered safely to pregnant patients [170]. Because IVIG is generally well tolerated and easy to administer, it has become the preferred therapy for GBS in the United States [171].

The optimal IVIG dose needed for patients with GBS remains somehow controversial. The dose of IVIG was set arbitrarily at 400 mg/kg/day for 5 days (total dose 2 g/kg) based on its use in hematologic disorders. This dose was used in most subsequent studies of IVIG in patients with GBS. A longer duration or higher dose of IVIG treatment in patients with severe disease may be beneficial. Indeed, Raphael et al. found that, in select patients on mechanical ventilation, a 6-day course of IVIG (total dose 2.4 g/kg) is more beneficial than a 3-day treatment (total dose 1.2 g/kg) with more rapid rate of recovery [172]. More recently, Kuitwaard et al. compared IgG level in serum before and 2 weeks after infusion with the standard dose of IVIG (total dose 2 g/kg) [173]. They identified a large variation of IgG levels at 2 weeks following the infusion of the same standard dose and a dose–response relationship. More significantly, patients with slight or no increase in serum IgG at 2 weeks had more severe clinical deficit at nadir, and fewer were able to walk at 6 months. An international study is currently assessing whether additional IVIG in patients who do not show a meaningful rise in IVIG level is beneficial.

Approximately 10 % of GBS patients treated with plasma exchange or IVIG relapse after initial treatment. This rate is equal with the use of plasma exchange or IVIG [167, 174]. The cause of these relapses is unknown but may be related to persistence of active disease after completing therapy or a rebound in antibody production. Patients with a more protracted course may be at higher risk for a relapse, but no other predictive factors have been identified [175]. Occasionally, a relapse may be triggered by an intercurrent infection or an ongoing CMV or EBV infection. A single study indicated that a repeated course of IVIG administered to patients who do not respond or relapse following the initial treatment may be of some benefit [176], but this regimen is currently being evaluated by a controlled study. A GBS relapse raises the concern of more chronic disorder, namely, CIDP. Ruts and colleagues found recently that GBS patients deteriorate more rapidly (15–27 days) while CIDP worsen much slower (31–63 days) [177]. Also, CIDP is the likely diagnosis if patients diagnosed with GBS exhibit more than two treatment-related fluctuations.

The difficult issue of how to treat patients with severe GBS who have not improved with standard therapies remains not well clarified. The "Sandoglobulin trial" showed that a course of plasma exchange followed by IVIG is not better than plasma exchange of IVG alone [167]. A repeated dose of IVIG has only been shown to be effective in a small study [176]. An international study is being conducted in assessing the use of additional IVIG in unresponsive server GBS patients or those who relapse.

A discussion on GBS treatment cannot be completed without addressing *corticosteroids.* Anecdotal reports indicated for decades that *corticosteroids* were beneficial to patients with GBS, but larger, prospective studies showed subsequently that oral and intravenous high-dose corticosteroids made no difference in outcome [178, 179]. There is also limited evidence suggesting that oral corticosteroids may

slow recovery from GBS [180]. In combination with intravenous immunoglobulin, intravenous methylprednisolone may have a short-term effect and hasten recovery but does not significantly affect the long-term outcome [181].

The efficacy of other pharmacological agents is unknown. A small randomized controlled trial demonstrated that interferon beta 1a (Rebif®) was not associated with significant clinical improvement [182]. A recent meta-analysis concluded that there are no beneficial effects on GBS from brain-derived neurotrophic factor or cerebrospinal fluid filtration [183].

Prognosis

The majority of patients with GBS have a rapidly progressive course followed by a plateau phase of varying duration. Three-quarters of patients reach a nadir by 1 week and virtually all (98 %) do so by 4 weeks (Fig. 28.5) [77, 184–186]. Approximately 15 % of patients have a mild condition, remain ambulatory, and recover after a few weeks. Conversely, 5–20 % of patients have a fulminant course and develop flaccid quadriplegia, ventilator dependence, and axonal degeneration, often within 2 days from the onset of symptoms [110, 187]. This group is often caused by axonal loss (AMSAN subtype); The recovery is delayed and virtually always incomplete [90]; at 1-year follow-up, most have substantial residual motor deficits [187]. In contrast to AMSAN, patient with AMAN have a prognosis which is comparable to patients AIDP. This may be due to rapidly reversible immune-mediated changes at the nodes of Ranvier (conduction failure) that occur in some patients with AMAN or the selective degeneration and subsequent quick regeneration of intramuscular motor nerve terminals [87, 89, 188].

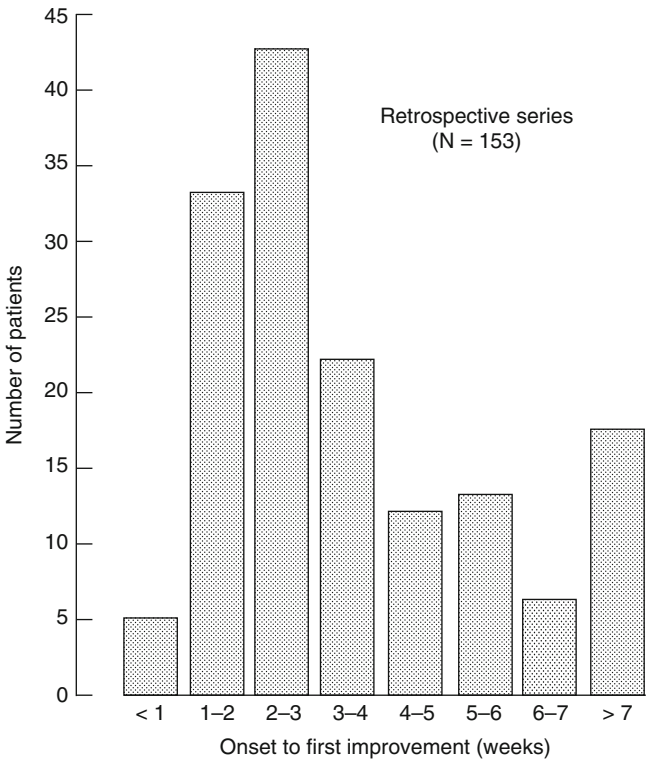

Fig. 28.5 Time from onset of the illness to onset of improvement (end of the plateau phase) in the Massachusetts General Hospital retrospective series. (Reprinted with permission from Ropper AH et al. [145])

Neurologic disability advances steadily until a plateau is reached. The plateau phase usually lasts several weeks but may be only a few days in mild cases or persist for months in patients with quadriplegia and ventilator dependence. At the time of the maximum deficit, approximately one-third of patients require assisted ventilation, almost half are wheelchair or bedbound, 7 % have trouble walking, and the remainder are ambulatory [189]. Once recovery begins, improvement follows a predictable course; patients who were quadriparetic often recover to walk in a few months, although about half have persistent symptoms at 1 year. An earlier study reported that at 1-year follow-up, 62 % had recovered completely, 14 % could walk but not run, 9 % could not walk without assistance, 4 % remained bedbound or ventilated, and 8 % died [190]. In a more recent study, full recovery or minor deficits were observed in 41 % of patients in the first month, 71 % in the third month, 86 % in the sixth month, and 92 % by the first year [184].

Features that predicted a poor recovery (inability to walk independently) in various studies include older age (>60 years), history of preceding diarrheal illness, recent CMV infection, fulminant and rapidly progressive course, ventilator dependence, hyponatremia, peroneal nerve conduction block, and greatly reduced CMAP mean amplitudes (<20 % of the lower limit of normal) or inexcitable nerves [66, 70, 159, 191].

Several clinical scoring systems to predict prognosis have been used in the past. The Erasmus University scales have been validated. The scales uses the GBS disability score [179] (Table 28.8) and the Medical Research sum (MRC) score [166] (Table 28.9), as well as several simple and easily obtainable clinical data. The Erasmus GBS Outcome Score (EGOS) was developed based on a prognostic model that uses easy-to-obtain patients' clinical characteristics during

Table 28.8 GBS disability score

0	A healthy state
1	Minor symptoms and capable of running
2	Able to walk 10 m or more without assistance but unable to run
3	Able to walk 10 m across an open space with help
4	Bedridden or chairbound
5	Requiring assisted ventilation for at least part of the day
6	Dead

the acute phase of illness to accurately predict the chance of being able to walk independently at 6 months. The EGOS is based on age, diarrhea, and GBS disability score at 2 weeks after hospital admission that accurately predicts the chance of being able to walk independently at 6 months [185]. A final score higher than four correlates with poor recovery (Table 28.10). The modified EGOS (mEGOS) model replaced the GBS disability score by the more detailed MRC sum score [186]. It is also applicable at hospital admission as well as 1 week after hospital admission (see Table 28.10). It is used to predict inability to walk independently at 4 weeks, 3 months, and 6 months. The mEGOS is advantageous because it can predict groups with poor prognosis early in the disease when treatment is considered to be most effective. In addition, the Erasmus respiratory insufficiency score was also validated with specific parameters which predict mechanical ventilation at the time of hospital admission. These include the time between onset of weakness and admission, the MRC sum score, and presence or absence of facial and/or bulbar weakness (see Table 28.10) [65].

The mortality from GBS, once reported to be as high as 10–20 % [192, 193], has been reduced to 1–5 % in North America and Europe, most likely because of the advent of critical care units with experience in the management of this disorder [194–196]. The predictors of death are similar to the predictors of poor disability outcome [194].

Approximately 3–6 % of patients with typical GBS develop a chronic relapsing course consistent with CIDP. These cases are referred to as *acute-onset CIDP*. There are no distinctive features that allow early recognition of these patients; however, CIDP should be considered very likely in patients with GBS whose relapses reach nadir after 8 weeks or have more than two relapses [177]. Some patients with a progressive phase of 4–8 weeks and a monophasic course have been labeled *subacute inflammatory demyelinating polyneuropathy (SIDP)* [197]. These patients fall between CIDP and a relapsing GBS. These patients often do not relapse and treatment could be completely tapered over several months. A few patients had bouts of *recurrent GBS* completely remitting and separated by long asymptomatic intervals [198, 199].

Table 28.9 Medical Research Council (MRC) sum score

Sum of Medical Research Council scores of six muscle groups tested bilaterally:	
Shoulder abductors	0–5
Elbow flexors	0–5
Wrist extensors	0–5
Hip flexors	0–5
Knee extensors	0–5
Foot dorsiflexors	0–5
MRC sum score	60 (normal) to 0 (quadriplegic)

Medical Research Council score of an individual muscle group ranges from 0 to 5:

0 No visible contraction
1 Visible contraction without movement of the limb
2 Active movement of the limb, but not against gravity
3 Active movement against gravity over (almost) the full range
4 Active movement against gravity and resistance
5 Normal power

Table 28.10 Erasmus GBS outcome score and respiratory insufficiency score

		Erasmus GBS outcome score	Modified Erasmus GBS outcome score		Erasmus GBS respiratory insufficiency score
Prognostic factors	Categories	At day 14 of hospital admission	At hospital admission	At day 7 of hospital admission	At hospital admission
Age at onset	<40 years	1	0	0

Guillain-Barré Syndrome Variants

Miller Fisher Syndrome

The triad of acute ophthalmoplegia, ataxia, and areflexia, initially described by Fisher in 1956, has been recognized as a variant of GBS on the basis of shared clinical features with the typical disease and EDX findings indicating an acute sensory neuropathy [200]. Miller Fisher syndrome accounts for approximately 5 % of GBS cases in North America and Europe but may represent as high as 20–25 % of GBS patients in Eastern Asia [201, 202]. In some patients, the illness progresses to generalized GBS that overtakes the other features [184, 203].

Diplopia is usually the first symptom, followed by limb or gait ataxia that appears within days. Additionally, there may be mild distal paresthesias, dysphagia, or mild proximal limb weakness in up to one-third to one-half of cases. In some patients, frank GBS develops with respiratory failure requiring ventilator support. In patients with the classical syndrome, respiratory failure is, however, rare [201, 202]. Unilateral or bilateral asymmetric abducens weakness is a common initial finding and often evolves to complete external ophthalmoplegia. Ptosis is present in the majority of patients but pupillary function is usually preserved (a small proportion do have internal ophthalmoplegia). Ataxia typically involves all the limbs and gait but may be asymmetric early in the illness. Large amplitude, discoordinated, and poorly metricated limb movements are indistinguishable from a cerebellar efferent ataxia. The deep tendon reflexes are absent in all fully developed cases. The Fisher syndrome can be confused with brainstem lesions such as encephalitis or infarction, but the presence of other central nervous system features (confusion, seizures, alternating hemiparesis, Babinski signs, etc.) and normal electrophysiologic studies in the latter conditions clarify the diagnosis.

The CSF protein level may be elevated in Fisher syndrome but less frequently than in typical cases of GBS [201]. The EDX findings are abnormal in half of the patients with absent or low-amplitude SNAPs or a sural spaing pattern. Motor conduction abnormalities are rare [204]. In almost all patients (95–98 %) with Fisher syndrome studied, there has been elevated antiganglioside antibodies directed against the epitope GQ1b (Table 28.11) [51, 205]. The observation that paranodal regions of the oculomotor, trochlear, and abducens nerves are enriched with GQ1b ganglioside supports a role of anti-GQ1b antibodies in the pathogenesis of ophthalmoplegia. Indeed, patients with incomplete forms (acute ataxic neuropathy and acute ophthalmoplegia), generalized GBS with ophthalmoplegia, and Bickerstaff's encephalitis also display the antibody [51, 205, 206]. Sera from patients with anti-GQ1b antibodies and Fisher syndrome induced rapid and reversible failure of release of acetylcholine from presynaptic motor nerve terminals and motor nerve terminal blockade [207, 208]. The ataxia is believed to be secondary to selective involvement of muscle spindle afferents [52, 205, 206].

Table 28.11 Clinical spectrum of the anti-GQ1b antibody syndrome

Disorder	Clinical features	Frequency of anti-GQ1b Ab (%)
MFS	Ataxia, areflexia, ophthalmoplegia	~95
Ataxic GBS	Ataxia, sensory loss and areflexia	~65
Bickerstaff encephalitis	Ataxia, ophthalmoplegia, hyperreflexia, and impaired consciousness	~70
GBS	Weakness, sensory loss, areflexia, cranial neuropathy	~25

About 20 % of patients with Miller Fisher syndrome have followed *C. jejuni infection* and 8 % followed *H. Influenzae* infection [209, 210]. The majority of patients peak at a median of 1 week and improvement starts at a median of 2 weeks [211]. Most patients are recovered completely by 6 months.

Miller Fisher Syndrome (MFS) and Bickerstaff's encephalitis with variable CNS and PNS involvement are considered now part of a continuous clinical spectrum with a common pathogenesis related to the presence of anti-GQ1b antibody. Ataxia and ophthalmoplegia are common to both conditions. Impaired consciousness and upper motor neuron signs are more characteristic of Bickerstaff's encephalitis. The current hypothesis is that this antibody reaches the brainstem via area postrema, attacking the reticular formation and corticospinal tract, among other structures. Hyperreflexia and Babinski's sign are present in 1/3 of the Bickerstaff's encephalitis patients. CSF albuminocytological dissociation occurs in around 25 % of patients during the first week of illness, increasing to 50 % in the second week. Pleocytosis is present in 30 % of cases, much more frequently than in the Fisher syndrome (around 5 %). MRI detects CNS lesions (brainstem and cerebellum) in 1/10 of the Bickerstaff's encephalitis patients [205]. Elevated anti-GQ1b antibody is seen in up to 70 % of patients with Bickerstaff's encephalitis (see Table 28.11).

Immunotherapy has been found to be effective only in retrospective studies [202, 212, 213]. IVIG slightly hastens the recovery of ophthalmoplegia and ataxia, but does not seem to influence patients' outcomes, presumably because of the good natural history of Fisher syndrome. However, plasma exchange or IVIG should be administered as early as possible when the disorder overlaps with GBS or Bickerstaff brainstem encephalitis, because these conditions may not have as good a natural course as the Fisher syndrome [202]. Animal models of MFS with transference of GQ1b antibodies have showed efficacy of C5 complement inhibitors as

promising treatment. Clinical application in human being is yet to be reported [214, 215].

Ataxic Variant (Acute Ataxic Neuropathy)

In 1962, Richter quoted the term ataxic GBS and described a patient with acute severe "cerebellar type ataxia" without proprioceptive sensory loss or ophthalmoplegia [216]. This group of patients presents with a rapid-onset ataxia, hypo- or areflexia, distal paresthesias, and CSF albuminocytological dissociation [206]. They have negative Romberg test with intact proprioception, and 65 % of them have elevated GQ1b antibodies (see Table 28.11). SNAPs are intact in 60 % and reduced or absent in the rest [206]. Clinically, this variant is similar to the Miller Fisher syndrome, except for the lack of ophthalmoplegia and reduced occurrence of elevated GQ1b antibodies (65 % vs. 98 % in Miller Fisher syndrome). Another group of acute ataxic patients, labeled "acute sensory ataxic neuropathy", has similar presentation but positive Romberg test and marked proprioceptive sensory loss [217, 218]. About 90 % of these patients have low-amplitude or absent SNAPs [206]. Antibodies against the epitopes GQ1b or GD1b are present in about 50 % of these patients. It is now likely that the ataxic GBS, originally described by Richter, and the acute sensory axonal neuropathy form a continuous spectrum and represent an incomplete form of the Miller Fisher syndrome with similarly good prognosis. Some authors recently proposed the terms "acute ataxic neuropathy" [206] or "acute sensory axonopathy-ganglionopathy" to encompass both of these disorders [219]. The main differential diagnoses of ataxic GBS are subacute paraneoplastic sensory neuronopathy (anti-Hu syndrome), Sjögren syndrome, pyridoxine intoxication, and vitamin B12 and thiamine deficiency. Anecdotal reports have shown improvement with IVIG or plasma exchange [206].

Pharyngeal-Cervical-Brachial Variant

A regional pattern of weakness of the cervical, brachial, and oropharyngeal muscles exclusively is a rare variant of GBS [143, 220]. The clinical picture is characterized by a recent history of viral illness followed by severe weakness limited to pharyngeal and neck muscles at the onset, with spread to the arms and legs only after several weeks. However, upper limb weakness may sometimes precede the dysphagia. Muscle power, reflexes, and sensation are entirely spared in the legs. Facial weakness and respiratory failure also may occur, thus simulating a disorder of neuromuscular transmission. Curiously, ptosis is almost universal, further emulating myasthenia gravis [143, 184]. Ophthalmoparesis is rare. Aspiration is a common complication and most require intubation for airway protection. The CSF protein concentration is usually slightly increased. About half of the patients exhibit elevated anti-GT1a antibodies, perhaps reflecting an immune attack that is restricted to nerves with that particular epitope serving as an antigenic target [221]. Antibodies against GQ1b are also present in around a third of patients [221]. Nerve conduction studies may demonstrate demyelinating and axonal changes limited to the upper limbs. The blink reflexes are very useful and often show demyelinative changes that are commensurate with the severity of facial paralysis. Some patients with the pharyngeal-cervical-brachial variant of GBS show low-amplitude distal CMAPs and SNAPs and partial motor conduction blocks which normalized within 4 weeks [222]. This is consistent with reversible conduction failure in both motor and sensory fibers which can account for a better prognosis and similar to what is observed in AMAN. In the rest of the patients, recovery may take months and many patients need a gastrostomy tube for nutritional support and a tracheostomy for airway management. Case reports have shown improvement with IVIG or plasma exchange [223].

Multiple Cranial Neuropathy Variant

This GBS variant is characterized by acute onset of multiple cranial nerve dysfunction, multiple ocular motor nerve palsies, and facial and bulbar dysfunction [224]. This form accounts for around 5 % of GBS patients in Taiwan [224]. The findings are often due to involvement of individual cranial nerves, often bilaterally and symmetrically. This also helps distinguish this from the pharyngeal-cervical-brachial variant of GBS. Bilateral IX, X, and XI cranial nerve impairment, resulting in dysphagia, laryngopharyngeal discomfort, and slurred speech, is the initial symptom in most cases [203]. The second most common mode of presentation is facial nerve palsy, which is usually bilateral and of the peripheral type [223]. Complete or partial bilateral extraocular nerve palsies may later develop. Although not initially present, within 2–3 weeks most patients will develop sensory symptoms and limb weakness. Areflexia is usually present.

CSF analysis shows the characteristic albuminocytologic dissociation in half of the patients in the first week after disease onset, a somewhat higher rate and earlier occurrence than that seen in typical GBS [223]. Most case series report abnormalities in motor and sensory conduction velocities and abnormal F-wave responses. The characteristic rapid, progressive course with respiratory paralysis makes early recognition and prompt treatment very important. IVIG was effective in most case series and this is considered the preferred therapy [223, 224].

Facial Diplegia with Paresthesias

A syndrome of acute-onset facial diplegia often associated with distal limb paresthesias is another GBS variant [225]. Other cranial nerve involvements, limb weakness, or ataxia are absent. The majority of patients have hyporeflexia, while hyperreflexia has been described in this syndrome [226, 227]. More than 2/3 of them have a preceding infectious illness. One-third of the patients have positive serology for a recent CMV infection. All the patients had elevated CSF protein. Nerve conduction studies shows demyelinating changes in limb nerves in 60 % of patients. Favorable outcome occurred in the majority of patients and in some have residual facial weakness [225].

Paraparetic Variant

Another regional variant of GBS has features of isolated leg weakness and areflexia simulating a cauda equina or spinal cord syndrome [143]. The arms, ocular, facial, and oropharyngeal muscles are spared, and sphincteric function is normal. Radicular leg pain is common and may be severe, but other sensory features are more variable. The spinal fluid protein level is elevated in the majority. EDX studies show typical demyelinating features of GBS restricted to the legs. MRI of the spinal cord and lumbar roots should be obtained in these patients to exclude a lesion of the caudal spinal cord or cauda equina. Imaging may also show gadolinium enhancement of the lumbosacral nerve roots, as also occurs in many typical GBS cases [124].

Acute Pandysautonomia (Acute Autonomic Neuropathy)

An acute autonomic neuropathy is thought to be another rare variant of GBS [184, 228, 229]. Gastrointestinal symptoms are commonly the initial features, namely, abdominal pain, vomiting, constipation, or diarrhea, all following a viral syndrome. Gastroparesis or abdominal distention with an ileus may develop. Patients complain of lightheadedness due to orthostatic changes in blood pressure following positional changes, and in extreme forms, severe orthostatic hypotension with recurrent syncope are seen. Additional manifestations that are acquired in the first week or two include erectile dysfunction, urinary frequency, urgency, and retention; vasomotor instability with acrocyanosis; and reduced salivation, lacrimation, or sweating. Sensation is normal initially but most patients develop various degrees of sensory impairment without motor dysfunction [230]. The sensory symptoms tend to be segmental and asymmetrical, often associated with pain. The majority of patients have reduced or absent deep tendon reflexes after several weeks. Routine nerve conduction studies are typically normal or show reduced SNAPs particularly in patients with sensory ataxia. Specialized testing of autonomic functions (heart rate variability testing, quantitative axon reflex studies, tilt table testing) are abnormal. The CSF protein concentration is usually mildly elevated. Combined sensory and autonomic GBS variants are probably common [219, 231].

In order to diagnose this condition, one has to rule out a large number of disorders that may cause autonomic dysfunction (cancer, multiple system atrophy, Parkinson's disease, amyloidosis, and others). Autoantibodies specific for nicotinic acetylcholine receptors in the autonomic ganglia are present in about 30 % of the paraneoplastic form and 50 % of the idiopathic autonomic ganglionopathies [232]. The seropositive group has less frequently a preceding viral illness but more frequently a subacute onset, abnormal pupillary responses, sicca complex, and lower gastrointestinal dysautonomia [233].

This GBS variant characteristically progresses and then plateaus after a few weeks, and approximately half the patients recover slowly after several months. There have been case reports of improvement with immunomodulatory therapy, including plasmapheresis or infusion of IVIG [234–236].

Other Possible GBS Variants

A number of other peculiar constellations of neuropathic disorders that develops acutely, often after a minor infectious illness, are possible variants of GBS. These conditions begin acutely, are mostly bilateral in one region, evolve over days or weeks, and are monophasic. Most are associated with an elevated spinal fluid protein concentration without a cellular response and with features of demyelination on EDX studies. These syndromes include acral paresthesias with diminished reflexes in either the arms or legs, abducens nerve palsies with distal paresthesias and hypo- or areflexia, isolated ophthalmoplegia (e.g., asymmetric oculomotor nerve palsies), and bilateral foot drop with upper limb paresthesias [237, 238]. A small fiber sensory neuropathy was also described and considered by some authors to be a GBS variant [239, 240]. The outcome in these patients was favorable.

Chronic Inflammatory Demyelinating Polyradiculoneuropathy and Related Disorders

29

Eduardo Nobile-Orazio, Francesca Gallia, and Elda Judica

Introduction

The chronic acquired demyelinating polyneuropathies constitute a rather heterogeneous group of disorders of the peripheral nervous system whose common feature is demyelination of peripheral nerves. They may be symmetric or asymmetric, predominantly motor, predominantly sensory, or sensorimotor. Most patients with these disorders can be treated successfully. The first disorder described within this group is chronic inflammatory demyelinating polyradiculoneuropathy (CIDP). Other different clinical phenotypes have been subsequently identified and were variably considered to be variants of CIDP or separate clinical entity. Major related disorders which are currently considered to be a variant of CIDP are the Lewis–Sumner syndrome (multifocal acquired demyelinating sensory and motor neuropathy, MADSAM neuropathy), distal acquired demyelinating symmetric neuropathy (DADS neuropathy), purely motor CIDP, purely sensory CIDP including chronic immune sensory polyradiculopathy (CISP), and focal CIDP. Other chronic acquired demyelinating neuropathies are considered separate diseases from CIDP and include multifocal motor neuropathy (MMN) and demyelinating neuropathy associated with an IgM monoclonal gammopathy, mostly of undetermined significance (MGUS), with antibody activity against the myelin-associated glycoprotein (MAG). This is in contrast to CIDP associated with IgG or IgA MGUS that is considered a form of CIDP associated with other diseases.

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

Introduction

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is a chronic disorder of the peripheral nervous system. A variety of names have been used to describe CIDP over the years, including chronic relapsing polyneuropathy, chronic relapsing Guillain–Barré polyneuritis, relapsing corticosteroid-dependent polyneuritis, steroid-responsive recurrent polyneuropathy, chronic relapsing polyneuritis, and chronic inflammatory polyradiculoneuropathy [1–4]. The disease may have either a relapsing or progressive course, and, after the initial reports on its response to steroids [5, 6], it has been now shown that it improves after therapy with steroid, plasma exchange, or high-dose intravenous immunoglobulin (IVIg) [7–9]. Several large series of patients with CIDP reported in the last years have provided insight into the clinical presentation, electrodiagnostic findings, clinical course, and prognosis [10–15]. In addition, a number of recent reviews addressed the most important aspects of the disease [16–19] and analyzed its possible variants [20–22].

Prevalence

The prevalence of CIDP ranges in different studies from 0.8/100,000 in Japan [23] to 1.32/100,000 in England [24]; 3.5/100,000 in Piedmont, Italy [25]; and 8.9/100,000 in Olmstead County, USA [26], with an annual incidence ranges from 0.50 to 1.60 per 100,000. These differences are probably more related to the use of different diagnostic criteria (see below) [27] than to geographical diversity. CIDP may affect individuals at any age ranging from early childhood to the ninth decade though the mean age of onset ranges from 30 to 50 years. The disease is slightly more common in men than in women.

Etiology and Pathogenesis

There is a general consensus that CIDP is an immune-mediated disorder affecting peripheral nerve myelin even if this has not been yet formally proved [17–19, 28]. This hypothesis is supported by several observations and data. The onset and relapses are sometime triggered by infections or immunizations which were reported in 20–30 % of the patients and inclusive of upper respiratory infections, gastroenteritis, other infections, vaccinations, surgery, and trauma [10, 13–15, 29–32]. More recent epidemiological studies showed, however, that the prevalence of antecedent infection is around 10 % and does not differ from what was observed in the control population [25]. Patients who developed CIDP after vaccination have been reported, however, to have an increased risk of relapse after vaccination [31]. These figures are, though, different from what were observed in the Guillain–Barré syndrome (GBS) where the incidence of antecedent events ranges from 60 to 70 % [33, 34]. Pathological studies on nerve biopsy of affected patients (see below) reveal the presence of infiltrates of macrophages and T cell infiltrates and of immunoglobulin deposits [16]. In addition, it was recently shown that the T cell receptor repertoire of infiltrating cells has a strong mono- or polyclonal restriction which corresponds to that of circulating T cells favoring an antigen-driven T cell attack [35]. Serum and cerebrospinal fluid levels of cytokines are often increased in CIDP and, in particular, those associated with cellular (Th1) immunity [36, 37]. On the other side, antibodies against several myelin antigens including the glycolipids GM1, LM1, asialoGM1, sulfatide, and chondroitin sulfate and the proteins P2, P0, PMP22, and β-tubulin have been reported in patients with CIDP [37–46] even if none of these antibodies was convincingly shown to be more frequent or consistently associated with CIDP [28]. Experimental studies on animals have demonstrated a similarity of CIDP with chronic experimental allergic neuritis (EAN) [47] induced in Lewis rat by immunization with the protein P0 or P2 and in rabbit with myelin or galactocerebroside C. Most importantly, however, the vast majority of patients with CIDP improve after receiving immune therapies (see below).

Clinical Presentation

CIDP is a chronic disorder that may have either a chronic progressive or a relapsing course. As in the case of multiple sclerosis, young patients tend to have a relapsing course, while older patients more frequently have a chronic progressive course [48]. This distinction is not always easy with available current therapies since patients with a progressive course may deteriorate after therapy suspension or reduction mimicking a relapse while this is only a wear-off effect of therapy. Initial symptoms may progress over several weeks to months, though in some patients a rapid progression over a few days or weeks leads to the diagnosis of GBS. These patients are initially treated and respond to therapy as if they had GBS even if the subsequent relapsing course eventually leads to the diagnosis of CIDP. Acute-onset CIDP may occur in up to 16 % of all CIDP patients and should be suspected if deterioration continues >2 months from onset or if ≥3 treatment-related fluctuations occur in GBS patients [49]. Prominent sensory symptoms and signs at presentation should also raise this suspicion [50]. These patients were initially considered to have GBS that had subsequently become chronic while they are now considered to have a GBS-like onset CIDP. This is also supported by the observation that during the course of the disease, a few patients may have subacute relapses leading them to a wheelchair in only a few days. The initial diagnosis of CIDP is, however, often delayed after the initial presentation by, in some series, 12–24 months [15, 29].

Most patients with CIDP present with sensory and motor symptoms, although a minority of them present predominantly with motor or sensory involvement. Over 90 % of patients have weakness at presentation. This may be severe in 17 % of patients resulting in marked disability and total dependence [15]. Numbness and paresthesias, usually of the feet and hands, occur at onset in 64–82 %. Pain at onset is less frequent but may occasionally be the presenting symptom [51]. Gait unbalance and upper-limb tremor may also occur in some patients. Cranial nerve symptoms, including dysarthria, dysphagia, facial numbness, facial weakness, blurred or double vision, and ptosis, occur in a minority of patients [10, 13–15], even if these are the symptoms that might raise the suspicion of CIDP in a patient with chronic neuropathy. Respiratory failure may seldom occur in CIDP [52]. When inquired, over 80 % of the patients reported fatigue as a major symptom [53], and this may occasionally be the presenting symptom when weakness is not yet present [54]. Symptoms of dysautonomia are considered uncommon [13], even if impotence [10] and micturition manifestations, including voiding difficulty, urgency, frequency, and incontinence, have been reported in up to 25 % of the patients [55]. More recent data shows however that symptoms of a usually mild autonomic dysfunction may be present in 65 % of the patients [56].

On examination, proximal and distal weakness is common, usually in a symmetric manner. The presence of proximal weakness is indeed considered one of the clues to the clinical diagnosis of CIDP in patients with chronic neuropathy. Distal weakness is, however, more common and severe than proximal weakness. Reflexes are classically deemed to be absent in CIDP even if total areflexia only occurs in 70 % of patients. Most other patients have a mixture of decreased and absent reflexes with ankle reflexes being most often

absent. Sensory deficits are present in over 80 % of patients, with vibratory impairment more common than deficits to pinprick. A postural action tremor in upper-limb and gait ataxia is seen in some patients. Cranial nerve dysfunction occurs in up to 16 % and may include ophthalmoplegia, facial weakness, and bulbar weakness. Papilledema may occur [10, 13–15]. In occasional patients, nerve root hypertrophy may lead to cervical myelopathy [57] or lumbar radiculopathy [58–60].

CIDP is a severe disease. In previous studies, 11 % of the patients were reported to die from CIDP, 11 % to be in a wheelchair or in bed at last follow-up, and 64 % to be ambulatory and working [10]. Subsequent studies showed that 73–87 % of patients had a good recovery and were independent [13, 61], with a death rate from CIDP of 3–6 % [13, 14, 61]. Recent epidemiologic studies showed that over 50 % of the patients have at least temporary severe disability in the course of the disease including temporary restriction to a wheelchair or inability to walk without support and approximately 10 % eventually become persistently disabled or die because of the illness [24, 25]. A few patients have, however, a disturbing but functionally indolent course with minimal weakness and minor sensory symptoms and are considered to have a clinically minimal and sometime asymptomatic CIDP [62].

Diagnosis of CIDP

Even if the diagnosis of CIDP is often easy in clinical practice, the use of expensive therapies for this disease and the description of a number clinical variants have led to the necessity to define the clinical boundaries of this neuropathy in order to avoid the inappropriate use of expensive therapies but at the same to include under this diagnosis the largest proportion of patients who might benefit from immune treatment. This is why, even if CIDP is not a common disease, at least 17 diagnostic criteria for CIDP [17, 63] have been proposed in the last few years. These selective criteria try to achieve the best compromise between the desire to include under this diagnosis, and treat, as many patients as possible and to avoid the inclusion of patients with similar but different neuropathies and the consequent expectation of potential benefit from ultimately ineffective therapies. For the same reason, despite the presence of a number of differences, variants of CIDP were variably included under the term of CIDP to allow affected patients to be reimbursed for the same therapies of CIDP. Most of these criteria have similar clinical feature and differ in term of the electrophysiological criteria necessary for its diagnosis [63]. Recently, Koski and colleagues [64] proposed a new set of criteria which also allowed the diagnosis of CIDP on clinical ground only. The presence of a symmetric neuropathy affecting four limbs with proximal weakness in at least one limb in the absence of a serum paraprotein or documented genetic abnormality was considered sufficient for the diagnosis. It was recently shown, however, that the sensitivity of these criteria (63 %) for the diagnosis of CIDP [65] was higher than that of the criteria of the American Academy of Neurology (45.7 %) [66] but lower than that of the European Federation of Neurological Sciences and Peripheral Nerve Society (EFNS/PNS) (81.3 %) [67] with a comparable specificity. The recently revised criteria of the EFNS/PNS (Tables 29.1, 29.2, and 29.3) have the great advantage of including patients with typical and atypical presentation of CIDP including a number of variants and of allowing the diagnosis of CIDP even in patients with demyelinating abnormalities in a single nerve when other supportive criteria for the diagnosis of CIDP are present. A few aspects of these diagnostic criteria will be now addressed.

Table 29.1 EFNS/PNS (2010) clinical diagnostic criteria for CIDP [67]

(1) Inclusion criteria
(a) Typical CIDP
Chronically progressive, stepwise, or recurrent symmetric proximal and distal weakness and sensory dysfunction of all extremities, developing over at least 2 months; cranial nerves may be affected
Absent or reduced tendon reflexes in all extremities
(b) Atypical CIDP (still considered CIDP but with different features). One of the following, but otherwise as in (a) (tendon reflexes may be normal in unaffected limbs):
Predominantly distal (distal acquired demyelinating symmetric, DADS)
Asymmetric (multifocal acquired demyelinating sensory and motor neuropathy [MADSAM], Lewis–Sumner syndrome)
Focal (e.g., involvement of the brachial or lumbosacral plexus or of one or more peripheral nerves in one upper or lower limb)
Pure motor
Pure sensory (including chronic immune sensory polyradiculopathy affecting the central process of the primary sensory neuron)
(2) Exclusion criteria
Prominent sphincter disturbance
Lyme disease (Borrelia burgdorferi infection), diphtheria, drug or toxin exposure likely to have caused the neuropathy
Hereditary demyelinating neuropathy
Multifocal motor neuropathy (MMN)
IgM monoclonal gammopathy with high-titer antibodies to myelin-associated glycoprotein (MAG)
Other causes for a demyelinating neuropathy including POEMS syndrome, osteosclerotic myeloma, diabetic and nondiabetic lumbosacral radiculoplexus neuropathy, PNS lymphoma, and amyloidosis

Clinical Criteria

All the criteria for CIDP, as well as some clinical series [10, 14], require a minimum 2-month period of symptoms. Others have accepted a shorter period of progression.

Table 29.2 EFNS/PNS (2010) electrodiagnostic criteria for CIDP [67]

(1) Definite: at least one of the following
(a) Motor distal latency prolongation ≥ 50 % above ULN in 2 nerves (excluding median neuropathy at the wrist from carpal tunnel syndrome)
(b) Reduction of motor conduction velocity ≥ 30 % below LLN in 2 nerves
(c) Prolongation of F-wave latency ≥ 20 % above ULN in 2 nerves (≥ 50 % if amplitude of distal negative peak CMAP <80 % of LLN values)
(d) Absence of F-waves in 2 nerves if these nerves have distal negative peak CMAP amplitudes ≥ 20 % of LLN + ≥ 1 other demyelinating parameter[a] in ≥ 1 other nerve
(e) Partial motor conduction block: ≥ 50 % amplitude reduction of the proximal negative peak CMAP relative to distal, if distal negative peak CMAP ≥ 20 % of LLN, in 2 nerves, or in 1 nerve + ≥ 1 other demyelinating parameter[a] in ≥ 1 other nerve
(f) Abnormal temporal dispersion (>30 % duration increase between the proximal and distal negative peak CMAP) in ≥ 2 nerves
(g) Distal CMAP duration (interval between onset of the first negative peak and return to baseline of the last negative peak) increase in ≥ 1 nerve (median ≥ 6.6 ms, ulnar ≥ 6.7 ms, peroneal ≥ 7.6 ms, tibial ≥ 8.8 ms) + ≥ 1 other demyelinating parameter[a] in ≥ 1 other nerve
(2) Probable
≥ 30 % amplitude reduction of the proximal negative peak CMAP relative to distal, excluding the posterior tibial nerve, if distal negative peak CMAP ≥ 20 % of LLN, in 2 nerves, or in 1 nerve + ≥ 1 other demyelinating parameter[a] in ≥ 1 other nerve
(3) Possible
As in (1) but in only 1 nerve

CMAP compound muscle action potential, *ULN* upper limit of normal values, *LLN* lower limit of normal values
[a]Any nerve meeting any of the criteria (a–g)

Table 29.3 EFNS/PNS (2010) diagnostic categories for CIDP [67]

Definite CIDP
Clinical criteria 1 (a or b) and 2 with electrodiagnostic criterion 1
Probable CIDP + at least one supportive criterion[a]
Possible CIDP + at least two supportive criteria[a]
Probable CIDP
Clinical criteria 1 (a or b) and 2 with electrodiagnostic criterion 2
Possible CIDP + at least one supportive criterion[a]
Possible CIDP
Clinical criteria 1 (a or b) and 2 with electrodiagnostic criterion 3
CIDP (definite, probable, possible) associated with concomitant diseases

[a]*Supportive criteria for CIDP*
1. Elevated CSF protein with leukocyte count <10/mm3
2. MRI showing gadolinium enhancement and/or hypertrophy of the cauda equina, lumbosacral or cervical nerve roots, or the brachial or lumbosacral plexuses
3. Abnormal sensory electrophysiology in at least one nerve:
   (a) Normal sural with abnormal median (excluding median neuropathy at the wrist from carpal tunnel syndrome) or radial sensory nerve action potential (SNAP) amplitudes
   (b) Conduction velocity <80 % of lower limit of normal (<70 % if SNAP amplitude <80 % of lower limit of normal)
   (c) Delayed somatosensory evoked potentials (SSEP) without central nervous system disease
4. Objective clinical improvement following immunomodulatory treatment
5. Nerve biopsy showing unequivocal evidence of demyelination and/or remyelination by electron microscopy or teased fiber analysis

McCombe et al. [13] found that 16 % of patients in their CIDP series reached a nadir within 4 weeks but went on to develop a relapsing or progressive course. Prineas and McLeod [11] found four CIDP patients whose nadir was reached in 2 months or less. Similarly, Simmons et al. [15] found that 16 of 77 patients (21 %) reached peak impairment less than 2 months after symptom onset, with a small number having an acute presentation indistinguishable from GBS. Treatment is often instituted less than 2 months after onset if the deficit was sufficiently severe and progressive. In these patients, the subsequent relapsing or progressive course supports the diagnosis before the classic 2 months even if theoretically none of the proposed criteria would allow the treatment of the patients as CIDP. A prominent sensory impairment is often helpful in distinguishing acute-onset CIDP from GBS [50].

Electrodiagnostic Studies

With the only exception of Koski's criteria, electrodiagnostic (EDX) studies have been always considered fundamental for the diagnosis of CIDP by demonstrating various typical features of demyelination in motor and sensory fibers. These criteria mainly differ in the number of abnormal nerves needed and in the degree of these abnormalities. Motor nerve conduction abnormalities are similar to those seen in GBS and generally demonstrate multifocal demyelination in motor nerves, characterized by prolonged distal latencies, slowed conduction velocities, prolonged F-wave latencies, and evidence of partial conduction block or abnormal temporal dispersion (Fig. 29.1). However, not all motor nerves demonstrate such abnormalities, due to the multifocal nature of the demyelination in CIDP. A review of the EDX studies of 70 patients who carried the diagnosis of CIDP found that only 48–64 % of those in whom a sufficient number of nerves were tested fulfilled the EDX criteria for CIDP, depending upon which criteria were used [68]. One of the advantage of the revised EFNS/PNS criteria [67] is to allow the diagnosis of definite CIDP even in the presence of a single motor nerve as far as two other supportive criteria are found (see Table 29.3). In addition, if EDX criteria for definite CIDP are not met initially, repeated study at a later date may help in the diagnosis. In any case, even if EDX tests are considered mandatory for the diagnosis of CIDP, they should be considered in conjunction with other clinical and laboratory features. Patients with POEMS or IgM monoclonal gammopathy with anti-MAG or anti-sulfatide antibodies also fulfill the EDX criteria for CIDP. The clinical presentation including skin changes and

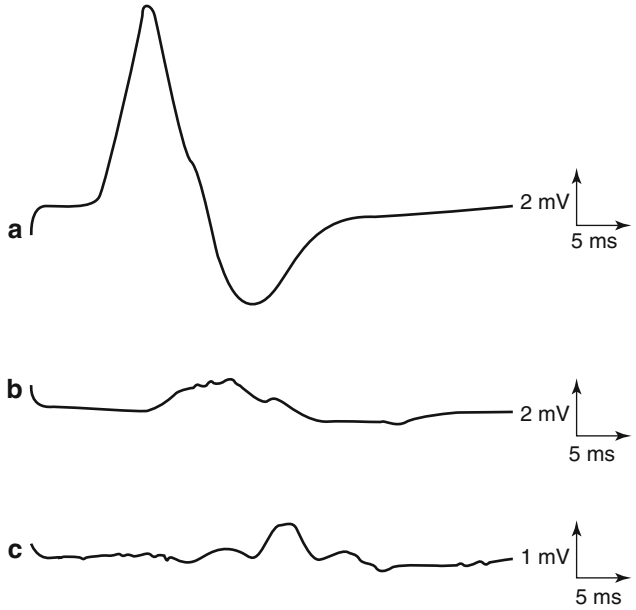

Fig. 29.1 Ulnar motor nerve conduction study in a CIDP patient, recording with surface electrodes over the abductor digiti quinti muscle and stimulating at the wrist (**a**), below elbow (**b**), and above elbow (**c**). There is a partial conduction block and abnormal temporal dispersion with proximal stimulation

serum VEGF levels may help in identifying patients with POEMS [69] while serum protein electrophoresis and antibody testing in patients with IgM monoclonal gammopathy (see below) [70]. Occasional patients with amyloidosis or nerve or root lymphoma may also have some EDX features suggestive for CIDP.

Electrodiagnostic studies of motor nerves are also helpful in distinguishing CIDP from hereditary demyelinating polyneuropathies (most commonly type I Charcot–Marie–Tooth disease) [71]. Patients with CIDP generally demonstrate differences in the degree of slowing of conduction velocity between different segments of a given nerve and between similar segments of different nerves, while those with hereditary neuropathies are more likely to demonstrate uniform slowing of conduction velocity both within and between nerves. In addition, temporal dispersion and conduction block on proximal stimulation are characteristics of acquired but not hereditary demyelinating polyneuropathies with the only exception of hereditary neuropathy with liability to pressure palsy (HNPP), which can be easily confirmed by demonstration of deletion of one allele of the PMP22 gene. Occasional patients with other forms of inherited neuropathy associated with conduction block have been, however, reported [72, 73].

Early reports demonstrated absent sensory responses in virtually all patients with CIDP [11, 12], but it is now clear that sensory responses vary from absent to normal [13, 15]. The most common sensory nerve pattern in CIDP is for both the median and sural sensory responses to be abnormal. An abnormal median sensory response in association with a normal sural sensory study may help to distinguish acquired demyelinating polyneuropathies such as CIDP from other neuropathies in the proper clinical setting [74], even if its specificity is quite low [75]. Similarly sensitive but also not specific is the reduction of sensory conduction velocities [76]. Somatosensory evoked potentials (SSEP) can be also useful in CIDP by demonstrating abnormal proximal sensory conduction, particularly in patients with sensory CIDP or with chronic immune sensory polyradiculopathy (see below) [77, 78].

The findings on needle electromyography (EMG) depend on the degree of secondary axonal degeneration. If there is no axonal loss, decreased recruitment may be the only finding. Otherwise, there may be variable amounts of acute and chronic partial denervation and reinnervation, including fibrillation potentials; positive sharp waves; high-amplitude, long-duration motor unit action potentials; and increased polyphasia [79]. Single-fiber EMG is often mildly abnormal in CIDP, demonstrating increased jitter in most patients and increased fiber density in a minority [80].

Cerebrospinal Fluid Analysis

Patients with CIDP generally have increased levels of proteins in the cerebrospinal fluid (CSF) with normal cell count (albuminocytologic dissociation). In large series of patients, CSF proteins were increased in 83–95 % of the patients with mean values ranging from 134 to 145 mg/dl and individual values varying between 20 and 1200 mg/dl [10, 13–15]. While most diagnostic criteria recommend CSF examination for the diagnosis of CIDP, this was only considered a supportive criteria by the EFNS/PNS [67] and was considered useful as supportive criteria only in patients in whom clinical and EDX criteria are not sufficient for the diagnosis of CIDP (see Table 29.3). This is not always accepted by neurologists who still consider this test fundamental in the diagnosis of CIDP. It is not so infrequent, however, to encounter patients with unclear EDX findings in whom a diagnosis of CIDP is based on increased CSF protein and who eventually prove to have POEMS, amyloidosis, lymphoma, or IgM monoclonal gammopathy.

Sural Nerve Biopsy Findings

As in the case of cerebrospinal fluid analysis, sural nerve biopsy is only considered by the EFNS/PNS as one of the supportive criteria for CIDP in patients in whom clinical and EDX criteria are not sufficient for the diagnosis of CIDP [67]. Supportive features for the diagnosis of CIDP are macrophage-associated demyelination, onion-bulb formation, demyelinated and to a lesser extent remyelinated nerve fibers, endoneurial edema, endoneurial mononuclear cell infiltration, and variation between fascicles [16]. Even if demyelination is relatively common, the degree of demyelination varies widely among patients [10, 11, 14, 81]. A study on a large series of

patients found that demyelination was the predominant histologic finding in only about half of the patients, while 21 % demonstrated predominantly axonal degeneration and 13 % a mixed axonal and demyelinating picture [14]. Another report indicated that demyelination was more severe than axonal degeneration in only half of 14 patients studied [81]. Dyck et al. [10] reported that Wallerian degeneration was the most common finding on nerve biopsy. A minority of biopsies demonstrate endoneurial mononuclear inflammatory infiltrates (commonly perivascular and usually rather mild), endoneurial edema, and onion-bulb formations. The presence of cluster of macrophages around endoneurial vessels in sural nerve biopsy was shown to represent an additional marker for the pathological diagnosis of CIDP [82]. Some patients with CIDP (15 %) have normal sural nerve biopsies [14], possibly reflecting a sampling error. In any case, sural nerve biopsy findings should be considered in the clinical context and cannot be relied upon in isolation to make the diagnosis of CIDP. It is also often recommended to perform sural nerve biopsy in patients with suspected CIDP not responsive to immune therapy in the context of a diagnostic reevaluation, even if this has not been formally proved to be effective. Sural nerve biopsy may be, however, useful in patients with a long-lasting story in whom several nerves are not excitable and therefore not helpful in the diagnosis of CIDP. In these patients nerve biopsy can help excluding axonal damaged caused by amyloidosis, nerve vasculitis, or lymphoma.

Radiologic Studies

Gadolinium-enhanced MRI of spinal roots and brachial or lumbar plexus may demonstrate hypertrophy and gadolinium enhancement of cervical and lumbosacral nerve roots in CIDP patients, some of whom have symptoms of radiculopathy, but also of brachial or lumbar plexus. The MRI findings appear to be due to demyelinating and remyelination with onion-bulb formation [58–60, 83–85]. This test is not recommended for patients with a definite clinical and EDX diagnosis of CIDP but may support the diagnosis in patients with inconclusive findings. Some recent report also suggests that nerve echography may help identify an increased size of nerve and may help support the diagnosis of CIDP [86, 87].

Response to Immune Therapy (See Below)

Response to immune therapy has been proposed to be a supportive criterion for the diagnosis of CIDP. This should be, however, considered with some caution since a few diseases that should be differentiated from CIDP including POEMS, IgM monoclonal gammopathy, and vasculitis may also improve with immune therapy. Response to therapy is particularly useful in patients in whom the EDX studies do not fulfill the diagnosis of CIDP for the absence of recordable nerves and not in those in whom recordable nerves are normal or show signs of axonal pathology.

Central Nervous System (CNS) Demyelination

Several patients with CIDP have been reported to have clinical, MRI, and electrophysiological (evoked potential) evidence of a CNS demyelination [88–90]. This has raised the hypothesis of a shared myelin antigen for both peripheral and CNS demyelination even if this has never been proved. The vast majority of patients with CIDP do not have evidence of a CNS demyelinating disease, either clinically or by MRI [91–93], and only occasional patients with multiple sclerosis have signs of CIDP. Unless signs of a possible involvement of CNS are present, patients with CIDP should not be routinely investigated for CNS abnormalities.

Variants of CIDP

Sensory CIDP

Some patients with CIDP may present with a pure sensory syndrome with a proportion in different series ranging from 5 to 15 % [20, 21]. Most of these patients have normal strength even if they also have EDX evidence of demyelination also on motor nerves [94–96]. A few patients have, however, a clinically and electrodiagnostically pure sensory neuropathy and are considered to represent the variant of sensory CIDP [97]. Follow-up studies in these patients reveal that while some of them evolve into a typical sensorimotor CIDP, others remain purely sensory even during long-term follow-up [18, 98]. The pathological features of CIDP were also reported on sural nerve biopsy in eight patients who presented with a clinical picture of cryptogenetic sensory neuropathy, four of whom improved with immune therapy [99]. It is, however, not so infrequent that patients with sensory CIDP have an unsatisfactory response to immune therapy and two patients were recently reported to deteriorate after plasma exchange [100].

A particular form of sensory CIDP is *chronic immune sensory polyradiculopathy* (*CISP*). This entity has been highlighted by Sinnreich et al. [78] who reported 15 patients who had only sensory symptoms for a few years with normal nerve conduction studies. Somatosensory evoked potentials were delayed, and CSF proteins were increased. Lumbar MRI revealed an enlargement of lumbar roots, and root biopsy confirmed the inflammatory nature of the process. All treated patients improved with IVIg or steroids.

Motor CIDP

A few patients have been reported to have purely motor impairment throughout the course of the disease [101, 102]. They represented 4–5 % of the patients with chronic demyelinating neuropathy, in two series of patients with CIDP [21]. There are, however, only a few reports of patients with motor CIDP, while most patients are only mentioned in series of patients with CIDP. Some patients have an asymmetric

presentation with partial conduction block and no slowing of motor conduction velocity that is somehow reminiscent of multifocal motor neuropathy (MMN) [101]. Even if motor CIDP is generally considered to be a variant of CIDP, most affected patients were reported to worsen after steroids and to improve with intravenous immunoglobulins [101–103] raising the possibility that this variant may represent more a diffuse variant of MMN (that also deteriorates under steroids) than a motor form of CIDP.

Focal CIDP

A few patients have been reported with a more restricted distribution of weakness and sensory loss which is often restricted to one or both arms. Thomas et al. [104] reported nine patients including five who had a sensorimotor impairment in one or both arms, one with a sensory monomelic impairment, and three with a purely motor impairment in one or two arms. One of these patients could be now considered to have MMN, while in the other patients impairment was not restricted to the distribution of individual nerves to raise the suspicion of Lewis–Sumner syndrome or of MMN. Seven of these patients improved with either steroids or IVIg. This clinical presentation is now classified as a focal variant of CIDP. A few other patients with upper-limb predominant multifocal CIDP have been reported even if the clinical features were more consistent with the diagnosis of Lewis–Sumner syndrome [105].

Lewis–Sumner Syndrome

In 1982, Lewis and colleagues [106] described five patients with a chronic, acquired, asymmetric sensorimotor demyelinating polyneuropathy which clinically resembled a mononeuritis multiplex. Electrodiagnostic studies demonstrated multifocal conduction block in motor nerves. CSF protein was normal to mildly elevated. Two patients were treated with prednisone and improved. Several similar patients have been subsequently reported under the name of Lewis–Sumner syndrome, motor and sensory demyelinating mononeuropathy multiplex, multifocal motor and sensory demyelinating neuropathy, multifocal inflammatory demyelinating neuropathy, and multifocal acquired demyelinating sensory and motor neuropathy (MADSAM neuropathy) [107–113]. This syndrome is now considered to be a variant of CIDP. It is, however, unclear why only 50 % of the affected evolve into CIDP within 4 years, while the remaining 50 % maintain a multifocal distribution [112].

There is no difference in age distribution compared to CIDP. Similarly to CIDP, patients have relapsing or progressive course. The arms are usually involved before the legs. Both weakness and numbness are present at onset in approximately 50–60 % of the patients, while 30 % of the patients have a selective sensory loss and 10 % a predominant motor impairment [112, 113]. The pattern of involvement is asymmetric, usually in the distribution of individual nerves as seen with mononeuritis multiplex. Pain is present in a minority. Cranial neuropathies occur in 10–20 % of the patients [112–114]. Reflexes are usually decreased in an asymmetric multifocal manner but rarely are completely absent [108, 109].

Electrodiagnostic studies in preliminary studies focused on the frequent presence of partial conduction block in motor nerve with normal conduction velocities [106]. Subsequent studies focused on the asymmetric mononeuropathy multiplex type of presentation with the concomitant presence of prolonged distal latencies, slowed conduction velocities, temporal dispersion, and prolonged F-wave latencies in an asymmetric manner. Sensory studies are abnormal as well. Needle EMG examination demonstrates active and chronic denervation. CSF protein levels are usually normal but may be mildly elevated in one-third of the patients [112], even if very high levels have been seldom reported. Anti-GM1 antibodies are either absent or present in less than 10 % of the patients [106–109, 112, 113]. Nerve biopsies demonstrate multifocal asymmetric demyelination as the primary process, and inflammatory infiltrates have been reported in some patients [110, 114, 115]. MRI imaging of the brachial plexus revealed in some patients swollen nerves and increased signal intensity on T2-weighted imaging [110].

Response to therapy is similar to CIDP (see below) even if more frequent response to IVIg than to steroids has been reported [112]. In a retrospective analysis on 120 patients, patients with a predominant impairment in arms had a more frequent response to steroids than to IVIg (74 % versus 52 %), while the reverse occurred in patients more impaired in lower limbs (25 % versus 80 %) [113].

Distal Acquired Demyelinating Symmetric (DADS) Neuropathy

Katz et al. [116] first introduced the term of DADS neuropathy to describe a group of patients with predominantly distal symmetric sensory ataxic demyelinating neuropathy. This clinical phenotype corresponded to what was observed in patients with neuropathy associated with IgM monoclonal gammopathy and antibodies to the myelin-associated glycoprotein (MAG) (see later). Not all patients with this phenotype had, however, IgM monoclonal gammopathy [116] or anti-MAG antibodies [117]. Other patients with IgM monoclonal gammopathy and this phenotype had antibodies to sulfatide [118] even if the specificity of this reactivity is still matter of controversy. This clinical pattern is now considered to represent a clinical phenotype more than a definite syndrome, and patients without IgM monoclonal gammopathy or anti-MAG antibodies are now considered to have a DADS variant of CIDP [117]. These patients have a chronic, slowly progressive polyneuropathy characterized by distal sensory loss, gait ataxia, normal strength or mild distal weakness, and demyelinating features on nerve conduction studies, generally

without conduction block. They have low motor conduction velocities and prolonged distal motor latencies. There is often an associated action tremor. Similarly to what was observed in patients with anti-MAG neuropathy, these patients tend to have a less satisfactory response to the therapy than was observed in patients with typical CIDP [22, 116].

CIDP with Associated Diseases

CIDP may coexist with a number of other diseases. In most of these conditions, the pathogenesis and pathology of CIDP are thought to be the same as in CIDP without a concomitant disease (usually referred to as idiopathic CIDP) [67]. These diseases include diabetes mellitus, HIV infection, chronic active hepatitis, IgG or IgA monoclonal gammopathy of undetermined significance (MGUS), systemic lupus erythematosus or other connective tissue diseases, sarcoidosis, thyroid disease, inflammatory bowel disease, membranous glomerulonephritis, or organ transplantation. In these conditions, treatment is the same than in idiopathic CIDP with the only caution derived from the possible effect of treatment on the associated condition.

In other conditions, the pathogenesis and pathology may be different from idiopathic CIDP and treatment is mainly directed at treating the associated disease. These include infection with Borrelia burgdorferi (Lyme disease), IgM monoclonal gammopathy with antibodies to myelin-associated glycoprotein (MAG) or other antigens, POEMS syndrome, osteosclerotic myeloma, and hematological and non-hematological malignancies, including lymphoma and Castleman's disease.

Some specific aspects of these related or unrelated conditions are addressed below, while neuropathy associated with anti-MAG antibodies will be addressed in a separate section.

Diabetes Mellitus

Patients with diabetes may develop a symmetric sensorimotor polyneuropathy which fulfills research criteria for CIDP. It is important to recognize CIDP in diabetic patients, since this neuropathy responds to immunomodulating therapy [119, 120]. It has been widely discussed in the recent years whether the prevalence of diabetes is increased in patients with CIDP or whether the prevalence of CIDP is increased in patients with diabetes. It has been also discussed whether patients with diabetes and CIDP have a different response to therapy [120]. Two recent epidemiological studies have shown that the association of these two diseases is not higher than would be expected from a casual association [26, 121]. It is, however, important to consider that diabetes is a contraindication to steroid therapy which should be avoided or used with caution in patients with CIDP and diabetes. In addition, steroids may induce diabetes in patients with a familial history of diabetes or glucose intolerance. In patients not responsive to the other effective therapy for CIDP, including IVIg and plasma exchange, a course of steroid should be not, however, denied even if blood glucose levels need to be strictly monitored in these patients and therapy accordingly adapted. A similar caution should be given to patients with CIDP and chronic active hepatitis.

IgM Monoclonal Gammopathy

The association of IgM monoclonal gammopathy of undetermined significance (MGUS) with a demyelinating neuropathy has been known for several years, and the pathogenetic relevance of this association has been widely debated [70]. It is now accepted that patients with a demyelinating neuropathy associated with IgM monoclonal gammopathy with IgM antibodies to the myelin-associated glycoprotein (MAG) have a distinct disorder caused by the binding of these antibodies to nerve. This neuropathy will be separately addressed.

More controversial is the association of neuropathy with IgM monoclonal antibodies directed against other neural antigens. IgM antibodies to sulfatide antibodies were originally associated with an axonal neuropathy [122] even if, in subsequent studies, they were associated with sensorimotor demyelinating neuropathy with prominent limb weakness and gait ataxia [118, 123, 124]. The clinically heterogeneous association of this reactivity has induced some skepticism on the pathogenetic relevance of this reactivity so that the EFNS/PNS did not consider it a causal factor for the neuropathy in patients with IgM monoclonal gammopathy [70] or an exclusion criterion for the diagnosis of CIDP. Morphological studies on nerve biopsy showed, however, in some patients the same abnormalities observed in patients with anti-MAG antibodies including abnormally spaced myelin lamellae and myelin deposits of the M-protein and complement [118, 125] supporting the hypothesis of a similar pathogenetic mechanism. In our opinion, unless a patient with IgM monoclonal gammopathy with or without anti-MAG antibodies has a clinical relapsing course compatible with the clinical diagnosis of CIDP, he/she should be considered to have a separate disease from CIDP and treated as patients with anti-MAG neuropathy.

IgG and IgA Monoclonal Gammopathy

It has been debated for several years whether patients with otherwise typical CIDP and IgG or IgA MGUS should be distinguished from patients with idiopathic CIDP and should require different therapies. Even if some clinical differences between the two groups have been observed by some [61, 126] but not other authors [29], there is little evidence that the presence of IgG or IgA MGUS has a role in the neuropathy or that it may affect its treatment [127]. A few reactivities of IgG or IgA M-proteins with nerve antigens have been reported in these patients, but these were seldom confirmed or were equally frequent in patients with and without

neuropathy [128]. In addition, in most patients the M-protein becomes manifest several months to years after onset of the neuropathy [128], making it unlikely a causative role of the M-protein in the neuropathy. The panel of experts of the EFNS/PNS concluded that patients with CIDP associated with IgG or IgA MGUS should be considered indistinguishable from patients with idiopathic CIDP and treated in the same way [67]. These patients have indeed an identical response to therapy compared to patients with CIDP with more than two-thirds of them responding to the same immune therapies known to be effective in CIDP [129] including steroids, IVIg [130], and plasma exchange [131].

HIV Infection

CIDP may occur early in the course of HIV infection and has clinical and EDX features similar to HIV-negative patients. The main distinguishing feature is that HIV-positive patients may have increased CSF cells compared to normal CSF cell count in HIV-negative patients and that HIV viral antigens can be found in the CSF. Prominent inflammatory infiltrates have been also reported in sural nerve biopsy. Effective treatments include intravenous immunoglobulin (IVIg), plasma exchange, and steroids [132].

Malignancies

CIDP has been reported in patients with pancreatic adenocarcinoma, rectosigmoid adenocarcinoma, cholangiocarcinoma, hepatocellular carcinoma, seminoma, melanoma [133–138], and hematological malignancies [139–141]. Some of these patients improved with treatment of the malignancy or with prednisone. It has been debated whether CIDP may be considered a paraneoplastic neuropathy or whether this association is merely casual. In a recent epidemiological study, 12/294 (4 %) patients with a diagnosis of CIDP or idiopathic demyelinating neuropathy had a malignancy [25]. The data from an aged-matched control population was not, however, available. Some interest derives from the association of malignant melanoma with CIDP that may improve with prednisone [137, 138]. A possible causal relationship was given by the observation that melanoma and Schwann cells are both of neuroectodermal origin and that they share surface antigens including the ganglioside GM2 [138], suggesting that in some patients a mechanism of molecular mimicry might have played a role in the induction of CIDP.

Diagnostic Evaluation of the Patient with Suspected CIDP

As for any patient, a comprehensive history and physical examination are keys in the evaluation of patients with suspected CIDP and should help the differential diagnosis. If CIDP is suspected on the basis of a relapsing course, a progressive impairment which might not be as slow as usually observed in other chronic acquired neuropathy or proximal muscle weakness, motor and sensory nerve conduction studies are usually sufficient to establish the diagnosis of CIDP. When, however, nerve conduction studies do not show unequivocal signs of multifocal demyelination with reduced conduction velocities, increased latencies, and conduction block, the diagnosis of CIDP may be supported by cerebrospinal fluid examination which might disclose an increase of CSF proteins with normal cells. MRI may be also helpful by revealing gadolinium enhancement or hypertrophy of spinal roots and brachial or lumbosacral plexus. As mentioned above, sural nerve biopsy is not necessary in most patients with suspected CIDP, since the findings are neither sensitive nor specific. In addition, it is an invasive procedure technique that should be probably considered only when other tests are inconclusive. In these patients nerve biopsy may occasionally identify vasculitis, amyloidosis, sarcoidosis, or neoplastic infiltration of the nerve.

Other laboratory tests may be done to exclude other possible causes for either a demyelinating neuropathy or axonal neuropathy [67]. In patients with a demyelinating neuropathy, serum and urine immunofixation or immunoelectrophoresis and serum immunoglobulin dosage should be performed looking for a monoclonal gammopathy in the serum and Bence-Jones proteins in the urine. If immunofixation reveals a previously unknown paraproteinemia, evaluation by a hematology specialist is warranted. In these patients skeletal surveys, looking for the possibility of osteosclerotic myeloma should be also considered [67, 70]. If the IgM level is elevated, antibody titers to myelin-associated glycoprotein (MAG), sulfatide, and disialoglycolipid such as GD1b or GQ1b should be determined [70]. Serum VEGF levels may help exclude the diagnosis of POEMS syndrome in patients with other possible features of this syndrome including a tanned skin, recent cutaneous hemangiomata, distal edema, recent thrombocytosis, hepatomegaly or splenomegaly, recent onset of severe diabetes, or other endocrinopathy [69]. Signs of cardiomyopathy, renal dysfunction, or autonomic impairment may raise the suspicion of amyloid neuropathy which should be investigated with periumbilical fat biopsy or genetic test to exclude transthyretin mutation. Genetic test for PMP duplication, connexin 32 mutation, or P0 mutation should be considered in patients with a very slowly progressive demyelinating neuropathy without conduction block and negative or unclear history of familial neuropathy.

In patients with an axonal neuropathy, the diagnosis of CIDP is often excluded unless the patient has a very long-lasting disease that might have led to secondary axonal degeneration. In these patients increased sedimentation rate, C-reactive protein, antinuclear factor (ANA), anti-extractable nuclear factor (ENA) and antinuclear cytoplasmic (ANCA) antibody, and complement levels may help exclude a vasculitic neuropathy [142]. A blood glucose level and a glycosylated hemoglobin or glucose tolerance test should be

performed to exclude diabetes. Even if a positive test does not exclude the diagnosis of CIDP (see above), this diagnosis should not be probably considered in a patient with axonal neuropathy. Screening tests for other causes of polyneuropathy [67], including thyroid function tests, vitamin B12 level, VDRL, antibodies to hepatitis C or B virus, and, in some geographic regions, Lyme titer, are helpful. Patients with a risk for HIV infection or with a significant CSF pleocytosis should be evaluated for HIV infection. Angiotensin converting enzyme is usually considered useful in the diagnosis of sarcoidosis. This diagnosis is usually considered in the presence of a pulmonary symptoms with evidence of enlarged lymph node on chest CT and can be only confirmed by the biopsy of an affected lymph node.

Tests to search for an associated condition should be only performed in the presence of suggestive symptoms, while the search for an underlying malignancy should be only considered if other symptoms or laboratory tests raise the suspicion of their presence. If a superimposed CNS demyelinating disorder is suspected, CSF studies for multiple sclerosis can be helpful including MRI of the brain and spinal cord.

Treatment and Management

Several controlled studies and retrospective series on large series of patients and a few randomized controlled trials have shown the efficacy of steroids, plasma exchange, and IVIg in CIDP [7–9] with approximately 50–70 % of the patients responding to each of these treatments. In addition, almost 50 % of patients not responding to one of these treatments respond to the second therapy used leading to 80 % of the proportion of patients improving with these therapies [143, 144]. The efficacy of these therapies was confirmed in recent Cochrane Reviews [7–9] and in the recently updated guidelines of the EFNS/PNS [67]. Also, the efficacy of IVIg was set in a consensus statement of the American Association of Neuromuscular and Electrodiagnostic Medicine (AANEM) [145] and in a more recent evidence-based guideline of the American Academy of Neurology (AAN) on the use of IVIg in neurological diseases [146].

It is often difficult for the clinician to decide what therapy should be first used in CIDP. This decision should consider the efficacy, cost, and side effects of each of these therapies. A few randomized trial have shown a comparable short-term efficacy of IVIg and oral corticosteroids [147] and of IVIg and plasma exchange [148] in CIDP, and more recent trials have shown that both IVIg [149, 150] and steroids [151, 152] have prolonged efficacy in CIDP. A recently published randomized controlled trial comparing the 6-month efficacy of IVIg and intravenous methylprednisolone showed that IVIg was more frequently effective and tolerated than steroids during the first 6 months of treatment, although, when effective, steroids were less frequently associated with deterioration than IVIg after therapy discontinuation [153]. There were not significant differences in the proportion of patients experiencing adverse events even if slightly more adverse events were observed after steroids. It remains unclear whether these advantages are sufficient to balance the much higher cost of IVIg compared to steroids [154, 155]. Even if similarly effective to IVIg, plasma exchange is usually considered the third choice since it is more invasive for the patients and has an higher prevalence of side effects, mostly related to hemodynamic changes and vascular access, that make it less suitable for the long-term treatment of the patients [67].

Several anecdotal reports have shown the efficacy of other immune therapies that have been used to reduce the cost and frequency of IVIg and the side effects of steroids or to treat patients not responding or becoming resistant to these therapies [156]. None of the randomized controlled trials so far performed with these therapies confirmed however their efficacy which remains therefore unclear [157–160].A summary of the major treatment modalities in CIDP is here provided.

Corticosteroids

A prospective, randomized, placebo-controlled trial of prednisone demonstrated a small but significant improvement in patients who were treated with prednisone compared to those with no treatment [161]. The effects of prednisone are not immediate since the mean time for improvement and to reach a clinical plateau is often delayed by several weeks [14]. In the recent PREDICT study, the median time to disability improvement in patients treated with pulsed monthly oral dexamethasone was indeed 17 weeks (range 13–20) and with daily oral prednisolone 39 weeks (range 30–48 weeks) [151, 152]. In the same study, the median time to remission was 20 weeks (range 12–28) with pulsed dexamethasone and 39 weeks (range 30–48) with oral prednisolone. This finding of a long delay before the therapy is effective is, however, rarely expected by the treating physicians (and by the patients) who might early decide failure of the therapy since previous recommendations indicated that 8–12 weeks is needed before considering the therapy ineffective.

The standard initial dose of corticosteroids in CIDP is considered to be 60 mg/day of prednisolone, i.e., the dose that was shown to be effective in a randomized controlled trial [161]. In the recent PREDICT study, the pulse dose of oral dexamethasone of 160 mg/month, divided in 4 consecutive days, was used for 6 moth and was found to be similarly effective than the standard daily prednisolone dose [151]. Side effects were usually minor and comparable among the two groups even though sleeplessness and Cushing's face were less frequent in the dexamethasone group. A similar efficacy of pulsed steroid therapy in CIDP was reported in an

uncontrolled study on 10 patients treated for at least 22 months with pulsed oral methylprednisolone therapy [162], with 60 % of the patients entering an off-treatment remission. Pulsed intravenous methylprednisolone and oral steroids (and IVIg) were reported to be similarly effective over 6 months, with over 80 % of the patients responding to therapy but with less weight gain and cushingoid features in the methylprednisolone group [163]. In a recent study [153], intravenous methylprednisolone was given at the dose of 0.5 g/day for 4 consecutive days for 6 months and was effective in 48 % of the patients, none of whom relapsed within 6 months after therapy discontinuation. All these studies support the notion that steroids are similarly effective in CIDP when given either daily orally or by monthly oral or intravenous pulse, with the suggestion that the pulse doses may be better tolerated.

Steroids are usually well tolerated over the short term even if agitation and hyperglycemia may early occur. Most common side effects over the long term include hyperglycemia, hypertension, gastritis and gastrointestinal bleeding, osteoporosis, glaucoma, cataracts, poor wound healing, susceptibility to infection, weight gain, depression, psychosis, and insomnia.

Plasma Exchange

Many case reports, uncontrolled studies, and prospective, double-blind, sham-controlled studies have shown the efficacy of plasma exchange in some patients with CIDP [9, 164, 165]. The time to improvement is generally short, with one series demonstrating a response beginning 2 days to 3 weeks after initiating plasma exchange [166]. The duration of response varies, but two-thirds of responding patients were reported to require repeated exchange to maintain improvement since they relapsed after about 7–14 days [164, 165]. Thus, concomitant immunosuppressive therapy is often suggested even if its efficacy has still to be proved (see below). A course of about five treatments on consecutive or alternate days is commonly used to initiate treatment, but regimes vary and single exchanges every few weeks are sometimes used for long-term treatment. Plasma exchange was similarly effective as IVIg over 6 weeks in a small randomized controlled trial on 20 patients [148]. In a larger retrospective study on 105 patients, a similar proportion of patients responded to plasma exchange (23/33; 70 %) or IVIg (14/22; 64 %). More complications were, however, observed after PE (10) than after IVIg (0) [167]. A higher prevalence of side effects after plasma exchange (19 %) than after steroids (12.5 %) and IVIg (4 %) was also observed in a recent retrospective study on 267 patients with CIDP [143]. Plasma exchange is therefore effective as initial treatment since neurological disability improves rapidly. However, adverse events related to difficulty with venous access, use of citrate, and hemodynamic changes are not uncommon, and this together with the inconvenience related to the necessity of frequent hospital admissions for repeated exchanges makes it less suitable for the chronic treatment of CIDP patients [67].

Intravenous Immunoglobulin

A number of retrospective, uncontrolled, or nonrandomized studies have shown the efficacy of IVIg in some patients with CIDP when administered at a dosage of 2 g/kg divided over 3–5 consecutive days [8]. Controlled studies confirmed that IVIg is effective in over 60 % of patients [149, 168–171] and is equally effective as oral prednisolone [147] and plasma exchange [148] over the short period. Improvement usually begins in 3–8 days but may occur as early as 2 days, while some patients only improve after 6 weeks and a second course of IVIg [171, 172]. In the IMC trial [153], IVIg was more frequently effective or tolerated (87.5 %) than intravenous methylprednisolone (47.6 %) over 6 months. Almost 40 % of the patients treated with IVIg deteriorated, however, in the 6 months following therapy discontinuation compared to none of the patients treated with steroids. These data confirm that while a few patients may have a monophasic course with a sustained response, the duration of efficacy in many patients lasts a few weeks with a reported range of 3–22 weeks and a mean of 6 weeks [170–173]. In one series, several patients who did not improve had predominantly sensory deficits [170].

IVIg was also shown to be effective as long-term treatment of CIDP. Patients with relapsing courses continue to respond to intermittent infusions of IVIg for 4 years or longer [167, 173]. For patients who require regular IVIg infusions to prevent or treat relapses, the necessary dose and interval vary greatly, with one series reporting maintenance IVIg doses ranging from 0.025 g/kg every 10 days to 0.4 g/kg once every 2–4 days [148]. Another series reports that IVIg was regularly administered at the dose of 1 g/kg or less prior to the expected relapse, which occurred 3–22 weeks after prior IVIg therapy [165]. The long-term efficacy of IVIg was recently confirmed in the ICE study [149] that showed that this treatment was safe and effective for 24 and possibly 48 weeks. During the first 24 weeks, treatment with IVIg resulted in a significantly greater improvement in disability and impairment compared to placebo, while continuing treatment for the following 24 weeks was associated with a significantly lower proportion of relapses. Though the 48-week duration of the study is by far the longest randomized controlled study conducted in CIDP to date, it only partially resolves the issue of the long-term treatment of this disease whose course is measured in several years. In an ancillary study, the authors also reported that this treatment not only improved weakness and disability but also had a significant beneficial effect on health-related quality of life [150].

The possibility to reduce the cost and the inconvenience of repeated hospital admissions for chronic IVIg therapy in

CIDP (and MMN; see below) was recently addressed with the use of subcutaneous immunoglobulin (SCIg). Two patients with CIDP were reported to maintain the improvement achieved with IVIg assuming the same dose subcutaneously at home during the week [174]. These observations were recently confirmed in a randomized placebo-controlled study on 15 patients indicating that SCIg is safe and effective in CIDP and may improve the quality of life of the patients who do not need to suspend their daily activities to receive periodic infusions [175].

Therapy with IVIg is usually well tolerated, even if fever, flu-like syndrome, and headache are not so uncommon. Serious adverse effects are rare and can include thromboembolic events, renal failure (mainly in patients with preexisting renal failure), anaphylaxis (especially in patients with IgA deficiency), or aseptic meningitis.

Immunosuppressive or Immunomodulating Agents

The necessity for long-term periodic treatments with IVIg or PE, the serious adverse events frequently associated with the chronic use of steroids, and the not so uncommon development of resistance to these therapies have led to the use of immunosuppressive or immunomodulating agents in CIDP. These agents are widely used in CIDP even in the early stage of the disease. Several uncontrolled studies have reported the efficacy of these therapies in CIDP [156], even if none of the randomized controlled trials performed with any of these agents in CIDP confirmed their efficacy. The first randomized trial with azathioprine (2 mg/kg) or placebo in addition to oral prednisolone (120 mg on alternate day tapered to 0 mg) given for 9 months to 27 patients with CIDP did not show any difference between the two groups [157]. In this study, the dose and duration of treatment with azathioprine were, however, smaller and shorter compared to what were later found to be effective in a similar trial in patients with myasthenia gravis [176]. In addition, only the adjunctive effect of azathioprine was analyzed and not its capability to reduce the dosage of steroids. A second randomized study was performed with oral methotrexate in addition to IVIg or steroids [159]. This therapy was well tolerated but was not more effective than placebo in reducing the dose of steroids or IVIg used to maintain the improvement in 60 patients with CIDP. In particular, 52 % of the patients taking oral methotrexate, 15 mg weekly, and 44 % of those assuming placebo reduced by at least 20 % the associated initial dose of IVIg or steroids by the end of the 40 weeks of the study. Similar negative results were obtained in two trials with intramuscular interferon beta-1a (IM IFNβ-1a) on a total of 77 patients [158, 160]. In the larger study on 67 patients with CIDP under chronic IVIg therapy [160], treatment for 32 weeks with either 30 or 60 μg of IM IFNβ-1a once or twice weekly was not more effective than placebo in reducing the mean dose of IVIg with 47 % of the patients in both groups not needing to restart IVIg after their suspension after 16 weeks of therapy with IFNβ-1a. The subgroup of patients severely affected or taking high baseline dose of IVIg could, however, reduce more IVIg after IM IFNβ-1a than after placebo. Both the study with methotrexate and IM IFNβ-1a showed that a consistent proportion of patients with CIDP are probably overtreated with steroids or IVIg since more than 40 % of them could reduce or suspend the therapy without worsening.

Despite the negative results from these randomized studies, immunosuppressives are still widely considered a valid option in the treatment of CIDP patients. This derives from the results of a number of uncontrolled or retrospective trials on small series of patients showing an overall efficacy in up to 80 % of patients treated with cyclosporin (82 %), cyclophosphamide (75 %), rituximab (anti-CD20) (75 %), methotrexate (70 %), azathioprine (64 %), interferon alfa (64 %), alemtuzumab (57 %), mycophenolate mofetil (46 %), interferon beta-1a (35 %), etanercept (30 %), tacrolimus, and autologous hematopoietic stem cell transplantation (reviewed in [156]). These figures should be considered however at the light of the above-mentioned consistent proportion of patients not worsening after therapy discontinuation even when assuming placebo. In a more recent retrospective multicenter study on 110 patients with CIDP not adequately responsive to IVIg, steroids, or plasma exchange, the proportion of patients responding to these therapies ranged between 20 and 30 % with 10–20 % of treated patients having adverse events related to the use of these therapies [177]. In a session on the use of immunosuppressive agent in CIDP at the Congress of the Peripheral Nerve Society hold in Wurzburg in 2009, the vast majority of the experts supported the used or oral azathioprine at the above-mentioned dose in patients with mild to moderate CIDP and of cyclophosphamide in severely affected patients. Cyclophosphamide was reported to be effective when given intravenously (1 g/m^2 of body surface area monthly for 6 months) in 75 % of patients unresponsive to standard treatment [178]. Higher dose of intravenous cyclophosphamide (200 mg/kg over 4 days without stem cell rescue) was also reported [179, 180]. Oral cyclosporine was also effective in inducing remission or reducing other therapies in CIDP patients when used at the dose of 3–5 mg/kg divided into two daily doses [181]. In recent studies, however, 50 % of treated patients had adverse events mainly related to renal dysfunction that we observed even using lower dosage of cyclosporin (2–3 m/kg/day) after a few months [177].

A Personal Approach to Treatment of the Patient with CIDP

Patients with mild sensory deficits and no weakness may be observed without treatment for days to weeks, since

spontaneous improvement may occur [67]. In those who do not improve, continue to worsen, or have motor as well as sensory deficits at presentation or are disturbed by their sensory symptoms, treatment with oral or intravenous steroids or IVIg should be first considered after discussing with the patients the pro and cons of each treatment. Contraindications to corticosteroids will influence the choice toward IVIg and vice versa. For pure motor CIDP, IVIg treatment should be the first choice, and if corticosteroids are used, patients should be monitored closely for deterioration. Steroids may become the preferred choice for economical problems related to either health insurance or national economy. Patients not responding to IVIg or steroids should be shifted to the other therapy considering that 50 % of patients not responding to one treatment respond to the alternative therapy [143]. We should, however, remember that steroids may become effective after several weeks and that over 50 % of the patients responsive to IVIg do so after the second course of IVIg [172]. We prefer to use plasma exchange in patients not responsive to the other two therapies.

For IVIg, we start at the dose of 2 g/kg body weight over 3–5 consecutive days. The onset of action is rapid, and the side effect profile is rather benign. In a few patients, the effects of IVIg are sustained, and the disease course is monophasic, eliminating the need for additional treatment. If improvement occurs but is unsustained, IVIg is then given periodically at the dose of 1 g/kg at a frequency sufficient to prevent the wear-off effect of the therapy. The dosage of IVIg is subsequently slowly reduced to achieve the minimal effective dose. The use of subcutaneous immunoglobulin has become a valid alternative for chronic therapy with immunoglobulins when given at the same monthly effective dosage for IVIg.

For steroids, we now prefer to use monthly course of intravenous methylprednisolone at the starting dose of 0.5 g for 4 consecutive days. Pulsed oral dexamethasone (40 mg for 4 days) is a valid alternative. This pulsed regimen can be also performed in patients with diabetes or glucose intolerance in whom we prefer to admit patients to better monitor and adjust glucose levels with insulin. Daily oral steroids can be also used at the standard daily dosage of 60 mg/day of prednisone or prednisolone even it may have more frequent adverse events than pulsed therapy. Patients should be educated regarding the side effects of steroids and instructed in the use of supplemental calcium and vitamin D, on gastroprotection, and on the need for monitoring of blood pressure, glucose, and electrolytes. After 2–3 months, the dose of pulsed steroid can be reduced and eventually suspended after 6 months closely monitoring the possible worsening of the patients in which case the effective therapy is resumed. Daily oral steroids are often initially shifted after 6–8 weeks to an alternate day regimen that is assumed to be better tolerated than the daily regimen and subsequently reduced and suspended over 1–2 years.

In patients who are nonresponsive or having contraindications to IVIg and steroids, we perform plasma exchange (usually 4–5 courses of one plasma volume on alternate days). The onset of action generally is rapid. If the effect is sustained, no further treatment is required. If improvement occurs but the patient relapses, plasma exchange may be repeated and progressively tapered possibly at the frequency of 1 course every 1–2 months.

Due to lack of consistent evidence supporting the use of immunosuppressive agents, we reserve them to patients who remain disabled despite the above-mentioned therapies or who have failed to respond to all of them, while we do not use them just to save on their cost. In these patients, we use intravenous cyclophosphamide at the monthly dose of 1 g/m^2 for 6 months.

Neuropathy Associated with IgM Monoclonal Gammopathy and Anti-MAG Antibodies

Introduction

In 1980 Latov et al. [182] first reported on a patient with neuropathy associated with IgM monoclonal gammopathy in whom the paraprotein reacted with a myelin antigen that was later characterized as the myelin-associated glycoprotein (MAG) [183]. MAG is a minor constituent of both central and peripheral nervous system myelin membranes that is deemed to have an important role on axonal–myelin interactions [184]. Since then several other laboratories reported this reactivity that is present in almost 50 % of patients with neuropathy associated with IgM monoclonal gammopathy [123, 185]. In these patients, the paraprotein also reacts with other nerve glycoconjugates (P0, PMP-22, SGPG, and SGLPG) sharing with MAG the HNK-1 carbohydrate epitope [186–189]. Even if this is considered a rare neuropathy, its prevalence has been estimated to be of at least 20–40 per 100,000 in the population above 50 years [190].

Clinical Features

High titers of anti-MAG IgM antibodies are almost invariably associated with a homogeneous clinical pattern with a DADS neuropathy phenotype [190]. The majority of affected patients are men presenting their first neuropathy symptoms in the sixth or seventh decade. Almost 80 % of them have IgM MGUS, while most remaining patients have Waldesntröm's macroglobulinemia that is frequently indolent [191]. Most patients present with sensory symptoms in legs including paresthesias, hypesthesias, dysesthesias, cramps, or other pains and unsteadiness of gait. Weakness is frequently absent at onset. An intentional and postural tremor in the upper limbs is often reported

and is sometimes quite disabling. In some patients, it can be the presenting symptom [192]. On neurological examination, the neuropathy is characterized by a distal and symmetric, predominantly large fiber sensory involvement, gait ataxia, and postural tremor in the upper limbs, while motor impairment is usually less prominent and often appears later.

The vast majority of patients with anti-MAG antibodies have a relatively favorable long-term prognosis. Approximately 25 % of the patients were reported to become at least moderately disabled (Rankin disability score higher that 2) after 10 years and 50 % after 15 years [193]. This was recently confirmed in a series of 140 patients with neuropathy associated with IgM monoclonal gammopathy [194], 44 % of whom had anti-MAG IgM. In these patients, the presence of anti-MAG antibodies reduced the probability of becoming disabled (approximately 50 % after 18 years in the MAG-positive group compared to 13 years in the MAG-negative group). Unfortunately, the possible effect on the prognosis of the therapies performed during the follow-up was not assessed.

Diagnosis

Anti-MAG IgM antibodies are currently examined in serum by western blot [123] or ELISA [195]. For both systems, it is, however, necessary to establish a normal range since low titers (usually 1/3,200 or less) can be encountered in some normal subjects. It was recently shown that a commercially available ELISA system was more sensitive but less specific than the western blot. This system has, however, the advantage to avoid the cumbersome procedure required for myelin isolation and western blot assay [195].

Electrodiagnostic studies in patients with anti-MAG antibodies are consistent with a demyelinating neuropathy with markedly reduced motor and sensory conduction velocities often in the range of 15–25 m/s [123, 196] and an even more pronounced delay of distal motor latencies [197, 198]. Conduction blocks are rarely observed in these patients facilitating the distinction from CIDP [199]. The severity of EDX abnormalities is often discrepant with the relatively mild clinical impairment of the patients and may induce the unexperienced clinician to formulate an unappropriately severe prognosis.

Morphological studies on sural nerve biopsy are consistent with a demyelinating neuropathy with reduced number of myelinated fibers, demyelination and remyelination on teased fibers, and, in over 90 % of examined patients, typical widely spaced myelin lamellae on ultrastructural studies [200]. In most patients deposits of IgM and complement around the myelin sheaths are found on immunohistochemical studies [201, 202]. Recent studies have shown that these deposits may be also found on myelinated nerve fibers obtained by skin biopsy [203]. Sural nerve biopsy is, however, unnecessary to confirm the diagnosis in patients with a clinically typical presentation and elevated antibody titers.

Pathogenesis

Several data support the pathogenetic role of anti-MAG IgM in the neuropathy [185, 190]: (1) high titers of anti-MAG IgM antibodies are almost invariably associated with an homogeneous clinical pattern or predict the development of a symptomatic neuropathy in asymptomatic patients with IgM monoclonal gammopathy [204]; (2) pathological studies on nerve biopsies show segmental demyelination with deposits of IgM M-protein and complement on nerve myelin, i.e., the target of the anti-neural reactivity, and loss of MAG in nerve biopsy correlates with antibody titers [205]; (3) complement-mediated demyelination of nerve has been experimentally induced in animals by intraneural or systemic injection of anti-MAG IgM M-proteins [206–209]; (4) more recently, immunization of cats with the cross-reacting glycolipid SGPG was shown to cause a sensory ataxic neuronopathy [210]; and (5) therapeutical reduction of anti-MAG IgM, though difficult to achieve, often correlates with clinical improvement (see below).

Therapy

The importance of the diagnosis of a demyelinating neuropathy associated with IgM monoclonal anti-MAG antibodies is highlighted by the fact that in these patients response to therapy is different from that observed in CIDP. Clinical improvement in patients with anti-MAG IgM most often correlates with the reduction of antibody titers even if this may be difficult to achieve [193]. Almost 50 % of reported patients improved, at least temporarily, after one of more immune therapies including steroids, plasma exchange, a number of cytotoxic agents, and, more recently, high-dose intravenous immunoglobulin, fludarabine, cladribine, interferon-α, and the anti-B lymphocyte (CD20) humanized monoclonal antibody rituximab [211]. The efficacy of these therapies has not been so far confirmed in randomized controlled trials, most of whom showed at the most a marginal effect [70]. More recently a number of open pilot trials have suggested the efficacy of the humanized monoclonal antibody rituximab directed against the CD20 antigen, in patients with anti-MAG IgM neuropathy [212–215]. The efficacy of rituximab in anti-MAG neuropathy was recently assessed in two randomized controlled trials, 1 on 26 patients [216] and the other on 54 patients [217]. Even if neither trials met the prespecified primary outcome measures, both studies showed a 20–30 % absolute improvement in the number of patients

improving in the disability scale in patients treated with rituximab compared to placebo, a figure which is higher than observed with approved immune therapies in other immune diseases such as multiple sclerosis. In responding patients the benefit was reported to last up to 2 years in 80 % of the patients and 3 years in 60 % of them [218]. This aspect is important for the long-term management of the patients and should be balanced with the side effects of this therapy including the possible development of progressive multifocal leukoencephalopathy [219].

We think that until therapies with a better efficacy/safety profile become available, symptomatic therapy for tremor and paresthesias and reassurance on the usually favorable functional prognosis for several years may be sufficient in patients not impaired in their daily life, while rituximab should be considered for patients worsening or impaired in their daily life [70]. The recent observations on the possible efficacy of the association of rituximab with other therapy used in WM such as fludarabine need to be confirmed in larger population and possibly in RCT [220].

Multifocal Motor Neuropathy

Introduction

The term multifocal motor neuropathy (MMN) was first introduced in the literature in 1988 by Pestronk et al. [221] who reported two patients with a progressive purely motor, predominantly distal, asymmetric neuropathy with multifocal persistent conduction blocks (CB) on motor but not sensory nerves. A few similar patients had been reported some years before [222–224], but Pestronk et al. highlighted two of the main features of this neuropathy, i.e., its frequent association with anti-GM1 IgM antibodies and response to immune therapies. Between 1992 and 1993, a number of authors independently reported the effectiveness of IVIg in MMN, which is now considered the gold standard for the treatment of this neuropathy [225, 226]. Even if MMN was originally variably related to CIDP or to motor neuron disease (MND), it is now considered a well-defined separate clinical entity [227, 228].

Prevalence

The prevalence of MMN has been originally estimated to be of 1–2 person per 100,000 [227] and was recently shown to be 0.6 per 100,000 inhabitants in the Dutch population [229]. Men are more frequently affected than women with a ratio of 2.6–2.7:1. The mean age of onset is around 40 years with 80 % of reported patients presenting their first symptoms between 20 and 50 years [227]. Onset in childhood has been occasionally reported.

Clinical Features

MMN almost invariably presents with progressive, usually distal, asymmetric arm weakness which can be often related to the distribution of individual nerves [227, 228]. Weakness remains occasionally confined to the territory of a single nerve for several years [230]. Some patients may present with more proximal weakness or with symptoms in their legs. The disease usually steadily progresses to affect other nerves sometime with a typical initial crossed distribution (one arm and contralateral leg). It is not so infrequent however that the disease has a stepwise progression with an interval of months or even years before spreading to other nerves with sometime a partial spontaneous remission of initial deficit [222, 231]. Asymmetry and predominance of arm weakness may become less evident during the course of the disease even if they are usually still present even after several years of disease. Localized muscle atrophy may be mild or irrelevant in the early stage of the disease but may become prominent during the course of the disease when it is usually associated with the development of signs of axonal degeneration. Fasciculations, cramps, and myokymia have been variably reported in these patients making the similarity of MMN with MND even more evident. Their clinical distinction may become even more difficult in the 20–30 % of patients in whom tendon reflexes, which are often reduced in a patchy way or diffusely, are normal or even brisk [221, 229, 232]. In these patients a marked asymmetry in the degree of clinical impairment and EDX abnormalities between contiguous nerves may orient the examiner toward a diagnosis of purely motor multiple neuropathy. Cranial nerve involvement or respiratory failure due to unilateral or bilateral phrenic nerve palsy may seldom occur in these patients. Even if some patients may report mild sensory symptoms sometime in the course of the disease, only a minority of them have a definite though minor sensory loss. It is still unsettled, however, the degree that sensory impairment should attain for a diagnosis of Lewis–Sumner syndrome instead of that of MMN. Based on the list of the above-mentioned symptoms and signs, it is not surprising that early and even recent reports [229] of MMN highlighted its similarity with MND, a diagnosis that, together with entrapment neuropathy, is not so infrequent for MMN patients to receive before they are correctly diagnosed.

Most patients with MMN carry an overall good prognosis *quoad vitam*, with only few of them having a fatal outcome after several years of disease. Still the majority of patients become somehow disabled in their daily life because of a reduced dexterity in manual activities, while very few of them become disabled in their deambulation. In our series, the proportion of patients with a disability score above 2 on the Rankin scale before starting effective therapy was 12 % at 5 years, 25 % at 10 years, and 60 % at

Table 29.4 EFNS/PNS (2010) clinical diagnostic criteria for MMN [235]

Core criteria (both must be present)
1. Slowly progressive or stepwise progressive, asymmetric limb weakness, or motor involvement having a motor nerve distribution in at least two nerves, for more than 1 month[a]
2. No objective sensory abnormalities except for minor vibration sense abnormalities in the lower limbs
Supportive clinical criteria
3. Predominant upper-limb involvement[b]
4. Decreased or absent tendon reflexes in the affected limb[c]
5. Absence of cranial nerve involvement[d]
6. Cramps and fasciculations in the affected limb
Exclusion criteria
7. Upper motor neuron signs
8. Marked bulbar involvement
9. Sensory impairment more marked than minor vibration loss in the lower limbs
10. Diffuse symmetric weakness during the initial weeks

[a]Usually more than 6 months
[b]At onset, predominant lower limb involvement account for nearly 10 % of the cases
[c]Slightly increased tendon reflexes, in particular, in the affected arm have been reported and do not exclude the diagnosis of MMN provided criterion 7 is met
[d]Twelfth nerve palsy reported

Table 29.5 EFNS/PNS (2010) electrophysiological criteria for conduction block in MMN[a] [235]

1. Definite motor CB
Negative CMAP area reduction on proximal versus distal stimulation of at least 50 % regardless of the nerve segment length (median, ulnar, and peroneal). The negative CMAP amplitude (baseline negative peak) on stimulation of the distal part of the segment with motor CB must be >20 % of the lower limit of normal and >1 mV and an increase of proximal negative peak CMAP duration must be ≤30 %
2. Probable motor CB
Negative CMAP area reduction of at least 30 % over a long segment of an upper-limb nerve with an increase of proximal negative peak CMAP duration ≤30 %
Negative CMAP area reduction of at least 50 % (same as definite) with an increase of proximal negative peak CMAP duration >30 %
3. Normal sensory nerve conduction in upper-limb segments with CB and normal SNAP amplitudes (see exclusion criteria)

[a]Evidence for conduction block must be found at sites distinct from common entrapment or compression syndromes

15 years, although most of them could still walk independently [233].

Diagnostic criteria for MMN have been proposed by several groups including the American Association of Neuromuscular and Electrodiagnostic Medicine (AANEM) [234] and more recently the Joint Task Force of the EFNS/PNS (Tables 29.4, 29.5, and 29.6) [235].

Table 29.6 EFNS/PNS (2010) diagnostic categories for MMN [235]

Definite MMN
Clinical criteria 1, 2, and 8–11 (Table 29.4) and electrophysiological criteria 1 and 3 in one nerve (Table 29.5)
Probable MMN
Clinical criteria 1, 2, and 8–11 (Table 29.4) and electrophysiological criteria 2 and 3 in two nerves
Clinical criteria 1, 2, and 8–11 (Table 29.4), electrophysiological criteria 2 and 3 in one nerve (Table 29.5), and at least two supportive criteria[a] 1–4
Possible MMN
Clinical criteria 1, 2, and 8–11 (Table 29.4) and normal sensory nerve conduction studies and supportive criteria 4
Clinical criteria 1 with clinical signs present in only one nerve, 2 and 8–11 (Table 29.4) and electrophysiological criteria 1 or 2 and 3 in one nerve (Table 29.5)

[a]*Supportive criteria for MMN*
1. Elevated IgM anti-ganglioside GM1 antibodies
2. Laboratory: increased CSF protein (but <1 g/l)
3. Magnetic resonance imaging showing increased signal intensity on T2-weighted imaging associated with a diffuse nerve swelling of the brachial plexuses
4. Objective clinical improvement following IVIg treatment

Differential Diagnosis

MMN should be clinically differentiated from MND, from which it can be distinguished by its weakness that follows multiple nerves distribution (and not simply asymmetric pattern of motor impairment), absence of bulbar involvement, and slower progression. The absence of a concomitant sensory impairment helps to distinguish MMN from entrapment neuropathies, vasculitic neuropathy or hereditary neuropathy with liability to pressure palsy (HNPP). More subtle is the distinction from Lewis–Sumner syndrome, which mainly relies on the absence in MMN of definite sensory impairment although this distinction may be difficult in patients with minor sensory symptoms (Table 29.7). Another diagnosis to be considered is pure motor CIDP where weakness is often symmetrical and proximal and the course is often relapsing with a more severe progression of symptoms.

Electrodiagnostic Features

The diagnosis of MMN mainly relies on the presence of persistent, multifocal, partial conduction blocks (CB) in motor nerves outside the usual sites of nerve compression. CB has been defined as a reduction in the amplitude or area of the compound muscle action potential (CMAP) on proximal compared to distal stimulation, accompanied by no significant or only focal abnormal temporal dispersion (TD) [236]. Unfortunately, no uniformly accepted criteria exists for CB

Table 29.7 Comparison of three different acquired demyelinating polyneuropathies: chronic inflammatory demyelinating polyneuropathy (CIDP), Lewis–Sumner syndrome, and multifocal motor neuropathy (MMN)

Feature	CIDP	Lewis–Sumner syndrome	MMN
Age at onset	Adults of all ages, children rarely	Adults of all ages	Adults of all ages
Sex	Slight male predominance	Males more common	Males more common
Duration of illness at presentation	Varies widely – days to years. Usually months	Usually years	Usually years
Weakness	Symmetric	Asymmetric, in the distribution of peripheral nerves UE>LE	Asymmetric, in the distribution of peripheral nerves UE>LE Distal>proximal
Sensory impairment	Symmetric	Asymmetric, in the distribution of sensory nerves	Minimal or none
Reflexes	Generally absent	Focally decreased or absent	Focally decreased or absent
Sensory nerve conduction studies	Usually abnormal	Usually abnormal	Normal
Motor nerve conduction studies	Acquired demyelination: conduction block, abnormal temporal dispersion, slowed conduction velocities, prolonged distal latencies, prolonged F-wave latencies	Acquired demyelination: conduction block, abnormal temporal dispersion. Other focal, and usually mild, abnormalities including slowed conduction velocities, prolonged distal latencies, prolonged F-wave latencies	Acquired demyelination: conduction block, abnormal temporal dispersion. Other focal and, usually mild, abnormalities including slowed conduction velocities, prolonged distal latencies, prolonged F-wave latencies
Anti-GM1 antibodies	May be present, usually not at high titers	Usually absent	High titers in about half
CSF protein	Usually elevated	Usually elevated	Usually normal. May be elevated to <100 mg/dl
Sensory nerve biopsy	Demyelination, axonal degeneration, mononuclear inflammation, endoneurial edema	Demyelination	Normal or minor abnormalities
Usual treatment	Prednisone, IVIg, plasma exchange	Prednisone, IVIg	IVIg
Course	Relapsing, monophasic, or progressive	Progressive until treated	Progressive or stepwise until treated

UE upper extremities, *LE* lower extremities, *IVIg* intravenous immunoglobulin

identification, as the reduction of CMAP amplitude or area required to be significant for CB varies considerably among different authors. Consensus criteria for the diagnosis of CB have been proposed by the AANEM [234] and by the EFNS/PNS (see Table 29.5) [235]. If the application of these criteria is useful for the inclusion of patients in therapeutic trials, it may risk to underestimate the presence of CB in the early phases of the disease and possibly delay the diagnosis of a potentially treatable disease. One of our patients initially presented with a 24 % reduction of proximal versus distal CMAP amplitude without temporal dispersion in the right ulnar and median nerves which, 2 years later, as the patient became more severely affected, increased to 70 and 88 %, respectively [237]. In addition, there are patients in whom typical CB may decrease or even disappear in some nerves after several years of the disease because of a progressive reduction of the distal CMAP amplitude, which may reflect either secondary axonal degeneration or the appearance of unrecognized very distal CB. CB is not specific for MMN (and Lewis–Sumner syndrome), as it can also be found in CIDP and Guillain–Barré syndrome (GBS), where it is associated with other abnormalities suggestive of demyelination; in acute compressive neuropathy or nerve entrapment, in which CB is found at the usual sites of nerve compression or entrapment; and in nerve ischemia, in which it rapidly evolves into axonal degeneration.

In some nerves, CB can be diagnosed, even if it does not attain the above-mentioned level, by stimulation at several sites as close as 2–2.5 cm apart ("inching" technique) [238, 239]. Magnetic or transcutaneous cervical stimulation may help in the localization of proximal CB in patients suspected of having MMN [240, 241]. This was more evident using the magnetic fatigue test that allowed to reveal increased CB or temporal dispersion after prolonged exercise [242]. More recently, a novel triple stimulation technique was reported to be more sensitive in detecting CB by revealing the presence of CBs proximal to Erb's point not detectable by routine nerve conduction studies [243]. The presence of CB distal to the most distal site of stimulation is suggested by a low-amplitude CMAP recorded by a weak, but not wasted, muscle [244].

Nerve conduction velocity across the regions with CB is usually reduced although it may be normal or only slightly reduced. Other, usually mild, features of demyelination, including prolonged distal CMAP latencies and prolonged or absent F-waves may be also found in affected nerves. Sensory nerve conduction studies are usually normal or only minimally affected in MMN, even in the nerves where motor CB has been detected. A possible concomitant proximal sensory impairment has been revealed in some patients with MMN by somatosensory evoked potentials [245]. More recently, a few studies have shown that 30–60 % of MMN patients develop some degree of electrophysiological sensory impairment in the course of the disease even if most of them remained clinically asymptomatic [246–248].

Laboratory Findings

Routine hematological and biochemical laboratory findings are usually normal in MMN apart from slightly to moderately increased serum creatine kinase activity, observed in up to two-thirds of patients [249]. Cerebrospinal fluid (CSF) examination shows slightly increased protein levels (usually up to 80 mg/dl) in one-third of MMN patients, with normal CSF findings in the others, including absence of oligoclonal bands [227, 248]. This finding may help in the distinction with CIDP where CSF proteins are often markedly increased. Serum protein electrophoresis may occasionally reveal the presence of a monoclonal or polyclonal gammopathy, mostly of IgM isotype.

The most typical laboratory findings in MMN are the presence of increased levels of serum IgM antibodies to the ganglioside GM1 and, to lesser extent, to other glycolipids including asialo-GM1, GD1a, or GM2, with frequency in most laboratories of 40–50 % [250]. These antibodies have been rarely reported in other immune neuropathies and in approximately 5–10 % of patients with MND. Attempts to identify differences in the fine specificity of the antibodies associated with these different diseases or to improve the sensitivity or specificity of anti-GM1 testing in MMN did not produce consistent results. This has led to some divergences on the interpretation of the diagnostic relevance of anti-GM1 IgM in the diagnosis of MMN [251]. Elevated antibodies were included as supportive criteria by the EFNS/PNS [235] (see Table 29.6) but not by the AANEM [234]. A few large studies indicated, however, that their presence may help in distinguishing MMN from MND even if their absence does not permit to exclude MMN [252–256]. Several attempts have been performed to improve the sensitivity of anti-GM1 antibodies in MMN using more sophisticated techniques [257] or testing GM1 in addition to other glycolipids [258]. The combination of GM1 with cholesterol and galactocerebroside increased indeed the sensitivity of GM1 testing in MMN of approximately 20 % with a marginal reduction of the specificity and positive predictive value for MMN [259]. More recently increased titers of IgM antibodies to a disulfated heparin disaccharide (NS6S) were also reported to increase the sensitivity with MN [260], but this was associated, in our hands, with a reduced specificity and positive predictive value for MMN [261]. In conclusion, testing for anti-GM1 and related antibodies may help in the diagnosis in patients in whom this cannot be established after comprehensive clinical and EDX evaluations, even though the absence of these antibodies does not exclude the diagnosis of MMN.

Magnetic resonance (MR) imaging studies of the forearm or brachial plexus may show in some patients an asymmetrically increased signal intensity in T2-weighted images or in T1-weighted images after gadolinium enhancement associated with diffuse nerve swelling of the brachial plexus [262]. Similarly promising results were observed with ultrasonographic study of the nerves [263].

Nerve biopsy is seldom useful in the diagnosis of MMN because it is routinely performed on the sural or other sensory nerves, which typically are clinically and electrophysiologically normal in MMN. In these patients, pathological studies on sural nerve were either normal or showed mild axonal degeneration or demyelination or both [227]. Mild pathological abnormalities consistent with a demyelinating process were however reported on ultrastructural studies [264]. Motor or mixed nerve biopsy adjacent to the site of CB revealed in two patients demyelination with onion bulbs without inflammatory infiltrates [265, 266]. These pathological findings were not subsequently confirmed in seven patients with typical MMM in whom fascicular nerve biopsy at the site of CB only disclosed multifocal fiber degeneration and loss and clusters of regenerating fibers without obvious sign of demyelination [267]. More recently, biopsy of motor nerves was shown to be helpful in the distinction of MMN from MND showing in the former a significantly higher density of clusters of regenerative small myelinated fibers compared to MND [268, 269].

Pathogenesis

The frequent association of MMN with anti-glycolipid antibodies and the improvement observed in most patients after IVIg or other immune therapies (see below) support the opinion that the disease is immunologically mediated and possibly caused by anti-GM1 IgM binding to neural structures (reviewed in [250]). There are, however, some aspects that still need to be clarified. Even if anti-GM1 IgM antibodies are significantly associated with MMN, their absence in the majority of patients makes it unclear what would cause the disease in negative patients, most of whom respond to immune therapies similarly to GM1-positive patients. The presence of anti-GM1 IgM in some patients with MND or

other immune neuropathies makes it unclear how similar antibodies cause different diseases. Similarly inconclusive are the results of experimental studies directed at testing the capacity of these antibodies to cause CB. Intraneural injection or exposure to sera from patients with high anti-GM1 antibodies and MMN but not with MND was able to induce focal CB in vivo or in vitro [270–272] even if the same results were not confirmed using purified anti-GM1 antibodies [273]. In addition, a similar blocking effect on mouse distal motor nerve conduction was induced in vitro by sera from MMN patients with and without high anti-GM1 antibodies [274]. These findings suggest that sera from patients with MMN contain indeed soluble factors able to affect the neural transmission even if the role of anti-GM1 antibody in this blocking effect remains unclear.

Therapy

Almost 80 % of patients with MMN respond to IVIg [225], whose efficacy has been confirmed in four randomized, double-blind, placebo-controlled trials on a total of 34 patients [275–278] and in a yet unpublished trial [279]. IVIg induces a rapid improvement which often occurs within 1 week of treatment and is usually more evident in recently affected regions with minor or no effect on older and stabilized deficits. Only a few patients have persistent improvement after a single or few courses of therapy, while in most patients the effect of IVIg only lasts for a few weeks and has to be maintained with periodic IVIg infusions for long periods of time, if not indefinitely [229, 233, 280–283]. IVIg therapy in MMN is usually started at the standard dose of 2 g/kg on 2–5 consecutive days followed by maintenance infusions ranging from 0.4 g/kg once a week to 1–2 g/kg every 2–5 weeks. Maintenance therapy may be also performed at home with subcutaneous immunoglobulin (SCIg) whose efficacy as maintenance treatment has been confirmed in two small randomized controlled trials [284, 285]. The long-term efficacy and adverse events of this therapy related to the repeated local injections still need to be clarified. Over time, several patients become progressively less responsive to IVIg and require increasing dosage (in case of insufficient response) or frequency (in case of reduced duration of the response) of IVIg to maintain improvement [233, 281].

A minority of patients with MMN do not respond or become resistant to IVIg, while in others IVIg infusions may be challenging to implement because of their elevated cost. Steroids are, however, ineffective in MMN, even when given at high-dose intravenously, and almost 20 % of treated patients were reported to worsen under this therapy [102]. Similarly ineffective is plasma exchange [286], and it can be also associated with clinical worsening [287]. This highlights the importance of the distinction of MMN from CIDP and Lewis–Sumner syndrome where steroids and plasma exchange are often effective. Cyclophosphamide given intravenously at high doses followed by oral doses was found effective in approximately 50 % of the patients [221, 288]. This drug has, however, several side effects and may be unsuitable for a nonfatal disorders and for young patients. Occasional patients were reported to improve or stabilize with azathioprine [232], while interferon beta-1a (IFN-β1a) was found effective in some patients with MMN, some of whom had failed to respond to other therapies including IVIg [289, 290]. The only randomized double-blind controlled trial with immunosuppressant in MMN showed, that mycophenolate mofetil did not permit to increase the effectiveness or to reduce the dose of IVIg [291]. More recent open trials showed that oral methotrexate [292] and eculizumab [293] were marginally effective in some patients but did not permit to consistently reduce the dose of IVIg therapy. A positive effect was initially reported with rituximab [212], but subsequent studies inconsistently confirmed these results [294, 295]. A recent Cochrane Review concluded that at the present time there is little evidence to support the use of any immunosuppressant in MMN [296] and confirmed that at the present time IVIg remains the gold standard for the treatment of MMN [235].

MMN Without CB and Axonal MMN

It is still debated whether the presence of CB is a mandatory criteria for the diagnosis of MMN for patients with otherwise typical clinical presentation. Some patients have lesser degree of amplitude reduction than required by the current diagnostic criteria [297, 298], while others neither have CB nor other features of demyelination [299, 300] leading to the diagnosis of axonal MMN [301]. Some of these patients have anti-GM1 antibodies and improve with IVIg similarly to patients with CB, while pathological evidence of immune-mediated axonal damages was observed in one patient [302]. Though the presence of CB should be considered crucial for the diagnosis of MMN, a course of IVIg therapy might be considered for patients with otherwise clinically typical MMN. A positive response to IVIg in these patients would support the diagnosis of MMN, as also indicated by the EFNS/PNS criteria [235] where a diagnosis of possible MMN can be posed under these conditions.

Dysproteinemic Neuropathies

30

Elham Bayat and John J. Kelly

Epidemiology and Pathogenesis

Approximately 10 % of patients with idiopathic peripheral neuropathy have an associated monoclonal gammopathy [1]. The frequency of monoclonal gammopathy in general population is around 2 % in those aged 50–70 years and 3 % in individuals older than 70 years [2, 3]. Most of these patients have monoclonal gammopathies of undetermined significance (MGUS) (Tables 30.1 and 30.2) with a risk of progression to malignant gammopathy of 1 % per year [5]. About half of MGUS neuropathies are associated with an IgM gammopathy [4, 6], and of these, about half have antibody activity against myelin-associated glycoprotein (MAG) [7]. MAG antibody neuropathy has an estimated prevalence of 1–5 per 100,000 adults [6]. The other half of the MGUS group is associated with IgG or IgA gammopathies, which are a much more diverse group in antibody activity [1]. The prevalence of peripheral neuropathy in multiple myeloma (MM) is low with 3–5 % of patients having neuropathy [8, 9], but subclinical neuropathy may be detected by nerve conduction study or histopathological evaluation in up to 60 % of patients [10–12]. In this category, osteosclerotic myeloma has the highest incidence of polyneuropathy reported at 50–80 % of patients [13, 14].

Peripheral neuropathy is the most common neurological manifestation in primary amyloidosis (AL) with sensory motor neuropathies present in 15 % of AL patients [15, 16]. Peripheral neuropathy is the presenting sign of systemic amyloidosis or multiple myeloma in about 15 % of patients [16–18] and may be the cardinal manifestation.

Plasma cell dyscrasias (paraproteinemias or dysproteinemias) (Table 30.1) are a group of disorders characterized by the proliferation of a single clone of plasma cells, which produces an immunologically homogeneous protein commonly referred to as a paraprotein or monoclonal protein (M protein) [4, 19]. The M protein (monoclonal immunoglobulin) can be an intact immunoglobulin (containing two light (L) chains and two heavy (H) chains). Occasionally, only the

Table 30.1 Classification of common plasma cell dyscrasias

Disorder	Diagnostic criteria
Monoclonal gammopathy of undetermined significance	MP in serum < 3 g/dl and no malignancy or amyloid
Osteosclerotic myeloma	Solitary or multiple plasmacytomas
Multiple myeloma	>10 % abnormal plasma cells in bone marrow or plasmacytoma and MP in serum or urine or osteolytic lesions
Waldenström's macroglobulinemia	IgM-MP >3 g/dl, >10 % lymphs or plasma cells in bone marrow
Primary systemic amyloidosis	Light-chain amyloid by histology
Gamma-heavy-chain disease	Monoclonal heavy chain in serum or urine

light chain or heavy chain may be secreted (light- or heavy-chain disease). M proteins are identified by the heavy-chain class (IgM, IgG, IgA, IgD, and IgE) that is produced. The light chains may be either kappa (k) or lambda (L).

Serum protein electrophoresis (SPEP) [4, 19] is the preferred method to screen M proteins [20, 21]. Among patients where a spike is identified by the SPEP and among all patients who are suspected to have a monoclonal gammopathy, such as idiopathic polyneuropathy, immunoelectrophoresis (IEP) or immunofixation (IFE) should be performed, even with a normal SPEP [19]. IEP and IFE are more sensitive than SPEP for detection of a small M protein and allow characterization of the single heavy and light chain, thus verifying the monoclonal nature of the immunoglobulin. Of the two, IFE is more sensitive and will detect M proteins occasionally when IEP and SPEP are negative. Urine should also be examined since monoclonal light chains (Bence-Jones proteins) may appear in urine when the serum is normal. Presence of a light chain in urine suggests either a malignant PCD or light-chain amyloidosis (AL). Measurement of serum free light chains (FLC) was introduced into clinical practice in 2002 [22]. The presence of abnormal kappa/lambda ratio indicates the presence of PCD. In such situations, a 24-h urine for protein electrophoresis and IFE are indicated to detect and quantify the M protein in the urine [20].

After identification and characterization of the M protein in serum or urine, further hematologic evaluation should be done to classify the PCD (Table 30.1) [4, 19]. If a diagnosis of MGUS is made, M-protein levels should be monitored on a yearly basis since a sudden increase may indicate malignant transformation of a benign plasma cell dyscrasia, which occurs in up to 20 % of patients.

Polyneuropathy Syndromes

MGUS-Associated Neuropathies

MGUS is the most common PCD and detectable in 0.1 % of the normal population by the third decade [21, 23], and the frequency increases with age to 3 % by the eighth decade [23]. MGUS may be a contributing factor to neuropathy pathogenesis in 5 % of all neuropathies and 10 % of idiopathic neuropathies (Table 30.3) [1]. MGUS-associated neuropathies comprise the largest number of polyneuropathies associated with PCD [1]. These can be divided into IgM associated and non-IgM associated [13, 24]. The IgM group is further divided into those with and without anti-MAG (myelin-associated glycoprotein) antibody.

Table 30.4 Antibody activities of IgM in peripheral nerve disorders

Antibody activity	Clinical syndrome	Pathology
MAG	Sensory > motor polyneuropathy	SD
Acidic glycolipids	Polyneuropathy	?
Gangliosides GM1 and GD1b	Motor neuron disease	SD, ?AD
Chondroitin sulfate C	Sensory polyneuropathy	AD
Intermediate filaments	Polyneuropathy	SD
Neurofilament	Polyneuropathy	AD
Sulfatide	Sensory polyneuropathy	AD, SD
SGPG	Polyneuropathy	AD, SD

Data from Steck et al. [30]
Abbreviations: *MAG* myelin-associated glycoprotein, *SD* segmental demyelination, and *AD* axonal degeneration

IgM Monoclonal Gammopathy

MGUS-IgM Anti-MAG Antibody Neuropathy (Latov's Syndrome)

Latov and colleagues first described this syndrome in 1980 [6, 7], and now multiple studies have shown that about 50 % of all polyneuropathies associated with PCD are of the IgM type and, of these, half have anti-MAG activity [6, 7, 24–29]. Anti-MAG is a glycoprotein with neural adhesion properties located in the myelin sheath of peripheral and central nervous system. Other anti-nerve antibodies (Table 30.4) are much less common and are less clearly related to the polyneuropathy.

Table 30.5 Major electrodiagnostic features of PN associated with PCD

Type of PN	demyelination	Axonal	CTS	Pure sensory	Other
MGUS-IgM	+++	+	–	++	+
MGUS-IgG,A	++	++	–	+	+
OSM	+++	+	–	–	–

[a]Autonomic involvement

[b]Root involvement and polyradiculopathies superimposed on PN

Clinical Presentation

Anti-MAG neuropathy is the most firmly this established and best characterized of the anti-nerve antibody neuropathy syndromes. The frequency of detection of this syndrome has increased steadily due to better recognition of the syndrome and the wider availability of the anti-MAG antibody test. As mentioned, the estimated frequency is 1–5 per 10,000 adults [6]. Based on our experience and that of others, a fairly consistent clinical picture has emerged. Patients are usually older (sixth through ninth decades) and predominately men [24, 31]. These patients typically present with the slow and insidious onset, over months to years, of sensory gait ataxia and progressive ascending numbness, usually with minimal pain or autonomic involvement. Intention tremor may be prominent in some [14, 24, 32–35]. Weakness is usually much less pronounced, and indeed, early on, the clinical picture may resemble the sensory neuronopathy syndrome with predominant discriminatory sensory loss (i.e., vibration and joint position sense) and preserved power. The manifestations are quite symmetric and progress in a slow and steady distal to proximal fashion, similar to a length-dependent axonopathy. However, most patients have palpable thickening of proximal nerves, a finding generally associated with demyelination and re-myelination, which are absent in axonopathies.

Diagnostic Studies

ELISA and Western blot both have been used to detect anti-MAG antibody; however, ELISA testing for MAG antibody is more sensitive and easier to perform than Western blot and the preferred assay [36]. Electrodiagnostic studies, especially nerve conduction and electromyography (Table 30.5), are helpful in suggesting the diagnosis. Sensory nerve action potentials are absent or severely attenuated. Despite the fact that weakness is generally not pronounced in these patients, there is often marked slowing of motor conduction velocities and severely prolonged distal latencies in the "demyelinating"

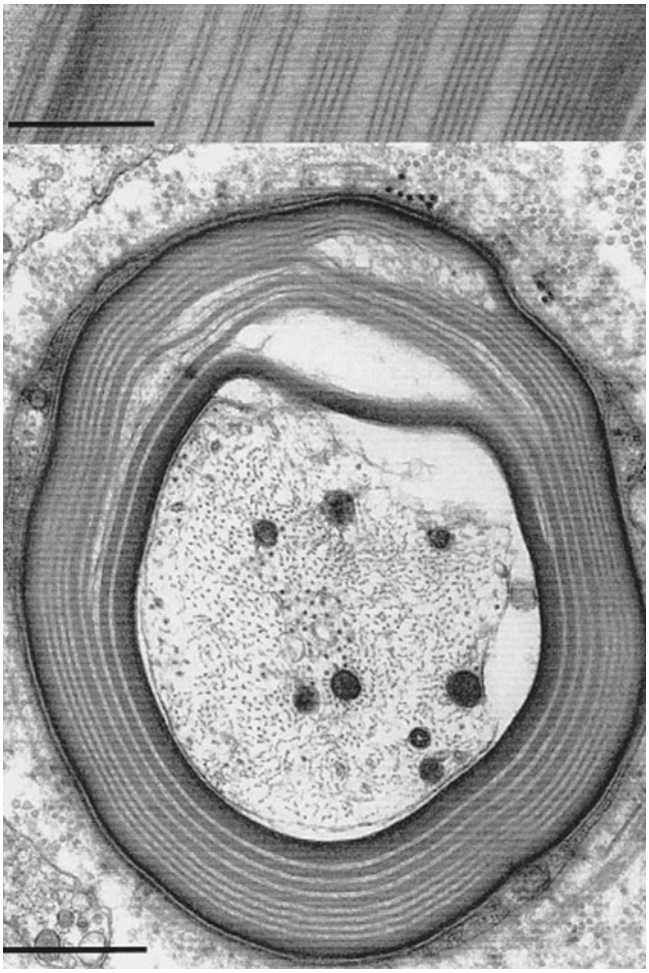

Fig. 30.1 Electron micrograph of a transverse section through a nerve fiber with enlarged periaxonal space and myelin splitting (Adapted from Cai et al. [38], with permission from Wiley publishing)

range associated with conduction blocks and focal areas of dispersion of the motor-evoked potentials. In one study, the highest anti-MAG titers correlated with the most delayed distal latencies and slowest motor conduction velocities [37]. Cerebrospinal fluid protein concentration is usually increased to greater than 100 mg/dl in advanced cases. Although spinal fluid and electromyography can suggest the etiology in the proper clinical setting, the diagnosis is firmly established by nerve biopsy and serological studies. Electron microscopic examination of nerve biopsy specimens has demonstrated widening of the myelin lamellae in more than 95 % of patients [29], as well as segmental demyelination with deposits of M protein and complement in the myelin sheath (Fig. 30.1) [39–42].

Anti-MAG antibodies may predict the subsequent development of neuropathy in asymptomatic patients [43] with the ELISA disclosing high titers of serum MAG antibodies in these patients. The IgM appears to react with a carbohydrate epitope which is shared by MAG and other glycoproteins

and glycolipids of the nervous system [44]. Recognition of these patients is important since treatment which lowers anti-MAG antibody levels can stabilize these patients or promote recovery.

Treatment

Treatment of these patients is difficult. They are often elderly and tolerate immunosuppressive drugs poorly. In addition, current therapies are effective temporarily and associated with side effects. Therefore, until more effective or safer treatments become available, aggressive treatment should be reserved for patients with progressive disease or those with disability due to neuropathy [14]. In general, therapeutic reduction of anti-MAG IgM levels correlates with improvement of neuropathy [7, 24, 45, 46]. Therefore, treatment in patients with anti-MAG neuropathy is directed at reducing the antibody concentration either by depleting the monoclonal B cells or by passive removal. Plasma exchange was effective in 25–50 % of patients in two randomized trials [43, 47]. Rituximab, a B cell-depleting monoclonal antibody, is an effective therapy in anti-MAG neuropathy and particularly for sensory impairment [48–52]. It is emerging as the best agent available, providing long-term benefits to almost half of these patients [53]. In the first controlled study done by Dalakas et al., rituximab showed encouraging results in treating anti-MAG neuropathy [54, 55] with up to 65 % of MAG neuropathies, unresponsive to other treatments, improved after 8 months, and sometimes with long-lasting remission [54, 56]. The authors have a similar experience with rituximab; however, further trails required to evaluate the long-term toxicity and safety of this new treatment. Rituximab appears to work by suppression of the IgM as well as the anti-MAG antibodies and by inducing immunoregulatory T cells [53]. Cyclic intravenous or oral high dose of cyclophosphamide when used with corticosteroids [44] or plasma exchange [57] was effective in two open-label trials. The first double-blind randomized trial with cyclophosphamide and prednisone in IGM MGUS neuropathy showed same beneficial effect on muscle strength and sensation but no beneficial effect on functional scales [58]. In our experience, a 6–9-month course of oral cyclophosphamide allows stabilization or recovery in the majority of patients who can tolerate the treatment [24]. Other treatment options including interferon-alpha, chlorambucil, fludarabine, and high-dose chemotherapy followed by autologous bone marrow transplant have been reported in small series; however, all need to be confirmed in controlled randomized studies [59–62].

In general, it is desirable to lower the serum M-protein level by at least half although clinical response does not always correspond to success in lowering the M-protein level [63]. The clinical remission is often prolonged. Based on our experience, after therapy is stopped, the M-protein level gradually rises to pretreatment levels, the deficit begins to slowly re-accumulate, and re-treatment may need to be considered.

Although the tremor may improve in some patients who respond to immunotherapy, it remains disabling in most. Recently, unilateral thalamic deep brain stimulation (DBS) was applied in a patient unresponsive to plasma exchange, cyclophosphamide, corticosteroids, primidone, and gabapentin [53, 64]. The rationale was that thalamic stimulation interferes with the cerebellar circuits implicated in the generation of tremor. A sustained improvement in tremor control was identified.

MGUS-IgM Non-MAG Neuropathies

These neuropathies are more diverse and represent a quarter of the MGUS neuropathies [17, 26, 27, 65]. Some patients have axonal polyneuropathy by electrodiagnostic evaluation and biopsy [4, 65]. However, many have demyelinating features similar to anti-MAG neuropathy and are difficult to distinguish without serologic testing [26, 27]. Immunofluorescent studies are generally negative, and myelin lamellar splitting is not observed. IgM antibodies in these patients may react with a variety of antigens (Table 30.4), but these reactions are, for the most part, less clearly related to disease activity than in the case of MAG antibody neuropathy. Anti-Ganglioside antibodies are significantly associated with demyelinating neuropathy and specially the IgM isotype [66]. Anti-GD1b and anti-GQ1b are associated with predominantly large-fiber sensory ataxic neuropathy in one series and with predominantly motor neuropathy in another [41]. Anti-sulfate-3-glucuronyl paragloboside (anti-SGPG) antibodies have been identified in 91 % of demyelinating and 50 % of axonal neuropathies associated with IgM monoclonal gammopathy [67]. Anti-sulfatide neuropathy associated with an M protein is associated with both demyelinating and axonal neuropathy without pain component [41, 68, 69]. These demyelinating neuropathies may also respond to treatment with steroids and cytotoxics [70]. Some resemble chronic inflammatory demyelinating polyneuropathy (CIDP) and respond to more conventional treatment with steroids, plasmapheresis, and IVIG. Patients with primarily axonal polyneuropathy must be evaluated for amyloidosis [71]. Axonal neuropathies respond poorly to any presently available therapies.

IgG and IgA MGUS-Associated Polyneuropathies

This group accounts for about half of MGUS neuropathies and the nature of polyneuropathies is much less clear [1, 17, 65, 72]. These both are heterogeneous disorders. IgG MGUS neuropathy can mimic anti-MAG neuropathy with late-onset, distal sensory motor large-fiber dominant neuropathy

Table 30.6 Medical syndromes in amyloid polyneuropathy

Syndrome	Percent frequency (%)
Orthostatic hypotension	42
Nephrotic syndrome	23
Cardiac failure	23
Malabsorption	16

Data from Kelly et al. [17]

associated with tremor and sensory ataxia [23]. IgG MGUS type sometimes fits the picture of chronic relapsing and remitting demyelinating polyneuropathy similar to CIDP [73]. Finally, it may present with painful axonal neuropathy similar to amyloid neuropathy. IgA MGUS neuropathies can present with a distal sensorimotor neuropathy [23] or a CIDP-like picture as well [74].

In general, patients with axonal polyneuropathies respond poorly to therapy, while those with demyelinating features (CIDP form) are more likely to respond to conventional immunosuppressive treatment. In studies comparing IgM with non-IgM neuropathies, the non-IgM patients were found to have less sensory loss than those with IgM gammopathies and less demyelination on EDX studies [26, 27]. It is important to exclude amyloidosis, especially when there is a recent onset axonal neuropathy, with rapid progression, and pain or autonomic manifestations [71].

Primary Systemic Amyloidosis (PSA) and Light-Chain Amyloidosis (AL)

Clinical Presentation: PSA generally presents as a multisystem disease due to the deposition of fragments of the variable portion of a monoclonal light chain in tissue, most often lambda in 75 % of patients and kappa in the remainder [75–80]. PSA can occur alone or in association with MM or, much less often, Waldenstrom's macroglobulinemia. Patients present with either a medical disease with associated (sometimes incidental) polyneuropathy or with severe polyneuropathy with minimal organ involvement. A similar illness can occur in a variety of inherited amyloid polyneuropathies due to an abnormal circulating prealbumin (transthyretin) protein with a single amino acid substitution. Polyneuropathy does not occur in amyloidosis secondary to chronic inflammatory disease or familial CNS amyloidosis.

Peripheral neuropathy is the most common neurologic manifestation in PSA [16, 17]. PSA is perhaps the best characterized of the polyneuropathies associated with M proteins and accounts for up to one-quarter of cases in some series [71]. This neuropathy characteristically occurs in older men and is rare prior to the sixth decade. Most patients are not associated with an underlying illness, but a few are associated with hematologic malignancies such as myeloma and Waldenström's macroglobulinemia (see below). More commonly, however, patients have major systemic disease, and neuropathy is diagnosed as a result of neurologic examination or EMG to investigate associated neuropathic manifestations [81].

Medical complications (Table 30.6) include the nephrotic syndrome due to amyloid infiltration of the kidneys, cardiac failure due to amyloid cardiomyopathy, chronic diarrhea with wasting due to amyloid infiltration of the gut wall, and autonomic neuropathy with prominent orthostatic hypotension. General laboratory studies reflect the medical syndromes, with proteinuria occurring in a high-percentage, elevated erythrocyte sedimentation rate in about half and mild increase in benign-appearing plasma cells in bone marrow in many. Up to 90 % have an M protein in serum or a monoclonal light chain in urine when thoroughly screened with serum and urine IFE. Those patients lacking an M protein, if not an inherited condition, are called "nonsecretory," although immunocytologic studies of their tissue disclose that the amyloid derives from single (monoclonal) light chains. Presumably, the serum concentration is too low to detect light chains in these patients. The light chains are deposited in tissue where they are digested by macrophages with the production of insoluble amyloid fibrils.

The polyneuropathy has been well characterized [71]. Sensory symptoms are typically most prominent and the earliest to appear. Almost all present with numbness of the hands and legs with complaints such as burning, aching, stabbing, and shooting pains. In greater than half of patients, cutaneous sensations (light touch, pain, temperature) are more frequently and severely affected than discriminative sensations (vibration and position sense). About 20 % present with typical symptoms of carpal tunnel syndrome before distal neuropathy symptoms appear, due to amyloid infiltration of the flexor retinaculum of the wrist [17]. Amyloid neuropathy can rarely present with a relatively pure autonomic neuropathy due to amyloid deposition restricted to dorsal root ganglia, autonomic fibers, and ganglia [82, 83]. An asymmetric presentation of chronically progressive peripheral motor and sensory deficit has been associated with amyloid involvement of lumbosacral plexus and nerve roots, causing distal axonal degeneration [84]. Otherwise, the findings tend to be symmetric and predominant distally with gradual proximal spread. Most patients soon complain of autonomic dysfunction with orthostatic lightheadedness and syncope, bowel and bladder disturbances, impotence, and sweating disturbances. Hypoactive pupils and orthostatic blood pressure drop with a fixed heart rate are the most easily detected autonomic signs at the bedside.

Laboratory Studies: EDX studies (Table 30.5) confirm the presence of a distal sensorimotor axonal neuropathy, which is most severe in the legs [17]. Motor conduction velocities in the "demyelinating" range (<60 % of the mean normal for

that nerve) occur rarely and then only in severely affected nerves where the evoked compound muscle action potential is very low in amplitude. Sensory nerve action potentials are usually absent. Often, there is evidence of carpal tunnel syndrome, which can suggest the diagnosis. Needle EMG shows the changes expected of a distal axonopathy, with abundant signs of distal denervation and reinnervation. CSF is usually acellular, often with mild elevation of protein level in the 50–70 mg/dl range.

Serum protein electrophoresis (SPE) is abnormal in up to 33 % of patients with PSA. Urine or serum immunofixation electrophoresis (IFE) may detect M protein in 80–90 % of patients. In patients without detectable M protein with routine laboratory tests, serum free light-chain immunoassay or clonal assay of plasma cells on bone marrow biopsy may be helpful [85, 86]. Free light-chain assay is useful for follow-up of patients with amyloidosis who have undergone stem cell transplantation [85]. Autonomic function tests can detect abnormalities early in the disease even in asymptomatic familial amyloidosis carriers [87].

Diagnosis depends on the identification of amyloid in tissue. Sural nerve biopsy is useful in detection of amyloid, although occasionally it has to be sought through multiple sections. One study reported that 6 of 10 patients with PSA neuropathy had negative nerve biopsies [12]; therefore, biopsy of two high-yield sites is generally recommended, such as sural nerve and fat pad. Other useful tissues to biopsy (Table 30.7) include rectum, skin, bone marrow, salivary glands, and other affected organs. Abdominal fat-pad aspiration is simple, rapid, and effective technique for diagnosis with 80–90 % sensitivity [79, 88, 89]. Rectal and skin biopsy are also positive in more than 80 % of patients [16, 90]. Bone marrow biopsies show amyloid deposit in up to 60 % of specimens [91]. On nerve biopsy, amorphous deposits of amyloid on congo red or cresyl violet stains typically appear in the perivascular regions of the epineurium or occasionally in the endoneurium. Amyloid is classically defined by its appearance under polarized light where the congo red-stained deposits emit an apple-green birefringence. Electron microscopy can also be used to identify the characteristic beta-pleated fibrils. Immunofluorescent staining for monoclonal light-chain fragments is helpful but is technically difficult [92, 93]. However, newer molecular techniques such as mass spectrophotometry and immunohistochemistry of amyloid show promise in determining types of amyloidosis [94, 95]. Teased fiber studies show predominant axonal degeneration. The reason for nerve fiber damage, however, is not always readily apparent in all patients. In some instances, marked axonal degeneration appears with minimal amyloid infiltration, possibly caused by more proximal amyloid, perhaps at the level of the dorsal root ganglion.

Pathogenesis: Pathologic findings have led to many theories of the pathogenesis of the neuropathy including vascular and pressure changes by the amyloid deposits. However, direct toxic effects of the amyloid fibrils on nerve fibers and dorsal root ganglion cells seem more likely.

Treatment: Treatment is challenging. The amyloid fibrils are insoluble once deposited in tissue. Thus, it is unlikely that much improvement would appear, even with cessation of amyloid deposition. Melphalan and prednisone, with or without colchicine and other chemotherapeutic agents, have been tried in multiple prospective trials [65, 96–98]. Overall, melphalan and prednisone treatment, continued for at least 1 year, has resulted in increased survival rates. The highest response rate (39 %) was obtained in patients with nephrotic syndrome with normal serum creatinine levels and no echocardiographic evidence of cardiac amyloidosis. However, peripheral neuropathy did not respond [16, 17, 96, 98]. The combination of melphalan and prednisone has proved superior to colchicine [96], and the addition of colchicine to the above regimen did not add any benefit in one randomized trial [65]. Thus, a trial of alkylating agents and prednisone is warranted in every patient. Treatment with cyclophosphamide and dexamethasone with either lenalidomide [99] or bortezomib [100] has been found to be effective. There have been reports of benefit from high-dose chemotherapy with melphalan and steroids followed by peripheral blood stem cell transplantation [101–107]. Small numbers of bone marrow transplants have been reported to date; however, the reports have been encouraging. In one study, neurologic improvement occurred in 4 of 5 neuropathy patients [101]. Another group reported that 12 of 20 patients with amyloidosis had improved organ function following transplantation [102]. Thus, early peripheral blood stem cell transplantation in the first year for those with minimal organ involvement is now the treatment of choice if the patient qualifies [103, 104, 108, 109]. Unfortunately, many patients by the time of diagnosis are too advanced to benefit from this treatment. The number of organs involved is the most important factor in predicting survival [103]. Treatment of peripheral neuropathy is mainly symptomatic, with tricyclic antidepressants, analgesics, and neuropathic pain medication. Dysautonomia, particularly orthostatic hypotension, can be controlled with medication and compressive stockings.

Multiple Myeloma (MM) Neuropathy

Multiple myeloma is a malignant PCD with high serum and urinary concentrations of MP, infiltration of bone marrow by malignant plasma cells, and multiple bone plasmacytomas. Diagnostic criteria require the presence of at least 10 % plasma cells on examination of the bone marrow, M protein in the serum or urine, and evidence of organ damage [110]. Most neurologic complications are due to secondary effects of the tumor (hypercalcemia, infections), malignant infiltration of nerve roots, or secondary compression of spinal cord or nerve roots due to vertebral fractures. Polyneuropathies are uncommon with MM and reported as high as 3–5 % in large series [8, 9]. They occur in only a few percent of MM patients and are diverse in nature [111], similar to the polyneuropathies associated with other malignancies. The exception is osteosclerotic myeloma, discussed separately below. Subclinical neuropathy, however, can be detected in up to 40–60 % of patients with MM using electrodiagnostic tests or histopathologic evaluation [11, 12].

Peripheral Neuropathy in Typical Lytic Multiple Myeloma Without Amyloidosis

Neuropathy associated with typical lytic MM includes distal sensorimotor axonopathy, CIDP-like syndrome, and sensory neuropathy [13]. The sensorimotor neuropathy is often mild and slowly progressive. A pure sensory neuropathy variant resembles the sensory neuropathy associated with small cell carcinoma [13, 112]. Patients usually have disabling sensory ataxia with minimal weakness. The CIDP syndrome is a pure motor neuropathy with symmetrical proximal and distal weakness [13].

Peripheral Neuropathy in Typical Lytic Multiple Myeloma with Amyloidosis

Twenty to forty percent of patients with typical MM can develop neuropathies due to deposition of light-chain amyloid in nerves. In this case, the clinical picture is similar to primary amyloidosis without MM with typical distal axonal sensorimotor neuropathy and dysautonomia [13]. Superimposed root involvement may confuse the clinician by mistakenly suggesting a picture of mononeuritis multiplex. The root and cord compressive syndromes should be managed by conventional therapy, but, like nonmalignant primary systemic amyloidosis, the amyloid neuropathy does not respond to chemotherapy.

Osteosclerotic Myeloma (OSM) and Polyneuropathy (and Related Syndromes)

Osteosclerotic myeloma is a rare accounting for only 5 % of all myelomas and is relatively benign variant of MM [13, 113–116]. While polyneuropathy is rare with typical MM, it occurs in 50 % or more of reported cases with OSM. In contrast to typical MM, patients with OSM are usually not systemically ill. They present because of the neuropathy or other remote effects of the malignancy, rather than as a direct effect of the malignancy. Anemia, hypercalcemia, and renal insufficiency are uncommon in OSM. The bone marrow is rarely infiltrated with malignant plasma cells, and the serum M-protein concentration is low. Finally, the course of OSM is indolent; these patients have prolonged survivals even without treatment. Thus, there is something singular about the syndrome of OSM and its paraneoplastic accompaniments. For these reasons, the syndrome can be difficult to diagnose even by experienced clinicians.

Clinical Features: Unlike MM, the polyneuropathy accompanying OSM is distinctive and homogeneous. Deficits are mainly motor and slowly progressive without sudden changes in severity or tempo of progression. Patients present with the onset of weakness, mostly in distal limbs initially, with gradual proximal spread accompanied by reflex loss. Sensory loss is typically less striking and tends to disproportionately affect the larger sensory fibers with greater loss of discriminative than cutaneous sensation. Pain and autonomic dysfunction, with the exception of impotence (actually due to endocrine insufficiency), are very uncommon. Nerves are often palpably thickened. The deficit is usually symmetrical and the speed of progression is slow, often over months to years.

Laboratory Studies: General laboratory studies are usually relatively uninformative. The best clue to the diagnosis is the presence of a serum M protein, which is present in about 75–80 % of patients. However, the M protein may be small and obscured by the normal serum protein components in the electrophoresis, emphasizing the importance of obtaining an IEP or IFE in all patients with idiopathic polyneuropathy. The M protein is characteristically IgG or IgA, lambda light chain (rarely kappa), and rarely present in the urine, as opposed to MM and AL. EDX studies are helpful but nonspecific (Table 30.5) and reveal a mixed axonal and demyelinating picture which is also nonspecific but helpful in categorizing the neuropathy into the group with clear-cut demyelinating features and thus more likely to be diagnosed. Nerve biopsy studies disclose a reduced concentration of myelinated fibers with mixed demyelination and axonal degeneration. There may be foci of mononuclear cells in the epineurium surrounding blood vessels. These changes are nonspecific and observed in a number of neuropathies, including CIDP and diabetic polyneuropathy. The clinical and laboratory picture thus resembles CIDP. However, these patients are resistant to the usual therapies used to treat CIDP, such as steroid and IVIg. Therefore, all patients with progressive CIDP should have been evaluated for PCDs including serology testing for M protein and skeletal X-ray surveys.

CSF typically is acellular but with a high protein concentration, generally greater than 100 mg/dl and sometimes as high as several 100 mg/dl. Since these findings are nonspecific, the diagnosis often hinges on the discovery of the characteristic bony lesions and subsequent bone biopsy. The osteosclerotic lesions may be solitary or multiple. They tend to affect the axial skeleton and very proximal long bones but spare the distal long bones and skull. They may be purely sclerotic or mixed sclerotic and lytic. Radioactive bone scans, although more sensitive than X-rays as a rule in detecting myeloma and other bony metastases, are not as sensitive as X-rays in detecting OSM lesions, probably due to the indolent nature of these plasmacytomas. Thus, all patients with unexplained polyneuropathies who fit the clinical profile described above should be screened with a radiographic skeletal survey. On occasion, these lesions are misinterpreted by radiologists who are unfamiliar with their appearance and significance. Three of our patients were felt to have benign osteosclerotic lesions (fibrous dysplasia in a rib in two and a vertebral hemangioma in one) with negative radionucleotide bone scans. We typically pursue biopsy based on the clinical picture and the presence of a serum M protein, and with plasmacytomas being discovered, leading to institution of treatment. Thus, if there is any question of the significance of a bony lesion in a patient with a suggestive clinical picture, the neurologist with the radiologist should review the X-rays, and the lesion should be biopsied if doubt remains. Open biopsy is often preferable to needle biopsy in our experience.

Pathogenesis: The cause of the polyneuropathy is not known, but most theories focus on the disease being induced by a secreted product of the tumor, most likely the M protein itself. The tumor does secrete cytokines, interleukin-a beta, tumor necrosis factor-alpha, and interleukin-6, which may play a role in pathogenesis [59]. Studies of anti-nerve antibody activity in the serum of these patients and immunocytochemical studies of nerves have been negative. The pathogenesis of nerve damage and even whether it is an axonopathy or a primary demyelinating disorder remains unresolved.

Treatment: The diagnosis of this disorder is of more than academic interest since these patients may be helped by tumoricidal therapy. Patients with solitary lesions do best. Radiation therapy to the lesion or surgical excision results in elimination of the M protein from the serum and gradual recovery from the neuropathy and other symptoms over the ensuing months in most patients. However, these patients should continue to be followed since they have a tendency to relapse with the development of new lesions months to years later [117]. This is usually heralded by the return of the neuropathy and other symptoms and the reappearance of the serum M protein. Patients with multiple lesions are more difficult to treat, and in general, the outcome is less favorable than for solitary lesions. Radiation therapy is usually not an option due to the risk of toxicity. In some patients, aggressive chemotherapy, with or without local radiation therapy to large lesions, can be helpful [117–119]. Treatment usually requires large doses of steroids and alkylating agents. Treatments which are usually effective in autoimmune inflammatory neuropathies, such as steroids, azathioprine, plasmapheresis, and IVIG, are typically ineffective in these patients.

Systemic Features

The disorder is of clinical and scientific interest since many patients develop a multisystem syndrome, which goes by a variety of names including the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes) or the Crow-Fukase syndrome. More than 95 % of patients with POEMS syndrome have a monoclonal lambda sclerotic plasmacytoma or bone marrow infiltration [120]. Manifestations of peripheral neuropathy usually dominate their clinical picture and begin in the feet with tingling, paresthesia, and coldness [1]. Motor involvement follows the sensory symptoms. The course is usually progressive. Bone pain and fractures rarely occur [121]. NCS has typical demyelinating features. Conduction blocks, the hallmark of acquired demyelination, occur in only 6 % of patients with POEMS syndrome [122, 123]. In contrast to MM, the course is chronic with a reported median survival of 13.8 years [121].

The pathology of POEMS is an area of active research. These patients have, in addition to polyneuropathy, other features (Table 30.8) suggesting an underlying endocrinopathy or malignancy. The etiology of the endocrinopathy is unclear. Limited data suggests a disturbance of the hypothalamic-pituitary axis rather than primary end-organ failure, possibly due to antibody activity against pituitary tissue. Vascular endothelial growth factor (VEGF) and cytokines have been proposed as possible causes of POEMS syndrome, as an increase in the blood level of VEGF is usually present in these patients. VEGF may increase the permeability of the blood-nerve barrier, leading to the exposure of nerves to complement, thrombin, and other substances that are toxic to nerves [124–127]. Plasma VEGF is also useful in monitoring disease activity after treatment and correlates with clinical improvements better than hematologic response [128]. Patients are frequently found to have higher levels of interleukin (IL) B, IL-6, and tumor necrosis factor compared with MM [129]. Biopsy of affected lymph nodes generally discloses hyperplastic changes, sometimes resembling the pathologic findings in the syndrome of angiofollicular lymph node hyperplasia (Castleman's disease), which is a benign localized or generalized hyperplastic lymph node syndrome of unknown etiology. Patients with generalized angiofollicular lymph node hyperplasia without bony lesions may also have the manifestations of Crow-Fukase syndrome associated with serum M proteins or polyclonal gammopathies. Thus, it is likely that the main pathogenetic determinant of these syndromes is the presence of a serum product, most

likely the IgG or IgA lambda M protein or polyclonal antibodies with similar specificity, directed against neural and other tissue. For these patients, the term POEMS syndrome, which focuses attention on a small number of patients to the exclusion of others, is not entirely accurate [130]. For example, of the patients with OSM polyneuropathy, most have features other than neuropathy which are fragments of a multisystemic disorder, but only a few would qualify for the term POEMS (Table 30.8). Also, patients without myeloma may develop all the features of the POEMS syndrome. Thus, I prefer the term Crow-Fukase syndrome when referring to patients with polyneuropathy and multisystemic disorder.

There is no standard therapy for POEMS syndrome; however, radiation of isolated plasmacytoma or multiple lesions in a limited area, systemic chemotherapy (alkylating agents and corticosteroids), and peripheral blood stem cell transplantation should be considered [131].

Miscellaneous Syndromes

Waldenström's macroglobulinemia (WM) is a rare disorder and characterized by a monoclonal IgM paraprotein and morphological evidence of lymphoplasmacytic lymphoma [132]. Seventy percent of MPs in WM are kappa light chains. It is sometimes difficult to differentiate WM from IgM-MGUS, and the latter may evolve into WM over time (Table 30.1). Demyelination in electrophysiologic studies is much more commonly seen in IgM-MGUS compared with WM neuropathy [133]. This difference may reflect varied immune mechanism(s) in the two disorders. The most frequent neuropathy in WM is a distal symmetrical and slowly progressive sensorimotor neuropathy causing paresthesia and weakness that affect lower extremities predominantly [134, 135]. Other patients may have a CIDP-like picture, a typical amyloid polyneuropathy, or even the sensory neuronopathy syndrome usually seen with small cell cancer of the lung. MAG antibody is found in about half of these patients with features similar to anti-MAG neuropathy in MGUS. Dimopoulos and colleagues classified neuropathies in WM into five categories [135]:

1. IgM anti-MAG demyelinating neuropathy
2. Monoclonal IgM non-MAG with ganglioside reactivity and demyelinating neuropathy
3. Monoclonal IgM (with no known antibodies) neuropathy
4. Cryoglobulinemic neuropathy
5. Amyloid neuropathy

Many of the same treatments used for MGUS-associated neuropathy have been used for WM, including rituximab in IgM-related neuropathy [52, 55, 136]. In moderate to severe IgM neuropathy, a combination of cyclophosphamide, prednisone, and rituximab is recommended [137, 138]. In refractory cases, bortezomib or thalidomide, in combination with rituximab, has been used [139, 140], although bortezomib or thalidomide usage is limited due to their neurotoxic effect. High-dose chemotherapy and peripheral blood stem cell transplant may be considered as other therapeutic options [59, 121].

Cryoglobulinemia: Cryoglobulins are circulating immunoglobulins that reversibly precipitate at temperatures lower than 37 °C. Their presence in serum is referred to as cryoglobulinemia. This disorder is usually divided into 3 types [141]. In type 1, accounting for about a quarter of patients, the M protein itself is a cryoglobulin in the setting of a plasma cell disorder. Type 2 involves another 25 % of patients; the cryoglobulin is a mixture of an M protein of IgM type with rheumatoid factor activity against polyclonal immunoglobulins, usually occurring in the setting of a lymphoproliferative disorder. Type 3 occurs in the setting of a collagen-vascular or other chronic inflammatory disease, and the cryoglobulin consists of polyclonal immunoglobulins. The polyneuropathy in all these syndromes is painful, symmetrical or asymmetrical, sensorimotor, and axonal in nature. Gemignani and colleagues reported that sensory neuropathy, often in the form of small-fiber sensory neuropathy (76 %), is by far the commonest form of neuropathy in mixed cryoglobulinemia [142]. They reported sensory motor polyneuropathy in 15 % of patients. In this large series, sensory neuropathy was found to mainly affect women in the sixth and seventh decades and was the initial manifestation of mixed cryoglobulinemia in about half of the patients. About one out of ten patients have an extensive mononeuritis multiplex of acute or subacute

onset, frequently reflecting a necrotizing vasculitis of the nerve [142–146]. Purpura occurs in distal limbs in a high percentage of patients, and the neuropathy is generally considered to be due to a vasculopathy or vasculitis of skin and vasa nervorum. Symptomatic treatment includes low-dose steroid and analgesic and avoidance of cold exposure [121]. High-dose steroid, plasmapheresis, and cytotoxic therapy are indicated for severe cases [121, 147]. Several reports have emphasized the usefulness of rituximab in cryoglobulinemia [148–151]. A few case series and a recent randomized controlled trial demonstrate improvement of peripheral neuropathy with rituximab [150, 152–154].

Lymphoma and Leukemia. These cancers can be associated with MP and polyneuropathy. In lymphoma with IgM M protein, the IgM may have anti-MAG activity with the usual associated clinical and pathological features. Other syndromes without clear anti-nerve activity in the M-protein fraction may respond to ablation of the malignancy. Still others have an unclear relation to the malignancy and show little response to tumoricidal treatment or to lowering of the M-protein concentration in serum.

Conclusion

The topic of plasma cell dyscrasias and neuromuscular diseases has been a fruitful area for active research over the last decade. These patients are of great importance to recognize since treatment may lead to remission. Also, careful study of these patients may lead to a better understanding of the pathogenesis of polyneuropathies and possibly motor neuron disease. This may in turn lead to effective treatment for conditions for which there are now no effective treatments. Therefore, despite their relative infrequency, increased recognition of these disorders will continue to be a high priority for peripheral nerve specialists and general neurologists.

Diabetic Neuropathies

31

Shawn J. Bird and Mark J. Brown

Introduction

Diabetic polyneuropathy (DPN) is the most common neuropathy and possibly the neuromuscular disorder most frequently encountered by internists and general physicians. DPN is responsible for substantial morbidity and is associated with increased cardiac mortality. Much is known about the clinical, electrophysiological, and neuropathological features of DPN. Excellent glycemic control has been shown to slow the progression of diabetic neuropathy. Despite many intriguing scientific observations, and decades of clinical neuropathy treatment trials, we still do not have disease-modifying therapies for those who cannot achieve good control. Diabetes mellitus is also associated with other forms of neuropathy, some of which are distinctive and yet subject to misdiagnosis and inappropriate management. Comprehensive publications have reviewed clinical and basic aspects of DPN and related disorders [1–4].

Overview of Diabetes Mellitus (Diabetes)

Diabetes is a metabolic syndrome with multiple causes. About 5 % of diabetics have the type 1 or ketosis-prone form, previously called juvenile diabetes. The usual cause is autoimmune necrosis of pancreatic β (beta) cells. Other causes of type 1 diabetes include pancreatitis, other illnesses, and pancreatectomy. The mainstay of treatment is insulin replacement. Patients with type 1 diabetes have fewer complications and a better prognosis than 30 years ago [5]. About 90 % of diabetics have type 2 diabetes, formerly called adult-onset diabetes. This results from relative insensitivity to insulin, often with gradual insulin loss. The pathogenesis of type 2 diabetes is multifactorial, with genetic predisposition, obesity, and inactivity as contributing influences [6]. Basic treatments include diet modification, weight loss, exercise, oral medications to increase insulin availability or improve insulin sensitivity, and insulin replacement. Individuals with type 2 diabetes may be undiagnosed for 5 or more years after laboratory and clinical evidence of the condition [7]. Less common types of diabetes include genetically determined insulin deficiency disorders and medication-induced diabetes [4]. Taken together the prevalence of diabetes is enormous. There are an estimated 25.8 million diabetics in the United States alone, including 26.9 % of persons age 65 or older [8].

Acute diabetic complications like ketoacidosis and hypoglycemia are generally associated with type 1 diabetes. Late complications occur with all types of diabetes. There is a strong correlation between the presence of late complications and the duration and severity of a patient's hyperglycemia. Late medical complications include atherosclerosis, cardiac disease, cataracts, retinopathy, and nephropathy. Late neurologic complications include neuropathies, cognitive impairment, Alzheimer disease, shingles, and other nervous system infections. Genetic factors, age, male gender, smoking, greater height, and other comorbid conditions are thought to influence susceptibility to late medical and neurologic complications. DPN, retinopathy, and nephropathy often coexist. However, the rate of progression for each may vary in the same individual.

Criteria for the Diagnosis of Diabetes

Internationally agreed-upon standards for the diagnosis of diabetes are regularly reviewed and updated by the American Diabetes Association and published on-line and in Diabetes Care [9]. The diagnostic gold standard remains the 2-h fasting

glucose tolerance test (GTT), done with a 75 g glucose load. The test should be repeated once if other measures do not support the diagnosis of diabetes. A fasting plasma glucose (FPG) of ≥126 mg/dL, or a 2-h glucose of ≥200 mg/dL, indicates diabetes. Plasma glucose levels are about 10–12 % higher than comparable whole blood glucose measurements. Diabetes can be diagnosed if plasma glucose is ≥200 mg/dL in association with symptoms of hyperglycemia.

The hemoglobin A1c (A1c) test is invaluable for monitoring glycemic control over the previous 3 months. More recently the A1c has been accepted as a screening tool for populations at risk for diabetes [9]. The A1c test has advantages over the GTT. There is no need for fasting and only a single blood specimen is required. An A1c value of ≥6.5 % indicates diabetes if the test method is certified and standardized. The test should be repeated if there is no supporting evidence of diabetes. A disadvantage is that the A1c level is not as sensitive for detecting new cases as GTT or FPG measurements [10].

Individuals with elevated blood glucose levels or glucose intolerance not meeting criteria for diabetes are called "borderline diabetic" or "prediabetic." Borderline diabetics are at a higher risk for developing diabetes than controls. Individuals with an FPG of 100–125 mg/dL or a 2-h post-glucose load PG of 140–199 mg/dL, or with AIC levels in the 5.7–6.4 % range, meet current criteria for borderline diabetes. About 3 % will develop overt diabetes each year. Those with a fasting glucose of 110–125 mg% should be followed, usually with a GGT. The relationship between neuropathy and borderline diabetes remains uncertain. There is a general understanding that borderline-diabetic individuals are more likely to have a coexisting sensory neuropathy than controls without IFG or IGT, but the epidemiologic importance of this association remains uncertain.

Classification of the Diabetic Neuropathies

Studies of large North American and European diabetic populations have shown that about 50 % have symptoms and/or signs of polyneuropathy. Diabetes specialists may use the designation "typical diabetic neuropathy" to indicate DPN, the most common phenotype. Patients with other patterns of neuropathy are classified as having "atypical diabetic neuropathy" and are often candidates for neurologic referral. Another classification scheme is based on the clinical course. "Chronic diabetic neuropathy" in this context usually means DPN. "Acute diabetic neuropathy" encompasses mononeuropathies, radiculopathies, radiculoplexopathies, and polyneuropathies with acute or subacute onset. In this chapter, we use a third classification scheme system that considers the topography of peripheral nervous system involvement along with the clinical course (Table 31.1).

Table 31.1 Classification of diabetic neuropathies by clinical course and topography

Diabetic polyneuropathy (DPN)
Mixed sensory-autonomic-motor polyneuropathy
Predominantly small-fiber polyneuropathy
Predominantly large-fiber polyneuropathy
Predominantly autonomic neuropathy
Asymptomatic polyneuropathy
Subacute painful polyneuropathy with changing glycemic control
Other patterns of polyneuropathy associated with diabetes
Chronic inflammatory demyelinating polyneuropathy (CIDP) with DPN
Distal motor polyneuropathy
Proximal motor neuropathy (also known as diabetic amyotrophy or diabetic lumbosacral radiculoplexus neuropathy)
Mononeuropathies and radiculpathies without focal nerve compression
Cranial mononeuropathies
Truncal radiculoneuropathies
Limb mononeuropathies
Mononeuropathies with focal nerve compression

Diabetic Polyneuropathy

Diabetic polyneuropathy (DPN) is a very slowly progressive disorder that may be asymptomatic for many years before discovery. The clinical features are those of a distal sensory-motor axonal polyneuropathy. The clinical and electrodiagnostic features of DPN are often indistinguishable from a wide range of acquired and genetically determined axonal neuropathies. There is no diagnostic test that can confirm DPN as the cause of polyneuropathy. The diagnosis is made by demonstrating that the patient has diabetes, that the pattern of neuropathy is consistent with DPN, and that a careful work-up has not shown another cause. The presence of other late diabetic complications, especially retinopathy and neuropathy, is strongly supportive evidence that the neuropathy is from diabetes. However and since diabetes is common, DPN may coexist with another peripheral nervous system disorder.

Symptoms of DPN

Because of the high prevalence of neuropathy with diabetes, every diabetic patient, with or without neuropathy symptoms, should be considered at high risk for having DPN. The earliest symptoms are distal, typically involving the toes and then the balls of the feet. For some, finger numbness is an early symptom. Over years, the entire sole, lower leg, and hands will become insensitive. Symptoms may include foot numbness with painless injuries; the false perception of cold, swollen, or hot feet; and the sense of walking on sponges or cotton. There may be spontaneous distal shock-like feelings

(paresthesias), burning pain, bone-deep aching, altered feelings when skin is lightly touched (dysesthesias), excessive responses after painful stimuli (hyperpathia), and discomfort with normally non-painful skin contact (allodynia). There may be non-healing ulcers and painless foot and finger injuries. Some report small foot muscle cramps early in the course, later followed by calf and finger cramps. Foot and leg discomfort may interfere with sleep. The patient or his family may be aware of leg restlessness, especially at night. Foot and hand weakness are late features that may not be recognized by the patient.

It is important to inquire about autonomic symptoms since they are underreported, often disabling, and an indicator of possible increased mortality from cardiac involvement. A report of dizziness on standing suggests orthostatic hypotension. There may be blurred vision in bright light from pupillary involvement. GI autonomic and somatic neuropathy leads to dysphagia, abnormal food absorption, gastric distention, constipation, diarrhea, and fecal incontinence. There may be overflow urinary incontinence. Standard doses of medications with anticholinergic properties may precipitate urinary retention. Male erectile dysfunction is common and an early symptom. Patients with longstanding diabetes may recognize that hypoglycemia no longer produces the warning uncomfortable autonomic symptoms. Most will not mention decreased sweating, especially if it is limited to the feet and small patches elsewhere. However, they will often express concern about compensatory hyperhidrosis of the trunk, neck, and face. Gustatory sweating is an unusual, incompletely understood autonomic symptom.

DPN and the Neurologic Examination

The resting pulse may be elevated because of cardiac autonomic neuropathy. Cardiac autonomic tests that can be done in the clinic with an EKG machine may show loss of normal R-R variability with breathing and decreased R-R variability with the Valsalva maneuver. Bedside tests for orthostatic hypotension may show a drop of systolic pressure of more than 20 mm after 1–3 min of standing [11]. When inspected the feet may be cool, suggesting diminished blood flow. Alternatively, diabetic foot temperature may be surprisingly warm with full pedal pulses and dilated foot veins, a manifestation of precapillary A-V shunting in the feet. In advanced cases, there may be signs of toe and foot vascular insufficiency from proximal leg artery disease. A potentially serious problem, and a predictor of future need for amputation, is foot pressure sores and ulcers. There may be unilateral or bilateral foot and ankle bone and joint degeneration with misshapen feet (Charcot foot). The degree of foot deformity is typically much greater than would be expected for the extent of foot proprioception loss. The cause of Charcot foot is not well understood. Lyons [12] opined that there is merit to both the "German" theory (micro-neurotrauma to insensate joints and ligaments) and the "French" theory (hyperemia followed by bone absorption).

Pupils may be irregular and react sluggishly. The sensory examination requires techniques that are able to detect loss of unmyelinated and small caliber myelinated sensory functions. Early findings are distal pin prick and cold temperature sensation loss. Since patients with longstanding distal neuropathies may judge blunted cold or pin prick feelings as normal, it is important to test proximal sites first to establish a baseline. Like other length-dependent polyneuropathies, finger sensory loss does not become evident until foot sensory loss has ascended to the calf. If there is loss of cold or pin prick sensation up to the mid-thigh, then expect hand and distal arm sensory loss. It is helpful to document the level of lower and upper limb sensory loss. It is likely to ascend proximally if the neuropathy progresses. Vibration sensation loss typically follows small-fiber sensory loss. An examiner without special training in sensory testing may detect vibration sensation loss first, using the examiner's sensibility as a control. The Rydel-Seiffer tuning fork provides a numeric value indicating when vibration is no longer detected. Tests of toe and ankle position sensation are relatively insensitive and may appear to be normal even though the patient has sufficient proprioception loss to cause gait imbalance. Inability to feel the touch of a 10 g calibrated filament on the feet is a late neuropathy sign but an important one. Patients who cannot feel the filament have an increased likelihood of developing foot ulcers and subsequent amputations [13].

Once the sensory level has ascended to the calf, then ankle jerks are likely to disappear. Arm reflexes typically remain until late in the course of DPN. Clinically, motor involvement comes long after distal sensory signs and symptoms. Bedside testing of foot and toe strength may give unreliable results. An early sign is the inability of non-obese patients under age 60 to heel walk without shoes. This presages foot drop, tripping, and falls. Late in the course of DPN, toes may be excessively flexed, arches may be high or flat, and there may be abnormal areas of callous over the metatarsal-phalangeal joints. Hand weakness and atrophy are late features. Surprisingly advanced hand muscle weakness and atrophy may be evidence of a coexisting focal median or ulnar neuropathy. Weakness of cranial nerve-innervated muscles and proximal limb muscles is unusual with DPN and indicates another cause.

Most patients with DPN have slow neuropathy progression, year after year, with a mixture of sensory, autonomic, and motor symptoms. There are others with symptom patterns that appear to reflect selective nerve fiber-type vulnerability or an atypically rapid rate of progression. It is likely that these are outliers in the DPN spectrum. However, one

cannot exclude the possibility of a fundamental difference in neuropathy pathogenesis among symptom subtypes.

DPN with Predominantly Small Fiber-Type Sensory Symptoms

This is an especially challenging group of patients because the diagnosis may be elusive and pain symptoms may be slow to respond to conventional treatments. Burning pain, paresthesias, and allodynia are prominent and often intense. Pain distribution may be distal, starting in the feet, or may be generalized, affecting limbs, trunk, abdomen, face, and scalp areas. There may be autonomic symptoms with anorexia, gastroparesis, and orthostatic hypotension. Physical findings are typically limited to distal loss of small-fiber-type sensory modalities. Position sensation may be normal or mildly affected. Reflexes and strength are often preserved. A physical examination that does not focus on small-fiber-type sensory modalities may be misleadingly normal. If an expert's examination does not give clear results, then QST or quantitative assessment of cutaneous axons with a skin punch or blister biopsy may be helpful.

These patients tend to be young type 1 diabetics with poor glycemic control. If the patient has type 2 diabetes with recent weight loss, then plasma glucose levels may be in the normal or near-normal range. Treating physicians may be reluctant to accept diabetes as the cause of the patient's symptoms if glucose and Hgb A1c measurements are not elevated. If the diagnosis of diabetes is in doubt, then tests for other causes of small-fiber-type sensory neuropathy should be carried out.

The basis for the pain in this and other forms of DPN is not known. Nerve fiber analyses from patients with and without painful neuropathy have not demonstrated neuropathological differences that might be responsible for neuropathic pain. Standard neuropathic pain medications may be ineffective for diabetic small-fiber sensory neuropathy. Narcotics are often required when pain is most severe. For most patients, the pain resolves over 6 months to 2 years. Many are then able to return to their previous activities. The small-fiber-type sensory loss persists. Over time there may be progression to mixed modality DPN.

DPN with Predominantly Large-Fiber Sensory Symptoms

A subgroup of older patients with chronic poorly controlled DPN for decades has prominent loss of large-caliber sensory function. The presenting problem may be imbalance, frequent falls, or hand clumsiness. Most often they have long-standing DPN that is relatively painless. They may attribute unsteadiness to age or vertigo and not neuropathy. The neurologic examination shows loss of proprioception and vibration sensation below the upper arms and thighs, ankle and knee reflex loss, and weakness of toe and foot dorsiflexion. There may be dysautonomia. Since the likelihood for neuropathy reversal at this stage is small, glycemic control should not be intensified at the risk of hypoglycemic episodes. If the degree of neuropathy is greater than expected for the known duration and severity of the neuropathy, then other causes of neuropathy must be considered.

DPN with Predominantly Autonomic Neuropathy

These are typically type 1 diabetic patients with brittle diabetes. Autonomic dysfunction may be so severe that in-hospital care is required. There are almost always symptoms and signs of a coexisting sensory polyneuropathy that often are painful. Orthostatic hypotension may make walking unsafe. Gastric motility slowing may lead to delayed food absorption, anorexia, and obstipation. Bladder enlargement and urinary retention are expected features. There may be blunting of hypoglycemic awareness. Diabetic control may be poor and there is weight loss. Symptoms respond in part to supportive treatments. There is usually substantial functional improvement over months or several years. Successful efforts to reverse weight loss are often associated with symptomatic improvement.

Asymptomatic DPN

About half of patients with diabetes and neuropathy are not aware of neuropathy symptoms. This is because the neuropathy is mild, or the patients do not question the meaning of toe tingling or foot numbness, especially if progression has been slow. It is important to identify patients with subclinical neuropathy early because improved blood glucose control appears to be most successful if started early. Asymptomatic individuals who are told about DPN may be more willing to take the steps necessary to improve glycemic control. All patients with diabetes who are not known to have neuropathy should be tested for foot sensory loss at least yearly with a calibrated filament, especially if no other neurologic evaluation is planned.

Subacute Painful Polyneuropathy with Changing Glycemic Control

Diabetic patients may develop intense diffuse neuropathic pain after declining or improving glycemic control. These patients appear acutely ill and typically report unwanted

weight loss. The rapid onset and pain severity may suggest an acute vasculitic or toxic neuropathy. These are described here as a variant of DPN, but sudden worsening or improvement could reflect a process that is unique to the disorder.

Subacute painful neuropathy with *declining glycemic control*, referred to as "subacute cachexic neuropathy" or "diabetic neuropathic cachexia" [14, 15], is primarily a disorder of young adults with poorly controlled type 2 diabetes. Anorexia and unintentional weight loss are common, and there may be gastroparesis. Pain may be intense, requiring narcotics for control. There may be small-fiber-type sensory loss or more generalized axonal breakdown. Nerve conduction abnormalities may be surprisingly mild for the extent of pain and cutaneous hypersensitivity. Improvement is slow, over months, perhaps related to the rate of axonal regeneration. Weight gain usually precedes improvement and may be necessary for recovery. Symptoms improve over months or several years. There is a residual sensory neuropathy.

In contrast, subacute neuropathy with *improved glycemic control* ("insulin neuritis") appears after the initiation of treatments to improve diabetic control with either insulin or oral agents [16–18]. There is intense burning pain that is difficult to manage. Objective signs of neuropathy are usually mild. Strength is preserved as are reflexes, aside from reduced or absent ankle jerks. In one case, the sural nerve biopsy showed loss of small caliber axons and signs of axonal regeneration [17]. Narcotics are often required for pain relief. Nutritional supplements may be necessary to achieve positive calorie balance, with the unwanted side effect of worsening diabetic control. The painful period generally improves after more than a year of follow-up [18], but the underlying polyneuropathy remains.

Neuropathology of DPN

Our understanding of the pathology of DPN is primarily based on studies of sensory nerve biopsies, a small number of autopsy studies using modern methods, and peripheral nerve specimens from animals with experimental or spontaneous diabetes. There is nonspecific diffuse axon loss that is more evident in distal than proximal axon segments. Myelinated and unmyelinated fiber populations are normal, reduced, or absent. However, an increase in unmyelinated fibers numbers may occur in the course in some cases [19, 20]. Endoneurial capillaries are thickened, but microvascular occlusions are unusual [21]. Infarct-like lesions were observed in proximal nerves of patients with diabetic polyneuropathy [22, 23]. This, and focal areas of axon loss in distal nerves, suggests that at least in some of the apparent length-related distal axon, loss may be the consequence of proximal axonal injury. Electron microscopy has shown increased glycogen in Schwann cells. Human axon-Schwann deformities at nodes of Ranvier have been observed but not by all investigators. Nodal changes have been suggested as a cause of nerve conduction slowing that is greater than predicted by changes in axonal diameter [24].

Nerve biopsy is now seldom done as part of the clinical evaluation for suspected DPN. Biopsy remains a useful tool when looking for other causes of neuropathy like amyloidosis, vasculitis, CIDP, or leprosy. Skin biopsies have low morbidity and provide a means for examining, staining, and counting intradermal nerve axons to confirm a small-fiber-type neuropathy. Material can be obtained from distal and proximal sites using skin punch biopsy or skin blister biopsy. Normal values are now available to take age-related axon loss and variable fiber densities from similar sites. Malik [25] and others have shown that corneal confocal microscopy can demonstrate changes in corneal axon morphology and density in a noninvasive way. This method is currently limited by the need for considerable technical expertise at the testing laboratory.

Clinical Neurophysiology of Diabetic Polyneuropathy

The peripheral nervous system is relatively accessible and thus allows the clinician to directly study nerve conduction from sensory, motor, and mixed nerves. Such nerve conduction studies (NCS) contribute to the measurement of axonal loss. NCS, along with quantitative sensory testing (QST) (see below), may detect neuropathy that is not yet clinically apparent. NCS may help determine if there are superimposed compression neuropathies, such as carpal tunnel syndrome or ulnar neuropathy at the elbow. Unmyelinated and small myelinated nerve fibers that subserve pain and autonomic function cannot be tested by standard nerve conduction studies. The function of these nerve fibers can be assessed by more limited, specialized techniques including autonomic function testing, QST, and intraepidermal nerve fiber (IENF) measures with skin punch biopsy.

The electrodiagnostic (EDX) evaluation of a patient with symptoms or signs of diabetic neuropathy usually is undertaken to confirm the presence of neuropathy, to determine its severity, and to look for another neuromuscular disorder that may produce such symptoms. This approach does not differ from that used to evaluate any patient with suspected polyneuropathy. A number of common disorders may mimic diabetic polyneuropathy and electrophysiologic studies may help differentiate the potential causes. For example, multiple lumbosacral radiculopathies due to lumbar canal stenosis may also produce distally predominant sensory and motor deficits with reflex loss. Patients with diabetes also may develop other neuromuscular causes of weakness, such as

motor neuron disease or chronic inflammatory demyelinating polyneuropathy (CIDP).

Electrophysiologic testing in diabetic neuropathy is primarily focused on nerve conduction velocities (CV) and evoked sensory and motor response amplitudes. Mean nerve CV values from populations of diabetics with symptomatic neuropathy are lower than those with normal matched individuals but only by 5–10 m/s [26–30]. Individual values may be normal in that they do not fall below the lower limit for normal controls. Asymptomatic diabetics also have mean CVs that are slower than matched controls [29, 31]. There is a positive correlation between the clinical severity of neuropathy and extent of CV slowing for type 1 and type 2 diabetics [32]. There is also a positive correlation between the degree of slowing and the duration of diabetes [30, 33]; F-wave and distal motor latencies in diabetic patients are prolonged in proportion to the slowing of leg or forearm CVs, indicating that conduction slowing is in general a diffuse process. However, slowing is more prominent in the lower extremities [34].

Nerve conduction slowing may on occasion be greater than one would expect from loss of large-fiber axons alone. Parallel biopsy studies have shown that this cannot be explained by segmental demyelination [24]. The basis for this additional slowing is not known. Metabolic factors are suspected. It is known that nerve conduction may slow shortly after induced hyperglycemia. Normalization of elevated blood glucose, or treatment with aldose reductase inhibitors and other compounds, may improve this slowing [35–37]. In experimental animals, these velocity changes occur without convincing alterations of Schwann cells or axons. Cool limb temperature slows conduction, and warming improves it. Transient biophysical alterations at nodes of Ranvier are likely to be responsible. These small changes in velocity are of uncertain clinical importance. They are not thought to result in sensory loss or weakness, but they may play a role in the development of fluctuating paresthesias during blood glucose fluctuations.

NCV is influenced by multiple factors, including the integrity of the largest diameter fibers, the presence of demyelination, and limb temperature. NCV can fall to 70–75 % of the lower limit of normal from large and medium axon loss alone. Once these myelinated axons are largely gone, there is no recordable distal response after nerve stimulation. Motor CVs below 70 % of the lower limit of normal, a sign of demyelination, are rarely seen with DPN when technical factors like low limb temperatures are corrected. In a study comparing the diagnostic accuracy of criteria used for the diagnosis of CIDP, Bromberg [38] included 63 patients with diabetic neuropathy. None of the diabetic patients met electrophysiologic criteria for CIDP. In a study looking for conduction block in diabetic neuropathy, only 6 of 76 nerve segments studied demonstrated block (defined as a >20 % peak-peak amplitude drop with a <15 % change in negative-peak duration), with a range of block from 21 to 41 % [39]. Likely none of these would meet current criteria for partial conduction block [40]. Thus, if there is electrophysiologic evidence of primary demyelination, with marked CV slowing or conduction block, then other causes of neuropathy should be sought.

Sensory nerve action potential (SNAP) and compound muscle action potential (CMAP) amplitudes are the result of potentials generated by functioning axons under recording electrodes. Loss of axons results in smaller response amplitudes. In DPN, SNAP amplitudes are more likely to decrease before CMAP amplitudes. The amplitude changes are most evident at distal sites [41]. A reduction of the sural SNAP is the most sensitive EDX abnormality in early DPN [26, 42]. Sural SNAP abnormalities have been recorded in up to 40 % of diabetics [24, 43]. Sural and superficial peroneal SNAPs are almost always reduced and may be absent from patients with a chronic DPN. In those with moderate or severe neuropathy, the distal lower extremity CMAPs are also reduced by 50 % and often both the SNAPs and CMAPs in the distal lower extremities are absent.

Needle electromyography (EMG) is helpful to document the extent of muscle denervation and reinnervation when present. This gives an additional measure of the extent of motor axon loss and a sense of the chronicity and activity of the neuropathy. Needle EMG also assists to confirm the length-related pattern of axon loss, where distal muscles are more denervated than proximal ones. Needle EMG may be helpful if there is reason to suspect another disorder, such as myopathy or motor neuron disease.

Other clinical electrophysiologic tests are available. Near-nerve sensory conduction studies can measure more slowly conducting potentials from the small myelinated fibers not assessed by standard clinical techniques [44]. In a study of 27 diabetic patients with mild clinical neuropathy, a correlation was seen between the slowly conducting nerve responses obtained by this technique and cool detection thresholds as measured by quantitative sensory testing [45]. Single-fiber EMG is a specialized technique that provides a sensitive measure of motor nerve reinnervation. Reinnervation is an early marker of motor axon loss. It is accompanied by abnormalities of fiber density and jitter and can be assessed by single-fiber EMG. Bril and coworkers [46] studied 90 diabetic patients with clinical neuropathy and found single-fiber abnormalities in all, even though 18 % had normal NCSs. These abnormalities also correlated well with poor diabetic control.

Clinical Autonomic Testing

Autonomic nervous system (ANS) testing consists of a variety of techniques aimed at assessing the small myelinated and unmyelinated nerve fibers that make up the peripheral

components of the autonomic nervous system. These nerve fibers cannot be studied directly, so it is necessary to use provocative tests. Currently available autonomic tests can provide measures of cardiovagal, adrenergic, and postganglionic sudomotor function (see Chap. 10). The complex nature of the tests and multiple confounding factors produce a considerable degree of variability. It is imperative that well-standardized techniques be employed to reduce the inherent variability [47, 48].

Cardiovascular heart rate (HR) tests are the most widely studied and best validated in diabetics with neuropathy [49–51]. These tests have about the same sensitivity to detect the presence of diabetic neuropathy as do NCS [31]. The most frequently used test is HR variability to deep breathing. This variation in HR (measured as the R-R variation) is produced by sinus arrhythmia, where the HR increases with inspiration and decreases with expiration. Slow and deep breathing at six times per minute maximizes this effect. A number of medications, aging, and other test factors can influence the results and must be taken into account. The other widely used test is the HR response to a standardized Valsalva maneuver. The sensitivities of the HR response to deep breathing and to the Valsalva maneuver are similar, and both are correlated with the duration of diabetes and severity of polyneuropathy. In a study of 261 patients with diabetic neuropathy, cardiovascular testing abnormalities were present in 0 % of normal controls, 13 % of diabetic patients without neuropathy, 34 % in those with subclinical neuropathy, 49 % with clinical neuropathy, and all of those with autonomic symptoms [52]. Abnormalities in these studies may be seen early, often at the time of diagnosis [53].

The most readily available quantitative measure of sudomotor function is the quantitative sudomotor axon reflex test (QSART). Sudomotor function can be quantitatively assessed by this method in which there is good normative data and the techniques can be rigidly standardized. Acetylcholine is iontophoresed into the skin and the resultant sweat response is measured using a sudorometer that quantifies the change in humidity over the skin [54, 55]. This device is commercially available and allows recordings to be made with less than a 20 % coefficient of variation. In a study of 73 patients with diabetic neuropathy, 58 % had an abnormal QSART response from the foot and this correlated with other cardiovascular measures of autonomic dysfunction [56]. Several studies have confirmed that QSART can detect distal sudomotor loss in patients with neuropathy with a high sensitivity and specificity [48].

The sympathetic skin response (SSR) is a transient reflex change in the electrical potential of the skin that can be elicited by stimuli that produce a central sympathetic discharge [56–58]. These include a painful electrical shock or an inspiratory gasp. SSR testing can be performed easily in an EMG laboratory. Limitations of the test include marked variability among normal individuals and it quickly habituates. Some have found this technique to be useful in measuring sudomotor involvement in diabetic neuropathy [59–62]. The SSR correlates with small-fiber involvement as determined from biopsied sural nerves [60] and with microneurographic evidence of abnormal autonomic physiology [59, 63]. Bril and colleagues [64] measured the SSR in 337 diabetics and found no correlation with symptoms of pain, autonomic dysfunction, or cool detection thresholds on quantitative sensory testing but did identify a relationship with sural SNAP amplitudes and vibration detection thresholds. They concluded that the SSR is not a reliable index of autonomic dysfunction in diabetic neuropathy.

Pathogenesis of Diabetic Polyneuropathy

Physicians have known about a relationship between diabetes and peripheral nerve symptoms, including foot ulcers, since the late nineteenth century [65]. In a landmark paper, Pirart [66] reported on 4,400 patients in his personal practice. He observed a correlation between the severity and duration of hyperglycemia and diabetic complications.

The pathogenic link between diabetic complications and hyperglycemia was strengthened by the results of the Diabetes Control and Complications Trial (DCCT) [67]. In this study, a cohort of 1,441 type 1 diabetics with no meaningful complications was followed for 5 or more years. The control group was treated with insulin to achieve standard good glycemic control. The intervention groups were managed the same way, except that intensive multi-dose insulin therapy was administered to achieve best-possible glycemic control. This resulted in Hgb A1c levels that were about 2 % lower than the control group. In the primary prevention group, the incidence of neuropathy was reduced from 10 to 3 % (69 % risk reduction). In a secondary intervention group, individuals with mild complications, the incidence of neuropathy was reduced from 16 to 7 % (57 % risk reduction). There were similar benefits for nephropathy and retinopathy. Individuals in the intensive treatment group maintained an advantage over the conventional treatment group years later if their Hgb A1c levels declined to that of the standard treatment group. This has been interpreted as evidence that a period of intensive glycemic treatment may confer a future advantage, even for individuals who cannot maintain that level of glycemic control. The mechanism for this memory effect remains obscure.

A similar benefit from glycemic control was found for type 2 diabetics. In the United Kingdom Prospective Diabetes Study [68], 3,867 of type 2 patients were treated with oral agents for an average of 10 years. The group with modest improvement of glycemic control (mean Hgb A1c of 7.0 %) had a 25 % risk reduction in microvascular complications when compared to a standard treatment group (mean Hgb A1c of 7.9 %).

Table 31.2 Mechanisms that have been implicated in the pathogenesis of DPN

Direct glucose toxicity
Insulin deficiency
Hyperglycemia-related metabolic derangements
Excess flux of sugar alcohols, accumulation of fructose and sorbitol, reduced nerve inositol
Reduced Na^+/K^+ ATPase at nodes of Ranvier
Slowed axonal transport
Deficiency of growth factors that support neurons
Oxidative stress with apoptosis, mitochondrial dysfunction
Nitrogen-based free radicals (nitrative stress)
Microvascular and circulatory abnormalities
Decreased nerve blood flow, endoneurial ischemia, depressed prostaglandins
Impaired vasodilation by nitric oxide
Abnormal nonenzymatic glycosylation of neural and other proteins
AGE deposition with alteration of RAGE receptors and other proteins
Altered nerve/endothelial protein functions
Autoimmune-mediated neurotoxicity
Abnormal signaling to neurons by circulating advanced glycosylated end products

Hyperglycemia and/or insulin deficiency are now considered central factors for determining diabetic complications. However, the variability of complications among seemingly similar patients indicates that there are coexisting modifying factors. These include hyperlipidemia, older age, male gender, smoking, and as yet unknown genetic factors. Although glucose is essential for the maintenance of neuronal function, elevated blood glucose may be toxic to peripheral nerves. Intravenous infusions of glucose can rapidly increase the intensity of neuropathic pain [69] and reducing hyperglycemia may relieve pain [70].

Animal models of type 1 and type 2 diabetes have been helpful. However, there is little axonal degeneration, an important feature of human DPN. Diabetic animals develop nerve CV slowing that may improve with blood glucose lowering or many other interventions. Studies of drug-induced or genetic diabetes in experimental animals have pointed to a number of ways that hyperglycemia can affect peripheral nerve function (Table 31.2). Hyperglycemia leads to reduced nerve blood flow and potentially toxic endoneurial hypoxia, which appears to be independent of hypoperfusion. Potentially toxic oxidative stress may occur in this setting [71]. In experimental animals, there is depressed Na/K ATPase at nodes of Ranvier and slowing of nerve conduction.

Glucose may bind nonenzymatically not only to fetal hemoglobin but also to proteins in nerves and vessels, with a potential toxic effect on nerve function. These "glycation products" may interfere with axon and endoneurial vessel function [72]. Nerve growth factors are suppressed after hyperglycemia, which may lead to complex derangements in nerve homeostasis and cell death [1, 73]. Autoimmunity is a possible cause of diabetic polyneuropathy and other diabetic neuropathies. Circulating anti-neuronal antibodies are reported in some diabetics, and inflammatory cells are observed in nerves of patients with diabetic neuropathy. Vascular mechanisms are appealing because the other late complications of diabetes, retinopathy, nephropathy, and large vessel ischemia also have a vascular basis. Microvascular disease has not yet been convincing liked to DPN.

Clinical Trials for Diabetic Polyneuropathy

Research Criteria for Diagnosing Diabetic Polyneuropathy

The clinical recognition and characterization of diabetic neuropathy can usually be readily accomplished by a focused history and neurologic examination. For the purposes of research studies, it is necessary to use standard techniques to detect, measure, and follow neuropathy [50, 74, 75]. An expert panel systematically reviewed the literature to develop a case definition of distal symmetric polyneuropathy in order to standardize and facilitate clinical research studies [76]. Diabetic neuropathy was the focus of most of the high-quality studies analyzed. The panel assessed the diagnostic accuracy of neuropathic symptoms, neurologic signs (decreased or absent ankle reflexes, decreased distal sensation, distal muscle weakness), and nerve conduction studies (NCS). They concluded that the highest likelihood of polyneuropathy (a definition useful for clinical trials) occurs with a combination of multiple symptoms, multiple signs, and abnormal NCS. Restrictive diagnostic criteria are best applied in the research setting where they can provide a more rigorous approach to the population under study but are not practical in the routine clinical setting [50, 75].

The diagnosis of subclinical diabetic neuropathy requires the presence of an objective abnormality of peripheral nerve dysfunction, preferably on nerve conduction studies, in the absence of symptoms or signs of neuropathy. In this cohort of patients, it is especially important to perform the NCS carefully with the appropriate control of testing conditions and techniques as well as the use of appropriate reference values [75, 77].

Measurement of Diabetic Neuropathy

There are several neuropathy composite scores that incorporate neurologic signs and have been well validated. These have been used as an outcome measure in clinical trials. These include the Michigan Diabetes Neuropathy Scale (MDNS) [78], the lower extremity portion of the Neuropathy Impairment Score (NIS-LL) [79, 80], and the Total Neuropathy Score (TNS) [81]. More recently, the Utah Early

Neuropathy Scale has been developed that includes more measures of small-fiber sensory function, a potential advantage in mild diabetic neuropathy [82].

Electrophysiologic testing in diabetic neuropathy is primarily focused on NCS. The issues relating to the electrodiagnostic confirmation of polyneuropathy are listed in the diagnosis section with regard to patients in clinical practice. In the setting of clinical trials, there is a trade-off between identifying patients with mild polyneuropathy with NCS criteria that may allow normal patients ("false positives") into the study who do not actually have neuropathy versus more rigorous criteria that have a higher specificity but may require the screening of a large number of patients to meet these stricter criteria. Dyck and colleagues [77] have carefully modeled eight different NCS criteria for the diagnosis of diabetic polyneuropathy. They concluded that the best criteria combined a composite score of normal deviates (from percentiles) of NCS.

When performing NCS as part of a longitudinal study, as is commonly done in clinical trials of new therapies, a special set of issues arises. Diabetic neuropathy is a slowly progressive disorder and thus small changes need to be detected over the usual study periods of less than 2 years. Over the 5-year DCCT study period, there was a 54 % mean risk of developing clinical neuropathy in the primary prevention cohort. This corresponded to a 0.8 m/s/year difference in the peroneal motor nerve CV between the experimental and control groups. The secondary prevention cohort showed a mean change in peroneal CV of 0.5 m/s/year, compared to the conventional treatment group [83]. Similar figures were obtained from smaller studies, such as the Oslo Study [84]. The goal of detecting a statistically significant difference of 0.5 m/s/year (e.g., 1.0 m/s over a 2-year study period) compared to untreated controls can be a daunting task.

NCS studies for clinical trials are usually performed at multiple centers that are widely distributed. The variability among sites can be reduced by requiring the use of the same techniques (electrode locations, measurements, skin preparation), standard equipment (particularly recording electrodes), and minimum limb temperatures. Training in the techniques used in the study should be provided in person in a centralized location and with a manual of the procedures to be followed. A central review of the data by experienced clinical neurophysiologists allows feedback and corrections to the sites as the study is in progress [85–87].

The test-to-test variability inherent in NCS needs to be considered as well. A 20 % change by chance alone at 1 year would obscure the true effects of an agent intended to result in a 20 % improvement. The reproducibility (coefficients of variation) of these measures in clinical trials has been reported to be 4–10 % for CVs, 15–75 % for amplitudes, and about 10 % for F-waves latencies [85, 87–90]. These studies may be performed in triplicate on different days to reduce this variability considerably [87].

Quantitative sensory testing (QST) allows more precise measurement of sensory function through the determination of the absolute sensory threshold to various stimulus modalities [91]. In these studies, the measured thresholds are the minimum vibratory or thermal (cold or warmth) stimuli that are detected using established psychophysical techniques. QST has advantages over the bedside sensory examination. The equipment provides precise control over the stimulus intensity in a graded fashion, there are validated testing algorithms, there is less subject or tester bias, and a numeric value is produced [92]. An individual's measured values can be compared with established normative data. This may be helpful in screening for mild neuropathy where there are few symptoms or signs. They may also provide information not readily assessed by NCSs, which provide information about the fastest conducting large diameter sensory nerves that primarily are associated with the modalities of vibration and proprioception. QST also measures the function of small-diameter nerve fibers that subserve pain and thermal sensation. These values may be assessed longitudinally or can be correlated with the development of other complication of diabetic neuropathy, such as foot ulcers.

QST abnormalities correlate well with the presence of neuropathy in diabetic populations [74] as well as individual patients. Vibratory detection threshold (VDT) testing at the standard frequencies (125 Hz) measures the function of Meissner and Pacinian corpuscles and their large diameter sensory nerve fibers. VDT abnormalities are associated with loss of the Achilles tendon reflexes and have been correlated with the development of diabetic foot ulcers [93]. VDT abnormalities have been shown to be related to longer duration of diabetes and sensory loss and areflexia on clinical examination, but not with neuropathic symptoms [94]. Thermal detection threshold reflects the integrity of the free nerve endings and their associated small-diameter myelinated and unmyelinated nerve fibers. Both warm and cold detection thresholds (CDT) can be assessed, have been validated, and correlate well with small nerve fiber dysfunction [95, 96]. In a large prospective study of 380 diabetic patients, abnormal VDT and CDT were strongly correlated with clinical examination deficits and abnormalities on NCSs [31]. Greater abnormalities in these QST attributes also were associated with increasingly severe degrees of clinical neuropathy. Heat-pain thresholds may also be measured as an additional attribute of small-fiber sensory function [97].

Since a relatively reproducible quantitative threshold value is measured, QST studies are well suited for use in longitudinal studies. As such, QST is an important endpoint in clinical trials of pharmacologic agents aimed at treating diabetic polyneuropathy. The reproducibility of QST studies depends on the equipment used, the patient population

studied, and whether they are done at multiple sites. In the Rochester Diabetic Neuropathy Study [98], the test-retest correlation coefficients were >0.9 for both VDT and CDT. Using standardized techniques, QST studies have excellent reproducibility even when performed in many centers as part of a clinical trial [87, 99].

Autonomic tests can provide quantitative measures of cardiovagal, adrenergic, and postganglionic sudomotor function. The complex nature of the tests and multiple confounding factors produce a considerable degree of variability. It is imperative that well-standardized techniques be employed to reduce the inherent variability [47, 48]. Ideally, a combination of cardiovagal and sudomotor studies should be performed to quantify the autonomic involvement in diabetic neuropathy.

There are other sensitive and quantitative techniques that are particularly suited to measuring small-fiber sensory nerves in diabetic neuropathy [100]. These surrogate markers are likely to be used as endpoints in future trials. These techniques include intraepidermal nerve fiber (IENF) measures with skin punch biopsy [48, 101] and corneal confocal microscopy [102, 103]. The latter technique has the advantage of being less invasive than skin biopsy but is less readily available at the current time.

Summary of Clinical Trial Results

There have been a number of agents designed to improve the underlying pathophysiology of the disorder rather than for symptomatic pain relief. Many of these are based on a reasonable scientific rationale [2, 104, 105], but none show convincing effectiveness. At this time, there are no agents approved in the United States for the treatment of diabetic polyneuropathy. This may be that the drugs are truly not effective. Alternatively, methodological difficulties inherent to the studies may have obscured a positive treatment effect.

Of the proposed mechanisms that underlie the diabetes-induced damage to peripheral nerve, two are linked to "oxidative stress." These include advanced glycosylation end products (AGEs) and the accumulation of sorbitol. There have been no clinical trials of AGE inhibitor in patients with diabetic neuropathy. Aldose reductase is the first enzyme of the polyol (sorbitol) pathway, which serves to convert glucose into sorbitol. Aldose reductase inhibitors (ARI) have been used in a number of trials over the past 30 years to alter the proposed metabolic insult from excess nerve sorbitol. There is considerable evidence in animal models that treatment with such agents might be beneficial [106, 107]. The first randomized, double-blind clinical trial of an ARI, sorbinil, demonstrated an improvement in sensory and motor CVs compared to placebo [37]. Subsequent studies suggested small improvements in other parameters. However, efficacy could not be established. Long-term trials were not performed as a result of the significant toxicity of this agent, which included rash, lymphadenopathy, and pancytopenia. Subsequent large, multicenter studies of other ARIs, including tolrestat, ponalrestat, epalrestat, zenarestat, and ranirestat, did not demonstrate a convincing, clinically meaningful effect as measured using standard trial design (NCSs, QST, autonomic testing, and clinical examination scales) [108]. Nonetheless, there were trends that suggested that these agents hold promise if a compound with adequate aldose reductase inhibition has an acceptable safety profile, and can be tested over a long enough period with clinically meaningful endpoints.

Recombinant human nerve growth factor (rhNGF) has been the subject of several trials. NGF is a neurotrophic factor that plays a role in the development, maintenance, and regeneration of neuronal tissue, particularly small sensory nerve fibers. There is some evidence that decreased availability of NGF contributes to the pathogenesis of diabetic polyneuropathy [109, 110]. A phase II trial of rhNGF over 6 months showed preliminary evidence of efficacy in patients with diabetic neuropathy. There was improvement compared to placebo in certain QST parameters (cooling detection threshold and perception of heat as pain) and trends toward an improved neurologic examination scale. However, larger phase III trials over a year period were not able to confirm any beneficial effects [111, 112].

Proinsulin C-peptide is deficient in patients with type 1, but not type 2, diabetes. C-peptide is a bioactive peptide with physiologic cellular effects that may play a role in the development of diabetic neuropathy [113]. C-peptide replacement therapy with short-term use (3 months) in a controlled trial of patient with type 1 disease had early beneficial effects on sensory nerve conduction studies and some measures of sensory function [114, 115].

Deficiency of myoinositol is reported in animal models of diabetic polyneuropathy. Dietary supplementation with myoinositol over 6 months improves NCSs in rats, but no definitive clinical or electrophysiologic benefits were seen in human trials [116, 117]. Other vitamin supplements, such as thiamine, vitamin B12, and pantothenic acid, were ineffective when performed as controlled clinical trials [2].

Evaluation of the Patient with Diabetic Polyneuropathy

All individuals with diabetes should be evaluated at least yearly for evidence of DPN, even if they do not report neuropathy symptoms. Patients without known diabetes but with symptoms consistent with neuropathy should be screened for diabetes if they are at high risk for developing type 2 diabetes. Risk factors include elevated BMI, hyperlipidemia, proteinuria, and a family history of diabetes.

There is an increased incidence of diabetes in association with seemingly unrelated genetic and acquired disorders. These include myotonic dystrophies, Friedreich ataxia, other spinocerebellar ataxias, mitochondrial disorders, and POEMS syndrome [4].

A challenging problem is determining whether a patient with neuropathy and known diabetes has diabetic neuropathy, another cause of neuropathy, or both. One step is to determine that the patient has an axonal polyneuropathy and that the severity of the neuropathy is consistent with the likely duration and severity of diabetes. DPN is more likely if there are other diabetic complications like retinopathy or retinopathy. Subsequent diagnostic testing should then be driven by the history. There should be an inquiry about possible other causes of an acquired or inherited neuropathy. For patients with painful small-fiber-type neuropathy, consider a prescribed or environmental neurotoxin, autoimmune vasculitis, sarcoidosis, Sjögren syndrome, HIV infection, amyloidosis, and uremia.

Vitamin B12 level should be tested, particularly if the patient with worsening diabetic neuropathy takes metformin [118]. If there is more weakness and greater reflex loss than expected for DPN, then serum protein electrophoresis with immunofixation and EDX studies are indicated. If there is intrinsic hand muscle weakness or more prominent sensory symptoms in the hands, upper extremities NCSs may detect median neuropathy at the wrist or ulnar neuropathy at the elbow. Needle EMG may be helpful to document the nature and severity of the neuropathy. Spine MRI imaging is helpful if there is a suspicion of cervical or lumbosacral radiculopathy, or a myelopathy. Diabetes and neuropathy may be the result of a shared underlying condition like mitochondrial disorders. It is helpful to rethink the diagnosis of DPN at follow-up visits if the patient's clinical course differs from that of typical DPN.

There may be clinical clues that a patient with neuropathy is unlikely to have diabetic neuropathy (Table 31.3). If present, these features should lead to further investigation. In one study of 100 consecutively evaluated diabetic patients with symptomatic neuropathy, one third had a neuropathy unrelated to diabetes [119]. Features that were more indicative of nondiabetic neuropathy included a short interval between diagnosis of diabetes and the onset of neuropathy, early motor deficits, markedly asymmetric deficit, and generalized areflexia.

Table 31.3 Clues that a diabetic patient's polyneuropathy may not be from diabetes alone

Late diabetic neuropathic complications are unlikely
Diabetes known to be of <5 years duration
No associated retinopathy or microalbuminuria
Onset or topography of polyneuropathy is unusual for diabetes
Painful rapid progression without weight loss or a change in glycemic control
Stepwise acute multifocal nerve involvement
Distribution of sensory loss is not length-related (stocking and glove)
Large fiber-type functions are selectively affected (ataxic neuropathy)
Weakness is present without sensory loss
Bulbar or proximal weakness when the distal findings are not advanced
Disproportionate loss of reflexes, suggesting demyelination
Shoulder girdle weakness
Electrodiagnostic features unusual for an axonal polyneuropathy
NCV < 70 % of low limit of normal with preserved CMAP amplitudes
Multifocal conduction slowing or block

Management of the Patient with Diabetic Polyneuropathy

General Considerations

Early assessment of the severity of a patient's DPN is helpful for establishing a neurologic baseline and determining prognosis and disability. The written history should include a relevant neurologic review of systems, including the autonomic systems. Resting pulse and blood pressure measurements should be documented. There should be a description of the feet, especially calluses and ulcers. The neurologic examination should include comments about possible hand and intrinsic foot muscle atrophy, foot and toe dorsiflexion strength, reflexes, and large and small-fiber sensory deficits, including arm and leg sensory levels.

There are excellent grading scales for the severity of DPN that use combinations of symptoms, signs, and nerve conduction studies. These include San Antonio criteria, the modified Toronto Clinical Neuropathy Score, the Utah Early Neuropathy Scale, the Michigan Neuropathy Scale, and Dyck/Mayo Clinic Neuropathy Impairment Score. The elements of these scales have been summarized [4].

The role of the neurologist in the care of a patient with DPN depends on the nature of the referral, the experience of the referring doctor, and the consultant's personal view about the limits of his or her responsibility. When possible the consultant should establish a diagnosis, recommend treatments, and make recommendations for the alleviation of pain. Consultants may consider it appropriate to verify that the patient is followed by a clinician or center with special expertise in the modern management of diabetes. There should be a plan to address treatable risk factors and diabetic complications including hyperlipidemia, cardiovascular disease, renal involvement including proteinuria, and diabetic retinopathy. Potentially reversible risk factors like obesity and smoking should be highlighted. If obesity is a factor, then the patient should be told about the importance of working with his or her caregivers to develop a plan for weight management and regular exercise.

Table 31.4 Medical therapies used or under evaluation to treat diabetic polyneuropathy

Proven effective
Intensive glucose control
Other therapies proven effective
None
Unproven in human trials but has scientific rationale
Aldose reductase inhibitors [ARIs] – normalize polyol metabolism
Nerve growth factor, other neurotrophic factors – replacement may restore axonal homeostasis; regeneration potential
C-peptide – lacking in type 1 diabetes; replacement binds with receptor and alters nerve metabolism
Alpha-lipoic acid [LA] – protect against oxidative stress
Gamma-linolenic acid [GLA, evening primrose oil] – increase nerve blood flow
Myoinositol [MI] – replace nerve inositol deficiency
Intravenous immunoglobulin (IVIG) – suppress autoimmune response

Therapy to Prevent Axon Loss

The neurologist should explain that there is currently no cure for DPN. The only proven treatment for diabetic neuropathy is best-possible glycemic control (Table 31.4). Evidence-based guidelines for managing diabetes and its complications are available [9]. Intravenous and oral 600 mg/day α-(alpha) lipoic acid has been shown to improve nerve conduction slowing and relieve sensory symptoms when given over short periods [120]. Trials of γ-(gamma) linolenic acid (evening primrose oil) reportedly improved NCSs but without evident clinical benefits. Many remedies with no proven value have been recommended to treat diabetic neuropathy. There is no scientific evidence that vitamin supplements containing thiamine, folic acid, pyridoxine, or cobalamin are of benefit unless the patient is deficient in that vitamin.

Neuropathic Pain

Although most patients referred to a neurologist with diabetic polyneuropathy have pain as a primary complaint, pain is also common in general diabetes clinics as well. Neuropathic pain effects 16 % of patients with diabetes [121] and is an important management problem. On the other hand, before embarking on medications that may ameliorate the pain, it is important to establish that the pain is due to diabetic polyneuropathy. The patient should have a history and examination consistent with polyneuropathy (see above). The quality of the pain should be consistent with painful diabetic polyneuropathy. This would include distal predominance (in the feet), the quality of the pain (burning, shock-like, or tingling), and the relation to rest and ambulation. Typically, diabetic neuropathic pain is more intense at rest, particularly in the evening or when trying to fall asleep, and less bothersome when walking. Pain that radiates down the legs with ambulation suggests lumbar stenosis. Foot pain that is largely limited to weight-bearing is likely mechanical or local at the foot and not due to neuropathic pain.

Table 31.5 Recommended treatments for painful diabetic polyneuropathy [122]

Recommended drugs	Recommended topical agents
Level A	
Pregabalin	
Level B	Level B
Other anticonvulsants	Capsaicin cream
Gabapentin	Isosorbide dinitrate spray
Sodium valproate	Percutaneous electrical nerve stimulation
Tricyclic antidepressants	
Amitriptyline	
Desipramine	
Nortriptyline	
Serotonin norepinephrine reuptake inhibitors	
Duloxetine	
Venlafaxine	
Opiod agonists[a]	
Tramadol	
Dextromethorphan	
Oxycodone CR	
Morphine sulfate	
Not recommended	
Other anticonvulsants – oxcarbazepine, carbamazepine, phenytoin, lemotrigine, lacosamide, topirimate	
Mexelitine	
Clonidine	
Magnetic field therapy	
Surgical nerve decompression	

Level A – established as effective; requires at least two class I studies
Level B – probably effective; requires at least one class I and two class II studies
[a]Some experts do not recommend these agents for chronic neuropathic pain

Drug treatment for neuropathic pain (Table 31.5) is considered in Chap. 80. A recent evidence-based guideline based on a systematic review of the literature on the treatment of painful diabetic neuropathy [122] concluded that pregabalin is established as effective (Level A). Other agents that are probably effective and should be considered (Level B) for treatment include other anticonvulsants (gabapentin and sodium valproate), tricyclic antidepressants (amitriptyline, desipramine, and nortriptyline), selective serotonin norepinephrine reuptake inhibitors (duloxetine and venlafaxine), and opiates (tramadol, dextromethorphan, morphine sulfate, and oxycodone). Topical agents that are probably effective and may also be considered included capsaicin cream, isosorbide dinitrate topical spray, and percutaneous electrical nerve stimulation.

Tricyclic antidepressants (TCAs) have been a mainstay for treatment of diabetic neuropathic pain [123]. Amitriptyline may be effective at a small dose, 10–25 mg at bedtime, and one can work up slowly to 75 or 150 mg if necessary. Somnolence is a common side effect, so these drugs are often

administered at bedtime. The associated sedation is helpful for pain-related insomnia. TCAs can cause prolongation of the QT interval and should be avoided for most patients with cardiac conduction defects, unstable angina, recent myocardial infarction, or ventricular arrhythmias. It should be used with caution in men with symptoms of an enlarged prostate. The universal dry mouth is a mild unwanted complication of these compounds. Desipramine and nortriptyline have less anticholinergic activity than amitriptyline.

The other antidepressant medications that have been demonstrated to be effective for diabetic neuropathic pain are those of the serotonin norepinephrine reuptake inhibitor class, duloxetine and venlafaxine. Common side effects include nausea, somnolence, and dizziness.

Pregabalin treatment resulted in a significant reduction in pain in a pooled analysis of seven randomized clinical trials involving 1,510 patients with painful diabetic neuropathy [124]. Adverse effects included weight gain, dizziness, somnolence, and peripheral edema. Gabapentin was effective in several randomized clinical trials [122]. The major side effects of gabapentin are dizziness, somnolence, and ataxia. A randomized trial of patients with painful neuropathy suggested that gabapentin combined with nortriptyline was more effective than either agent alone for reducing pain [125]. There are several small trials that suggest that sodium valproate is effective in reducing pain and diabetic neuropathy. Sodium valproate should not be used in women of childbearing potential because of teratogenic effects. Some of the other anticonvulsants, such as topiramate, phenytoin, carbamazepine, lacosamide, and lamotrigine, are not currently recommended due to lack of data supporting efficacy.

The antiarrhythmic mexiletine has been used for diabetic neuropathic pain based on favorable case series, but the only class one study of this agent suggested that it is ineffective [122]. Opioid agonists in the right circumstances should be considered for the treatment of pain from diabetic neuropathy. This is supported by clinical trial evidence of the effectiveness of tramadol, dextromethorphan, oxycodone controlled-release, and morphine sulfate. Adverse events are common and include sedation, nausea, constipation, and rebound headache. Chronic use of opiates may result in dependence, tolerance, and frequent escalation of dose. It is clear that they are effective for short-term pain management, but there are concerns regarding long-term opiate therapy for nonmalignant pain.

Various topical treatments are likely effective and can be considered for the treatment of painful diabetic neuropathy. Capsaicin cream includes a component of hot peppers and presumably causes pain relief through the completion of substance P in the skin. It may have modest benefit and may be useful in combination with an oral agent. Local burning and skin irritation are the major side effects. Many patients are unable to tolerate the burning pain that is prominent with initial use. That side effect decreases with continued use. Given the limited evidence from small trials, isosorbide dinitrate spray and percutaneous electrical nerve stimulation may be beneficial [122].

There are proposed algorithms for the treatment of painful diabetic polyneuropathy, based on the effectiveness of therapy and the side-effect profile. A common approach [126, 127] is to start with one of the three potential first-line agents: an anticonvulsant (pregabalin or gabapentin), a tricyclic antidepressant, or a SNRI (duloxetine). If pain control is ineffective or there are unacceptable side effects, substitute or add one of the other agents. For example, if gabapentin is used first and it is ineffective for pain relief, the next step would be to substitute or add a tricyclic antidepressant or duloxetine. If pain control is still inadequate, some experts would add an opioid agonist. Others, based on the special concerns regarding chronic opioid use, would not use this class of agents at all.

Surgical decompression of multiple peripheral nerves has been proposed as a potential method for treating painful diabetic neuropathy. The rationale for such an approach is dubious and there are no adequately designed clinical trials to support the use of invasive surgical decompression of multiple nerves as treatment for diabetic polyneuropathy. This treatment is not recommended.

Autonomic Symptoms

When autonomic neuropathy accompanies DPN, a wide spectrum of symptoms may occur. These symptoms may arise from the cardiovascular, gastrointestinal, genitourinary, pupillary, sudomotor, and neuroendocrine systems. Orthostatic hypotension is a common accompaniment of diabetic polyneuropathy, but symptoms usually are mild. A prescribed cardiovascular exercise program, elastic stockings, increased salt intake, and elevating the head of the bed are helpful. Fludrocortisone and midodrine [128] are effective but may cause unacceptable hypertension. Erectile dysfunction often responds to sildenafil, or other phosphodiesterase-5 inhibitors, in about half of treated patients. Bladder dysfunction should be confirmed by urodynamic testing. This is often effectively treated by scheduled urinations coupled with bethanechol. Chronic gastroparesis is treated by dietary modification (e.g., hydration and multiple, small low-fat meals) and adding agents, like metoclopamide or domperidone, to increase gastric motility.

Other Patterns of Polyneuropathy Associated with Diabetes

Chronic Inflammatory Demyelinating Polyneuropathy (CIDP)

Chronic inflammatory demyelinating polyneuropathy (CIDP) is an autoimmune polyneuropathy associated with demyelinating electrophysiology, elevated spinal fluid protein, and response to immunotherapy. Most often it is also

characterized by proximal and distal weakness, hyperreflexia or areflexia, and a subacute course. These features are quite distinct from diabetic polyneuropathy. However, there are patients with diabetes who develop CIDP.

Early reports suggested that CIDP is much more common in diabetics. There is speculation that diabetes is a risk factor for CIDP [129, 130]. Most of these reports were not population based and were likely subject to referral bias. It is likely that these disorders are coincidental. Laughlin and colleagues [131] detailed the prevalence of CIDP in a population-based cohort from Olmstead County, Minnesota. They found that diabetes was not a risk covariant for CIDP. The prevalence of diabetes in CIDP was 4 % compared to 12 % in the control population. The number of CIDP patient was relatively small, so the authors could not exclude a small association between diabetes and CIDP with certainty. It is likely that some patients with painless, symmetric radiculoplexopathy (proximal diabetic neuropathy) are mislabeled as having CIDP.

There have been several studies that have compared patients with diabetes and CIDP to CIDP patients who do not have diabetes [132–134]. These have found no significant differences between the two groups. The two CIDP cohorts, those with and without diabetes, have similar clinical features, electrophysiologic findings, and pathologic abnormalities. There was no identifiable difference in the response to immunotherapy in these nonrandomized comparison studies. One of the larger series [133] found minor differences between the two groups. The patients with diabetes and CIDP were older and the electrophysiology and pathologic findings on nerve biopsy showed more axonal loss in the idiopathic CIDP patients. Although the diabetic CIDP patients also responded to immunotherapy, the degree of improvement was less favorable. The authors speculated that these differences likely reflected the additive effects of diabetic polyneuropathy in patients who develop superimposed CIDP.

It is important to recognize CIDP in patients with diabetes so that it can be treated appropriately. Although mild forms of CIDP may be difficult to distinguish from diabetic polyneuropathy, there are clinical clues to the possibility of this superimposed autoimmune demyelinating neuropathy. Since the temporal progression of DPN is slow, a subacute progression or a relapsing-remitting course would not be consistent with DPN and should suggest the possibility of proximal diabetic neuropathy, CIDP, or another neuromuscular disorder. If the weakness is as prominent proximally as distally, or if there is disproportionate weakness in the absence of significant sensory loss, then CIDP would also be a consideration. Widespread areflexia or prominent ataxia would also suggest CIDP. There are also important electrodiagnostic findings that are not consistent with DPN. The NCS and needle EMG features of diabetic polyneuropathy are those of an axonal polyneuropathy and the EDX criteria for primary demyelination are usually not met [38, 135]. Patients with both diabetic polyneuropathy and uremic polyneuropathy may have nerve CVs sufficiently slowed to meet the criteria used by most authors to identify primary demyelination. Cerebrospinal fluid (CSF) examination and nerve biopsy are generally unhelpful. In most cases, the CSF examination is unlikely to be helpful because the protein is often elevated in patients with diabetic polyneuropathy, even to the degree seen in CIDP. Although not routinely performed, nerve biopsy findings also may not distinguish these two neuropathies [104].

Motor Neuropathy

When a patient develops a predominantly motor neuropathy in the setting of diabetes, it is most likely another less common form of diabetic neuropathy (i.e., proximal diabetic neuropathy) or an alternative neuromuscular disorder, such as CIDP. There is no convincing evidence that a predominantly motor form of diabetic polyneuropathy occurs. There are reports of a motor neuron disorder occurring in the setting of a chronic hypertensive anemic state and repeated periods of severe hypoglycemia. This is seen in the context of an insulinoma [136].

If the neuropathy is subacute, asymmetric, and with prominent pain and weakness, proximal motor neuropathy of diabetes (diabetic lumbosacral radiculoplexus neuropathy) should be considered. CIDP can also present as a subacute neuropathy that is predominantly motor. A painless, symmetric form of proximal motor neuropathy (diabetic lumbosacral radiculoplexus neuropathy) may be confused with CIDP. Other neuromuscular disorders can occur coincidentally with diabetes and also produce weakness, sometimes superimposed on a preexisting diabetic polyneuropathy. These include motor neuron disease, inflammatory myopathies, disorders of neuromuscular transmission (such as myasthenia gravis or Lambert-Eaton myasthenic syndrome), and other non-length-related patterns of neuropathy.

Proximal Motor Neuropathy (Diabetic Lumbosacral Radiculoplexus Neuropathy or Diabetic Amyotrophy)

This disorder is much less common than chronic diabetic polyneuropathy. It was first described by Bruns [137], but Garland and Traverner [138] emphasized it as a distinct clinical entity seen with diabetes and manifested by asymmetric pain and proximal leg weakness but little demonstrable sensory loss. Garland was uncertain of the underlying pathology and termed this entity diabetic amyotrophy [139].

Other designations have been proposed including the Bruns-Garland syndrome, diabetic femoral neuropathy, femoral-sciatic neuropathy, ischemic mononeuropathy multiplex, proximal diabetic neuropathy, diabetic polyradiculopathy, diabetic proximal amyotrophy, and diabetic lumbosacral radiculoplexus neuropathy [137–148]. These names emphasized different aspects of the clinical presentation and possible sites of peripheral nervous system involvement. There is a varying degree of importance ascribed to the pain and asymmetry, association with weight loss, and amount of sensory involvement. Due to these divergent views, it was proposed that diabetic amyotrophy be discarded in favor of the term proximal motor neuropathy (PMN) [144]. This term appropriately highlights the proximal leg weakness without implying a localization or pathogenesis. Others prefer the term diabetic lumbosacral radiculoplexus neuropathy (DLRPN), which emphasizes the complex localization of this disorder to the lumbosacral plexus, nerve roots, and peripheral nerves [147, 148].

There appears to be a spectrum of features between the painful, asymmetric cases of acute or subacute onset and the painless, more slowly progressive cases [144]. These features overlap in most patients (see below), with a rapidly evolving, asymmetric onset followed over several months by a slower progressive course frequently affecting both legs [137, 147, 148]. Although less common, progressive, painless proximal leg weakness can be seen as a sole manifestation of this disorder [146, 149–151].

Etiology and Pathogenesis

There is fairly strong evidence that this disorder is due to an inflammatory microvasculitis causing ischemic nerve injury [152, 153]. The clinical feature of acute or subacute onset with prominent pain favors an inflammatory or ischemic basis. The association with weight loss in many patients and the anecdotal reports that recovery is hastened by improved nutritional support suggest that some metabolic process may play a role.

Said and colleagues [154] performed nerve biopsies of the intermediate cutaneous nerve of the thigh, a sensory branch of the femoral nerve, in ten patients with PMN. All had an asymmetric disorder of subacute onset and signs of polyneuropathy. True vasculitis, inflammation and vasonecrosis, was seen in two and perivascular inflammatory infiltrates in four others. Nerve lesions felt consistent with ischemia were seen in three specimens. A subsequent by the same group [155] of four additional patients with proximal motor neuropathy demonstrated similar inflammatory lesions. The mean duration of symptoms prior to biopsy ranged from 4 to 18 months. The inflammatory lesions at that point were a mixture of B and T lymphocytes and macrophages. Inflammatory cell infiltrates or microvasculitis in this disorder has been reported by others [147, 156, 157].

A study by Kelkar and coworkers [157] examined nerve biopsy specimens, most from the intermediate nerve of the thigh, in 15 patients with PMN. These biopsies were performed relatively early after the onset of asymmetric, progressive, and painful proximal leg weakness. The duration of symptoms at the time of biopsy ranged from 5 weeks to 12 months, but several were done within six 6 weeks. Four patients had transmural infiltration of polymorphonuclear leukocytes into the small epineurial blood vessels. Six patients had "perivasculitis" with mononuclear cell infiltrates around small vessels without signs of true vasculitis (i.e., fibrinoid necrosis of the vessel walls or transmural inflammation). Activated complement was demonstrated in the endothelium of the small vessels and IgM in the endoneurium. They suggested that the primary event early in the course of PDN is a polymorphonuclear vasculitis secondary to immunoglobulin or immune complex deposition. This evolves, later in the disorder, into a perivasculitis involving primarily lymphocytes.

Dyck and colleagues [147, 148] prospectively studied 33 patients with proximal motor neuropathy, which they termed DLRPN. They performed an ipsilateral nerve biopsy and found strong evidence implicating an ischemic injury due to microvasculitis. There was increased inflammation in all nerves, with inflammatory cells in the vessel walls (suggestive of microvasculitis) and evidence of ischemic injury. The latter evidence included focal or multifocal fiber loss, perineurial thickening, and epineurial neovascularization. In two cases, there was evidence of necrotizing vasculitis. However, the overall pathologic changes were those of a microvasculitis involving small arterioles and venules without fibrinoid necrosis.

The link between diabetes and such localized inflammatory infiltrates is uncertain. Some have postulated that the primary event in PMN is an immune attack and microvasculitis within nerve [148]. Abnormal blood vessels or blood-nerve barrier secondary to diabetes might trigger a reactive vasculitis. IgM or immune complex deposition could set off a complement cascade which further disrupts the blood-nerve barrier and hastens the vasculitic process. The final result is epineurial and perineurial blood vessel occlusion that then produces nerve ischemia and infarction. There are no convincing data that a metabolic abnormality plays a primary role in the pathogenesis of PMN. It is possible that a metabolic insult triggers the events in some fashion, such as abruptly changing the small blood vessel endothelium with an alteration of the blood-nerve barrier. This could set the stage for the inflammatory processes.

Clinical Presentation

PMN (DLRPN) is primarily a disorder of older adults with type 2 diabetes. Men are more often affected than women. In general, patients with PMN are not known to be diabetic for a long period of time. Glycemic control is often not poor [148]. In some patients, this is the presenting feature, leading to the diagnosis of diabetes. This was seen in 7 of 33 patients in a recent series [147]. The mean age at diagnosis ranged from 57 to 65 years [147, 158–160], with very few patients younger than age 50. Anorexia and substantial weight loss occurred before or during the progressive phase of the neuropathy in most. Weight loss was usually modest, but Pascoe and colleagues [161] noted a mean weight loss of 18 kg in 31 of 38 patients. Dyck and coworkers [147] found that there was 10 lb or more of concomitant weight loss in 85 % of patients. Blood glucose may normalize following weight loss, confusing the diagnostician.

The characteristic presentation is abrupt, asymmetric severe thigh pain, followed within weeks by mild to severe hip and thigh muscle weakness. The pain is typically in the hip and thigh but may involve the leg or foot particularly later in the course. It less commonly involves the low back and buttock [147]. Pain is often severe, requiring treatment with long-acting oral narcotics. Weakness and atrophy of the affected muscles follows. The muscles most often affected early in the course are the iliopsoas, quadriceps, and thigh adductors. Hip extensors and hamstrings are often involved. The combination of thigh muscle weakness with sparing of distal muscles is a clinical pattern of weakness distinctive for PMN. Distal muscles also may be weak, particularly peroneal-nerve innervated. Proximal muscles are always more affected initially, which is the reverse of the usual pattern with axonal polyneuropathies. Over subsequent months, the unaffected segments of the limb are often affected and the contralateral side may be involved. In a large prospectively studied series [147], this syndrome began unilaterally in 88 % of patients but became bilateral in 97 %. The median time to bilateral disease was 3 months.

Sensory loss generally is minor in PMN, except distally from the commonly associated polyneuropathy. About two third of patients with PMN have clinical or EDX signs of a distal symmetric polyneuropathy [154, 162]. Cutaneous sensory loss or hyperesthesia over the thigh may be demonstrated in half of patients, but it is usually subtle [155, 158].

Recurrent episodes are uncommon [145, 158]. The progressive phase of weakness may develop over a few days or more slowly, over months. A relatively symmetric, slowly progressive disorder has been reported [146, 149, 151, 163] but is less common in practice. A large, well-characterized series of 23 patients with this disorder convincingly demonstrated that this is painless PMN and not a different entity [151]. The diabetic patients in this series had a similar median weight loss of 30 lb and the physiologic studies and nerve biopsy features were similar to painful PMN. These patients differed only in the lack of pain, more symmetrical involvement, and slower progression. Barohn and colleagues [137] suggested that two phases are seen in patients with PMN; a rapid phase associated with pain is followed by a slower phase of weakness that progresses over weeks or months. There also appears to be an apparent spectrum of PMN from an acute painful, asymmetric, and rapidly progressive form to a less common painless, more symmetric form with slower progression.

Spontaneous recovery was noted in early reports. Coppack and Watkins [158] followed 27 patients who had a mean time to pain recovery of 3 months which varied from 1 to 12 months. Pain was the first manifestation to improve, as early as a few weeks, but little beyond 12 months.

On occasion, patients develop a similar disorder affecting the upper extremity. Upper limb involvement was noted in 2 of 13 patients reported by Leedman and coworkers [164]. In a larger series of 60 patients with PMN, 9 patients had upper extremity involvement [165]. Seven of the nine patients had the onset of upper extremity involvement after the leg symptoms began, ranging from 3 weeks to 15 months later. The clinical and electrodiagnostic features showed multifocal, axonal loss in the cervical roots, brachial plexus, and upper limb peripheral nerves analogous to the pattern of involvement in the lower extremities.

Evaluation and Diagnosis

PMN is a consideration in any patient with proximal lower extremity weakness. It may be the presenting feature of late-onset type 2 diabetes. Alternatively, weight loss may normalize the serum glucose and the diagnosis of diabetes may be missed at the time of neurologic presentation. It may be necessary to search for distant blood work for clues that diabetes was a preexistent disorder, perhaps mild and overlooked. Pain and weight loss are most often present, although not invariably.

There are no laboratory, hematologic, or biochemical abnormalities that characterize PMN. The serum CK is often mildly elevated as observe in other denervating disorders. All patients have an elevated CSF protein. In one series of 26 patients, the mean CSF protein was 92.5 mg/dL [161]. In another large series [147], the mean CSF protein was 89 mg/dL with a range of 44–214. The CSF cellularity and other parameters are normal.

The typical clinical presentation and the EDX findings of PMN support the diagnosis. A focal lesion of the lumbar roots needs to be excluded by lumbar magnetic resonance imaging. If clinically appropriate, imaging of the pelvis and lumbosacral plexus may be warranted. On occasion, another

disorder may mimic PDN and present with proximal leg weakness in the setting of diabetes, such as chronic inflammatory demyelinating polyneuropathy, polymyositis, or motor neuron disease. In most cases, these can be distinguished from PMN by the EDX studies, serum CK, and the clinical course. If the course is atypical of PMN, repeat electrophysiologic studies are often helpful.

EDX evidence of a distal symmetric polyneuropathy is found in the majority of those patients who present with PMN [145, 161, 162]. Subramony and Wilbourn [162] found no convincing evidence on NCSs of distal polyneuropathy in 10 of 27 patients studied. The disorder is heterogeneous, not only with respect to the distal polyneuropathy, but also the extent and asymmetry of the EDX findings. In patients with a distal polyneuropathy associated with PMN, the NCS findings are those of axonal loss. Since NCSs of the lower extremities generally examine distal sensory and motor nerve function, conclusions about the nature of PMN cannot be drawn from studies of distal nerves and muscle.

Femoral motor NCSs with recording from the quadriceps muscles add little to the diagnostic efforts [159, 162, 166]. However, in patients with significant weakness and atrophy of the quadriceps muscle, the femoral compound muscle action potential (CMAP) of the affected limb is either low in amplitude or absent, reflecting the degree of axonal loss. The delayed distal latency, that may accompany reduced amplitude CMAP, reflects loss of the largest diameter conducting motor axons. The femoral CMAP should be compared to the other side, particularly when it is an asymmetric process, to get a better estimate of the amount of axonal loss. This may provide some prognostic information regarding the expected pace of recovery. When this study is performed early in the course of the disease, the reduction in CMAP amplitude accurately reflects the degree of axonal loss. However, later in the illness, after collateral sprouting has occurred, the CMAP amplitude may be relatively normal. The evidence of marked collateral sprouting and reinnervation would, however, be evident on the needle EMG examination.

The needle EMG abnormalities observed in affected muscles are a function of the timing of the study and the onset of illness. In the first few months, needle EMG signs of acute denervation (fibrillation potentials) are present. They are more abundant in more severely weak muscles but can be detected often in strong muscles. Initially, motor unit action potential (MUAP) morphology is normal, but neurogenic MUAP recruitment is evident in weak muscles. Several months later, after collateral sprouting has begun to reinnervate muscle fibers previously denervated, fibrillation potentials are less evident. At this time, normal amplitude, polyphasic MUAP morphology is a prominent finding and may be mistaken for myopathy. As time progresses, the MUAP configuration is characteristic of chronic denervation with large amplitude and long duration MUAPs.

The needle EMG examination is always abnormal but quite heterogeneous in the distribution of findings. The abnormalities are typically most severe in the quadriceps, iliopsoas, and thigh adductor muscles. Abnormalities may also be seen in the hamstrings and glutei, as well as lumbar paraspinal muscles. Distal muscles may be affected in several ways. There may be variable involvement of any of the foreleg muscles, most pronounced in the tibialis anterior and the anterior compartment muscles. In many, there is bilateral distal chronic denervation, as part of coexistent chronic diabetic polyneuropathy, even in those who clinically have only unilateral leg weakness.

In general, the EDX findings reflect involvement of nerve roots, plexus, and peripheral nerve in the limb, or limbs, affected. The electrophysiologic abnormalities are more widespread than the clinical deficits suggest [147].

Treatment and Management

There are anecdotal reports that patients who regain a portion of the lost weight and begin insulin therapy seem to improve faster than those who remain cachexic. Some physicians instruct their patients to refrain from caloric restriction and to try to regain their pre-morbid weight until they recover from this disorder. However, there have been no controlled trials, or large series, to support this approach.

Since pain is the most common symptom at the onset of PMN, and usually the most severe and limiting feature early on, it should be managed with narcotic analgesics. These generally can be tapered and discontinued after the pain begins to remit. Chronic pain may respond to the agents used in other forms of neuropathic pain, such as gabapentin and tricyclic antidepressants. Physical therapy is beneficial after the progressive phase of the illness [167]. As an inflammatory process may play a role in PMN, immunotherapy may be considered. No controlled trials have been published to support the efficacy of immunotherapy in PMN [168]. However, intravenous immunoglobulin (IVIG) therapy was reported as effective in several case series [129, 161]. Several case series also have documented improvement with corticosteroids, particularly with regard to pain relief [129, 161, 169]. Occasional patients respond to corticosteroids dramatically, although this greatly complicates the problem of glucose control. Since the natural history is one of spontaneous improvement, it is difficult to know if immunotherapy is beneficial.

Prognosis

Spontaneous recovery occurs in most patients, albeit to varying degrees. Coppack and Watkins [158] followed 27 patients

who had a mean time to the start of recovery of 3 months with a range of 1–12 months. Recovery was generally complete by 18 months. Pain was the first manifestation to improve, as early as a few weeks, but little beyond 12 months. Although a minority had residual weakness when reexamined at an average of 45 months, none had disabling weakness. Others found that improvement is seen in a majority but often incomplete. In a follow-up study of 21 patients at about 3 years after the onset of symptoms, Pascoe and coworkers [161] found 12 had resumed normal walking, 7 ambulated with an aid, and 2 were wheelchair bound. In the 33 patients followed prospectively by Dyck and colleagues [147], most of the patients required wheelchairs at the initial evaluation, but most had substantial improvement. Only 10 % still required a wheelchair after a median follow-up of 2 years.

Mononeuropathies and Radiculopathies Without Nerve Compression

Much like PMN, the mononeuropathies and radiculopathies that occur in association with diabetes have a very different onset and course than chronic diabetic polyneuropathy. Diabetic polyneuropathy tends to be insidious in onset and progression and develops usually in patients with longstanding disease. In contrast, diabetic mononeuropathies are usually acute or subacute in onset and are often associated with substantial pain. Many are associated with a recent weight loss or a change in glucose control. They run a defined course and then tend to remit, at least in part, in 6–12 months. They occur in middle or later life and may be an early manifestation of diabetes. All of these features imply a different pathogenesis underlying the focal neuropathic complications.

Cranial Neuropathies

Acute cranial mononeuropathies may coexist with chronic diabetic polyneuropathy. Watanabe and colleagues [170] compared the incidence of cranial nerve palsies in 1961 diabetic patients and 3,841 patients without diabetes. They found that cranial nerve palsies occurred more frequently in diabetics (1 %) compared to nondiabetic patients (0.1 %). The cranial nerves most frequently affected were the facial nerve (VII), followed by the oculomotor nerves (III, IV, and VI).

Since these mononeuropathies are uncommon, there are few population-based studies that give reliable figures for the incidence of *ocular motor mononeuropathies* due to diabetes. Many older individuals have other risk factors for the development of these so-called vasculopathic neuropathies. These risk factors include diabetes, hypertension, advanced age, smoking, atherosclerotic disease, and hypercholesterolemia. In a large study of 2,229 patients with oculomotor palsies, 306 (13.7 %) were associated with diabetes [171]. In the diabetic group, cranial nerve VI was most often affected (50.0 %), followed by III (43.3 %) and IV (6.7 %). In another large study of 4,278 patients with third, fourth, and sixth nerve palsies, the authors ascribed 103 cases (2.4 %) solely to diabetes [172].

Unilateral ocular motor neuropathies appear suddenly, over hours or a few days, and are usually painful. Symptoms begin with ocular pain or unilateral headache in more than half of patients, with pain and diplopia progressing over several days. With *third nerve palsies*, the pain is accompanied by diplopia and ptosis. There is ptosis and paresis of third nerve-supplied extraocular muscles, but pupillary function is typically spared. This is likely due to the fact that the disorder is thought to occur as a result of peripheral nerve infarction. Asbury and colleagues [173], in a postmortem histopathologic study of a patient with diabetic third nerve palsy, demonstrated centrofascicular fiber loss in the mid-cavernous portion of the nerve, findings supportive of nerve ischemia. Since pupillary fibers lie on the outside of the third nerve, they are less susceptible to ischemia. There may be minimal pupillary involvement (less than 2 mm anisocoria) in a minority of patients. Pupillary sparing helps to differentiate this from a compressive third nerve lesion, such as a cerebral aneurysm or tumor. However, pupillary function may be partially spared with a compressive lesion in up to 20 % of cases, particularly early in the course of the illness.

Patients with *sixth nerve palsies* develop binocular horizontal diplopia. As with other cranial mononeuropathies associated with diabetes, the onset is usually acute and painful. The examination demonstrates unilateral weakness of the lateral rectus muscle. An associated facial neuropathy on the same side or contralateral hemiparesis should suggest a pontine lesion as an alternative cause. Bilateral abduction deficits should suggest increased intracranial pressure ("false-localizing sign") or an infiltrative or inflammatory process in the subarachnoid space. Patients with *fourth nerve palsies* complain of binocular vertical diplopia. They have weakness of the superior oblique muscle and generally have an ipsilateral head tilt. Other associated neurologic signs, such as a Horner's syndrome or dysmetria, should suggest a brainstem lesion rather than diabetic mononeuropathy.

The diagnosis of an acute third, fourth, or sixth nerve palsy as a diabetic mononeuropathy is supported by the typical presentation with pain and acute diplopia. Some authors suggest that patients over age 50 with pupil-sparing, complete third nerve palsies should have neuroimaging performed with MRI and MRA or CT angiogram [174]. Even isolated, pupil-sparing third nerve palsies can be caused by small infarcts in the mesencephalon or by compressive lesions. In patients in this age group who have risk factors like diabetes, other authors suggest performing neuroimaging

if there has been no improvement after 12 weeks of close follow-up [175]. These patients should be examined frequently in the first 2 weeks for the possible development of delayed pupillary involvement. Patients with partial third nerve palsies that are also pupil sparing should have neuroimaging and be followed closely in the first 2 weeks for evidence of pupillary involvement that may not be evident on first examination. Pupillary involvement raises the possibility of a compressive lesion, and of most concern is an aneurysm of the posterior communicating artery. This generally requires brain neuroimaging, including cerebral angiography. Diabetic patients over 50 with isolated sixth or fourth nerve palsies should also have neuroimaging to exclude an intracranial process [174]. Others suggest performing neuroimaging if there has been no improvement after 4–12 weeks [175]. All patients under 50, even with a history of diabetes, should be thoroughly evaluated for alternative causes of cranial mononeuropathies.

There is no specific treatment for these ocular motor mononeuropathies. The prognosis for vasculopathic ocular motor mononeuropathies, including those due to diabetes, is excellent [175]. In one series, 72 % recovered completely or partially in 4–6 weeks [172]. In another series, the mean time to recovery was 2.5 months [176].

Idiopathic facial neuropathy (*Bell's palsy*) appears to be more common in older diabetics than nondiabetics. The incidence of diabetes in patients with Bell's palsy ranges from 6 to 10 % [177–179] and is higher if impaired glucose control, by glucose tolerance testing, is considered [178, 180, 181]. It is clearly more common in older diabetics, making up 17 % of those 30 or older but only 4 % of those under 30 in some series [179, 182]. However, some investigators have not found diabetes to be an independent risk factor for Bell's palsy [183].

The presentation is that of any other case of idiopathic facial palsy. There is an acute onset of facial weakness that may progress to maximal over several days. There is involvement of upper and lower facial muscles, often pain, and varying loss of taste and hyperacusis. The examination is notable only for unilateral peripheral facial weakness. Other neurologic signs, such as ophthalmoparesis or sensory loss, are not present. Pecket and Schattner [178] found a disturbance of taste in 14 % of those with diabetics compared to 83 % of those with no diabetes. This suggests that the lesion in diabetics is most often distal to the chorda tympani. Other features of the facial neuropathy are identical to those without diabetes.

The acute unilateral facial weakness should not be accompanied by other neurologic symptoms or signs. If it is, then an alternative diagnosis should be considered and investigated. The differential diagnosis of typical Bell's palsy in a diabetic includes idiopathic facial neuropathy, Lyme disease, varicella-zoster infection, and trauma.

The EDX findings in Bell's palsy associated with diabetes are similar to those seen with others with the idiopathic form. The facial CMAP amplitudes on NCSs 1 week or more after the onset are normal, low in amplitude, or absent, reflecting the variable amount of axonal loss. MRI imaging studies may show enhancement of the affected seventh nerve but need not to be done routinely.

Patients with incomplete facial weakness generally recover fully over weeks to months. Those with complete paralysis of facial muscles are more likely to have slower and incomplete recovery. The recovery depends on the degree of axonal loss which can be estimated by measuring the amplitude of the facial CMAP on NCSs done at least a week after the onset of weakness (after completion of Wallerian degeneration). In those patients who have a preserved distal CMAP (20 % lower limit of normal or better), the prognosis for recovery is good [184]. For those who have no elicitable motor response, there is a reasonable likelihood of incomplete recovery with persistent weakness and aberrant regeneration. This is also reflected in the amount of fibrillation potentials seen on needle EMG examination more than 3 weeks after the onset and also by a reduction in the MUAPs recruited with voluntary muscle contraction.

Truncal Radiculoneuropathies

This unusual disorder, also termed thoracic polyradiculopathy, truncal neuropathy, and diabetic thoracoabdominal neuropathy, is distinctive [185]. It occurs in older patients, more often in men with either type 1 or 2 diabetes, and the symptoms commonly appear during a fluctuation of diabetic control. It may occasionally be the presenting feature of diabetes. Like PDN, it often occurs in the setting of weight loss. Most of the five patients reported by Sun and Streib [186], as well as previous reports that they summarized, had substantial associated weight loss, as much as 19 kg. Four of the five patients detailed by Watkins and Thomas [187] had a weight loss of at least 10 kg. An occasional patient will have simultaneous onset of this disorder with diabetic proximal neuropathy [186, 188, 189].

Patients develop pain, cutaneous hypersensitivity, sensory loss, and sometime weakness in the distribution of one or more somatic nerves or roots. Pain is usually present at the onset and is the predominant symptom. It is typically aching or burning in quality and may be quite severe. The chest or abdomen may be involved. The affected segments usually are contiguous but do not necessarily follow classical root distribution territories, and involvement may be patchy. It is usually unilateral but can be bilateral. The examination may show only evidence of cutaneous hypersensitivity in the general distribution of the pain that is difficult to localize to a particular nerve or root level. When present, the pattern of

sensory loss may be quite variable. Stewart [190] carefully mapped out the topography of the sensory deficits in 17 episodes of truncal neuropathy. Some patients had a unilateral or bilateral dermatomal band of sensory deficit from the involvement of adjacent main spinal nerves. However, two thirds of patients had involvement restricted to the ventral or dorsal rami of the spinal nerves or a combination of these distributions. Focal muscle weakness may lead to local areas of abdominal wall weakness and a local bulge, simulating an abdominal hernia [191, 192].

The diagnosis of diabetic truncal radiculopathy is generally a clinical one. Most patients have abnormalities on the needle EMG examination that may help confirm this disorder. The pain intensity and location may incorrectly suggest a myocardial infarction, acute cholecystitis, or acute appendicitis [189]. The differential diagnosis should focus on mimicking medical, surgical, or orthopedic conditions. With weight loss, a search for cancer is often carried out before referral to a neurologist. Once the neuropathic nature of the pain and sensory loss is clear, the evaluation should include consideration of herpes zoster, a central cord syndrome, and a length-related polyneuropathy, with the associated shield of anesthesia on the chest and anterior abdomen. A slowly developing truncal sensory loss in a patient with a length-related pattern of sensory loss due to diabetic polyneuropathy is called diabetic truncal polyneuropathy [193]. It should not be confused with the very different acute, painful focal radiculoneuropathy detailed above.

The subacute onset, associated pain and weight loss, and course suggest a similar pathogenesis to diabetic proximal neuropathy (PMN, DLRPN, diabetic amyotrophy). This is supported by the observation that these disorders may develop together [186, 188]. The anatomic site of the lesions has not been established. EDX studies indicate a multisegmental disorder at the root or proximal intercostal and abdominal nerve levels, or both. This is generally manifest by fibrillation potentials in paraspinal, intercostal, and abdominal muscles in varying combinations [186, 194]. Stewart found patterns of paraspinal sparing that were more suggestive of multiple proximal neuropathies than radiculopathies [190]. Lauria and coworkers [195] showed that cutaneous skin biopsies in three patients with diabetic truncal radiculoneuropathy had loss of intraepidermal nerve fibers. There was return of the intraepidermal nerve fibers after clinical recovery suggesting a lesion distal to the dorsal root ganglion. It is likely that this disorder is at the level of the thoracic roots, or posterior primary rami, and the intercostal or abdominal nerve in varying combinations. Until the site of the lesion is firmly established, its heterogeneous involvement is best characterized by the term radiculoneuropathy.

The progressive phase is generally short, days or weeks. Pain control may be difficult in the early months of the disorder, but pain usually subsides within 4–10 months. Cutaneous sensory loss in the same distribution may persist lifelong. The role of corticosteroids or intravenous immunoglobulin for treatment is uncertain. More potent immunosuppression or long-term use of corticosteroids is not warranted. The focus of treatment is symptomatic management of the neuropathic pain. Protein-calorie supplements may be useful if there has been appreciable recent weight loss.

Limb Mononeuropathies

Cervical and lumbosacral radiculopathies and other focal neuropathies can occur coincidentally with diabetes, and it may be difficult to distinguish the etiology. Other common causes should be considered and investigated. Diabetic focal limb mononeuropathies not at the common sites of local nerve compression do occur but are rare. Despite frequent statements to the contrary, isolated femoral neuropathies are rarely due to diabetes. The distribution of weakness, after careful examination, is more widespread and is usually due to proximal diabetic neuropathy (DLRPN).

Acute mononeuropathies that result from nerve infarction are quite different from the compression/entrapment neuropathies that occur with diabetes (see below). Most of the compression neuropathies, other than peroneal neuropathy, are slowly progressive. Nerve infarction is acute and painful. When the localization of the lesion can be identified clinically or electrophysiologically, it is not at a common site of compression (e.g., radial nerve in the forearm). It is characterized by axonal loss, so conduction block or focal slowing across the lesion is not seen on nerve conduction studies. Recovery is slow and determined by the site and extent of axonal loss. A lesion with severe axonal loss (reflected in absent motor responses on the NCS) that is very distant from the weak muscle, such as proximal sciatic neuropathy producing foot drop, may not have any improvement at all. In contrast, a lesion with partial axonal loss only a few inches from the weak muscles would be expected to recover completely over a few months time.

Multiple noncompressive mononeuropathies in the same patient are known as mononeuropathy multiplex. Mononeuropathy multiplex is not a complication of diabetes, although the coexistence of focal compressive neuropathies and polyneuropathy in the same patient may superficially resemble such a disorder. An acute, or subacute, mononeuropathy multiplex should raise a concern for vasculitis.

Mononeuropathies with Focal Nerve Compression

Diabetic patients and others with chronic polyneuropathy are considered more susceptible to focal compression neuropathies than those without polyneuropathy. The sites

of compression are the conventional ones, including the median nerve at the wrist, the ulnar nerve at the elbow, and possibly the peroneal nerve at the knee [29, 196]. These compressive, or entrapment, neuropathies are clinically and electrophysiologically similar to those that develop in the absence of diabetes. However, the frequent coexistence of diabetic polyneuropathy results in manifestations and EDX abnormalities that also need to be considered in this context. For milder compression neuropathies, the EDX features are that of focal slowing of motor and sensory conduction and/or conduction block across the usual sites of compression. With more severe lesions, the SNAPs are absent, the CMAP amplitudes are reduced, and there is denervation on needle EMG examination of the affected muscles. However, these latter changes do not necessarily reflect focal compressive lesions, as do focal slowing or conduction block. They may also represent coexistent polyneuropathy. It is necessary to study other sensory and motor nerves of the limb to assess how much of the involvement is secondary to polyneuropathy or whether the abnormality is limited to the nerve and likely due primarily to the compressive neuropathy. This differentiation has important treatment and prognostic implications, as discussed below.

It is unclear why diabetics, particularly those with polyneuropathy, have an increased likelihood of developing compressive neuropathies. A number of possible mechanisms are proposed. Obesity may be a factor rather than diabetes itself.

The best evidence for increased susceptibility for the development of compressive neuropathy exists for *carpal tunnel syndrome* (*CTS*). The development of CTS seems to be related to the body mass index in diabetic patients [197], and increased nerve tissue vulnerability may also play a role [198]. Population studies of diabetics have unequivocally demonstrated an increased incidence of CTS. A large case–control study compared 3,391 patients with CTS to 13,564 matched controls [199]. The presence of diabetes was identified as a risk factor with an OR of 1.51. Stevens and colleagues [200] reviewed the records of 1,016 patients with CTS and found a standardized morbidity ratio of 2.3 for diabetes. The relative risk of CTS is also about 1.6 in patients with prediabetes [201]. Most studies show that CTS is about threefold more common in diabetic patients than matched controls [202, 203]. EDX evidence of CTS may be found in about a quarter of diabetic patients including those with mild diabetic neuropathy [197], but only a third of those are symptomatic. The occurrence of median neuropathy at the wrist increases with longer duration of diabetes. Most often the patient presents with numbness and paresthesias in the hand, particularly the thumb, index, and middle fingers, but symptomatically all the digits may be involved. These sensory symptoms are often worse at night and accompanied by pain. They may note a tendency to drop objects from the hand. Other than the nocturnal symptoms, the other manifestations are similar to what may be seen with diabetic polyneuropathy with hand involvement. Late in the course of CTS with severe axonal loss present, thenar weakness and atrophy is present. If there is also ulnar-innervated hand weakness and atrophy, such as in the interosseous muscles, then polyneuropathy should be considered as an alternative cause.

The diagnosis of CTS is best made electrophysiologically using the same criteria as for other patients [204]. However, in those with polyneuropathy and upper extremity involvement, the diagnostic challenges are greater [205]. Electromyographers have difficulty distinguishing CTS in the presence of advanced polyneuropathy with severe axon loss. Other nerves not subject to compression must be assessed to understand the severity of the polyneuropathy. Diabetic focal compression neuropathies may improve after surgical decompression, and diabetics with compressive neuropathy should be managed like others [206]. Patients with CTS and diabetes have the same beneficial outcome after carpal tunnel release as nondiabetic patients [207, 208]. Patients must be reminded that their underlying polyneuropathic symptoms will not change after successful CTS surgery. For example, nocturnal pain and paresthesias, undoubtedly due to CTS, would be expected to improve, but the hand numbness may not, if it is due in part to the polyneuropathy [209].

Ulnar neuropathy at the elbow, although much less common than CTS, also occurs more frequently in diabetics. Ulnar neuropathy has been found in 1.2–4.9 % of diabetic patients in most series [29, 210]. In the large population-based cohort study by Dyck and colleagues [74], 2 % of patients with type 1 and type 2 diabetes had ulnar neuropathy at the elbow. In a large series of 414 patients with ulnar neuropathy, identified postoperatively after procedures for unrelated disorders, 11 % had diabetes compared to 3 % of controls [211]. The incidence of diabetes in the setting of ulnar neuropathy at the elbow ranges from 5 to 17 % [212, 213].

Clinically, ulnar neuropathy presents with numbness and sensory loss in the ring and small digits of the hand, usually intermittent initially. This may be followed by progressive weakness and atrophy in ulnar-innervated hand muscles. This needs to be differentiated from the distal hand weakness that may occur from a coexistent polyneuropathy where median-innervated thenar hand muscles would also be involved [214]. Sudden onset of a significant sensory and motor deficit should suggest nerve infarction rather than compression. The EDX features should reflect the effects of compression at the elbow. As discussed with CTS, other nerves in the limb need to be examined by NCSs to determine the extent of coexistent polyneuropathy.

There is no generally accepted therapeutic approach for ulnar neuropathy at the elbow, and the same issues exist in the setting of diabetes. Conservative treatment with avoidance of positions that cause compression and the use of an

elbow pads is generally the first step. In those with a progressive deficit and clear electrophysiologic evidence of focal compression, surgical decompression is an option. Surgical decompression with or without nerve transposition may be performed, with no evidence to date that one is superior to the other. Compared with CTS surgery, successful outcome after these procedures is less common.

Peroneal neuropathy at the fibular head is infrequent enough that it may be a coincidental occurrence with diabetic polyneuropathy [29]. It was seen in only one of the 380 diabetics studied by Dyck and coworkers [74]. In a series of 103 patients with peroneal neuropathy at the fibular head, 8 % had diabetes [215]. The presentation is like that seen in nondiabetics, manifest by unilateral acute, painless foot drop. The EDX features demonstrate a variable combination of peroneal nerve conduction block and axonal loss. Usually, focal CV slowing cannot be demonstrated [215, 216]. The needle EMG may show evidence of acute denervation in peroneal-innervated muscles distal to the knee with sparing of the shorthead of biceps femoris muscle confirming that the lesions is at the level of the knee. The painless onset and demonstration of focal conduction block at an otherwise common site of compression in nondiabetics suggests that this is a compression neuropathy rather than nerve infarction.

Weakness is limited to peroneal-innervated muscles, as opposed to the more widespread, proximally predominant and painful course of diabetic amyotrophy. This needs to be differentiated from the more slowly developing symmetric weakness of severe polyneuropathy. The latter develops insidiously and is accompanied by severe distal sensory loss and areflexia. The natural history in diabetics is not different from those without diabetes and largely is dependent on the amount of axonal loss that has occurred. A lesion that is predominantly caused by conduction block due to segmental demyelination recovers quickly over weeks, in contrast to one with severe axonal loss that requires nerve regeneration for improvement to begin. The latter often takes 9–12 months for any recovery to be evident. Most are treated conservatively since recovery occurs spontaneously in most, if not all. This reflects the nature of the injury, acute external compression rather than chronic entrapment.

Lateral femoral cutaneous neuropathy (*meralgia paresthetica*) occurs in about 1 % of diabetics [74]. In a recent population study from Olmstead County, Minnesota, meralgia paresthetica was significantly associated with diabetes with an incidence rate in the diabetic population being 7 ½ times the general population [217]. Although obesity may be an alternative explanation for this occurrence in diabetic populations, patients with meralgia paresthetica were twice more likely to have diabetes than age-, gender-, and body mass index controls [217]. Meralgia paresthetica presents with burning and numbness over the anterolateral thigh in the distribution of the lateral femoral cutaneous nerve distribution. Most often it is unilateral but may occur bilaterally. Most resolve spontaneously after several months.

Other compression neuropathies, such as radial neuropathy at the spiral groove and tarsal tunnel syndrome, have rarely been described in patients with diabetes.

Nutritional and Alcoholic Neuropathies

32

Robert W. Shields Jr.

Introduction

Polyneuropathy due to dietary nutritional deficiency is relatively uncommon in developed countries except in the setting of the nutritional deficiency that occurs in association with chronic alcoholism [1–4]. Nevertheless, polyneuropathy due to dietary nutritional deficiency may still occur in underdeveloped countries particularly in the setting of famines [5]. More often, polyneuropathies due to nutritional deficiency are caused by specific disorders such as pernicious anemia, sprue, and following gastrectomy that result in malabsorption of single or multiple vitamins. It has been suggested that the nutritionally related polyneuropathies are more likely caused by an imbalance of nutrition than a complete deficiency that may occur in starvation [6]. In addition, these polyneuropathies are more often associated with a deficiency of multiple vitamins rather than an isolated deficiency of a single vitamin [6]. This is particularly true regarding the etiology of alcoholic polyneuropathy.

Neuropathic Beriberi

Introduction

Since the 1600s, neuropathic beriberi or dry beriberi was recognized as a condition that caused pain, paresthesias, and paralysis of the limbs [6]. When cardiac manifestations including tachycardia, dyspnea, and edema predominated the clinical picture, the term "wet beriberi" was used. By the mid- to late 1800s, numerous detailed clinical descriptions of wet and dry beriberi were recorded [6, 7] and it became evident that both forms of beriberi represented different manifestations of the same disease [6, 8]. Beriberi was a relatively uncommon disorder until the latter part of the nineteenth century when it reached epidemic proportions, particularly in areas of the world in which rice was the mainstay of the diet. This epidemic was the result of a new method of processing rice utilizing steam-powered rice mills. This process resulted in separating the pericarp and germ from the rice shaft rendering this "polished" rice deficient in thiamine and other nutrients [9]. Although beriberi was initially believed to be caused by an intoxication or an infection [7], evidence of a nutritional etiology was observed by Van Leent, a Dutch naval physician [6, 7], and Admiral Kanehiro Takaki of the Japanese Navy [6, 7, 10]. These naval physicians were able to reduce the incidence of beriberi among sailors by providing them with diets that were similar to that of officers [6, 7, 10]. Admiral Takaki incorrectly presumed that the cause of beriberi was a protein deficiency. In 1897, Christiaan Eijkman, a Dutch military surgeon, discovered that a disease similar to beriberi occurred in birds that were fed a diet of steamed cooked polished rice as opposed to crude rice [6, 7, 9, 10]. Initially, Eijkman speculated that the rice husks countered a toxin in the polished rice, but subsequently he and others postulated theories suggesting that certain foods may contain protective substances which are essential for health [7, 9]. Casimir Funk, working in the Lister Institute in London, was successful in isolating a water-soluble substance from rice polishings that appeared to be an essential neurotrophic factor [7, 10–12]. Funk demonstrated that polyneuritis similar to beriberi could be produced in pigeons fed a diet deficient in this water-soluble substance [7, 12]. He named this substance "vitamine" to indicate that it was a "vital amine" and suggested that other diseases including scurvy, pellagra, and rickets may also be due to a deficiency of this particular vitamin or other vitamins yet to be discovered [6, 7, 12, 13]. Subsequently, it was discovered that not all vitamins are amines and the term "vitamine" was changed to "vitamin." Jansen and Donath in

1926 isolated the "antineuritic vitamin" and, subsequently, it was synthesized and named thiamine by Williams in 1936 [14].

The discovery of thiamine had a dramatic impact on the management of wet beriberi as administration of thiamine quickly and effectively reversed the cardiac manifestations of the disease. However, the effect of thiamine on peripheral neuropathy was more difficult to demonstrate and led some to speculate that thiamine deficiency was not the specific cause of polyneuropathy occurring in neuropathic beriberi [6]. This concern was also fostered by the difficulty in developing an animal model of neuropathic beriberi due to isolated thiamine deficiency [6]. Nevertheless, animal models were eventually developed and demonstrated that isolated thiamine deficiency may result in polyneuropathy [6, 15, 16]. Thus, the discovery of thiamine deficiency as a cause of beriberi was instrumental in developing the concept of disease due to nutritional deficiency.

Etiology and Pathogenesis

Thiamine or vitamin B1 is a pyrimidyl-substituted thiazole that is found in most animal and plant tissues but it is abundantly present in unrefined cereal grains, wheat germ, yeast, soybean flour, and pork [17]. The recommended daily allowance for thiamine ranges from 1.0 mg/day for older women up to 1.5 mg/day for young men [17]. Thiamine is absorbed in the small intestine by passive diffusion and an active transport process [17]. In the jejunum, thiamine is phosphorylated to thiamine pyrophosphate (TPP), the principal coenzyme form of thiamine [17]. Thiamine and TPP are primarily involved in carbohydrate metabolism. The two primary biochemical reactions in man utilizing thiamine and TPP are the oxidative decarboxylation of alpha-keto acids and the formation of alpha-ketols catalyzed by transketolase [17]. Although the precise biochemical mechanism of nerve injury in neuropathic beriberi has not been defined, it is likely that thiamine's role in carbohydrate metabolism may be the mechanism by which peripheral nerves are affected [18]. Neuropathic beriberi is rarely encountered in developed countries as a result of dietary nutritional deficiency except in the context of the general nutritional deficiency seen in chronic alcoholics [6]. However, wet and dry forms of beriberi may still be observed in the context of total parenteral nutrition and in other situations in which alternative methods of nutritional support are provided to patients [19–21]. Thiamine deficiency has also been reported in patients following various bariatric surgical procedures [22, 23] and has been termed bariatric beriberi [24]. Gestational polyneuropathy due to thiamine deficiency may occur, usually triggered by hyperemesis gravidarum and is often associated with encephalopathy and other signs of Wernicke's disease [25].

Clinical Presentation

The very best clinical and pathologic descriptions of beriberi are found in the writings of Pekelharing and Winkler who traveled to the Dutch East Indies during the beriberi epidemic in order to study this disease and determine its etiology [6, 7]. The neuropathic features include a rather nonspecific clinical syndrome often characterized by painful paresthesias, muscular aches and pains, and limb weakness all conforming to a generalized sensorimotor polyneuropathy [7, 8]. The symptoms are typically symmetrical and are distributed in a distal to proximal gradient. The polyneuropathy usually evolves rather slowly over weeks or months, but occasionally it may develop rapidly over a period of several days [6]. On occasion, pain may dominate the clinical picture resulting in the syndrome of a painful small-fiber neuropathy. Cranial nerve involvement, including tongue and facial weakness, is occasionally observed. However, involvement of the recurrent laryngeal nerve is a relatively common clinical feature that manifests as hoarseness and weakness of the voice [6]. Rarely, amblyopia manifested by central and centrocecal scotomas presumably due to retrobulbar optic neuropathy has been attributed to beriberi [6]. However, it was suggested that the occurrence of optic neuropathy is more likely due to Strachan's syndrome, especially when there is orogenital dermatitis accompanying a predominately sensory polyneuropathy [26]. Other features that have been attributed to beriberi, including ocular motor weakness and nystagmus, are more likely related to coexistent Wernicke's disease. The clinical features of beriberi tend to progress in a slow chronic fashion until the nutritional deficiency is corrected.

Differential Diagnosis

Because neuropathic beriberi produces a relatively nonspecific clinical syndrome of a symmetric and generalized sensorimotor polyneuropathy, a wide variety of other disorders causing similar clinical syndromes need to be considered in the differential diagnosis (see Table 32.1). The clinical features of recurrent laryngeal nerve involvement, facial weakness, and tongue involvement are not often encountered in other common causes of generalized polyneuropathy and may provide important clues to the presence of beriberi. In developed countries, neuropathic beriberi is likely to occur due to an iatrogenic mechanism, especially total parenteral nutrition [19–21]. Thus, this diagnosis should be considered in all patients with the typical clinical features of beriberi who are at risk for nutritional deficiency. Many authors have commented on the striking similarities between neuropathic beriberi and alcoholic polyneuropathy and have suggested that alcoholic polyneuropathy is in fact

Table 32.1 Generalized chronic sensorimotor polyneuropathies

14. Hereditary polyneuropathies

a manifestation of neuropathic beriberi or thiamine deficiency [6, 27–29]. Certainly both wet and dry forms of beriberi can be seen in the setting of the general malnutrition associated with chronic alcoholism. These issues are discussed later in the section on alcoholic polyneuropathy (see below).

Evaluation and Diagnosis

The electrodiagnostic (EDX) features of neuropathic beriberi are those of an axon loss generalized sensorimotor polyneuropathy [30–33]. Pathologic features also conform to axonal degeneration [6, 33, 34]. Thus, these aspects of the evaluation may characterize the nature of the underlying polyneuropathy as an axonal degenerative process, but do not provide specific diagnostic criteria for neuropathic beriberi. The specific diagnosis of neuropathic beriberi centers on the documentation of thiamine deficiency. Historically, attempts to directly measure thiamine in the blood and urine have failed to provide consistent and reliable results [6, 17, 18, 35]. A more accurate and reliable indicator of thiamine deficiency is the assay of red blood cell transketolase activity [36–39]. Transketolase, a thiamine diphosphate-dependent enzyme, discloses reduced activity in the setting of chronic thiamine deficiency [39]. Although this test has been utilized as an indicator of thiamine deficiency, it has not been sufficiently studied to establish its precise sensitivity and specificity [18]. Furthermore, transketolase activity may normalize rapidly following dietary supplementation [36, 37, 40]. Although elevated levels of blood lactate and pyruvate are observed in thiamine deficiency, these findings are nonspecific for diagnostic purposes [18, 41, 42]. More recently, new methods utilizing high-performance liquid chromatography have provided more reliable assays for thiamine deficiency [43–45]. These methods, which quantitate the amount of thiamin diphosphate in whole blood and erythrocytes, compare favorably to results via transketolase activity and provide clear technical advantages regarding sensitivity, specificity, precision, and robustness [43, 44].

Treatment, Management, and Prognosis

Once a diagnosis of neuropathic beriberi is made or considered, thiamine replacement therapy should be initiated and maintained until proper balanced nutrition is restored. Typically, thiamine is administered intravenously or intramuscularly at a dose of 50–100 mg daily. In contrast to the dramatic response thiamine has on wet beriberi [46], it has been more difficult to demonstrate a beneficial effect on neuropathic beriberi [6]. Some clinical improvement is expected in most patients but improvement tends to develop slowly, and in patients with rather severe deficits there may be permanent residual deficits [32].

Alcoholic Polyneuropathy

Introduction

The association between chronic alcoholism and polyneuropathy was first documented in the reports of Lettsom in 1787 [47] and by Jackson in 1822 [48]. These early descriptions were subsequently followed by numerous similar reports such that by the late 1800s, the clinical features of alcoholic polyneuropathy were well described and widely known [6]. During that time, it was believed that the polyneuropathy encountered in chronic alcoholism was due to a direct toxic effect of alcohol on peripheral nerves. This concept went unchallenged until 1928 when Shattuck first suggested that the polyneuropathy seen in chronic alcoholism was caused by a nutritional deficiency of vitamin B and thus should be regarded as a manifestation of beriberi [28]. Since Shattuck's proposal, considerable evidence has been gathered which documents that nutritional deficiency caused by alcohol displacing essential nutrients from the diet is the principal pathogenic mechanism of alcoholic polyneuropathy [1–3, 6, 27, 29, 42, 49–52]. However, controversy still remains as to whether alcohol may also act as a toxin to peripheral nerve and in some alcoholic patients may be the primary cause or contributing factor to their polyneuropathy [53–59].

Chronic alcoholism associated with malnutrition is a relatively common cause of generalized sensorimotor polyneuropathy. Although the precise incidence of alcoholic polyneuropathy is unknown, it occurs in approximately 9 % of alcoholic patients admitted to hospital for alcohol-related disorders [1, 60]. The magnitude of the problem of alcoholic polyneuropathy is underscored by the high prevalence of

asymptomatic alcoholic patients with physical signs of polyneuropathy [6, 60], abnormalities of nerve conduction studies [61–65], or alterations on autonomic nervous system testing indicating autonomic neuropathy [58, 66, 67].

Etiology and Pathogenesis

The proposal that alcoholic polyneuropathy is, in fact, a nutritional disorder stems from the observation that the clinical features of alcoholic polyneuropathy are essentially identical to those of neuropathic beriberi [6, 28]. Furthermore, it is well documented that alcoholic patients may develop both wet and dry forms of beriberi [6, 27, 68, 69]. More compelling evidence regarding the nutritional etiology of alcoholic polyneuropathy comes from the writings of Victor and Adams who methodically studied hundreds of alcoholic patients with various neurological complications including polyneuropathy [1–3, 6]. These authors documented that a history of poor nutrition was invariably present in every patient with alcoholic polyneuropathy in whom an accurate nutritional history could be obtained [1–3, 6]. In addition, these authors emphasized that it is often difficult to obtain an accurate history of nutritional deficiency in alcoholic patients. Thus, the nutritional history should be pursued and confirmed with family or friends. Direct clinical evidence supporting a nutritional etiology of alcoholic polyneuropathy is provided by an experiment performed by Strauss in 1935 [52]. He allowed ten hospitalized alcoholic patients with polyneuropathy to continue drinking alcohol according to their current habit (between one pint and one quart of whiskey per day) providing that they ate an adequately balanced nutritious diet. These subjects were under observation between 14 and 129 days with a mean duration of 64 days. Despite the continued alcohol intake, the clinical features of alcoholic polyneuropathy improved in all ten subjects. In another experiment, Victor and Adams studied ten alcoholic patients admitted to hospital who were given diets deficient in thiamine for 5 days while ceasing alcohol consumption upon admission [2]. None of the ten patients improved until thiamine was subsequently added to their diet.

The clinical evidence citing that alcohol may indeed act as a neurotoxin in the genesis of alcoholic polyneuropathy comes from reports of polyneuropathy occurring in alcoholic patients who do not appear malnourished [53, 55, 58]. However, in most of these reports, the assessment of nutritional status and the criteria used to define nutritional deficiency may not be sufficient to completely exclude the possibility of malnutrition as a pathogenic factor. One of the most widely cited studies that supports the toxic etiology for alcoholic polyneuropathy was reported by Behse and Buchthal [53]. They studied 37 alcoholic patients with alcoholic polyneuropathy. Twenty-three of the patients had no clinical evidence of nutritional deficiency by virtue of a history of adequate dietary intake and the absence of weight loss, whereas 14 patients had overt evidence of nutritional deficiency on the basis of a marked weight loss. The clinical, EDX, and pathologic features of polyneuropathy in the alcoholic patients were identical in both groups leading Behse and Buchthal to conclude that malnutrition was not a requirement for polyneuropathy in alcoholic patients and that alcohol may act as a toxin on peripheral nerve [53]. However, the issue of nutritional status in their patients is somewhat complex. Most of the subjects were beer drinkers and thus weight was not a reliable indicator of malnutrition in this setting. Furthermore, details regarding the nutritional status of their patients were not documented by outside sources other than the patient's own history.

A study by Monforte et al. has been widely cited as evidence that alcoholic polyneuropathy is due to the cumulative toxic effect of the total lifetime dose of alcohol [58]. These authors studied 107 alcoholic patients and 61 controls with clinical surveys, careful examinations, EDX studies, and autonomic tests to assess somatic and autonomic neuropathy related to alcoholism. A detailed history of alcohol intake, dietary habits, and nutritional status was assessed by a standard structured questionnaire and was confirmed with family members. However, the details of the nutritional history extended only 2 months prior to hospital admission. Only 15 of the 107 patients met their criteria for malnutrition, although the alcoholic patients had a smaller arm circumference, a thinner tricipital skin fold, and a significantly lower mean percentage of ideal body weight than the control group. Despite these findings, a multivariate analysis showed that the only independent variable that was related to peripheral neuropathy was the total lifetime dose of alcohol. However, this study failed to take into account the fact that alcoholic polyneuropathy is often a chronic disorder and that the nutritional deficiency that may be associated with chronic alcoholism may evolve intermittently over many months or years. Thus, the assessment of a lifetime exposure to alcohol without a similar measure of nutritional status does not permit a direct comparison of these two potential mechanisms in the genesis of polyneuropathy in these patients.

A more recent study supporting the contention that alcoholic polyneuropathy is due to a direct toxic effect of alcohol rather than nutritional deficiency provided evidence that alcoholic polyneuropathy is clinicopathologically distinct from nonalcoholic thiamine-deficient polyneuropathy [70]. These authors used the thiamine level at presentation as the indicator of the influence of the thiamine status during the evolution of the clinical features. Although thiamine status at presentation is likely to correlate well with acute or subacute presentations of thiamine-deficient polyneuropathy, it may not correlate well with the more typical chronic course of alcoholic polyneuropathy. Alcoholic polyneuropathy often evolves over many months or years and may be influenced

by intermittent fluctuations in the amount of alcohol consumed and the nutritional status of the patient. Furthermore, the authors did not report on other indicators of poor general nutrition, such as diet or weight loss, that may reflect a high risk for other nutritional deficiencies that may contribute to the polyneuropathy.

Animal studies have also been utilized to investigate the pathogenesis of alcoholic polyneuropathy. Although numerous animal models appear to indicate that alcohol may act as a toxin on peripheral nerve, in nearly all of these studies, the animals often sustained a coexistent nutritional insult which may certainly have contributed to the development of peripheral nerve damage [54–57]. In a carefully performed study utilizing a rat model of alcoholism, Windebank and colleagues were unable to demonstrate a toxic effect of alcohol on peripheral nerves [18]. In this study, nutrition was carefully controlled in eight rats who were given 16.8 g of alcohol per kg of body weight per day and in eight control rats. No weight loss occurred in either group. When the nerves were analyzed at 3 and 9 months into the study, there was no evidence of polyneuropathy on 1 μm thin section or on teased fiber analysis. In a primate model of alcoholic polyneuropathy reported by Hallett et al., five male monkeys who were given a diet in which 50 % of their calories were derived from alcohol were compared to four control monkeys [50]. The duration of this experiment spanned 5 years. At the conclusion, there was no histological or electrophysiological evidence of polyneuropathy in either group. In a similar study of 19 female monkeys, 9 monkeys derived 30 % of their calories from alcohol and were compared with ten controls over a 3-year span [50]. Again, there was no evidence histologically or electrophysiologically of polyneuropathy in either group.

Clearly, the precise etiology of alcoholic polyneuropathy remains controversial. There is abundant evidence that many alcoholic patients suffer from nutritional deficiency and that poor nutritional status is associated with the development of polyneuropathy in these patients [1–3, 6]. Thiamine deficiency has been regarded as the most likely nutritional factor involved in the genesis of alcoholic polyneuropathy. Clinical studies arguing that alcohol acts as a toxin in the development of alcoholic polyneuropathy have not been convincing as most of these studies have difficulty in separating the influence of poor nutrition from the consumption of alcohol, factors which are nearly always intertwined in the alcoholic patient. In addition, both nutritional status and the amount of alcohol consumed are difficult to measure, especially in the typical patients with chronic alcoholism who have a slowly evolving polyneuropathy. When alcohol consumption and nutrition can be controlled, as in the animal studies involving both rats and primates that insured stable general nutrition during the consumption of alcohol, no pathological or electrophysiological evidence of polyneuropathy was found [18, 43]. This provides additional evidence supporting the role of nutrition in the development of alcoholic polyneuropathy. More study in this area is needed to better define this complex issue.

Clinical Presentation

The best clinical descriptions of alcoholic polyneuropathy are found in the writings of Victor and colleagues who have carefully and methodically studied hundreds of alcoholic patients with polyneuropathy and other alcoholic-nutritional disorders [1–3, 6]. Alcoholic polyneuropathy occurs in the setting of serious, chronic, persistent alcoholism and prominent nutritional deficiency [1, 3, 6]. In many patients, there may be a substantial and profound weight loss often in the range of 30–40 lb or at least 10 % of body weight. However, weight loss is not uniformly present and, in fact, obesity is sometimes observed in alcoholics who consume large quantities of beer [6]. However, careful nutritional histories can usually document malnutrition in nearly all alcoholic patients with polyneuropathy [6]. It should be emphasized that the nutritional deficiency that results from alcohol displacing essential nutrients from the diet does not occur in the spree or periodic drinker, but only in alcoholics with sustained and persistent alcohol intake and poor nutrition. Although most of the non-nutritional complications of alcoholism occur predominantly in men, alcoholic polyneuropathy occurs equally in men and women [1], a curious observation for which no adequate explanation has been provided.

The clinical manifestations of alcoholic polyneuropathy conform to those of a generalized, sensorimotor polyneuropathy. The symptoms are usually symmetrical and often encompass complaints of weakness as well as sensory disturbance. In approximately 25 % of patients, severe dysesthetic burning pain may dominate the clinical picture suggesting a small-fiber neuropathy [1, 6]. The severity of the polyneuropathy may vary from subclinical involvement detected only upon neurological or EDX examinations to severe and profound polyneuropathy that may prevent the patient from standing and walking. Autonomic fiber involvement is frequently documented on autonomic nervous system testing [58, 66], but overt symptoms or signs of autonomic dysfunction are relatively uncommon [67, 71, 72]. In most patients, alcoholic polyneuropathy represents a chronic disorder that evolves slowly over weeks, months, or even years. However, patients with chronic polyneuropathy may experience subacute or acute worsening that may be so profound that it mimics the Guillain-Barré syndrome [73].

The neurological examination discloses a generalized sensorimotor polyneuropathy [6]. Sensory impairment is typically noted in the lower extremities in a distal to proximal gradient. All sensory modalities are usually involved,

although in some patients more prominent involvement of superficial sensation or deep modalities may occur. Hyperpathia or allodynia may be observed in some patients, while in others, tenderness of muscles in the feet and legs to light pressure may be noted [6, 28, 49]. Muscle weakness is also distributed in a relatively symmetric fashion with a distal to proximal gradient and is often accompanied by reduction or absence of tendon reflexes. On occasion, proximal lower extremity muscles may also be involved giving the false impression of a chronic alcoholic myopathy [6, 74, 75]. In some patients, clinical findings of other alcoholic-nutritional disorders may be observed including cerebellar degeneration and Wernicke-Korsakoff syndrome [1, 3, 6]. In addition to the neurologic findings, many patients with alcoholic polyneuropathy will demonstrate physical findings indicative of their chronic alcoholism and poor nutrition including rhinophyma, abnormal pigmentation of the skin, acne vulgaris, and dry scaly skin [6]. In addition, signs of chronic liver disease may also be observed [6, 76].

Differential Diagnosis

The diagnosis of alcoholic polyneuropathy rests on the recognition of the characteristic clinical syndrome occurring in the setting of chronic sustained and serious alcoholism with malnutrition. Because alcoholic polyneuropathy produces a relatively nonspecific clinical syndrome, a wide variety of other chronic sensorimotor polyneuropathies need to be excluded (see Table 32.1).

Evaluation and Diagnosis

The EDX features of alcoholic polyneuropathy are nonspecific and conform to those of a generalized axon loss sensorimotor polyneuropathy [53, 63, 77–80]. Typical findings on the nerve conduction studies include low or absent sensory nerve action potentials (SNAPs) in the lower extremities [53, 63, 65], mild slowing of motor conduction velocities [53, 65, 78], prolongation of distal sensory and motor latencies [53, 65, 78], and, in more advanced disease, a reduction in amplitude or absence of compound muscle action potentials (CMAPs). These findings are first observed in the lower extremities but in more severe cases, similar alterations may be observed in the upper extremities. F-waves and H-reflexes latencies may also be increased or these late responses may be absent [63, 65, 78]. Needle electromyography (EMG) often discloses changes consistent with a distal to proximal gradient of motor fiber loss manifested by fibrillation potentials and chronic neurogenic motor unit potential alterations of increased duration, amplitude, and polyphasia [80]. Special quantitative methods including single-fiber EMG may also disclose changes consistent with axonal degeneration including an increased fiber density and jitter [81]. The pathologic features of alcoholic polyneuropathy reported on nerve biopsy are relatively nonspecific and tend to conform to changes seen in axonal polyneuropathies [6, 18, 53, 82]. There is usually a reduction in myelinated axons of all sizes [53, 82] and inflammatory changes are not observed [18]. Involvement of the autonomic nervous system was reported in autopsies [6, 83].

General laboratory studies may disclose findings consistent with liver disease and chronic malnutrition including macrocytic anemia and altered liver function tests [6, 18, 76]. Cerebrospinal fluid examination is usually normal, although modest elevations of protein may be observed [6]. Because alcoholic polyneuropathy is regarded as a nutritional disorder, predominantly due to thiamine deficiency, efforts have been made to document a deficiency of thiamine in these patients. As noted previously, the direct measurement of thiamine in the blood and urine is problematic [18, 35]. Although measuring red cell transketolase activity has been the preferred method for assessing thiamine status [36–38], this method has been largely replaced by more modern methods using high-performance liquid chromatography assessing thiamin diphosphate in whole blood or erythrocytes [43–45].

Treatment, Management, and Prognosis

The treatment of alcoholic polyneuropathy consists of stopping the consumption of alcohol and restoring proper nutrition. In this context, it is essential that multivitamins be administered parenterally until adequate balanced nutritional intake can be achieved. Patients with relatively mild or modest polyneuropathy will experience definite improvement over the weeks and months that follow restoration of balanced nutrition. However, patients with more serious or severe polyneuropathies have a less favorable prognosis. Ultimately, prognosis resides in the management of the chronic alcoholism. Thus, detoxification and persistent abstinence are the keys to a long-term recovery.

Vitamin E Deficiency

Introduction

The first observation that vitamin E deficiency could result in a neurological disorder is credited to Evans and Burr who published a report in 1928 documenting paralysis in the suckling offspring of mother rats deficient in vitamin E [84]. Subsequently, other observations were made in various animal models that vitamin E deficiency could result in

neurologic and neuromuscular disorders [85]. However, it was not until 1965 that Kayden et al. proposed that vitamin E deficiency was the pathogenic mechanism of the neurological disorder associated with abetalipoproteinemia [86]. Since then, numerous other observations were made documenting that vitamin E deficiency plays an important role in the neurological disorders associated with chronic lipid malabsorption states [87–92].

Etiology and Pathogenesis

Vitamin E typically refers to alpha-tocopherol, the most active of the major four forms of vitamin E. Gamma-, beta-, and delta-tocopherol have less bioactivity [85]. Dietary vitamin E is predominantly in the form of alpha- and gamma-tocopherol and is found abundantly in wheat germ and vegetable oils [85]. Vitamin E is a lipid-soluble molecule that is absorbed in the small intestine after it is acted upon by bile acids. The bile acids solubilize vitamin E into mixed micelles that also contain other dietary lipids including free fatty acids and cholesterol [85]. Vitamin E is then absorbed by the intestinal mucosa by a noncarrier-mediated passive diffusion process. Once inside the enterocyte of the small intestine, vitamin E is incorporated with other dietary lipids into chylomicrons that are transported via the mesenteric lymphatics into the systemic circulation [85]. Vitamin E is then processed in the liver and resecreted as a component of very low-density lipoproteins (VLDL) which are later converted to low-density lipoproteins (LDL). Vitamin E appears to play an important role as a scavenger of free radicals and may also have an important role in maintaining the structure of cell membranes [93].

In developed countries, vitamin E deficiency is rarely related to a true dietary deficiency as vitamin E is widely distributed in animal fat, vegetable oils, and various grains [85]. More often, vitamin E deficiency is observed in disorders in which lipid malabsorption may occur [85, 87, 89, 90, 92, 94–97] and in rare selective vitamin E deficiency syndromes [98–102]. A wide variety of inherited and acquired disorders results in vitamin E deficiency and the accompanying neurologic syndromes [103]. Inherited or familial disorders include abetalipoproteinemia, a relatively rare autosomal recessive disorder characterized by steatorrhea, pigmentary retinopathy, acanthocytosis, and progressive ataxia [86, 90]. In fact, it was in this disorder that vitamin E deficiency was first proposed as the mechanism of the neurologic disease [86]. Cystic fibrosis is another autosomal recessive disorder associated with steatorrhea and vitamin E malabsorption [94, 104]. Familial syndromes of isolated vitamin E deficiency without evidence of lipid malabsorption have conformed to autosomal recessive [98], X-linked, or autosomal dominant inheritance [101]. In some patients with selective malabsorption of vitamin E, a mutation occurs on the alpha-tocopherol transfer protein gene on chromosome 8q13 [105, 106]. The resulting defect in the alpha-tocopherol transfer protein results in decreased incorporation of vitamin E into plasma VLDL. Vitamin E deficiency may also occur as a result of numerous chronic cholestatic and hepatobiliary disorders [87, 89, 91, 92, 95, 96, 107, 108] as well as in the short bowel syndrome that may follow small bowel resections for treatment of various intestinal disorders [96, 97, 109].

The principal pathologic features of vitamin E deficiency include axonal spheroids in the cuneate and gracile nuclei of the brain stem as well as axonal dystrophy in the posterior columns of the spinal cord, Clarke's column, and the dorsal and ventral spinocerebellar tracts [91, 94, 108, 110–112]. In addition, loss of large-caliber myelinated axons in peripheral sensory nerves is a prominent finding [91, 92, 94, 110, 113, 114] and tends to correlate with the observation that the dorsal root ganglion cell may be a principal target for vitamin E deficiency [18].

Clinical Features

Vitamin E deficiency is associated with a wide array of neurological manifestations [85]. The clinical features of vitamin E deficiency may not be apparent until several years after the onset of deficiency and progression tends to be slow and insidious. In adults it may take up to 5–10 years of vitamin E depletion for neurologic symptoms to develop, although in children the symptoms may occur after shorter intervals of time. The principal clinical features are those referable to a spinocerebellar ataxia associated with a polyneuropathy [85]. The syndrome is usually manifested by progressive gait and limb ataxia and signs of posterior column dysfunction including vibratory and joint position sense loss and hyporeflexia [85, 91, 95–97, 99, 102, 107, 112, 115, 116]. Other neurologic manifestations which may be present include visual loss from pigmented retinopathy [85, 97, 109, 116], ophthalmoplegia [85, 91, 95, 112, 115, 116], ptosis [116], dysarthria [99, 100, 102, 116], dystonia and bradykinesia [100], and generalized or proximal weakness attributable to a myopathic mechanism [113, 117]. Rarely, vitamin E deficiency may present as an isolated polyneuropathy [87, 118].

Differential Diagnosis

Although the constellation of a spinocerebellar degeneration with chronic fat malabsorption makes a diagnosis of vitamin E deficiency relatively straightforward, there are other disorders that may present with similar neurologic features. Certainly, all of the spinocerebellar degenerations should be

considered in the differential diagnosis, particularly when evidence of malabsorption may not be apparent [119]. These disorders include, but are not limited to, Friedreich's ataxia and other inherited spinocerebellar ataxias, as well as adult-onset hexosaminidase A deficiency (late-onset Tay-Sachs disease). The ataxias that manifest predominantly with cerebellar signs without evidence of a polyneuropathy or posterior column involvement may usually be distinguished readily from the spinocerebellar features of vitamin E deficiency. The polyneuropathy of vitamin E deficiency is relatively nonspecific. Thus, when vitamin E deficiency presents as a polyneuropathy, a wide array of other etiologies need to be considered in the differential diagnosis (see Table 32.1).

Evaluation and Diagnosis

The occurrence of a slowly progressive spinocerebellar degeneration in the context of a chronic disorder of lipid absorption provides the essential diagnostic criteria to suspect a vitamin E deficiency syndrome. Documenting vitamin E deficiency is achieved by direct measurement of alpha-tocopherol in the serum, usually by high-performance liquid chromatography [85]. The lower normal limit for children 12 years of age and older and adults is 5 ug/ml, but for children aged 6 months to 12 years the lower limit is in the range of 3–4 ug/ml [120]. Because vitamin E appears in the plasma lipoproteins, the vitamin E concentration may appear normal in hyperlipidemic states despite a true deficiency [121]. For this reason, the ratio of the total serum vitamin E to the total serum lipid concentration has been advocated as a better assessment of vitamin E status [121]. Normal values for children age 1–12 years is >0.6 mg of total tocopherol/g of total lipid and for older children and adults the normal limit of the ratio is >0.8 mg/g [120]. In patients with chronic vitamin E deficiency, the alpha-tocopherol level is typically undetectable [92].

EDX studies often reveal reduced or absent SNAPs with normal motor nerve conduction studies and needle EMG [95, 100, 109, 114, 122]. H-reflexes are usually absent or prolonged but F-responses are normal [122]. These findings are consistent with a pure sensory neuropathy or sensory neuronopathy in which the dorsal root ganglion cells are preferentially involved [18]. On occasion, motor nerve conduction responses may be involved to a mild degree and signs of active and chronic denervation may be noted on needle EMG [107, 122]. In some adult-onset cases, EDX studies may be normal [98, 102]. Somatosensory evoked potentials typically demonstrate a delay in central conduction or failure to conduct beyond the cervical segments [96–98, 100, 102, 109, 112, 122]. The electroretinogram (ERG) may be abnormal in patients with pigmented retinopathy [122] and visual evoked potentials may be abnormal in those patients with abnormal ERGs [122]. Auditory evoked potentials are usually normal [122].

Treatment, Management, and Prognosis

The primary goal of treatment for the neurologic disorders associated with vitamin E deficiency is to prevent further progression of the neurologic deficits. This is usually accomplished by rather high doses of oral vitamin E supplementation. Treatment guidelines have been created for the specific disorders that cause the vitamin E deficiency. For patients with isolated vitamin E deficiency, treatment usually consists of 1–4 g (1,500–6,000 IU) of oral vitamin E per day in divided doses [85]. In the setting of chronic cholestasis, treatment may begin with 50 IU/kg/day of oral vitamin E. The dose may be increased in 50 IU/kg increments up to a dose of 200 IU/kg/day pending normalization of the tocopherol/lipid ratio in the blood [85]. In cystic fibrosis patients who are receiving oral pancreatic enzyme therapy, good responses are usually achieved with doses of 5–10 IU/kg/day of oral vitamin E [85]. However, in cystic fibrosis patients with cholestasis, treatment should conform to guidelines for patients with chronic cholestasis. In patients with short bowel syndrome, good responses are achieved with 200–3,600 mg/day (300–5,400 IU/day) of oral vitamin E [85, 96, 109, 112, 123]. In abetalipoproteinemic patients, treatment usually begins with 100–200 mg/kg/day (150–300 IU/kg/day) of oral vitamin E in divided doses [85]. Because vitamin E levels do not typically improve following successful therapy in this condition, methods other than blood levels are used to assess adequate vitamin E replacement. These methods include peroxide hemolysis testing [116], serial needle aspirate biopsies of adipose tissue for vitamin E stores [124], and serial electrophysiological studies, particularly somatosensory evoked potentials. Concomitant treatment with 15–20,000 IU/day of vitamin A is also recommended along with monitoring the vitamin A concentrations. With this regimen begun early in life, the neurological features of vitamin E deficiency may be averted or stabilized in older patients [85].

Vitamin B12 Deficiency

Introduction

The neurological disorder associated with vitamin B12 (cobalamin) deficiency was first reported in the 1880s [125]. Subsequent reports documented that the principal pathologic alterations were found in the cervical and upper thoracic spinal cord and consisted of a vacuolar myelopathy primarily

involving the posterior columns and the corticospinal tracts [125–127]. This pathological pattern prompted the term subacute combined degeneration of the cord (SCDC) [128]. Although there is clear evidence that peripheral nerves may be involved in vitamin B12 deficiency [6, 129–133], it is often difficult to delineate the clinical features of a polyneuropathy from the sensory and motor features of the spinal cord involvement [6, 134].

Etiology and Pathogenesis

Vitamin B12 is a complex corrinoid compound with four pyrrole rings and a central cobalt atom [135, 136]. Cobalamin, which is active in two coenzyme forms, methylcobalamin and adenosylcobalamin, is required for two enzymatic reactions in man. Methylcobalamin is essential for methionine synthase, the enzyme that catalyzes the reaction between homocysteine and methyltetrahydrofolate, which results in the formation of methionine and tetrahydrofolate [136, 137]. Adenosylcobalamin is an essential cofactor for methylmalonyl-CoA mutase, the enzyme that converts methylmalonic coenzyme A to succinyl coenzyme A, which ultimately enters the Krebs cycle [136, 137]. In the setting of cobalamin deficiency, both methylmalonic acid and homocysteine will accumulate in the blood. Detection of increased levels of these metabolites in the plasma and urine is a sensitive test for the metabolic consequences of cobalamin deficiency [137].

Because cobalamin is found only in cobalamin-producing microorganisms, animal products are the sole dietary source for mammals [138]. The recommended daily requirement is approximately 1 mcg/day [139]. Cobalamin is bound to R proteins in the saliva and gastric juice but is liberated from the R protein by pancreatic proteases in the duodenum. Intrinsic factor, a glycoprotein secreted by gastric parietal cells, binds the cobalamin and the cobalamin-intrinsic factor complex is then absorbed in the jejunum by active transport. An acidic environment in the stomach is necessary for cobalamin to be released from its protein-bound state [138]. Cobalamin is bound to transcobalamin II in the blood and is transported to various tissues where it is absorbed by endocytosis and converted into its coenzyme forms, adenosylcobalamin and methylcobalamin.

The most common cause of vitamin B12 deficiency is pernicious anemia, an autoimmune disorder often associated with antibodies to intrinsic factor. In this disorder, there is a selective defect in vitamin B12 absorption due to failure of gastric parietal cell secretion of intrinsic factor, a substance that is essential for vitamin B12 absorption [138, 140]. Less common causes of vitamin B12 deficiency include ileal or gastric resection [141, 142], bariatric surgery [22, 143], strict vegetarian diet, severe steatorrhea [144], and infection with the fish tapeworm *Diphyllobothrium latum* [145]. The neurological syndrome of SCDC may also result from nitrous oxide use [146, 147] or abuse [148, 149] and rare genetic disorders involving methionine synthase [150] and the binding protein for vitamin B12 transport [151]. The mechanism by which vitamin B12 deficiency causes SCDC and its other neurologic manifestations is unknown. Inhibition of the vitamin B12-dependent enzyme methionine synthase may have a role in pathogenesis [152–154]. The pathological features in the spinal cord consist of demyelination as well as axon loss of the posterior columns of the lower cervical and upper thoracic segments with extension up and down the cord as well as extension into the lateral and anterior columns [126]. Although many of the pathological studies of peripheral nerve in pernicious anemia were incomplete or inconclusive [6, 18], peripheral nerves usually show modest demyelination or axonal degeneration [126, 133].

Clinical Presentation

Vitamin B12 deficiency typically produces prominent sensory disturbances including paresthesias that begin in the feet and legs but which may evolve into the upper extremities [127, 155]. As the disorder progresses, weakness in the lower extremities may develop along with spasticity, hyperreflexia, ataxia, and extensor plantar signs. Sensory signs usually reflect abnormalities of the posterior columns including loss of vibratory sense and joint position sense [127, 155]. However, it is conceivable that an underlying peripheral neuropathy may also contribute to the sensory manifestations to some extent. The absence of Achilles tendon reflexes that may be observed in some patients may represent the most significant clinical evidence for peripheral nerve involvement [18].

Differential Diagnosis

The diagnosis of the neurologic syndromes associated with vitamin B12 deficiency is usually considered in the clinical setting of a myelopathy in which there is a progressive syndrome of corticospinal tract and posterior column dysfunction, conforming to the syndrome of SCDC. Thus, a wide array of disorders causing spinal cord disease needs to be considered in the differential diagnosis including spinal cord compression from spondylosis, abscess or tumor, various forms of myelitis, vascular malformations, intraspinal tumors, multiple sclerosis, and copper deficiency [156]. Vitamin B12 deficiency should also be considered in the differential diagnosis of chronic generalized sensorimotor polyneuropathies, especially when sensory features predominate (see Table 32.1). Clearly, when clinical features of a

generalized sensorimotor polyneuropathy occur in combination with signs of myelopathy, the diagnosis of vitamin B12 deficiency should be considered.

Evaluation and Diagnosis

Vitamin B12 deficiency may be diagnosed by a direct blood assay of vitamin B12 [152, 157]. However, even in patients with apparently normal or low normal vitamin B12 levels, performing assays for serum homocysteine and, in particular, methylmalonic acid adds greater sensitivity to the detection of a vitamin B12 deficiency state [137, 152, 157]. Megaloblastic anemia may occur in B12 deficiency, but it is not invariably present even in the setting of neurologic manifestations [127, 132, 158]. A diagnosis of pernicious anemia may be made on the basis of gastric atrophy and achlorhydria on gastroscopy, as well as the presence of antibodies to parietal cells and/or intrinsic factor. In patients with a history of gastrectomy, malabsorption, or other obvious cause of vitamin B12 deficiency, it is rarely necessary to pursue more formal evaluation for the etiology of the deficiency. In patients without an apparent cause of the vitamin B12 deficiency, a Schilling test should be done. If the Schilling test documents malabsorption of vitamin B12 that is corrected by coadministration of intrinsic factor, then a diagnosis of pernicious anemia can be made. If intrinsic factor does not correct the malabsorption, then the Schilling test should be repeated after an interval of antibiotic or vitamin B12 therapy. Further investigations should also be pursued to look for an occult cause of the malabsorption.

A wide array of neurophysiologic methods is utilized to study vitamin B12 deficiency. EDX tests disclose features of an axon loss sensorimotor polyneuropathy [129–131, 133, 148, 155, 159]. Typical findings on nerve conduction studies include mild slowing of motor or sensory conduction velocity [129, 130, 132], and reduced or absent sensory responses [130, 131, 133]. The needle EMG may disclose signs of denervation, particularly in distal lower extremity muscles [131]. Somatosensory evoked potential studies are typically abnormal, particularly when testing the lower extremity nerves, and are indicative of spinal cord involvement [131, 160]. Visual evoked potentials may be mildly abnormal [131] but auditory evoked potentials are often preserved [131].

Treatment, Management, and Prognosis

Treatment guidelines for vitamin B12 deficiency vary considerably [161, 162]. A typical plan begins with intramuscular injections of 1,000 ug of cobalamin per day for 5 consecutive days [163]. This 1,000 ug dose may be repeated weekly for an additional month and then monthly for the remainder of the patient's life depending upon the specific etiology of the B12 deficiency state. Because approximately 1 % of ingested cobalamin may be absorbed by passive diffusion, some patients may be treated with high doses of oral cobalamin at 1,000 ug/day [164, 165]. If treatment is initiated relatively early in the course of the neurological disorder, prognosis may be excellent [155, 166]. However, symptoms and signs present for 6 months or longer may persist despite replenishment of the B12 stores [155].

Vitamin B6 Deficiency and Toxicity

Vitamin B6 (pyridoxine) may cause a polyneuropathy due to a deficiency state [167] and as a result of a direct toxic effect [168, 169]. Pyridoxine deficiency is most often observed in patients treated with the antituberculosis drug isoniazid or the chemically related antihypertensive drug hydralazine [170–172]. Vitamin B6 deficiency may also be observed in the setting of general malnutrition that accompanies chronic alcoholism [173] and in patients receiving hemodialysis [174]. The polyneuropathy of vitamin B6 deficiency conforms to a chronic axon loss sensorimotor polyneuropathy [170, 171], with a wide differential diagnosis (see Table 32.1). The diagnosis of vitamin B6 deficiency can be confirmed by a direct assay of vitamin B6 in the blood [17]. Vitamin B6 supplementation at a dosage of 50–100 mg of vitamin B6 per day is recommended in patients treated with isoniazid and hydralazine [18] and is a reasonable dosage for dietary deficiency. In alcoholic patients with vitamin B6 deficiency, it is likely that other vitamins and nutrients are also deficient. Thus, treatment in this group should address general nutritional therapy along with abstinence from alcohol.

The neuropathy that results from excessive dietary intake of vitamin B6 produces a syndrome of sensory neuronopathy with profound deafferentation and ataxia dominating the clinical picture (see Chap. 35) [168]. However, EDX studies have documented some element of motor axon loss as well [168]. The toxic sensory neuronopathy of vitamin B6 may result from as little as 200 mg of pyridoxine per day [175, 176]. Unfortunately, the prognosis of the sensory neuronopathy is relatively poor, although modest improvement of the EDX findings of motor fiber involvement was reported [177].

Pellagra

Pellagra is a nutritional disorder of niacin deficiency. Although rare in developed countries, pellagra continues to occur in certain underdeveloped parts of the world, particularly in Africa and Asia, where corn remains the principal source of carbohydrate in the diet. More recently, pellagra

was observed in India and Egypt where it is associated with diets based upon jowar, a type of sorghum [178]. Although pellagra is occasionally encountered in malnourished patients, especially alcoholics [4, 179, 180], it has essentially been eradicated in many Western countries by the practice of enriching bread with niacin.

Pellagra is a disorder characterized by the classic triad of dermatitis, diarrhea, and dementia [6, 179, 180]. The skin lesions are hyperkeratotic and reddish brown in coloration with a somewhat typical distribution over the face, neck, and dorsal surfaces of the limbs [180, 181], sometimes resembling a sunburn indicating photosensitivity [180]. Diarrhea and the other associated gastrointestinal symptoms usually contribute to general weight loss and fatigue. The neurological manifestations are rather diverse and may correlate with involvement of the brain, spinal cord, and peripheral nerves. Because of the rather protean neurologic manifestations, there is a controversy as to how often the neurological symptoms of pellagra are indeed related to peripheral nerve involvement [6]. It appears that when peripheral nerves are involved, the disorder is relatively mild and shares many features with beriberi [6, 182]. Pathologic findings in peripheral nerves disclose signs of axonal degeneration. Despite the discovery of niacin and the demonstration that it is the principal vitamin deficient in pellagra, it has been observed that supplementation with niacin may not resolve the peripheral nerve symptoms [46, 182–184]. Furthermore, there is evidence that some of the neurological manifestations of pellagra may indeed be due to other coexisting vitamin deficiencies including thiamine and pyridoxine [6]. Niacin supplementation at doses of 40–250 mg daily is usually adequate to reverse most of the non-neuropathic symptoms and signs of pellagra [6].

Strachan's Syndrome

The syndrome of painful polyneuropathy with associated features of amblyopia, and orogenital dermatitis was first described by Strachan in 1888 [185] and later in 1897 [186]. Strachan observed this clinical syndrome in Jamaican sugarcane workers and subsequently the disorder was termed peripheral neuritis of Jamaica. A similar clinical syndrome was later described by Scott in 1918 [187]. Although Strachan initially proposed that this disorder was caused by malaria, it was subsequently regarded as a nutritional deficiency disorder [6]. Numerous reports of similar clinical syndromes appeared in the literature in the 1930s and 1940s in which the central clinical features were polyneuropathy and optic neuropathy [6, 188].

The principal clinical features of Strachan's syndrome are those of a painful, predominantly sensory polyneuropathy accompanied by visual loss secondary to central or centrocecal scotomas [6]. The orogenital dermatitis may be expressed to variable degrees and may include excoriation of the corners of the mouth, prepuce, anus, and vulva [6]. In addition, corneal degeneration and stomatoglossitis may be observed [6].

The typical pathologic features of Strachan's syndrome were carefully studied by Fisher in Canadians held as prisoners during World War II [189]. Prominent findings included demyelination and axon loss in the posterior columns of the spinal cord and the columns of Goll as well as degeneration of fibers in the optic nerves referable to the papillomacular bundle [189]. There was no obvious abnormality of peripheral nerves but comprehensive study of peripheral nerves was not undertaken. Furthermore, definitive pathologic studies on peripheral nerves have not been reported [6, 18].

In 1992 and 1993, there was an epidemic in Cuba of a clinical syndrome resembling Strachan's syndrome which included polyneuropathy, sensorineural deafness, optic neuropathy, and dorsolateral myeloneuropathy [5]. These clinical features clearly overlap those attributed to Strachan's syndrome. In this disorder, sural nerve biopsies showed an axonal neuropathy predominantly affecting large-diameter myelinated axons [190]. The myeloneuropathy was manifested by clinical deficits reflecting posterior column involvement as well as sensory ataxia and mild corticospinal tract signs [5]. Bilateral high-frequency sensorineural hearing loss was accompanied by tinnitus. Many patients displayed isolated optic neuropathy or combinations of optic neuropathy and myeloneuropathy, as well as other variations [5]. Although overt malnutrition was not present in most of the patients, a deficiency of micronutrients, including thiamine, cobalamin, folate, and sulfur amino acids, appears to have been the primary mechanism of this disorder [5]. The vast majority of patients improved with treatment of B group vitamins and folate. Thus, it is likely that this syndrome as well as the classical Strachan's syndrome represent disorders of multiple deficiencies especially thiamine, niacin, riboflavin, pyridoxine, and cobalamin. An epidemic of optic neuropathy and polyneuropathy resembling Strachan's syndrome occurred in coastal Tanzania in 1988. This epidemic was also attributed to micronutrient deficiency [191]. In classical Strachan's syndrome, treatment with riboflavin (vitamin B2) rapidly reverses the orogenital dermatitis, but does not appear to have a substantial benefit regarding the optic neuropathy and myeloneuropathy [18].

Copper Deficiency

Copper is an essential trace element that is present in all living cells and involved in electron transport and oxidative reactions [192]. It serves as a cofactor for oxidative enzymes such as cytochrome c oxidase, a key enzyme in oxidative

metabolism, and superoxide dismutase, an important scavenger of superoxide radicals. Copper influences functions in many organs and, in particular, is important in maintaining bone marrow function and maintenance of the central nervous system [192]. Copper is absorbed primarily via active transport from the duodenum and to a lesser extent the stomach. Copper is bound to albumin and transported to the liver where it is complexed to ceruloplasmin, albumin, and transcuprien and ultimately released into the blood where it is transported to the tissues [192]. Dietary deficiency of copper is rare as it is ubiquitous in many foods and the dietary requirement of copper is low, 1.0 mg/day for adults with lower requirements for children and higher requirements for pregnant and/or lactating women [193]. Nevertheless, copper deficiency disorders have been recognized in both man and animals. In veterinary medicine, copper deficiency was documented in 1937 to cause a condition in ruminants called enzootic ataxia or swayback as well as anemia [194]. The hematological disorders in humans related to copper deficiency, primarily anemia and leukopenia often resembling a myelodysplastic syndrome, are also well established [195]. However, the appreciation that copper deficiency in humans may cause a myeloneuropathy is relatively recent.

The first report of copper deficiency causing a myelopathy in humans is attributed to Schleper and Stuerenburg in 2001 [196]. They reported a 46-year-old woman with progressive myelopathic symptoms for the preceding 18 months. The patient had undergone two gastric resection surgeries for peptic ulcer disease 18 and 3 years prior to presentation. Copper level in the blood was markedly reduced as was the ceruloplasmin level. The patient also had microcytic anemia and neutropenia. MRI scan revealed hyperintense signal on T2 images in the dorsal and medial region of the spinal cord from C1 to C7. Electrodiagnostic testing did not disclose evidence of polyneuropathy. After parenteral copper infusion, the sensory symptoms improved and the copper and ceruloplasmin levels returned to normal. However, the spastic tetraparesis persisted. Since then, numerous cases of copper deficiency have been reported in the literature [156, 197–203]. These cases resembled that of Schleper and Stuerenburg but in most of the cases in which careful electrodiagnostic testing was done, there was evidence of an axon loss polyneuropathy [156, 197–203].

The most common causes of the copper deficiency in these cases have included disorders resulting in malabsorption [156, 200], gastric surgery [156, 198, 199, 202, 204], bariatric surgery [143, 156, 205, 206], and excessive zinc ingestion [156, 197], including zinc ingestion from denture creams [203]. The mechanism of excessive zinc consumption causing copper deficiency is accounted for by the competitive absorption of copper and zinc in the stomach and duodenum [207]. In many patients, no specific etiology for the copper deficiency is noted [156, 201]. In a retrospective survey of 51 patients with copper deficiency, the most common causes were bariatric surgery, celiac disease, liver disease, surgery for Crohn's disease, and total parenteral nutrition [208]. In approximately 25 % of patients, no etiology for the low copper level was noted.

The clinical syndrome of copper deficiency shares many features with that of vitamin B12 deficiency [156]. Typically, patients present with paresthesias in the lower limbs and problems with gait. Neurological examination typically discloses spasticity in the lower extremities with hyperreflexia and Babinski signs. Sensory exam reveals prominent posterior column dysfunction with loss of vibratory and joint position sense. Sensory ataxia is common. In addition, in some patients, Achilles reflexes are absent and a distal to proximal loss of light touch and pin perception is noted, consistent with a polyneuropathy. Laboratory testing typically discloses a low copper level in the blood and reduced serum ceruloplasmin. In one series, copper levels ranged from undetectable to a 45 % reduction from the lower limit of normal and ceruloplasmin levels were reduced by 85 % from lower limit of normal [156]. Serum zinc was elevated in approximately half of patients but 24-h urine zinc excretion was elevated in 80 %. Cerebrospinal fluid was normal except for a modest elevation of protein in less than half of the patients [156]. Electrodiagnostic testing typically discloses findings of an axon loss length-dependent sensorimotor polyneuropathy [156]. Anemia and leukopenia may be seen in half of patients presenting with neurological symptoms [156]. Neuroimaging of the spine with MRI may disclose increased T2 signal in the paramedian dorsal cervical cord extending variably into the thoracic cord [156, 199, 201]. In some cases, the spine MRI may be normal [199, 200, 202]. Treatment with copper supplementation, either oral or parenteral, or both, will normalize the copper and ceruloplasmin levels and further progression of the myeloneuropathy should cease [156]. Clinical response regarding the neurological symptoms and signs is variable with some patients noting improvement, typically in the paresthesias [198, 200, 201], but most will have permanent neurologic residuals [156, 200, 201].

Nutritional Deficiency Polyneuropathy Associated with Bariatric Surgery

The worldwide epidemic of obesity is substantial with estimates of overweight or obesity affecting nearly 68 % of the US adult population [209]. Although the awareness of the serious medical consequences of obesity [210] has prompted more aggressive medical management for this condition [211], most medical interventions have not provided consistent results [212–214]. On the other hand, surgical treatments for obesity have demonstrated excellent efficacy with low morbidity and mortality [215, 216]. A variety of surgical

procedures have been employed for weight reduction in obese patients. These methods include laparoscopic adjustable gastric banding, laparoscopic sleeve gastrectomy, and gastric bypass, typically the Roux-en-Y procedure [216]. The most commonly performed procedure in the USA is the Roux-en-Y gastric bypass and approximately 90 % of all procedures are done laparoscopically [216].

The advent and the increased availability of bariatric surgery for the treatment of obesity have been accompanied by increased awareness of its neurological complications [22, 147, 217, 218]. Neurologic complications from these surgeries are not uncommon and are diverse, and many have been attributed to nutritional deficiency [22, 143, 217–220]. The most common neurological complications include encephalopathy, often Wernicke encephalopathy, a myelopathy conforming to a posterolateral syndrome, ataxia, polyneuropathy, and mononeuropathies [22, 143, 217–220]. Wernicke encephalopathy is often associated with polyneuropathy and is clearly related to thiamine deficiency, often in the setting of severe and persistent vomiting in the postoperative setting [22, 23, 143, 218–221]. This has been referred to as bariatric beriberi [24]. However, other micronutrients have also been documented to be deficient in bariatric surgery patients with neurological complications, including vitamin B12 and copper, either of which may be responsible for a posterolateral myelopathy and polyneuropathy [22, 143, 205, 206]. These nutritional complications most often occur within 6–18 weeks of the surgery but in some cases the onset may be delayed for many years [143].

Approximately, two thirds of the neurological complications following bariatric surgery conform to a generalized polyneuropathy [22]. In one large retrospective series of 435 bariatric surgery patients, 16 % of patients experienced a peripheral nerve complication following the surgery [217]. Peripheral polyneuropathy was noted in 6 %, radiculoplexus neuropathy in 1 %, and a mononeuropathy in 10 %. In the majority of patients with polyneuropathy, the disorder had features of a symmetrical sensory-predominant disorder that was insidious in onset and chronic in evolution. In approximately 20 % of patients, the polyneuropathy was subacute or acute in evolution. Pain and autonomic symptoms were noted in about half of the patients. Electrodiagnostic testing disclosed changes of a large-fiber axon loss polyneuropathy in approximately 80 % of patients. In the remaining 20 % of patients with normal electrodiagnostic testing, the clinical features conformed to a small-fiber neuropathy. Risk factors for the development of polyneuropathy included the amount of weight lost, the rapidity of the weight loss, lower post-surgery BMI, lower serum albumin and transferrin, prolonged postoperative gastrointestinal symptoms, less vitamin and calcium supplementation, and lack of attendance at nutritional clinics postoperatively. These authors concluded that malnutrition was the most likely cause for the polyneuropathy [217]. In some patients, the polyneuropathy conforms to an acute or subacute polyradiculoneuropathy, superficially resembling Guillain-Barré syndrome [143]. This form of polyneuropathy has axon loss features on electrodiagnostic testing and has often been associated with thiamine deficiency [23, 218, 221].

Comprehensive preoperative medical assessments emphasizing nutritional status are very important in the bariatric patient as micronutrient deficiencies in these patients are not uncommon [222]. In addition, careful postoperative follow-up designed to assess and provide optimal nutrition in bariatric surgery patients is essential as this may reduce the incidence of these neurological complications [222–224].

Metabolic and Endocrine Neuropathies

33

Beth B. Murinson and Vinay Chaudhry

Introduction

Peripheral neuropathy occurs with variable frequency due to metabolic abnormalities associated with renal and hepatic failure and endocrine dysfunction of the thyroid and pituitary glands (Table 33.1) [1–3]. Even in the absence of overt symptoms, clinical examination and electrophysiological testing may reveal measureable neuropathy in patients with these disorders. Although nerve conduction studies show a length-dependent reduction of sensory and motor amplitudes suggesting an axonal process, reduction in velocities and prolongation of the distal and F-wave latencies may also be seen suggesting a mixture axonal and demyelinating picture. The severity of neuropathy generally correlates to the severity of the underlying metabolic or endocrine disease. In terms of clinical management, it is important to recognize that clinical reversal of metabolic or endocrine dysfunction may arrest the progression of neuropathy and may even result in meaningful improvements. While substantive peripheral neuropathy is typically observed only in association with advanced or end-stage liver or renal disease, it is important to note that carpal tunnel syndrome may be the first manifestation of underlying endocrine disease suggesting that thoughtful clinical appraisal is appropriate.

Uremic Neuropathy

Incidence

Peripheral neuropathy is the most common neurological complication of chronic uremia, with prevalence estimates ranging to over 80 % of patients with end-stage renal disease [4–6]. In as many as 50 % of patients, this neuropathy is asymptomatic but demonstrable by nerve conduction abnormalities [5].

Uremic neuropathy is typically a progressive symmetrical sensory and motor axonopathy that is length dependent. Although features of uremic neuropathy were recognized by Charcot and Osler in the nineteenth century, it was not well characterized before 1960 [5]. With the advent of hemodialysis, the support of patients with renal failure permitted the study of uremic neuropathy. Early reports of progressive neuropathy supported the conclusion that frequent dialysis decreased the likelihood that peripheral neuropathy would worsen. Asbury, Victor, and Adams provided the first detailed description of uremic polyneuropathy [7].

Clinical Features

Clinically, uremic neuropathy presents as predominantly large-fiber neuropathy with distal, symmetrical, and "painless" paresthesias [8]. However recent work has highlighted the effects of renal failure on the small nerve fibers [9]. The tempo of progression is chronic and progressive in most cases, although an accelerated, acute neuropathy mimicking Guillain-Barré syndrome has been described [10]. The typical symptoms are tingling paresthesias, restless legs, and distal weakness. Tingling paresthesias may be a prominent first symptom but in some cases weakness precedes sensory symptoms. Muscle cramps are often described. Restless leg syndrome is commonly experienced at night and is characterized by the sensation of needing to move the legs to restore comfort [7, 11]. On physical examination, distal leg reflexes

Table 33.1 Characteristics of metabolic neuropathies

	Uremic	Hepatic	Hypothyroid	Hyperthyroid	Acromegaly
Incidence	80 %	70 %	40 %	20 %	CTS 35 %
Fiber types	S(LF>SF)>M>A	S (SF>LF), M, A	S (SF>LF), M, CTS	M>S	CTS; rare SM neuropathy
Distribution	Length dependent, also CTS, ischemic monomelic neuropathy related to fistula	Length dependent, also CTS	Length-dependent sensory	Proximal-distal weakness	Entrapment neuropathy more common
Physiology	Reduced SNAP and CMAP; prolonged F-wave and reduced velocities	Length- dependent reduction of SNAP and CMAP amplitudes; mild reduction in CV	SNAP amplitudes reduced; reduced velocities; dispersion	Decreased CMAP amplitude and distal denervation	Mixed axonal and demyelination plus entrapments
Pathology	Axonal degeneration, segmental demyelination, decreased epidermal nerve fiber density	Thinly myelinated fibers; short internodes	Segmental demyelination	Acute denervation on muscle biopsy; no nerve biopsy available	Increased connective tissue in the perineurium and endoneurium; onion bulb
Severity	Asymptomatic 19 % Nondisabling 48 % Disabling 14 %	Mild	Mild	Severe	Varies
Treatment	Renal transplant reversal; dialysis stabilization; erythropoietin	Liver transplant	Hormone replacement	Treatment of thyrotoxicosis	Surgery or radiation of the pituitary; CTS release
Time course	Chronic progressive, rarely acute GBS-like	Progressive	Indolent	Acute to subacute	Chronic
Correlation	GFR <12 ml/min	Related to severity of liver disease	Severity of hypothyroidism	Other signs of hyperthyroidism	Visible enlargement of the hands
Mechanism	K^+ transients, middle molecule, PTH	Portosystemic shunt	Axonal transport; CTS; mucopolysaccharides and edema	Direct effect of thyroxine on muscle	Proliferation of cartilage, bone, connective tissue

S sensory, *M* motor, *A* autonomic, *SF* small fiber, *LF* large fiber, *PTH* parathyroid hormone, *GBS* guillain-barré syndrome, *GFR* glomerular filtration rate, *CTS* carpal tunnel syndrome, *SNAP* sensory nerve action potential, *CMAP* compound muscle action potential

are reduced or absent; decreased vibration sense may be the earliest objective evidence of uremic neuropathy. Other sensory alterations include loss of touch and position sense. Motor findings include weakness of foot dorsiflexion and eversion; mild atrophy may be found.

Abnormalities of the autonomic nervous system are seen in 45–59 % of uremic patients. Orthostatic hypotension, impotence, and constipation are associated with uremic peripheral neuropathy [12]. Tests of autonomic function including beat-to-beat (R-R) variability, tilt table, and galvanic skin response are often abnormal [13]. In a battery of tests, parasympathetic functions were much more frequently abnormal (14 of 16 patients) than were sympathetic functions (3 of 16) suggesting that myelinated parasympathetic nerve fibers are more affected by terminal uremia than are unmyelinated sympathetic fibers [13]. Parasympathetic responses normalize after renal transplant, whereas during dialysis they remain persistently abnormal [14–16].

In addition to the generalized symmetric polyneuropathy, median neuropathy at the wrist is common and mononeuropathies associated with fistula placement in the forearm are well established [17, 18]. The placement of an arteriovenous shunt in the limbs for hemodialysis may result in "stealing" of blood flow from the limb distal to the fistula and cause an ischemic monomelic neuropathy affecting radial, median, and/or ulnar nerves [17–19]. Distal ischemia and edema are also thought to be the mechanism for carpal tunnel syndrome in this setting. Another mechanism for carpal tunnel syndrome in persistent uremia is the deposition of amyloid protein, beta-2 microglobulin, as a manifestation of generalized amyloidosis in long-term renal failure. Uremic patients who are bedridden and cachectic may develop compressive neuropathies including the ulnar nerve at the elbow or peroneal nerve at the fibular head.

The development of uremic neuropathy appears to correlate with the degree of renal failure appearing after glomerular filtration rate falls below 12 ml/min [20, 21]. Laaksonen and colleagues studied 21 patients who were on chronic maintenance hemodialysis treatment and noted only four with no neuropathy; four were asymptomatic but had abnormal electrophysiology; ten had nondisabling symptoms with abnormal nerve conduction studies; and three had disabling symptoms and abnormal nerve conduction studies [21].

Electrophysiology

Abnormalities in nerve conduction studies generally precede clinical manifestations of the neuropathy and are consistent with axonal loss as the dominant pathology [22]. The most marked abnormality on nerve conduction studies is a progressive reduction in the amplitude of sensory and motor action potentials. In addition, prolonged distal and F-wave latency, reduced velocities, and dispersed morphology have been reported suggesting a mixed physiology as also seen with diabetic neuropathy. The number of motor units is decreased in patients on chronic hemodialysis [23]. This is consistent with a decrease in muscle action potential amplitude resulting from fewer large myelinated fibers. In several studies, a progressive reduction in nerve conduction velocities correlated with declining renal function measured by creatinine clearance [24]. In fact among patients with creatinine clearance of <10 ml/min, 50 % showed reduced nerve conduction velocity [24]. EMG demonstrates denervation-reinnervation in distal musculature.

Abnormalities of beat-to-beat variation (R-R interval) generally correlate with a loss of sensory and motor amplitudes. Autonomic neuropathy in renal failure has been the subject of recent studies [13]. For example, the assessment of autonomic, large-fiber, and small-fiber function in 42 dialyzed patients with ESRD excluding those with diabetes and amyloidosis showed that large-fiber peripheral neuropathy was the most prevalent peripheral nerve disorder (60 %), followed by parasympathetic dysfunction (50 %), sympathetic dysfunction (28 %), and small-fiber (thermal) dysfunction. About half of the patients with sympathetic dysfunction also manifested parasympathetic dysfunction. The patients in this study were relatively young with an average age of 46, with an average time on dialysis of 5 years [25]. The assessment of small-fiber structure as well as autonomic and large-fiber function in 40 dialyzed patients with ESRD excluding those with diabetes and other neuropathy-associated conditions found that epidermal nerve fiber density was reduced in these patients and that autonomic dysfunction was very prevalent with abnormal sympathetic skin responses measured in 63 % and heart rate variability reduced (parasympathetic function) in 54 %. Intriguingly, only 38 % of the patients in this study were found to have evidence of large-fiber dysfunction, an estimate that is lower than that reported elsewhere [21, 26]. This is especially noteworthy as the patients in this study were relatively old with an average age of 61 and an average time on dialysis of 7 years [9].

Pathology

Histopathologically, uremic neuropathy shares many features of toxic neuropathy. Axonal degeneration is the hallmark of uremic neuropathy; large myelinated fibers are decreased, there is axonal shrinkage, and nerve fiber loss is frequent. Nerve biopsies in uremic neuropathies demonstrate both chronic and active axonal degeneration as well as some segmental demyelination and remyelination and paranodal demyelination [6]. Some early studies emphasized changes in myelin but have been subsequently interpreted as representing alterations in segmental myelination secondary to

distal axonopathy [4, 5, 27]. There is a gradient of pathological alteration so that distal sites are more severely affected. The assessment of small-fiber structure as well as autonomic and large-fiber function in 40 dialyzed patients with ESRD excluding those with diabetes and other neuropathy-associated conditions found that epidermal nerve fiber density was reduced in these patients in the aggregate but that in 68 % of these patients the lower leg was completely devoid of epidermal nerve fibers [9].

Mechanism

The mechanism of uremic neuropathy is not known but accumulating evidence supports a role for persistent elevations in potassium as a pathogenic mechanism. And although recent work has highlighted the importance of ionic shifts associated with renal failure and dialysis, see below, the marked improvement of patients after renal transplantation led to the middle molecule hypothesis [28]. Essentially, the middle molecule hypothesis proposed that some molecule or molecules of size 1,350–5,000 Da are not efficiently filtered in routine hemodialysis and produce a toxic effect on axons [29]. The middle molecule theory however was not strongly supported by dialysis experience [4].

A series of studies by Krishan, Kiernan, and colleagues collaborating with Bostock has led to a new appreciation for the role of elevated potassium as a cause of peripheral neuropathy in renal failure [30–34]. In one study, 12 patients were studied using an experimental method of electrophysiological function of peripheral sensory nerves called "threshold tracking." This method uses a series of pre-pulses and graded stimulation pulses to assess the basal electrophysiological state of the peripheral nerve (electrotonus). The findings of this group of patients pre-dialysis showed a leftward shift in the stimulus response curve consistent with axonal depolarization, and there was an increase in refractoriness. When these same patients were restudied 1 h after dialysis, there was a dramatic correction in most but not all parameters. Correlation analysis of excitability parameters with serum potassium demonstrated a significant association, suggesting to the authors that hyperkalemia could account for many of the changes observed. There was also some correlation with urea levels; however, this co-correlated also with potassium. The authors comment that rebound hyperkalemia occurring in the hours after dialysis would produce changes likely to contribute to axonal degeneration [31]. A subsequent study of motor nerve excitability before and immediately after dialysis also demonstrates largely reversible changes in electrophysiological parameters consistent with axonal depolarization. This study includes a more extensive analysis of other potential toxins, including calcium, urea, uric acid, parathyroid hormone, and beta-2 microglobulin, and more conclusively demonstrates that potassium has a uniquely strong association with reversible electrophysiological dysfunction [32]. More recent studies supported the conclusion that dysfunction of the sodium-potassium pump (Na+-K+=ATPase) did not play a major role in neuropathy associated with renal failure [34].

There is clinical and experimental evidence to support a role for parathyroid hormone (PTH) in uremic neuropathy. Renal dysfunction produces impaired phosphate excretion, and the resulting hypocalcemia leads to excess secretion of PTH. Serum PTH was negatively correlated with motor nerve conduction velocity in humans [35, 36]. Experimental studies show that acutely uremic animals developed slowed motor NCV which was reversible upon withdrawal of PTH; however, slowed motor nerve conduction was not seen in animals that underwent parathyroidectomy prior to renal failure [37].

Differential Diagnosis

In the differential diagnosis of uremic neuropathy, it is important to consider other causes of progressive distal symmetrical neuropathy. Diabetes mellitus is a common cause of uremia and can independently cause peripheral neuropathy. Cranial neuropathies, autonomic neuropathies, and compressive mononeuropathies are much more frequent in diabetic neuropathies than in uremic neuropathies. Toxic and nutritional neuropathies may mimic the clinical picture of uremic neuropathy. Certainly, patients with suspected uremic neuropathy must demonstrate evidence of substantive renal failure and laboratory values consistent with the diagnosis. CSF is characteristically acellular although increased protein may be found in some patients. Cyto-albumenemic dissociation, typical of GBS, has been observed in the rare acutely progressive form of uremic peripheral neuropathy making the distinction difficult [10].

Treatment

The treatment of uremic neuropathy depends on management of the underlying renal disease. Renal transplant is particularly effective in reversing symptoms and signs and is often associated with subjective and objective improvement [22, 38, 39]. A regimen on frequent dialysis is viewed as beneficial [32]. Some early reports indicated that peritoneal dialysis had an advantage over hemodialysis; further studies have revealed no clear advantage [8, 40]. In either case, dialysis is less likely to produce reversal of progression than renal transplantation [40]. Dialysis is associated with halting the clinical progression of uremic neuropathy and

symptomatic improvement although electrophysiological abnormalities persist. Symptomatic improvement of paresthesias occurs quickly with transplantation and occurs often with dialysis [8, 38]. Strength returns more slowly, some patients on dialysis do not experience improvements in strength. The loss of vibration, proprioception, and light touch sensation are the clinical signs of disease most resistant to treatment. The prognosis for improvement without treatment of renal disease is poor; progression tends to be slowly relentless and may result in disability. The prospects for recovery are better when renal transplantation is performed early in the course of neuropathy. Renal transplantation is the best treatment of uremic neuropathy. Patients with mild early neuropathy may be fully treated and nerve conduction values may return to normal.

There has been some anecdotal evident to indicate that erythropoietin has an ameliorating effect on the neuropathy of end-stage renal disease. The role of erythropoietin in correcting anemia associated with end-stage renal disease has been recognized for some time [41], but evidence regarding the effects of erythropoietin on peripheral nerve function has been limited. There is strong support for the beneficial effects of erythropoietin on peripheral nerve function in preclinical models [42, 43]. A study of patients with pre-dialytic end-stage renal disease indicated that improvements in motor nerve amplitudes were observed and trends to improvements in motor nerve conduction velocities were observed following treatment with erythropoietin, and sensory nerve conduction parameters were not significantly improved although the conduction velocity and amplitudes values were higher after treatment [44]. Further study is needed in this area.

Hepatic Neuropathy

Incidence

Peripheral neuropathy has been reported in patients with liver disease with a frequency ranging from 19 to 100 % [45–52]. A study of 58 patients with end-stage liver disease reported peripheral neuropathy in 71 % of these patients [53].

Clinical Features

In most patients, the neuropathy is subclinical or associated with minimal symptoms. Examination shows distal sensory loss and loss of distal reflexes consistent with a length-dependent neuropathy. Small-fiber function (cooling threshold) is generally more affected than large-fiber function (vibration threshold) [53]. Besides distal symmetric polyneuropathy, autonomic neuropathy also occurs in chronic liver disease [53–60]. Abnormalities of heart rate variation with deep breathing and with the Valsalva maneuver are more likely to be present than orthostatic drop in blood pressure suggesting a predominance of parasympathetic dysfunction. The severity of autonomic dysfunction appears to correlate with severity of hepatic dysfunction [60]. A majority of patients with autonomic dysfunction have additional evidence of sensorimotor polyneuropathy [53].

Electrophysiology

Electrodiagnostic studies reveal a length-dependent reduction of sensory and motor amplitudes with preservation of conduction velocities confirming an axonal physiology. Although some reports of a demyelinating physiology exist in the literature [46–48], careful analysis of these reports shows that the conduction velocities are rarely in the demyelinating range and the findings are alternatively explained as reflective of large-fiber axonal loss. Furthermore, in these studies, entrapment neuropathies were not excluded as possible explanations for the reduced conduction velocities. Carpal tunnel entrapment of the median nerve occurs in one-third of patients with hepatic disease [53].

Pathology

A few pathology reports have interpreted the presence of thinly myelinated fibers and short internodes to suggest that hepatic neuropathy may be demyelinating [45–47, 61]. Active demyelination or inflammatory cells have not been reported and it remains possible that thinly myelinated fibers and small internodes may reflect axonal degeneration followed by regeneration [27, 62, 63].

Mechanism

The mechanisms of peripheral neuropathy associated with end-stage liver disease are not well defined and there are persistent questions regarding the extent of a causal relationship between liver disease and neuropathy as many systemic illnesses that cause liver dysfunction also are independent causes of peripheral nerve dysfunction [64, 65]. Alcohol-induced cirrhosis, porphyria, polyarteritis nodosa, certain intoxications, primary biliary cirrhosis, hepatitis C, and amyloidosis are examples of disorders that may cause neuropathy and hepatic disease independently [64–68]. Nonetheless, patients with cryptogenic liver disease also develop peripheral neuropathy of varying severity [53]. Furthermore, there is a correlation of the severity of neuropathy to the severity

of liver disease suggesting that the peripheral neuropathy is caused by metabolic dysfunction resulting from liver disease [53]. A study suggested portosystemic shunting to be the causative factor in the genesis of hepatic neuropathy. However, two other studies found no differences in the presence or severity of neuropathy in patients with or without portocaval shunt [48, 61]. An experimental study of portocaval anastomosis in rats also favored hepatocellular failure as the principal pathophysiologic mechanism in hepatic neuropathy [69]. Patients with chronic liver disease secondary to primary biliary cirrhosis appear to form a separate group as these patients present with pure sensory neuropathy with or without xanthomatous infiltration of the nerves [70, 71]. A recent study of 83 patients awaiting liver transplantation showed that sensory and sensorimotor neuropathies predominated. A length-dependent pattern was found, and the prevalence of neuropathy significantly correlated with disease severity. The authors also observed that the diagnosis of hepatitis C was associated with peripheral neuropathy independent of the severity of liver failure [52]. Unfortunately, the methodological approach of these authors makes direct comparison to their results difficult.

A series of 11 patients with end-stage liver disease were studied prior to liver transplantation, using the experimental method of threshold tracking developed by Bostock and colleagues. This method has the capacity to assess relative but not absolute states of polarization in peripheral nerves as well as refractoriness, subexcitability, and superexcitability. The study of patients with ESLD, which also includes standard approaches to peripheral nerve assessment, demonstrated prominent small-fiber involvement with a minority of patients having abnormal nerve conduction results indicative of large-fiber dysfunction. The evaluation of dynamic electrophysiological function showed evidence of axonal depolarization although these changes were mild in comparison to the changes demonstrated in studies of patients with end-stage renal disease. The authors did not observe a correlation between changes in these electrophysiological measures and putative toxins associated with ESLD [72].

Treatment

Liver transplantation may have a beneficial effect for patients with neuropathy related to end-stage liver disease, although the evidence for this is mixed. Lee and colleagues studied 25 patients before and 6 months after liver transplantation. Their study found that end-stage liver disease patients demonstrated sensory neuropathy (11 patients) and motor neuropathy (seven patients) prior to transplantation. Assessed 6 months after transplantation, there was an improvement in motor and sensory function with three patients demonstrating persistent abnormal nerve function study results [73]. McDougall and colleagues examine 42 patients with ESLD, 13 of who underwent liver transplantation subsequently. This study included assessment of autonomic, sensory, and motor nerve function. Their findings indicate that sensory nerve conduction abnormalities were widely prevalent (39 or 42) and persisted after transplantation (12 of 13). Parasympathetic measures were abnormal in about 60 %, motor nerve conduction studies were abnormal in half, and sympathetic measures were abnormal in about 20 %. Repeat testing performed between 4 and 27 months after transplantation did not demonstrate substantial improvement although a trend for improved responses to Valsalva was noted [74].

Hypothyroidism

Incidence

Sensorimotor axonal neuropathy occurs in 42 % and entrapment of the median nerve at the carpal tunnel occurs in 29 % of patients with hypothyroidism [75, 76].

Clinical Features

The symptoms of distal sensory polyneuropathies include paresthesias of the feet and muscle cramps in the legs along with severe burning distal pain and lancinating pains. Sensory involvement of the hands should raise the clinical suspicion for carpal tunnel syndrome. Progression may include motor symptoms but examination usually shows no more than mild distal leg weakness. Signs include decreased touch, position, and vibration sense; absent leg reflexes; and less commonly distal leg weakness [77, 78]. The findings on physical examination may be confounded by coexistent muscle disease, which should be considered if proximal weakness is observed [79]. Hypothyroid myopathy is much more common than the distal sensory neuropathy of hypothyroidism described here. Prolongation of the relaxation phase of the ankle jerks is a classical sign of hypothyroid state, although it is not directly related to neuropathy. The symptoms of entrapment neuropathy are no different in hypothyroid state than those seen with carpal tunnel syndrome of other etiologies and include paresthesias at the fingertips.

The diagnosis is suggested by observable symptoms and signs of hypothyroidism that include dry skin, fatigue, constipation, hair loss, muscle aches, and cold intolerance. The hearing loss associated with hypothyroidism is sensorineural but the relationship to distal sensory neuropathy is unclear; the hoarseness associated with hypothyroidism is probably not neurogenic in origin. A decreased thyroxine (T_4) level is

central to the diagnosis of hypothyroidism and thyroid function studies should be assessed. TSH is elevated in primary hypothyroidism. Long-standing hypothyroidism may be undetected because symptom onset is insidious.

Electrodiagnosis

Electrodiagnostic studies are important to characterize the neuropathy in question. There is no consensus regarding the findings of electrophysiological studies, which may show axonal, demyelinating, or mixed results. As a rule, the distal sensory polyneuropathy of hypothyroidism produces a mild-moderate decrease in conduction velocity and decreased amplitude of sensory nerve action potentials. There may be increased distal latency and dispersion of compound muscle action potentials [78–80].

Pathology

The mild chronic sensory polyneuropathy of hypothyroidism is histologically indolent. There are frequent regenerative clusters and an increased number of Pi granules are found in nerve biopsy [76, 77, 81]. Also seen, although not diagnostic of hypothyroidism, is the deposition of glycogen. Glycogen is observed ultrastructurally in most cells of the nerve fascicle including the Schwann cell, myelinated and unmyelinated axons, endothelial cells, and perineurial cells. Nerve biopsy studies have shown segmental demyelination and myelinated fiber loss. Large myelinated fibers are particularly affected. These findings suggest a process of axonal degeneration; however, in other studies, demyelination and remyelination was a prominent feature [77, 78, 81].

Mechanism

The mechanism of the distal sensory neuropathy of hypothyroidism is not known. It has been proposed that defective slow axonal transport produces this entity. The mechanism of carpal tunnel syndrome in hypothyroid state is related to collection of mucopolysaccharides and edema in the extracellular connective tissue within the nerve, in the tendon sheaths, and in the synovial membranes.

Treatment

Correction of thyroid insufficiency is the cornerstone of treatment. Improvement is likely; however, if axonal loss is severe, recovery may be incomplete. The prognosis of symptomatic and objective improvement may be anticipated with hormone replacement.

Hyperthyroid Neuropathy

Incidence

Polyneuropathy can be one manifestation of severe hyperthyroidism, reported in up to 19 % of patients [79].

Clinical Features

Basedow's paraparesis is a term used to describe subacute onset of proximal and distal weakness of the lower limbs with areflexia, sparing sensations, and sphincters, occurring as a complication of hyperthyroidism. It was described by Charcot in 1888. There is marked proximal and distal leg weakness, severe hypotonia, and areflexia in legs. Sensory signs and symptoms are mild; proprioceptive loss may be seen. The diagnosis is usually immediately evident given the other clinical manifestations of hyperthyroidism including exophthalmos, goiter, tachycardia, diaphoresis, tremor, and agitation [82]. The presentation of hyperthyroidism can be highly variable. Thyroid storm, which is rare, presents with fever, marked tachycardia, diarrhea, hypotension, and agitation. Evaluation of thyroid function studies is necessary.

Electrophysiology

The electrodiagnostic findings of hyperthyroid paraparesis are decreased CMAP amplitude and denervation of distal musculature [83]. There are descriptions of postexercise augmentation and fatigue of CMAP amplitudes [84].

Pathology

A published report with muscle biopsy evidence of acute denervation was suggestive of nerve involvement but nerve biopsy has not been studied in this disorder [81].

Mechanism

The precise mechanism of the Basedow's paraplegia is however not known; however, a direct effect of thyroxine on muscle cells has been proposed [83].

Treatment

Treatment of hyperthyroidism may produce clinical improvement that paradoxically may be accompanied by worsening nerve conduction findings. Treatment of the underlying hyperthyroidism is necessary. Supportive care and rehabilitation of motor deficits is important. With appropriate treatment of hyperthyroidism, improvement may be anticipated; however, return of motor function may require weeks to months.

Acromegaly

Incidence

Acromegaly is usually caused by excessive growth hormone secretion from an eosinophilic adenoma of the pituitary gland. Entrapment neuropathies, particularly carpal tunnel syndrome (30–50 %), are far more common than distal symmetric polyneuropathy in acromegaly [2, 85–89].

Clinical Features

Carpal tunnel entrapment of the median nerve occurs in more than one-third and may be the presenting complaint of acromegaly. The distal symmetrical polyneuropathy associated with acromegaly is rare relative to entrapment neuropathy. The initial symptom of the distal symmetrical polyneuropathy of acromegaly is distal paresthesias. Progression leads to weakness more prominent distally. Examination findings include decreased light touch, vibration, and proprioception sense in the lower extremities. Reflexes are absent in the legs and decreased in the arms. There is mild distal weakness of the legs. The symptoms and signs of carpal tunnel syndrome associated with acromegaly are essentially similar with median nerve dysfunction at the level of the wrist due to any cause and are discussed above with carpal tunnel of hypothyroidism. However, the visible enlargement of hands and fingers is a key clinical feature of acromegaly. Carpal tunnel syndrome in acromegaly may precede the obvious stigmata. Glucose intolerance is frequently associated with acromegaly and it is important to determine if diabetic neuropathy may account for confounding findings. Growth hormone levels vary diurnally and with fasting. As the measurement of elevated growth hormone may be insufficiently sensitive in mild cases, the measurement of IGF-1 (insulin-like growth factor) when reliably performed may be more informative and the diagnostic criteria incorporate this biochemical data as well as the results of MRI studies looking for pituitary adenoma. As discussed above, serum glucose may be elevated; assessment should include thyroid function studies as well. CSF is normal.

Electrophysiology

Electrodiagnostic studies may show decreased amplitude of sensory and mixed nerve action potentials and mild slowing of motor conduction velocity. Evidence of reduced velocity across compression sites (carpal tunnel and across elbow) as occurs with typical median neuropathy at the wrist and ulnar neuropathy at the elbow is commonly seen.

Pathology

Nerve biopsies from patients with the distal symmetrical polyneuropathy of acromegaly display increased connective tissue in the perineurium and endoneurium. Although there are a decreased number of myelinated and unmyelinated axons, there is no active degeneration and supporting a mixed axonal/demyelinating process is the observation of onion bulb formation [87].

Mechanism

The mechanism by which acromegaly leads to distal symmetrical polyneuropathy is not known. Carpal tunnel syndrome occurs as a result of proliferation of cartilage, bone, connective tissue, and synovial membranes in the area of the carpal tunnel.

Treatment

Treatment of acromegaly is carried out by an endocrinologist and may include irradiation of the pituitary or transsphenoidal extirpation. Even though resolution of acromegaly can be slow and may require years, removal of the growth hormone-secreting tumor is typically followed by resolution of carpal tunnel symptoms. For this reason, carpal tunnel symptoms are considered useful indicators of disease activity [88]. However, in some patients, surgical release of the carpal tunnel is necessary.

Environmental Toxic Neuropathies

34

Michael T. Pulley and Alan R. Berger

Introduction

Toxic neuropathies can be caused by exposure to substances including chemicals or heavy metals. These exposures may be accidental (in the workplace or through drinking water) or intentional (homicide or suicide). Most toxic neuropathies produce symmetric deficits, but the symptoms and signs may vary, even when the intensity or duration of exposure to the substance is changed. Most heavy metal exposures produce other organ involvement such as skin, hair, or gastrointestinal symptoms and rarely cause an isolated peripheral neuropathy. Some toxins, particularly chemicals, produce damage to the distal ends of both central and peripheral axons and, in some cases, produce morphological changes such as giant axonal swellings. Diagnosing a toxic neuropathy requires suspicion and recognition of associated signs. Also, there are principles of toxin-induced disease that should be present such as consistency of disease in individuals with similar exposures. Treatment of toxic neuropathy involves removing the patient from exposure and, in the case of heavy metals, increasing the excretion of the toxin using chelating agents. Most toxic neuropathies have a good prognosis, but the ultimate outcome depends on the degree of impairment at the time exposure ceases.

Identification of Toxic Neuropathies

Toxic neuropathies have received significant attention due to a few well-publicized clusters of cases [1]. However, epidemics of toxic peripheral neuropathies are rare, particularly in North America. Most toxic neuropathies are sporadic occurrences due to either intentional exposures (suicide or homicide) or accidental (individual or small group) occupational exposures.

The first step in identifying a neuropathy as toxic is a high degree of suspicion. The usual pattern of toxic neuropathy involves distal, symmetric sensory greater than motor abnormalities. As this presentation is similar to that of many other polyneuropathies, a good history of potential exposure usually is needed to raise suspicion. Toxic exposure must often be specifically inquired about, as many patients are unaware of the potential harmful effects of many compounds. Certain key principles of toxin exposure help to establish a cause and effect relationship [2]. First, there should be a consistent pattern of disease, commensurate with the dose and duration of exposure. Second, individuals with similar exposures should experience similar symptoms and signs. Third, the latency of symptom onset following presumed exposure should be short. Finally, removal of the individual from continued exposure should result in improvement or at least stabilization of the disease process. There are a few exceptions to the last rule that involve "coasting," which is the continued worsening of neuropathy after cessation of exposure, seen with certain toxins. Coasting may continue for weeks to months, but not indefinitely.

Another problem in diagnosing toxic neuropathies is the frequent absence of reliable laboratory tests for many of the compounds that cause neuropathies. Even when available, the person may have been removed from exposure before the responsible toxin could be measured and it may no longer be present. The diagnosis of neuropathy from an

B. Katirji et al. (eds.), *Neuromuscular Disorders in Clinical Practice*,
DOI 10.1007/978-1-4614-6567-6_34,

environmental toxin is a challenging and often difficult process that may require a visit to the patient's home or workplace to investigate potential sources of exposure. This chapter describes some of the more common environmental causes of toxic neuropathy.

Lead

Introduction

Lead toxicity is a well-known cause of neurologic dysfunction. Exposure to lead was previously common given its use as solder for drinking water pipes and metal food containers. Lead oxide was added to house paints, ceramic tableware, and toys; tetraethyl lead was added to gasoline [3]. The frequency of lead intoxication has been significantly reduced by the elimination of lead-based paints and other environmental sources. Nonetheless, potential for exposure to lead still exists, especially in the industrial setting. Inorganic lead exposure may occur in lead miners, plumbers, solderers, cable makers, automobile factory workers, lead glass blowers, and pottery glazers. Those employed in battery manufacturing, smelting plants, demolition, and automobile radiator repair [4] are also at risk. Using a torch or other heat source can vaporize lead paint producing intoxication via inhalation of lead. Other potential sources of exposure include drinking "moonshine" whiskey [5], working in indoor gun firing ranges [6], and burning batteries for heat. Exposure to organic lead is less common and is primarily through leaded gasoline products.

Pathogenesis

Lead gains access to the tissues via ingestion, inhalation, or dermal contact. Once in the body, lead interacts with sulfhydryl, amino, phosphate, and carboxyl groups [3]. The interaction with the sulfhydryl groups of enzymes in the heme biosynthetic pathway contributes to anemia. Detoxification of harmful free radicals is also hindered because of deficient activity of cytochromes that contain heme. High levels of inorganic lead may promote cell death by accumulation of intracellular calcium. Calcium levels are increased due to displacement of calcium ions, disruption of ion transport through calcium channels, and inhibition of calcium adenosine triphosphatase [7, 8].

Clinical Presentation

Lead intoxication in children is most commonly associated with central nervous system (CNS) dysfunction. This may lead to chronic cognitive dysfunction (developmental delay or loss of milestones) or acute encephalopathy. High-level acute exposure in adults can also lead to encephalopathy. The encephalopathy may progress to seizures, coma, or death in patients of any age [5, 9]. Ataxia, tremulousness, and choreiform movements are other potential manifestations of acute high-level exposure. CNS disturbances including hallucinations may occur with high-level intoxication and correlates with blood lead levels [10]. Chronic, low-level lead exposure may also have deleterious effects on cognitive or behavioral function.

Peripheral neuropathy resulting from chronic lead exposure may occur in children but is more often seen in adults. Other systemic features of lead toxicity are usually present at the time of presentation, including gastrointestinal (GI) disturbance (abdominal pain might include that the abdominal pain seen with acute lead toxicity can resemble that seen with acute cholecystitis and constipation), anemia (hypochromic, microcytic), weight loss, fatigue, renal dysfunction, bluish discoloration of the gums ("lead lines") and occasional gout. Due to the presence of GI manifestations, anemia, and peripheral neuropathy along with CNS disturbance, lead toxicity needs to be differentiated from porphyria, which lead exposure may precipitate [11].

Lead neuropathy develops insidiously with chronic exposure. Sensory symptoms and signs are minimal or absent while motor complaints predominate. Distal symmetric weakness with reflex loss and atrophy that may initially involve the arms is the usual pattern. Focal deficits such as finger drop are noted in the literature, but these may be due to secondary compression neuropathies [12]. Although lead exposure is associated with some lower motor neuron damage, the development of idiopathic motor neuron syndromes such as amyotrophic lateral sclerosis has not been linked to lead exposure [13]. Some recent reports have challenged the notion that sensory complaints due to lead exposure are unusual, particularly in those with chronic occupational exposure [14, 15].

Evaluation and Diagnosis

Laboratory evaluation reveals a microcytic, hypochromic anemia with basophilic stippling of erythrocytes. Urinary and blood lead levels can be measured. Chelating agents that draw lead from the tissues and allow for its excretion increase the diagnostic yield and may be beneficial therapeutically. The ratio of the micrograms of lead excreted to milligrams of calcium ethylenediamine tetraacetic acid (CaEDTA) administered should not exceed 0.6, and the 24 h urinary lead level after chelation therapy (usually with CaEDTA) should not be greater than 1 mg [16]. A blood lead level greater than 40 ug/100 ml of whole blood is considered abnormal. Although recent exposure causes an elevation of blood lead levels, this does not reflect the total body lead burden.

Axonal and demyelinating features are reported in different electrodiagnostic (EDX) studies. Nerve conduction

studies (NCS) clearly show evidence of sensory axon loss although sensory symptoms or signs are unusual. Asymptomatic individuals and those exposed to "safe" lead levels may have abnormal nerve conductions [17]. The amount of lead in the body predicts the degree of electrophysiologic abnormality [17]. Axonal degeneration leads to electromyographic (EMG) evidence of active denervation and chronic motor unit reinnervation. Somatosensory-evoked potential amplitudes are correlated with blood lead levels in exposed workers. Abnormalities of attention, visuospatial functioning, and memory are detected by neuropsychologic testing.

Treatment and Management

The presence of lead paint in older buildings makes children at risk for ingestion. Eradication efforts have significantly reduced the prevalence of children with elevated blood levels. Measures that may help to decrease the potential for lead exposure in the environment and workplace include enforcement of regulations regarding industrial lead emissions and occupational exposure levels, education of those at high risk regarding the potential long-term effects, promoting good hygiene, regular monitoring of exposure levels, and use of protective clothing and respirators. Urinary lead level monitoring may identify those with excessive exposure prior to symptom onset. Subclinical neuropathy may be detected by nerve conduction studies before it becomes severe [17].

The initial step in the treatment of lead toxicity is preventing further exposure. Chelating agents are then used to promote lead excretion. Penicillamine, succimer, CaEDTA, and British anti-Lewisite (BAL) administered in a short course are all effective chelating agents. Improvement usually begins within 2 weeks. Succimer and penicillamine are usually adequate for milder cases while combination therapy with both CaEDTA and BAL is recommended for more severe intoxication that includes encephalopathy. Diazepam should be tried for treatment of seizures associated with lead toxicity, although they are often refractory. In patients with brain edema, mannitol, hyperventilation, and fluid restriction should all be utilized to lower intracranial pressure. The mortality rate is high in patients presenting with seizures and encephalopathy. The neuropathy has a good prognosis for full recovery except in the most severely affected.

Arsenic

Introduction

Arsenic is famous as a poison used for suicide or homicide. This usually results from a massive, acute ingestion, although toxicity can also result from chronic low-grade exposure. Exposure may also occur in the occupational setting (smelting of lead and copper ore, mining, manufacture of integrated circuits or microchips [18]), through contaminated well water [19, 20], due to tainted illicit drugs, and with the burning of preserved wood [21] or arsenic-contaminated fossil fuels.

Pathogenesis

Absorption of arsenic occurs by inhalation (particulate arsenic and arsine gas), from the GI tract and via dermal contact. The underlying pathophysiology of arsenic neuropathy may be related to the affinity of this compound for thiol groups [22]. This affinity leads to binding with lipoic acid, which interferes with the conversion of pyruvate to acetyl CoA and, thus, energy metabolism. The accumulation of arsenic in hair and skin is also related to the thiol affinity in keratin molecules.

Clinical Presentation

The manifestations of arsenic exposure are dependent on the level of exposure [10]. High-level acute exposure causes severe GI disturbance (abdominal pain, vomiting, and diarrhea), tachycardia, hypotension, and vasomotor collapse with possible death [10]. Exposure to high levels of arsenic may also cause transient (organic psychosis, somnolence, or stupor [23]) or prolonged CNS dysfunction (behavioral and cognitive problems). The peripheral polyneuropathy manifests within weeks and may continue to worsen for a period of weeks after removal from exposure (coasting). Positive sensory symptoms (painful paresthesias, burning, aching, and tingling) occur in the toes and feet first and later in the fingers. Weakness is also dependent on nerve length, manifesting first in the distal lower extremities and later in the hands. There is early depression or loss of reflexes. Respiratory muscle weakness may occur with acute high-dose exposure or inadequate treatment, mimicking Guillain-Barré syndrome. Although the rapid presentation of the neuropathy may mimic Guillain-Barré syndrome, the associated GI symptoms, absence of demyelination on physiologic testing, and normal spinal fluid protein allow differentiation from Guillain-Barré syndrome. With high exposure levels, skin changes and bone marrow suppression are often present in addition to the nervous system manifestations.

Exposure to lower levels of arsenic for longer periods causes dermatologic abnormalities before neuropathy becomes apparent. Nonspecific symptoms develop including malaise, generalized weakness, vomiting, and anorexia. White transverse lines in the nails (Mee's lines), hyperkeratosis, hyperpigmentation of the skin, and irritation of the mucous membranes occur. The neuropathy is usually

subclinical at this time but may be detected by careful examination and electrodiagnostic testing. With continued exposure, clinical polyneuropathy develops that typically involves burning and numbness of the feet followed by the hands. Small- and large-fiber sensory modalities are affected causing abnormality of joint position sense in addition to dysesthesias. Weakness is usually not very severe, limited to the most distal muscles.

Evaluation and Diagnosis

Arsenic levels in the urine may remain elevated even when measured weeks after exposure [18]. Urinary levels greater than 25 ug per 24 h specimen are abnormal unless there was recent seafood ingestion, a source of pentavalent arsenic. Blood levels are not reliable even with very large exposure, as arsenic is cleared within 24 h. Testing of hair and nails may be necessary in chronic exposure or exposure that has since ceased. The electrodiagnostic findings are typical of a distal sensorimotor axonopathy [24]. There is mild slowing of motor conduction velocities with low-amplitude sensor nerve action potentials (SNAPs). Some active denervation is usually detected acutely on needle EMG with reduced motor unit action potential recruitment. Acute high-dose arsenic poisoning may initially produce EDX changes typical of acquired demyelinating polyradiculoneuropathy, as in Guillain-Barré syndrome [25]. However, serial electrodiagnostic testing confirms the progression to a distal dying back axonal loss polyneuropathy.

Treatment and Management

Prevention of arsenic toxicity involves limiting exposure and education of those at risk. Employees likely to be exposed to high levels of arsine gas or arsenic trioxide should be provided with respirators. Excessive exposure may be detected prior to development of symptoms by monitoring urinary levels [26]. Treatment with chelating agents is usually beneficial, but complete recovery may not occur, especially in advanced cases [27]. The CNS effects of arsenic poisoning may also be persistent after treatment [28]. Due to the life-threatening nature of acute arsenic intoxication, the patient should be treated in an intensive care unit with aggressive fluid and electrolyte resuscitation. Chelation therapy with penicillamine and dimercaptopropanol (British anti-Lewisite – BAL) promotes arsenic elimination. Treatment should be initiated as early as possible after exposure with several months of continued therapy often required. The fully developed neuropathy is unlikely to respond significantly to therapy, but milder cases recover completely.

Thallium

Introduction

Thallous salts were previously used as rodenticides and pesticides but are rarely used currently. Thallium ingestion continues to occur either accidentally by children or intentionally by homicide or suicide. Chronic low-level exposure in industrial occupations is much more common than acute high-level toxicity [29]. Another potential source of thallium toxicity is consumption of contaminated food and water [30].

Pathogenesis

Absorption of thallium takes place through the GI tract, dermal contact, or by inhalation. Thallium enters cells through potassium channels, substitutes for it in reactions, and can compete with potassium for sodium potassium ATPase [31, 32]. The substitution for potassium, however, may not be the mechanism of its toxicity.

Clinical Presentation

Thallium intoxication causes a distal, symmetric peripheral polyneuropathy. The pathology is predominately axonal loss with large fibers most affected. Sensory symptoms including pain are much more prominent than motor complaints. The distal portions of the longest axons undergo degeneration initially while the proximal segments are spared. Small unmyelinated fibers may also be involved as indicated by the appearance of delayed autonomic dysfunction [33].

Depending on the duration and intensity of exposure, there are three distinct syndromes of thallium neuropathy [10]. After acute high-level exposure, symptoms begin in 1–2 days. Abdominal pain, diarrhea, and vomiting usually begin within hours, but may not appear for up to a day. Within 2–5 days, distal burning paresthesias in the legs and intense joint pains develop. Both large- and small-fiber sensory systems are affected. The sensory disturbance occasionally involves the hands and trunk. Although not a prominent complaint, weakness is usually detected on examination. Massive ingestion may result in severe respiratory or cardiac failure. Declining mental status leading to lethargy, coma, or even death may result. The classic sign of thallium intoxication is alopecia, which appears after 15–39 days. However, alopecia is not specific for thallium intoxication, is not always present, and is not helpful in the acute setting.

Subacute thallium toxicity occurs following a smaller initial ingestion. The neuropathy begins more than a week after exposure and evolves more slowly. Sensory deficits in pin,

light touch and position sense are prominent. Weakness is frequently detected in distal muscles but tends to be mild in comparison to the degree of sensory dysfunction. Reflexes are also relatively preserved. Painful paresthesias in the feet may interfere with walking early in the course. Autonomic dysfunction resulting in hypertension or tachycardia may occur. Associated dermatologic abnormalities including Mee's lines (white striae of the nails), alopecia, and hyperkeratosis are often present. Chorea, ataxia, and cranial neuropathies may also occur in the subacute syndrome [34].

Chronic thallium toxicity due to prolonged low-level exposure is rare. The neuropathy is the primary finding and is identical to that described above.

The differential diagnosis of thallium neuropathy includes arsenic intoxication. Both cause alopecia and other dermatologic manifestations along with painful neuropathy and autonomic dysfunction. The rapid development of neuropathy with acute thallium intoxication may initially suggest Guillain-Barré syndrome. However, GI symptoms are much more prominent with thallium toxicity.

Evaluation and Diagnosis

Thallium levels can be measured in blood, urine, or tissue (hair and nails). Microgram quantities can be detected by the methods available. Although standard blood levels are available that indicate toxicity, this does not reflect the total body burden, as it does not measure the thallium in tissue. In cases where the baseline level of thallium in blood and urine is normal, but thallium toxicity is suspected, giving a challenge of potassium chloride will cause the urinary excretion of thallium to rise. The cerebrospinal fluid (CSF) protein is normal in thallium neuropathy. Mild slowing of motor conduction velocities and reduced SNAP amplitudes are seen on NCS. Needle EMG reveals evidence for motor axon degeneration. The severity of peripheral nerve damage may be monitored serially with EDX testing [35].

Treatment and Management

Prevention of thallium toxicity involves avoidance of exposure. Enforcement of established workplace exposure levels along with good personal hygiene and protective clothing helps to accomplish this goal. If no measures are taken to promote thallium excretion, the elimination half-life is 30 days. Elimination of thallium from the GI tract may be enhanced by treatment with activated charcoal, Prussian blue, and laxatives [36]. Urinary excretion is aided by administration of potassium chloride and forced diuresis.

Recovery from acute thallium intoxication is frequently incomplete. Anoxic injury often causes residual CNS dysfunction. Residual sensory loss usually remains after a slow recovery from the acute neuropathy. The prognosis for complete return of function is much better in subacute thallium neuropathy. Hair growth usually begins within 10 weeks of discontinuing exposure, and the neuropathy is fully recovered in most patients within 6 months.

Mercury

Introduction

Elemental mercury is a silver-colored liquid at room temperature that was used in thermometers [I do not believe that mercury is used in home thermometers any longer], barometers, and other gauges. Organic mercurial compounds are found in latex paints as a preservative, in various disinfectants, and are also used as industrial catalysts [37]. Inorganic mercurial salts and elemental mercury are used in the manufacture of chlorine, in dental amalgam, and in the natural gas industry. Outbreaks of mercury intoxication include the Minamata Bay incident in Japan with ingestion of contaminated seafood [1] and an episode of poisoning in Iraq through an organic mercury-containing fungicide applied to grain [38].

Pathogenesis

Elemental mercury vapor is absorbed by inhalation. Mercury salts are absorbed through the skin and GI tract and organic mercury is usually absorbed through the GI tract. There is some evidence of inhalation of mercury vapor in individuals with mercury amalgam dental fillings [39, 40], and several reports have linked mercury amalgam dental fillings to various diseases [41, 42]. However, after careful review, no clear relationship has been established between the presence of mercury amalgam dental fillings and any disease or toxicity [43].

Clinical Presentation

Intoxication with mercury results in predominantly CNS dysfunction, while there are some reports of peripheral nervous system (PNS) effects. The form of mercury determines the pattern of nervous system involvement and whether there are associated systemic symptoms.

Elemental mercury is very lipid soluble and tends to cause predominantly CNS involvement with little or no systemic signs. Micromercurialism refers to low-level toxicity caused by elemental mercury. Symptoms include anorexia, fatigue, GI dysfunction, tremor, and weight loss. With further

exposure, personality change, hyperexcitability, insomnia, and much more prominent tremor that may involve the head, face, and even the eyelids may occur. Systemic toxicity associated with mercury salts includes GI symptoms and nephrotic syndrome. The classic phrase "mad as a hatter" refers to the mental impairment that may occur with excessive exposure to mercury salts from the felt of hats. [Unless mistaken the mercury was used to treat the felt so that it became stiff – to enable a "top hat" to hold its shape (note the depiction of the hat worn by the mad hatter in Alice in Wonderland and subsequent works).]

Organic mercury compounds have varying effects depending on their structure. Short-chain compounds such as methyl mercury cause tremor, hearing loss, constriction of visual fields, mental impairment, and dysarthria with prolonged exposure. The other prominent symptom seen more often with organic mercury toxicity is sensory ataxia due to damage of dorsal root ganglion neurons. The earliest sign of sensory neuron damage may be paresthesias, which begin distally and progress to involve more proximal areas including the tongue. Complex organic mercurials are associated with nephrotoxicity.

PNS involvement has been reported with exposure to all forms of mercury. The relationship is better established with elemental or mercuric salt exposure than with organic mercury compounds. Mercury vapor exposure is associated with an acute neuropathy that may be confused with Guillain-Barré syndrome. There is usually a preceding irritation of the upper respiratory tract that may be mistaken for an infection [44]. As with other forms of mercury exposure, mercury vapor tends to cause prominent neuropsychologic dysfunction [44]. Some reports of mercury intoxication describe presentations mimicking motor neuron disease [45].

Evaluation and Diagnosis

Diagnosis of mercury intoxication is based on eliciting the appropriate exposure history in the setting of a neurologic syndrome as described above. Mercury levels can be measured in urine, blood, and hair. Blood mercury level is a good indicator of recent exposure [37] while serial urine measurements (especially with penicillamine administration) or hair samples are better for chronic exposure [38]. NCS may reveal evidence of a developing neuropathy in exposed workers prior to symptom onset [46]. Electrodiagnostic testing shows a motor greater than sensory axonal loss polyneuropathy [47].

Treatment and Management

Prevention is the ultimate goal in any form of toxin exposure. In the case of mercury, this includes education, protective equipment, and monitoring air levels. Treatment of mercury intoxication is primarily by removal from exposure. Although chelation with agents such as dimercaprol [48] or penicillamine increases excretion of mercury in the urine, it is not clear that this speeds recovery from the toxic effects. The prognosis for complete recovery in most patients is good.

Carbon Disulfide

Introduction

Carbon disulfide (CS_2) is a clear liquid that vaporizes at room temperature and is readily absorbed by inhalation. It is also a major metabolite in the breakdown of the drug disulfiram (Antabuse ®) which is used as a deterrent for alcohol abuse [49]. It is used in the production of cellophane films [50] and viscose rayon fibers [51].

Pathogenesis

CS_2 is most commonly absorbed by dermal contact or inhalation but can also be absorbed through the GI tract if swallowed [52]. The reactivity of CS_2 with amine, sulfhydryl, and hydroxyl groups in biologic systems is most likely responsible for its toxicity. Reactive sulfur atoms are formed which bind with and suppress the activity of the cytochrome P-450 enzymes. Inactivation of metalloenzymes such as dopamine B-hydroxylase (which is vital to norepinephrine production) may occur when di- and trithiocarbamates lead to chelation of copper. These compounds are also metabolized to isothiocyanates which covalently bind to and cross-link cytoskeletal proteins such as neurofilaments. This process may cause the formation of giant axonal swellings seen in experimental studies performed in rats.

Clinical Presentation

Acute or subacute exposure to high levels of CS_2 causes primarily CNS dysfunction including memory impairment, confusion, hallucinations, and emotional lability [53]. Low-level chronic exposure results in a combination of peripheral neuropathy and CNS abnormalities. The neuropathy can be subclinical when exposure is low and detected only by EDX testing. Higher exposure leads to a progressive sensorimotor distal polyneuropathy. Headache, dizziness, depression, memory impairment, and impaired sexual arousal are often signs of prolonged exposure [52]. Extrapyramidal signs of tremor, bradykinesia, and cogwheel rigidity, as well as hemiparesis or spasticity, may also be seen.

Evaluation and Diagnosis

Urinary levels of the CS_2 metabolite, 2-triothiazolidine-4-carboxylic acid are a sensitive measure of exposure. NCS reveal slowing of conduction velocities and prolongation of motor and sensory latencies [54, 55]. Acute and chronic denervation changes are seen in distal leg muscles on needle EMG due to axonal degeneration and chronic motor unit reinnervation. The CSF protein is normal.

Treatment and Management

Occupational exposure is usually via the respiratory route. Thus, sufficient ventilation, fume hoods or respirators, and periodic air sampling [52] are all helpful for prevention. The severity of the CNS and PNS dysfunction at the time of removal from exposure determines the degree of recovery. Nearly complete recovery from neuropathy and most of the CNS dysfunction can be expected in mild cases. Residual spinal cord damage may prevent complete recovery. Also, recovery is often incomplete in the case of severe neuropathy. In one series, symptoms and signs of neuropathy were present after 10 years of follow-up in more than one third of patients with severe CS_2 neuropathy [55]. Pyridoxine may have a role in treatment, as there is some reactivity of CS_2 with pyridoxine [52].

Acrylamide

Introduction

Acrylamide is a chemical compound used in grouting agents and in research laboratories; polyacrylamide is a flocculator used in wastewater treatment plants [56]. Acrylamide is absorbed by dermal, GI, or respiratory contact. It appears to interfere with axonal transport [57, 58] resulting in axonal swelling [59] due to accumulation of neurofilaments in the paranodal region [60]. The monomer is the toxic form while the polymer is innocuous. Both the parent compound and its metabolite, glycidamide, are neurotoxic [61].

Clinical Presentation

The duration and extent of exposure determine the manifestations of acrylamide toxicity [10]. As skin exposure is the usual route of entry, contact dermatitis is usually present prior to the symptoms of neuropathy. Low to moderate acute exposure leads to headache, malaise, dizziness, and anorexia. As the level of exposure increases, the neurologic picture may include encephalopathy, with seizures and truncal ataxia followed by peripheral neuropathy [10]. Family members or coworkers may report behavioral changes, as the patient may not be aware of them early on. With more chronic, low-level exposure, the dermatitis and neuropathy persist, but the CNS effects are not as prominent.

Acrylamide toxicity causes a specific pattern of neuropathy known as central-peripheral distal axonopathy [62]. Exposure first causes damage to the distal portion of the longest peripheral axons, but with continued exposure, subsequent damage to the distal segments of corticospinal, spinocerebellar, and dorsal column axons may occur [63]. Initial clinical manifestations include toe numbness and widespread hyporeflexia. Large-fiber sensory dysfunction with loss of vibration and proprioception is common while pain and paresthesia are rare [10]. Although sensory complaints dominate, motor and cerebellar deficits may be evident on physical examination. Acute, high-level exposure often results in widespread autonomic dysfunction including impairment of reflex changes in heart rate and blood pressure, vasomotor changes in fingers and toes, and excessive sweating. Overt autonomic dysfunction is less common in chronic exposure and may be limited to excessive sweating of the hands and feet.

Evaluation and Diagnosis

Electrodiagnostic testing reveals reduced SNAP amplitudes with preservation of motor amplitudes and conduction velocities [64]. In some instances, the electrophysiologic abnormalities may precede the development of symptoms. Sural nerve biopsy demonstrates reduced numbers of large-diameter, thickly myelinated fibers [64].

Treatment and Management

Education of those handling acrylamide regarding its potential toxic effects is the first step in preventing disease. As dermal absorption is a potential source of exposure, protective clothing and gloves should be worn. Good personal hygiene such as washing hands prior to eating should be stressed. Adequate ventilation can help prevent respiratory exposure, and respirators should be used in areas with high acrylamide levels in the air. Removal from exposure usually results in recovery if the neuropathy is mild. Some residual loss of vibratory sensation may be apparent. However, in the case of severe neuropathy, spasticity, ataxia, more profound sensory dysfunction, and memory problems may remain. CNS dysfunction, such as spasticity and upper motor neuron weakness, may be obscured initially by the peripheral nerve dysfunction. Coasting, the worsening of symptoms after termination of exposure, may occur [60]. Acute ingestion should prompt gastric lavage to reduce levels of intoxication.

Liver and renal failure may necessitate blood transfusions or hemodialysis.

Organophosphates

Introduction

Organophosphorous (OP) compounds are used as insecticides, antioxidants, petroleum additives, flame retardants, lubricants, and plastic modifiers. Although these compounds have a variety of industrial uses, group exposure in the occupational setting is rare. Accidental exposure from agricultural spraying is the most common cause of individual intoxication. Estimates of the annual incidence of pesticide-induced toxicity range from 150,000 to 300,000 cases, but less than 2 % of cases are actually reported to public health officials [65]. Individuals mixing or applying the pesticide may become intoxicated. Those working in the fields after spraying may be affected by dermal contact [66]. Most OP esters are quickly degraded in the environment. OP esters are occasionally ingested intentionally in suicide attempts.

Pathogenesis

In addition to dermal exposure, OPs are absorbed through the GI and respiratory tracts. OP causes irreversible inhibition by phosphorylation of the enzyme acetylcholinesterase (AChE) in erythrocytes and nervous tissue. This prevents degradation of acetylcholine resulting in excessive stimulation of both muscarinic and nicotinic receptors (see Chap. 52). There are acute (type I) and intermediate (type II) cholinergic syndromes depending on which receptor is preferentially affected. A delayed central-peripheral axonopathy may develop with exposure to some OPs, independent of the development of the type I or type II syndromes. The neuropathy is not related to the inhibition of AChE.

Clinical Presentation

The acute or type I OP syndrome [67] results from excessive stimulation of muscarinic cholinergic receptors. The acute syndrome frequently begins hours after exposure and always within 1 day. Symptoms include diarrhea, salivation, nausea and vomiting, micturition, sweating, and tachy- or bradycardia. CNS involvement including emotional lability, decreased alertness, fatigue, cognitive impairment, nervousness, convulsions, and coma may occur in extreme cases. These behavioral changes are the only manifestations on rare occasion. Susceptibility to the acute syndrome may be increased by previous OP exposure due to a decrease in functional AChE.

The type II or intermediate OP syndrome [68] occurs within 12–96 h of exposure and is due to nicotinic ACh receptor activation in skeletal muscle. The term intermediate indicates that it precedes the delayed peripheral neuropathy but follows the early muscarinic symptoms. The patient may seem to recover after the acute syndrome only to have onset of the intermediate syndrome after an interval of 1–4 days. Although the neuropathy is discussed more frequently, it probably occurs less often than the type II syndrome. The initial feature is usually respiratory insufficiency followed by weakness of the neck flexors and proximal muscles. The cranial muscles including extraocular muscles may be involved, but strength in the distal extremities typically is normal. Dystonic posturing may be seen. Sensory function is unaffected. Recovery begins 5–15 days after exposure, proceeding from the cranial muscles to the respiratory muscles, proximal muscles, and lastly the neck flexors. As atropine is specific for muscarinic receptors, it does not prevent or treat the intermediate syndrome [67].

The neuropathy has been labeled the organophosphate-induced delayed polyneuropathy (OPIDP), since there is an interval of 7–21 days after exposure. Although less common than the cholinergic syndromes, OPIDP causes significant morbidity. Fortunately, most OPs applied as pesticides are not associated with development of the OPIDP. The most severe cases of neuropathy seem to be caused by compounds that cause very mild cholinergic symptoms. OPIDP is more likely to occur in the setting of chronic low-level exposure. In contrast to most toxic central-peripheral axonopathies which are chronic, the onset of OPIDP is subacute. The maximal deficit occurs by 2 weeks or less after onset. Cramping pain in the calves and painful paresthesias in the feet are the initial manifestations. Although sensory loss is detected by examination, motor symptoms and signs dominate the clinical picture. Leg muscle weakness with foot drop occurs early. Later, the intrinsic hand muscles are affected. The proximal muscles are spared until late in the course. Gait ataxia is more profound than expected based on the sensory loss. Although ankle reflexes are invariably lost, the activity of the other reflexes reflects the degree of CNS impairment. Involvement of the cranial nerves or autonomic nervous system is unusual.

Differential Diagnosis

The acute syndrome (type I) may have prominent mental status abnormalities, and other drug or toxin ingestion needs to be excluded. The intermediate syndrome (type II) with prominent muscular weakness that may present in a fulminant fashion can mimic Guillain-Barré syndrome, periodic

paralysis, or a severe attack of myasthenia gravis. The delayed neuropathy needs to be distinguished from other central-peripheral distal axonopathies caused primarily by other toxins. It may also present in an earlier stage as a simple distal axonopathy, which has a very broad differential diagnosis.

Evaluation and Diagnosis

Electrodiagnostic testing in OPIDP reveals a sensorimotor axonal loss polyneuropathy. Although motor symptoms are most prevalent, sensory conduction abnormalities are more dramatic and appear earlier. SNAPs are reduced in amplitude or absent while motor conduction studies are either normal or reveal minimal slowing of conduction velocity. Needle EMG reveals evidence of acute and chronic denervation in the distal and, occasionally, proximal limb muscles in OPIDP but is normal in the intermediate syndrome [69]. Shortly after OP exposure, spontaneous repetitive motor action potentials (SRMAPs) following the initial compound motor action potential are elicited by a single stimulus [69]. The ability to elicit SRMAPs is a sensitive indicator of OP exposure, but does not reflect the degree of intoxication. With the onset of weakness, a decremental response to repetitive nerve stimulation is seen. In the case of mild intoxication, rapid stimulation rates may be required to demonstrate a decremental response. Decrements may be followed by increments when SRMAPs are present. With more severe exposure, decrements are evident even with slow rates of stimulation and SRMAPs may be absent [70].

Standard laboratory testing is usually normal. Recent exposure to OP causes reduced AChE levels in erythrocytes. Levels below 20 % of normal are associated with severe weakness. Serial measurements documenting a progressive decline in AChE activity is the best indicator of toxicity as there is significant variability of normal erythrocyte AChE levels. The AChE level cannot be used to reliably predict which patients will eventually develop OPIDP. Because regeneration occurs at the rate of 1 % per day, AChE levels may have recovered to normal values prior to testing. Pseudocholinesterase levels are not helpful. There may be slight elevation of the CSF protein level, but there is typically no CSF pleocytosis.

Treatment and Management

Prevention involves education regarding potential toxicity, use of protective clothing, good hygiene, and monitoring for toxicity. As noted above, after emergence of the acute syndrome, administration of atropine has no effect on the later development of the intermediate syndrome or OPIDP. However, NCS may reveal evidence of early, reversible neuropathy in exposed individuals [71].

Organophosphate poisoning carries a significant risk of respiratory failure, and even when respiratory function is not compromised, intubation may be necessary due to excessive secretions or vomiting in the setting of depressed level of consciousness. In acute intoxication, contaminated clothing should be removed and the skin cleansed to prevent further dermal absorption. Cathartics and gastric lavage are indicated in the case of ingestion. Reactivation of AChE may be accelerated by the administration of pralidoxime. This is most effective if given early in the course. Pralidoxime may prevent the emergence of the intermediate syndrome [72]. Fortunately, the muscarinic symptoms are typically relieved with atropine. However, as the duration of action is short, it must be continued, to prevent the recurrence of symptoms that may still be fatal. As there is some evidence that administration of atropine to patients with respiratory insufficiency may be associated with increased risk of ventricular arrhythmias, patients need to be adequately ventilated and cardiac monitors in place, before it is given. Atropine is specific for muscarinic receptors and has no effect on depolarizing neuromuscular blockade due to overstimulation of nicotinic receptors.

With good supportive care, there is usually complete recovery from the acute and intermediate syndromes. Although only 40–60 % of AChE content is regenerated by 1 week after exposure, this is usually sufficient for functional recovery. If CNS damage occurs, this may persist after recovery from the acute syndrome. Patients with mild OPIDP usually have a good outcome. Residual foot drop, claw hand deformity, or atrophy is sometime seen in cases of severe neuropathy. The damage to distal dorsal column and corticospinal axons may only become apparent after recovery from the peripheral neuropathy and is more likely to persist.

Hexacarbons

Introduction

Both n-hexane and methyl n-butyl ketone (MnBK) are clear, colorless, volatile liquids. They are metabolized to the toxic compound 2,5 hexanedione [73]. Methyl ethyl ketone (MEK) is not neurotoxic by itself, but is present in many solvent mixtures and may potentiate the neurotoxicity of n-hexane and MnBK. Hexacarbons are components of glues and lacquers and are used as solvents. Hexacarbon exposure occurs in the production and refining of petroleum products. The cabinet-making and shoe industries use these compounds in lacquers and glues [74, 75]. The sandal and shoemaking industries of Japan [76] and cabinet-finishing plants in the USA [75] have been responsible for reports of

hexacarbon neuropathy. An epidemic of peripheral neuropathy resulted from the substitution of MnBK for MEK and methyl isobutyl ketone in the manufacturing of plastic-coated and color-coated fabrics [77]. High-level exposure also occurs with intentional inhalation (glue sniffing [78]). Hexacarbon-related neuropathy is less common at present with the removal of hexacarbons from many industrial and commercial products. However, recreational abuse usually via glue sniffing remains a substantial epidemiologic problem.

Pathogenesis

Hexacarbons gain entry to the body via inhalation, dermal contact, and, rarely, ingestion. The peripheral nerves of patients with hexacarbon toxicity have a very characteristic morphological abnormality that involves the formation of giant axonal swellings. These occur due to the accumulation of neurofilaments but are also seen with exposure to carbon disulfide or acrylamide [79] and in the genetic neuropathy, giant axonal neuropathy [80]. The paranodal regions are the focus of neurofilament accumulation [60]. Cross-linking and disruption of axonal transport cause the accumulation of neurofilaments. This leads to a distal-central dying back neuropathy.

Clinical Presentation

High-level acute exposure causes CNS depression and narcosis. Repeated massive exposure (i.e., glue sniffing) leads to a subacute, predominately motor neuropathy with cranial nerve dysfunction [81]. Autonomic dysfunction including impotence, hyper- or anhidrosis, and vasomotor instability may sometimes occur with this neuropathy, leading to a mistaken diagnosis of Guillain-Barré syndrome. In contrast to that seen with chronic high-level exposure, chronic low-level exposure results in a slowly developing, length-dependent, central-peripheral axonopathy. This refers to a process whereby distal portions of peripheral axons degenerate first, but continued exposure leads to damage of distal dorsal column, corticospinal, and other central pathways. Pinprick, temperature, and vibratory sensations are initially impaired in the feet with proximal progression if exposure continues. Ankle reflexes are lost early in the course, but relative to the degree of sensory loss, the other reflexes may be preserved. Weakness of distal arm and leg muscles may be present. Atrophy and weakness may become the prominent complaint if the neuropathy becomes advanced. Weight loss, abdominal pain, malaise, and leg cramps may be present in severe cases. Symptoms frequently continue to worsen after removal from exposure (coasting).

Evaluation and Diagnosis

Electrodiagnostic studies characteristically show prominent slowing of distal latencies and motor conduction velocities [79]. This is an unusual finding in toxic neuropathies in general, but not in subacute hexacarbon neuropathy. Asymptomatic workers employed in factories with documented cases of solvent polyneuropathy may also have slowed conduction velocities. CSF protein may be elevated if the nerve roots are involved.

Treatment and Management

The toxic effects of solvents containing n-hexane or MnBK need to be discussed with those who will come in contact. Gloves and other protective clothing help to reduce dermal contact [82]. Adequate ventilation is essential and ventilators should be provided in areas with high concentrations. The risk of exposure can be gauged by monitoring ambient air levels [83]. Urinary measurement of 2,5 hexanedione may allow detection of exposure prior to the appearance of significant toxicity [84]. The only available treatment is cessation of hexacarbon exposure. Complete recovery usually occurs in cases of mild neuropathy. Severe neuropathies frequently leave residual sensory loss, atrophy, and distal weakness. Hexacarbon neuropathy is well known for the "coasting" phenomenon, which refers to the progression of clinical manifestations despite removal from exposure. Central damage (spasticity, long-tract weakness) may only become apparent after resolution of the peripheral neuropathy.

Drug-Induced Toxic Neuropathies

35

Kevin R. Hargrave, Gregory J. Ferenz,
and Milind J. Kothari

Introduction

Drug-induced toxic neuropathies can be grouped either by their clinical pattern or by their underlying pathology. Clinically, drug-induced peripheral neuropathies may present with sensorimotor, primary sensory, or primary motor patterns (Table 35.1). Pathologically, the site of damage may be the cell body (neuronopathy), the axon (axonopathies), or the myelin sheath (myelinopathies) (Table 35.2). Most drug-induced toxic neuropathies are axonal, sensorimotor polyneuropathies with a typical "dying back" pattern (Fig. 35.1).

Chemotherapeutic Agents

Chemotherapeutic agents often result in peripheral neuropathies. *Vincristine* sulfate (Oncovin®, part of the common "CHOP" regimen) is an antineoplastic agent derived from the periwinkle plant, Vinca rosea. Like its predecessor, *vinblastine*, and its lesser-used relative vindesine, it inhibits microtubule polymerization and interferes with axonal transport. Peripheral nerve toxicity occurs in most patients treated with vincristine. It is a dose-dependent phenomenon which leads to a dose reduction or discontinuation of the drug in many patients [2–5]. Patients complain of numbness and tingling of the hands and feet, with the hands being symptomatic first in some. Weakness is often prominent and may be of sudden onset; it predominantly affects the upper extremity extensors and distal lower extremity muscles, often leading to foot drop and gait dysfunction [6]. Some patients become totally areflexic [7], whereas others lose their ankle jerks only [2, 8]. Loss of ankle reflexes is usually the first objective finding and is often permanent [4]. In some cases, autonomic dysfunction may result in constipation, ileus, and orthostatic hypotension [9].

Table 35.1 Clinical presentations of drug-induced toxic neuropathies

Sensorimotor	Primarily sensory	Primarily motor
Allopurinol	Acetazolamide	Chloroquine
Amiodarone	Almitrine	Cimetidine
Amitryptiline	Ara-C	Dapsone
Atorvastatin	Bortezomib	Imipramine
Captopril	Chlorambucil	Methimazole
Chloroquine	Chloramphenicol	Zimeldine
Colchicine	Cis-platinum	
Cyclosporine	Clioquinol	
Disulfiram	Colistin	
Docetaxel	ddC	
Ethambutol	ddI	
FK506	Ethionamide	
Gold	Etretinate	
Hexamethylmelamine	Flecainide	
Indomethacin	Glutethimide	
Interferon alpha	Hydralazine	
Isoniazid	Mercury	
Leflunomide	Methimazole	
Linezolid	Ixabepilone	
Lithium	Metronidazole	
Lovastatin	Niacin	
Methaqualone	Nitrous oxide	
Nitrofurantoin	Oxaliplatin	
Paclitaxel	Paclitaxel	
Perhexiline	Procarbazine	
Phenytoin	Propylthiouracil	
Podophylin	Pyridoxine	
Pravastatin	Stavudine	
Sodium cyanate	Streptomycin	
Suramin	Thalidomide	
Thalidomide		
TNF alpha		
Vincristine

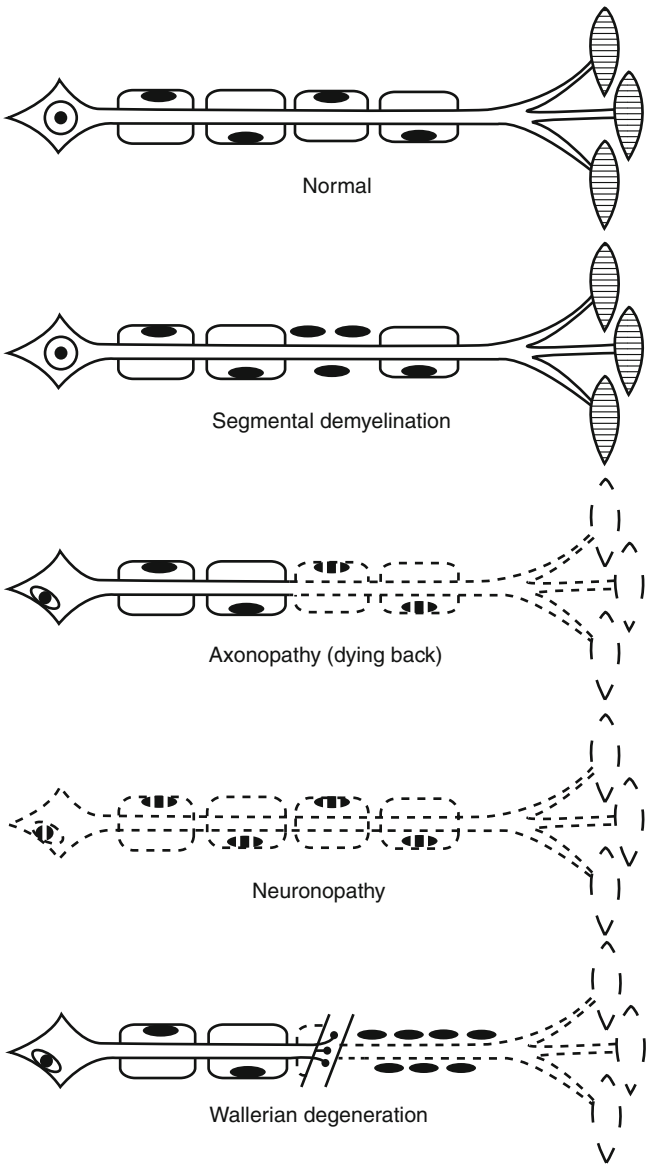

Fig. 35.1 Schematic showing the main sites of damage in the four principal types of polyneuropathy. The cell body of the neuron is shown at the *left*. Note that muscle fiber degeneration due to denervation occurs only when the axon or motor neuron is affected (Reproduced with permission from Guberman [1])

Electrodiagnostic studies (EDX) show low-amplitude sensory nerve action potentials (SNAPs) and compound motor nerve action potentials (CMAPs) and mild slowing of conduction velocities [2, 4]. Denervation and reinnervation are evident on needle electromyography (EMG), usually more prominent distally [4, 8, 10]. Nerve biopsy shows primarily axonal degeneration of both large and small fibers [2]. Teased fiber preparations typically show evidence of wallerian degeneration with a minority of fibers showing secondary demyelination [2]. Increased intra-axonal filaments/tangles may be present [6] (Fig. 35.2).

Patients often improve after discontinuation of the drug but may be left with permanent deficits [3, 8]. Some patients may worsen for several months after discontinuation of the drug before recovering [2]. SNAPs often remain abnormal despite disappearance of sensory signs and symptoms [4].

The chemotherapeutic agent *cis-platinum* causes a dose-dependent large fiber sensory polyneuropathy [11, 12]. As nephrotoxicity has been reduced with use of hyperhydration, peripheral neuropathy remains the major dose-limiting toxicity, often occurring after a total dose of >200–500 mg/m^2

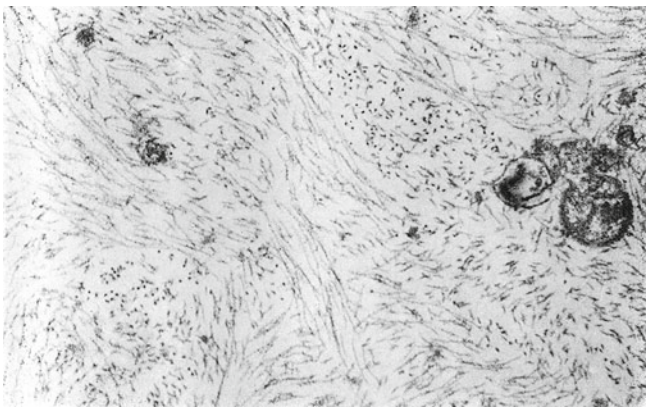

Fig. 35.2 Vincristine-induced neurofibrillary tangle. Filaments measure 90–100 Å in diameter (×41,700) (Reproduced with permission from Shelanski and Wisniewski [6])

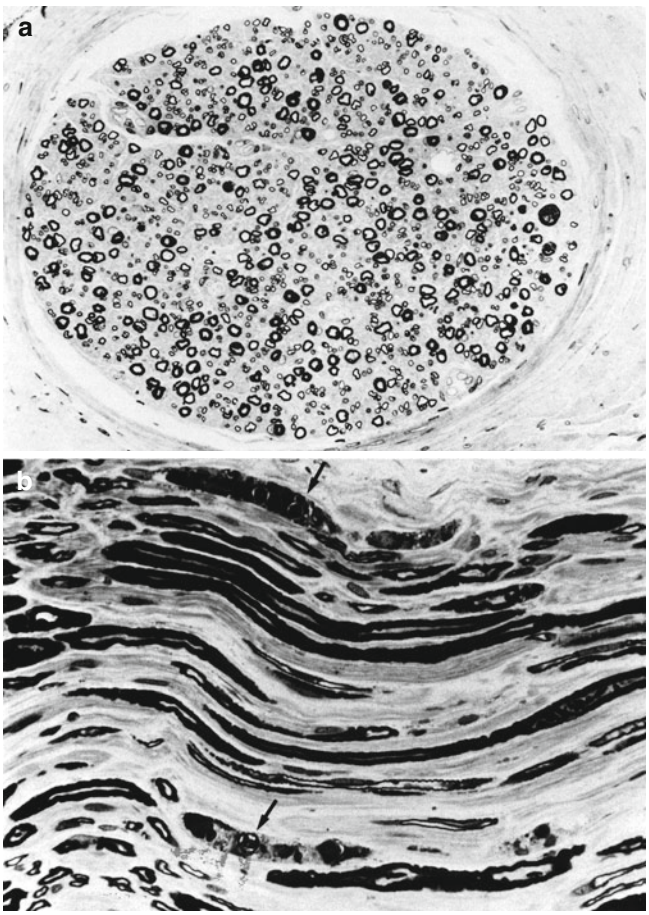

Fig. 35.3 Cisplatin neuropathy – cross section of sural nerve (*top*). The fascicle shows a marked loss of large myelinated fibers. Few degenerating fibers are present. Longitudinal section of sural nerve (*bottom*). Axonal degeneration is apparent in two myelinated fibers (*arrows*) (Reproduced with permission from Thompson et al. [12])

[3, 11, 13]. In general, patients develop numbness of the hands and feet, which may progress to a sensory ataxia. A Lhermitte's sign and lancinating pains are often present [14, 15]. Physical exam shows loss of reflexes and vibratory loss distally, sometimes before symptoms develop [16]. Later, light touch and pinprick loss may be seen in the lower extremities [3]. Weakness is observed only in the most severe cases [8]. One series showed that all patients receiving five daily doses of 40 mg/m^2 developed neuropathy [16]. In another series, 10 of 11 patients developed neuropathy, but only one discontinued therapy because of neuropathy [12].

Intra-arterial administration of cis-platinum may cause plexopathies. In addition, cranial neuropathies and ototoxicity have been reported [17–19]. Experimental studies have shown that the dorsal root ganglion may be the primary site of damage [20].

EDX may be normal early but later show low-amplitude SNAPs with prolonged distal latencies and slowed conduction velocities. Motor conduction studies are normal [12, 21]. Needle EMG may show denervation or may be normal [3, 16]. Biopsy shows axonal degeneration, especially of large myelinated fibers, but segmental demyelination may also be present in association with disintegrated axons [12] (Fig. 35.3). Recovery is often incomplete and protracted, continuing for up to 1 year or more [5]. *Glutathione* (*GSH*), a nucleophilic sulfur containing compound/tripeptide thiol, has shown promise in protecting against various toxicities of cis-platinum toxicity, including nephrotoxicity, hematologic toxicity, and peripheral neuropathy [22].

Combination chemotherapy with cis-platinum and either *doxorubicin* [12, 16] or *docetaxel* [23] may be more neurotoxic than with cis-platinum alone. *Carboplatin* causes much milder peripheral nervous system disease and usually only occurs at markedly high doses [5].

Oxaliplatin is a third-generation platinum derivative that has a unique structure from cisplatin in that it contains, 2-diaminocyclohexane [24]. It is used in combination with other drugs in the treatment of advanced colorectal cancer, and its combination with fluorouracil/leucovorin as adjuvant therapy in stage III colon cancer is currently the standard of care [25]. Though chronic therapy produces a predominantly sensory neuropathy similar to cisplatin, the drug causes an idiosyncratic acute neuropathy not found in other chemotherapeutics [26].

The drug frequently causes an acute neuropathy consisting of jaw tightness, perioral paresthesias, dysphagia, shortness of breath, or cramps that develop with 2 days of the infusion. A unique feature is paresthesias precipitated by cold exposure [26, 27]. The incidence is reported between 85 and 95 % [28]. NCS shows reduced CMAPs, and needle EMG shows neuromyotonic discharges consistent with peripheral nerve hyperexcitability [26]. The pathophysiology is not yet fully described but may be related to voltage-gated sodium channels [29]. These symptoms invariably transient and do not require dose modification [26, 28, 29].

Though the incidence of oxaliplatin-induced chronic neuropathy is less common than the acute neuropathy, its role as being a common adverse effect to lead to dose modification makes it potentially more serious. The chronic neuropathy is predominantly sensory, axonal, and distal greater than central [30].

Paclitaxel (Taxol®) produces a dose-dependent, axonal, sensorimotor neuropathy at cumulative doses usually above 200–250 mg/m^2 [31, 32]. Large and small fibers are affected. A reversible axonal neuropathy with distal deficits is most common, although a sensory neuronopathy affecting the upper extremities and face may occur with higher doses [32–34]. The incidence of neuropathy is more common with concurrent cis-platinum therapy or ethanol abuse [32]. Symptoms may begin as early as 1–3 days after initiating therapy [33]. Mild paresthesias have been reported in 50 % of patients treated for ovarian cancer [12]. Motor involvement has been reported in 17 % of cases; autonomic involvement is infrequent [31, 35]. Paresthesias of the hands and face may occur before the feet and trunk which may become involved later. Dysesthesias are common with narcotics often needed to treat acute pain [3, 32, 36]. Improvement usually occurs but may require several months [5].

The neurologic exam shows a stocking-glove loss of most sensory modalities and decreased or absent reflexes [3, 32, 37]. EDX shows low-amplitude SNAPs and slowed conduction velocities [33, 37, 38]. Similar findings are seen in motor nerves in severe cases [33]. Paclitaxel causes polymerization of microtubules and blocks depolymerization [12]. On biopsy, aggregates of microtubules are found in axons, Schwann cells, and dorsal root ganglia [33, 39] (Fig. 35.4). However, the pathophysiology may be multifactorial [35], with other biopsy studies showing axonal atrophy, nerve fiber loss, and secondary demyelination, suggesting a primary ganglionopathy [40].

The semisynthetic derivative of Taxol known as *docetaxel* (Taxotere®) is derived from the needles of Taxus baccata, a European yew tree. It is much more abundant and easier to extract than its predecessor Taxol, which is derived from the bark of the Pacific yew, Taxus brevifolia, and requires the sacrificing of whole trees [36]. This antineoplastic is more potent than its predecessor [23] and is primarily used in breast, ovarian, and lung cancers. Neuropathy has been seen with doses of as little as 50 mg/m^2 (but usually >400 mg/m^2) of docetaxel [32]. One series showed an 11 % frequency of peripheral neuropathy with docetaxel [37]. Another study of 55 patients undergoing combination therapy with docetaxel and cis-platinum showed a 53 % frequency of neuropathy [41].

Clinically, some patients appear to have a small fiber neuropathy with prominent pain [23], but nerve biopsies have shown large myelinated fiber loss and axonal degeneration [37]. EDX shows denervation and reinnervation in distal leg muscles [37]. Muscle biopsy shows neurogenic atrophy [37]. Nearly all patients improve after withdrawal of the drug [37].

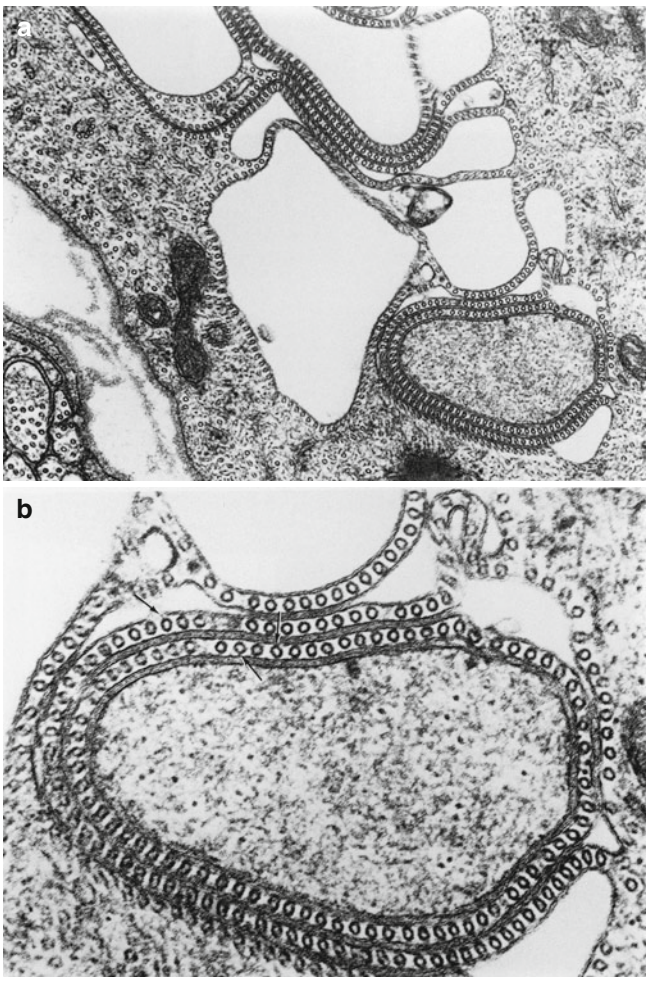

Fig. 35.4 Taxol-induced neuropathy. A multinucleated, large Schwann cell that is devoid of axons and contains complex stacks of membranes and microtubules. (*Top*) Note the regular alignment of microtubules along the membranes forming the walls of the intracellular cisternae. Narrow channels of cytoplasm traverse these cisternae and contain regularly spaced microtubules. The basal lamina of the Schwann cell lies to the left and the plasmalemma is not affected by the microtubule anomaly (×40,000). (*Bottom*) Detail of the circular stack of cytoplasmic bridges containing microtubules. Some microtubules appear to be attached to the membranes by stalks (*arrows*). Note how the outer leaflets of the affected membranes become closely apposed to form a structure similar to the intraperiod line of the myelin sheath (×115,000) (Reproduced with permission from Roytta and Raine [39])

The semisynthetic alkaloid *vinorelbine* (Navelbine®) is used to treat solid tumors. In combination therapy with paclitaxel, vinorelbine is associated with a mild neuropathy in 44 % of patients [42] and a severe sensory neuropathy in 28 % of patients [39].

The widely used chemotherapeutic agent *cytarabine* (Cytosine arabinoside, Ara-C®) most often causes prominent

CNS dysfunction but rarely leads to peripheral neuropathy (0.6 %) [43]. The neuropathy is often associated with painful paresthesias [7], usually occurring with doses greater than 200 mg/m²/day [44]. Clinical presentations in these cases range from pure sensory neuropathies to Guillain-Barré-like syndromes requiring ventilator assistance for life support [43, 45]. The onset may occur within hours after the first dose [44]. Recovery is often incomplete [44]. Sural nerve biopsies have shown axonal loss and demyelination [46].

Chemically similar to metronidazole, *misonidazole* is a radiosensitizer used in cancer therapies. It is associated with a dose-limiting painful peripheral neuropathy at cumulative doses greater than 18 g [47]. Sural nerve biopsies have shown axonal degeneration and demyelination [48, 49]. Partial recovery occurs after discontinuation [21].

The agent *suramin*, used as an antiparasitic since the 1920s and later an antiretroviral, has recently been used to treat refractory neoplasms. In one series, the drug resulted in a severe sensorimotor neuropathy in 4 of 38 patients after 5–8 weeks of therapy [50]. Toxicity is associated with high serum drug levels and is not necessarily related to cumulative dose. The risk of developing neuropathy was 40 % in patients with drug levels greater than 350 mcg/ml. Patients experienced paresthesias followed by weakness. A Guillain-Barré-like syndrome occurred in two patients with bulbar, respiratory, and autonomic involvement, requiring mechanical ventilation. EDX showed conduction block and decreased nerve conduction velocities. The primary pathology in these two patients appears to be demyelinating [50].

Bortezomib is a boronic acid dipeptide which reversibly inhibits the chymotryptic site of the 26S proteasome interfering with cancer cell-signaling cascades. It has been approved by the FDA for the treatment of patients with multiple myeloma and for patients with mantle cell lymphoma who have received at least one prior therapy. Neuropathic symptoms are typically small fiber, length dependent, and accompanied with significant neuropathic pain [51]. Motor neuropathy can occur in a minority of patients [52]. Neuropathy is a dose-limiting complication in 5–10 % of patients and typically occurs within the first few courses of treatment [53]. The prevalence increases with cumulative dose, reaching a plateau at the fifth cycle [54]. The incidence of mild neuropathy has been reported in two large trials to occur in 35 % of all patients with severe neuropathic symptoms in 14 % [55, 56]. However, other studies have shown a higher incidence, particularly in patients with baseline neuropathy or recurrent disease [57]. The mechanism of neuropathy from bortezomib is as yet not well understood [58]; however, risk factors for the development of symptoms may include preexisting neuropathy, age, and impaired renal function [59–61].

EDX testing may show decreased amplitudes of SNAPs and CMAPs and denervation changes in more distal muscles of the lower limbs [52]. However, this is complicated by evidence of peripheral neuropathy in up to 54 % of patients with multiple myeloma before treatment with bortezomib [62]. With dose modification or discontinuation, the majority of patients have improvement or resolution of their symptoms within 3 months [54, 62]. Dose modification guidelines have been shown to reduce the severity of symptoms [63].

Ixabepilone is a semisynthetic epithilone analog used in the treatment of breast cancer. It was approved by the FDA in 2007 for the treatment of metastatic or locally advanced breast cancer in combination with capecitabine in which the cancer is resistant to anthracycline or a taxane. It is additionally approved for monotherapy in the treatment of metastatic or locally advanced breast cancer resistant or refractory to treatment with anthracyclines, taxanes, and capecitabine [64]. The mechanism of action includes microtubule stabilization, alteration of mitotic spindle formation, and induction of apoptosis [65]. The incidence of peripheral neuropathy is reported to range from 20 to 63 % with increased risk ascribed to advanced disease and prior treatments [66]. The neuropathy is predominantly sensory with 9 % reported to have a motor component [67]. Sensory findings are often mild and length dependent occurring in a stocking-glove pattern. Less than 20 % of patients have been reported to develop a severe neuropathy, and when this does occur, it is typically after the fourth treatment cycle [68]. More than 75 % of patients with neuropathy will have improvement in their symptoms with dose reduction in 4–5 weeks [67, 69]. Guidelines for dose reduction have been published [64].

Thalidomide, once touted as a sedative hypnotic, and used as an immunosuppressant in rheumatoid arthritis and autoimmune skin conditions, is now FDA approved for use in multiple myeloma. A sensorimotor neuropathy appears in persons taking the drug after 1–18 months at daily doses of 50–400 mg [70]. Patients develop numbness and paresthesias which begin in the feet and later ascend along with proximal weakness. Reflexes may be decreased, absent, or increased with Babinski signs in some patients. CSF exam may show elevated protein [70]. EDX shows decreased to absent SNAPs [71]. Sural nerve biopsy shows selective loss of large diameter fibers [72]. Recovery is often very slow and deficits are sometimes permanent [70].

Other chemotherapeutic agents have been associated with neuropathies. Sensory neuropathies have occurred with *chlorambucil* [73]. Mild peripheral neuropathy may be seen with repeated courses of high-dose therapy with *etoposide* (VP-16) [5]. The alkylating agent *ifosfamide* rarely causes peripheral neuropathy [5]. The chemotherapeutic agent *procarbazine*, structurally similar to INH, has been associated with a mild peripheral sensory neuropathy at high doses [5, 74]; whether pyridoxine (vitamin B6) ameliorates or prevents this neuropathy is uncertain [5]. Isolated limb perfusion with *interferon*, *tumor necrosis factor*, and *melphalan* in

melanoma patients has caused a dose-dependent local sensory neuropathy [75].

Antituberculous Agents

Isoniazid (isonicotinic acid hydrazide/INH®), the most commonly used antituberculous agent, may result in an axonal sensorimotor polyneuropathy that is in part preventable by concurrent administration of vitamin B6. Before the recognition of B6 deficiency with INH therapy, the incidence of neuropathy was quite high, with 17 % of patients receiving a dose of 400 mg/day developing neuropathy [76, 77]. With supplemental vitamin B6, one study showed only one of 62 INH-treated patients developed neuropathy [78].

Excretion of vitamin B6 is increased with INH administration [79–81]. Poor nutritional status, alcohol abuse, liver disease, thyroid dysfunction, and pregnancy are risk factors for INH neuropathy [3]. Slow acetylators are more commonly affected [3, 12].

Symptoms usually begin with numbness and paresthesias of the hands and feet. If the drug is discontinued after the first symptoms begin, recovery is rapid [8]. Myalgias, muscle cramps, ataxia, and weakness may be seen as well [3, 8, 78, 82]. Examination shows distal sensory loss, weakness, absent reflexes, and ataxia [3]. Late in the course, atrophy and fasciculations may be seen [83]. EDX shows a sensorimotor axonal polyneuropathy [3]. Nerve biopsies show axonal degeneration and loss of myelinated and unmyelinated fibers [12, 84].

The recommended prophylactic dose of pyridoxine is 25–50 mg/day [78]. If much higher doses are used, a separate pyridoxine-induced sensory neuronopathy may occur [85]. Some studies suggest that even 10 mg/day is effective [81]. Recovery from the neuropathy is often slow and ranges from incomplete to good. Whether B6 deficiency is the only cause of INH neuropathy remains unsettled [3, 79, 85, 86]. Experimentally, INH may result in multifocal axonal lesions in animals after a single oral dose [87].

Ethambutol, a common additional antituberculous drug, causes a sensorimotor polyneuropathy [88]. An optic neuropathy is more commonly seen [21]. Distal paresthesias and a reversible neuropathy have been reported with *ethionamide* [86, 89]. Improvement occurs slowly after the drug's discontinuation [89].

Antiretroviral Agents

A dose-limiting painful, dysesthetic sensory neuropathy occurs with *Zalcitabine*® (2′3′dideoxycytidine or ddC) in approximately one-third of patients treated with 2.25 mg/day [90]. The neuropathy may be confused with distal sensory neuropathy associated with HIV [91] but can be differentiated by its more rapid progression (weeks vs. months) with a median onset at 16 weeks of therapy [3, 90]. Patients complain of numbness, tingling, and pain. Examination shows decreased pinprick sensation, hyperpathic pain, and ankle areflexia; vibratory loss occurs in only a third of patients [90]. Patients may or may not improve after discontinuation of the drug [90, 92]. Risk factors for neuropathy include coexistent diabetes, weight loss, advanced HIV disease, preexisting peripheral nerve problems, alcohol abuse, and nutritional deficiency [90, 93].

In one study of 44 patients treated with *didanosine* (ddI), neuropathy occurred in nine and a preexisting neuropathy worsened in one [94]. The neuropathy seen with ddI is similar to that seen with ddC [94]. Biopsies may show intramyelin edema and myelin infolding (Fig. 35.5) [84].

Peripheral neuropathy is the major dose-limiting toxicity of the antiretroviral *stavudine*. The neuropathy limits the maximum tolerated dose to 4 mg/kg/day, at which dose 60 % of patients develop neuropathy. At a dose of 2 mg/kg/day, less than 40 % of patients develop neuropathy; current doses approved for use are approximately 1 mg/kg/day [95]. The neuropathy is similar to that seen with ddI and ddC [95].

Other Antimicrobial Agents

The antimicrobial drug *metronidazole* (Flagyl®) may cause a predominantly axonal sensory polyneuropathy, more common after a cumulative dose of 50 g [81]. Patients complain of distal dysesthesias. Examination shows distal sensory loss, weakness, and decreased reflexes [78]. EDX shows reduced SNAP amplitudes with normal latencies; less frequently, motor fibers are affected [21]. Sural nerve biopsy shows axonal degeneration of myelinated and unmyelinated fibers and segmental demyelination [10, 86, 96]. Recovery may be slow but is usually good [3, 81].

Nitrofurantoin, a commonly prescribed agent for urinary tract infections, may result in an axonal sensorimotor polyneuropathy and rarely a fulminant radiculoneuropathy. Total toxic doses are usually greater than 20 g but can be less in patients with compromised renal function [97]. When polyneuropathy occurs, it usually does so within 6 weeks of starting the medication [86]. Patients complain of paresthesias and numbness followed by weakness [3, 86]. Severe weakness and loss of reflexes, similar to the Guillain-Barré syndrome have been reported [98]. In addition, patients have been reported with pure motor neuropathies [7, 99, 100]. EDX have demonstrated decreased conduction velocities and distal denervation even in some asymptomatic patients [101]. Nerve biopsies and autopsies have shown wallerian degeneration [102]. Renal failure and volume depletion predispose patients to nitrofurantoin's neurotoxic effects [102].

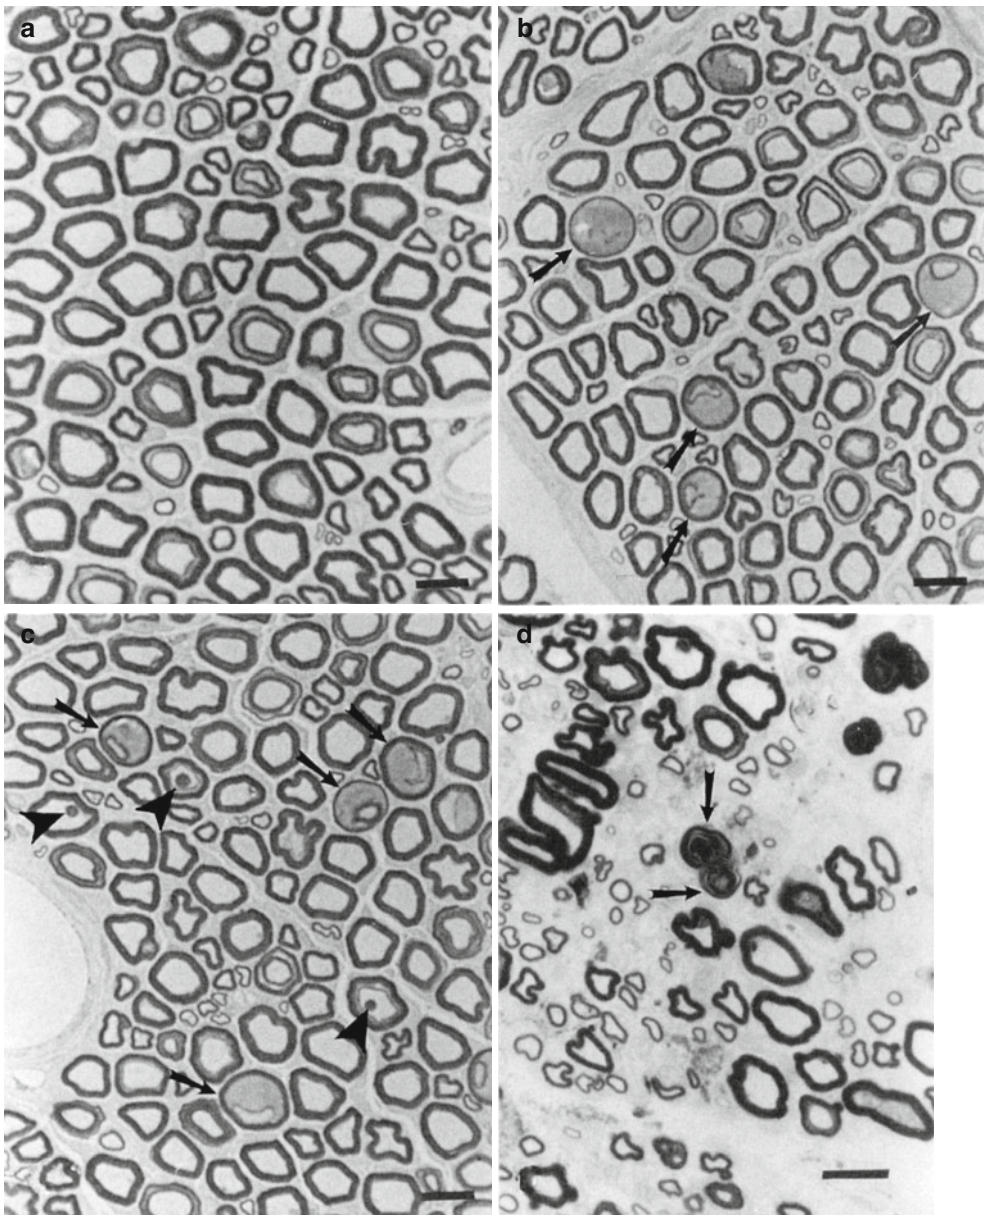

Fig. 35.5 ddI neuropathy. Brightfield photomicrographs of semithin plastic-embedded sciatic nerve stained with toluidine blue and basic fuchsin. (**a**) Reveals mostly normal morphology of nerve tissue from animals dosed with the vehicle control. (**b**, **c**) Myelin pathologies frequently seen following chronic ddI dosing. *Solid arrows* indicate examples of intramyelin edema, whereas *arrowheads* indicate myelin infolding. Neuropathies resulting from chronic isoniazid administration (**d**) include a decrease in axonal volume, an increase in extracellular debris, and an increase in the appearance of whorls (*arrows*). Scale bars equal 10 um (Reproduced with permission from Schumued et al. [84])

Partial recovery sometimes occurs after discontinuation of the drug [21].

Linezolid is the first in a new class of oxazolidinone antibiotics effective against multidrug-resistant gram positive infections. It is indicated in the treatment of drug-resistant streptococcus pneumonia, complicated skin and soft tissue infections including methicillin-resistant *Staphylococcus aureus*, and osteitis [103]. It is an attractive antimicrobial agent due to its effectiveness, general tolerability, and bioavailability making oral preparations available [104]. Neurologic adverse effects include peripheral neuropathy, optic neuropathy, and seizures. Additionally, one case of auditory neuropathy has been reported [105]. Peripheral neuropathy has been reported to be the second leading cause for treatment discontinuation occurring in 9.1 % of patients with osteomyelitis treated for more than 4 weeks [106], though the incidence has been reported as low as 0.36 % [107]. In a 2007 survey of the Infectious Diseases Society of America Emerging Infections Network, 17 % of the physicians who responded as having prescribed linezolid reported having observed at least one case of peripheral neuropathy while on the drug [108]. Although reported as predominantly length-dependent axonal sensorimotor polyneuropathy by EDX studies [109, 110], frequent complaints of neuropathic pain and demonstration of decreased epidermal nerve density indicate small-fiber sensory nerve denervation as well [111]. The most significant risk factor for development of peripheral neuropathy is chronic use with symptoms usually developing after the recommended maximal dose of 28 days and often after 3 months [112]. The etiology is unknown but may

be associated with mitochondrial protein synthesis [113]. Despite discontinuation of the drug, most symptoms of peripheral neuropathy do not resolve [106, 110, 114]. However, cases of neuropathic pain have been reported to improve over time [111].

Chloramphenicol causes a painful sensory neuropathy, more commonly in the pediatric population. It usually occurs after large doses administered for extended periods; renal failure increases the risk. It may occur before, concomitantly with, or after an associated optic neuropathy. Patients complain of distal paresthesias with a stocking-glove distribution of sensory loss on examination [3, 86]. Decreased ankle and patellar reflexes may also be seen [115]. Complete recovery is possible after discontinuation of the drug [10]. The pathophysiology may be related to interference with vitamin B12 activity [116], but the efficacy of using vitamin B12 supplementation as preventive therapy is not established [3].

The antimalarial *chloroquine* (Plaquenil®) is also widely used as an anti-inflammatory agent. Although more commonly associated with a vacuolar myopathy, neuropathy can also occur. Dose and duration of treatment vary but the neuropathy usually occurs after several months to a few years of therapy [86]. In some patients, motor fibers are predominantly affected [117], whereas others have a sensorimotor polyneuropathy with both axonal and demyelinating features [118, 119]. Examination shows weakness and reduced or absent reflexes. Needle EMG may show fibrillation potentials, myotonic discharges, and complex repetitive discharges, along with neurogenic motor unit action potential (MUAP) recruitment [118]. Nerve biopsy shows segmental demyelination and remyelination [118, 119]. Electron microscopy shows abnormal Schwann cell inclusions similar to those seen in amiodarone neurotoxicity [118]. Improvement is seen with discontinuation of the drug [21, 118], but the extent of improvement depends on the severity of the neuropathy at the time of drug discontinuation [86].

Cardiovascular Agents

Amiodarone, a di-iodinated benzofuran derivative, is notable for several toxic effects, but its efficacy as an antiarrhythmic has disallowed its retirement. Neuropathy occurs in 6 % of patients [120, 121] and is a dose-dependent phenomenon. Patients receiving greater than 400 mg a day are at increased risk. More often, distal sensorimotor findings develop, but proximal weakness can occur as well, resulting in marked gait disturbance [10, 120, 122]. In addition, a predominantly motor neuropathy has been described [121].

Amiodarone-associated peripheral neuropathy affects both myelinated and unmyelinated fibers. EDX shows both demyelinating and axonal features [121–123]. Serum amiodarone levels of 2.4 mg/l have been associated with peripheral neuropathy, with sural nerve specimens showing high levels of the drug [124]. One study showed that the sural SNAP was inversely related to serum concentration [125].

Electron microscopy of sural nerve biopsies have shown lysosomal inclusion bodies (Figs. 35.6 and 35.7) in Schwann cells, muscle fibers, and capillary endothelial cells, similar to chloroquine and perhexiline [12, 126], along with loss of myelinated fibers [121, 122] (Fig. 35.7). The pathophysiology is likely related to inhibition of lysosomal phospholipases [12, 126]. A reversible tremor and ataxia are more common than polyneuropathy [127] and occur in about 70 % of patients taking 800 mg/day [21, 120]. An optic neuropathy also occurs [128].

Hydralazine (Apresoline®) results in distal paresthesias in a minority of patients and rarely causes an axonal polyneuropathy that is primarily sensory in nature. Chemically, the drug resembles INH, and thus some speculate that its pathophysiology may be related to vitamin B6 depletion; the neuropathy does often improve after the drug's discontinuation or B6 supplementation [10, 129].

Reversible neuropathies with prolonged motor and sensory latencies and decreased conduction velocities have been associated with *captopril* (Capoten®) [130]. A temporal association of captopril with a Guillain-Barré-like syndrome has been reported in two cases [131, 132]. Whether this represents cause-and-effect relationship or a chance occurrence remains not settled. In a similar manner, the thrombolytic agent, *streptokinase*, derived from group C streptococci, has been associated with Guillain-Barré syndrome in at least nine cases of since 1983 [133, 134]. Streptokinase may also cause permanent median and ulnar neuropathies after post-injection extravasation [135].

Lipid-Lowering Agents

The 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors are widely known to cause symptomatic myopathies, but most of these agents have also been implicated in drug-induced neuropathies, with most patients recovering fully after discontinuing the drug.

Lovastatin (*Mevacor*®) has been shown to cause neuropathies affecting peripheral and cranial nerves [12, 136]. When lovastatin is used with *gemfibrozil* (Lopid®), toxic effects, particularly myopathy, can be up to 5 % [137], and with cyclosporine A, up to 30 % [138]. *Simvastatin* (*Zocor*®) has caused axonal sensorimotor polyneuropathies [139]. Manifestations range from mostly sensory to sensorimotor neuropathy to profound and disabling weakness [139]. EDX shows widespread chronic denervation along with mild slowing of conduction velocity. Sural nerve biopsy shows axonal degeneration with reduced numbers of small and large myelinated fibers [139]. Some patients may develop symptoms abruptly after the first dose, while others require months to years of therapy.

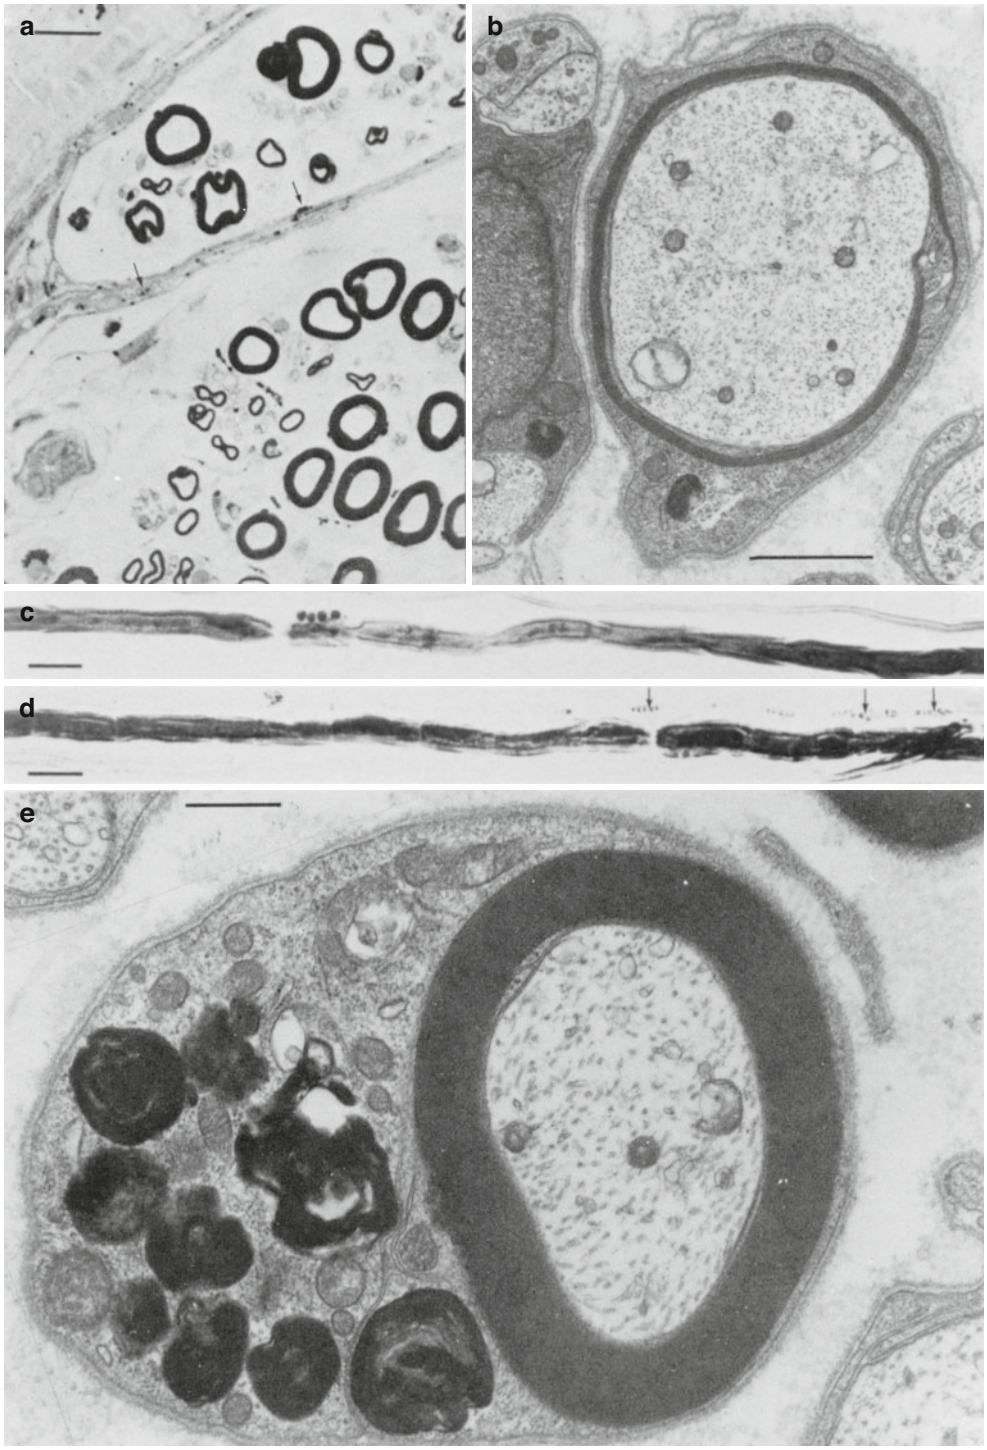

Fig. 35.6 Amiodarone neuropathy. Pathological changes with amiodarone. (**a**) Small granular lipid inclusions in Schwann cells and perineural sheath (*arrows*), PPD staining, bar = 10 µm. (**b**) Remyelinating axon, bar = 1 µm. (**c**) Teased fibers, lipid inclusions in a large myelinated fiber, bar = 20 µm. (**d**) Teased fibers, lipid inclusions in an unmyelinated fiber, bar = 20 µm. (**e**) Membranous lamellar lipid inclusions in Schwann cell of a myelinated fiber, bar = 0.5 µm (Reproduced with permission from Pellessier et al. [122])

Immunosuppressants

The immunosuppressant agents in the class of tumor necrosis factor alpha antagonists (*infliximab*, *etanercept*, and *adalimumab*) are used in the treatment of rheumatoid arthritis, ankylosing spondylitis, psoriasis, and Crohn's disease. In the peripheral nervous system, rare case reports have associated their use with Guillain-Barré syndrome [140, 141], Miller Fisher syndrome [140], chronic inflammatory demyelinating polyneuropathy [142–144], multifocal motor neuropathy with conduction block [145–148], mononeuritis multiplex [149], and axonal sensorimotor polyneuropathy [144, 148, 150]. In a review of these case reports, most peripheral neuropathies improve over months with drug discontinuation. However, recent studies suggest that symptom resolution with drug discontinuation may not be as favorable as previously described and chronic immunosuppressive and immunomodulating therapy may be necessary [143, 151].

There are reports of *cyclosporine A* (Neoral®, Sandimmune®) associated with reversible neuropathies [152]. Later studies suggest that a solvent used in IV cyclosporine preparations containing Cremophor EL may be neurotoxic, as it interferes with axonal transport in vitro [153]. However, animal studies, which used Cremophor injections as a control, have not confirmed this finding [34].

A demyelinating neuropathy have been reported weeks after starting therapy with *FK506* (tacrolimus/Prograf®) and manifesting with dysesthesias and progressive weakness. CSF protein was elevated and EDX showed demyelination, similar to Guillain-Barré syndrome or chronic inflammatory demyelinating polyneuropathy. Some patients improve after dosage reduction. Others improve with intravenous gamma globulin (IVIG) or plasmapheresis, implying a probably coincidental development of Guillain-Barré syndrome or chronic inflammatory demyelinating polyneuropathy [154–156].

Interferon alpha, an immunomodulating agent used in cancer and other fields of medicine, has been reported to cause a mild sensorimotor neuropathy [5, 157]. *Interleukin 2*, an immunomodulator, has been associated with carpal tunnel syndrome and brachial plexopathies [158, 159]. The pathophysiology is possibly from increased vascular permeability and perineural tissue swelling.

Neurologic/Psychiatric Agents

The peripheral nervous system complications of *lithium* may be underdiagnosed, secondary to the prominent CNS toxic manifestations [160]. There is an inverse linear correlation between motor and sensory nerve conduction velocities and lithium levels [161]. Objective deficits may be seen on EDX after only 1 week of treatment in normal volunteers with therapeutic levels [162, 163]. Patients may develop sensory complaints, decreased or absent reflexes, and varying degrees of weakness [3, 160, 164]. EDX shows reduced CMAPs and SNAPs, slowing of conduction velocities, and distal denervation on needle EMG [162, 163]. Sural nerve biopsy shows axonal degeneration and loss of myelinated fibers [164]. Partial improvement may occur after discontinuation of the drug [164], but the degree of recovery is highly variable [160]. Since lithium therapy mainly causes subclinical peripheral neuropathy, perhaps more clinically relevant is its potential to exacerbate other comorbid neuropathies, such as with peripheral neuropathies related to alcohol or diabetes [162].

Amitriptyline (Elavil®), an antidepressant drug well known for its use in treating pain and dysesthesias of peripheral neuropathies, has been rarely reported to cause acute polyradiculoneuropathies [3, 7, 165]. Only five cases are reported prior to 1987. A case report of a patient who overdosed on amitriptyline developed quadriplegia, areflexia, bulbar dysfunction, and respiratory compromise requiring ventilatory assistance [165]. The CSF protein was initially normal but became remarkably elevated to 1,500 mg/dl 1 week after the ingestion and remained high for 1 month. EDX showed decreased conduction velocity of motor nerves and denervation on needle EMG. CMAP amplitudes were decreased and F waves prolonged. No evidence of conduction block was seen.

Approximately 50 % of patients on anticonvulsants have either peripheral nerve symptoms or abnormalities on EDX [166]. *Phenytoin* (Dilantin®) often causes asymptomatic loss of reflexes in 50 % of patients on the drug for 15 years or more [167]. Some patients develop lower extremity sensory and vibratory loss with EDX demonstrating an axonal sensorimotor neuropathy [168]. Sural nerve biopsies show axonal degeneration with segmental demyelination [169] and increased numbers of small myelinated fibers suggesting axonal atrophy [12]. Prolonged administration and elevated serum levels predispose patients to the development of neuropathy [168]. Improvement in the physical examination and electrophysiologic parameters occurs after drug discontinuation [169].

Methysergide (Sansert®), well known for its complication of retroperitoneal fibrosis, has rarely been associated with ischemic neuropathies [170, 171]. The sedative agent *methaqualone* has been implicated in some cases of sensorimotor neuropathies [7].

Rheumatologic Agents

Allopurinol (Zyloric®) used to treat hyperuricemia and gout may rarely result in a delayed axonal sensorimotor polyneuropathy characterized by distal weakness and dysesthesias [172, 173]. Examination shows stocking-glove sensory loss and, often, absent reflexes. Sural nerve biopsies have shown axonal degeneration and segmental demyelination [173]. Improvement may follow discontinuation of the drug [173].

Colchicine is associated with a distal axonal polyneuropathy and a vacuolar myopathy. The mechanism of colchicine-induced neuropathy is inhibition of polymerization of tubulin and blocking of axonal transport. The incidence of neuropathy is higher in patients with renal insufficiency and in patients with cyclosporine-induced gout [174]. Along with the neuropathy, a vacuolar myopathy is the more common neurologic sequela of colchicine therapy, most frequent in patients with hepatic and/or renal failure [8, 10, 12, 174–176].

Leflunomide is a disease-modifying drug approved for use in the treatment of rheumatoid arthritis [177]. Though peripheral neuropathy was not reported in phase II and III clinical trials [178, 179], several case reports after its approval

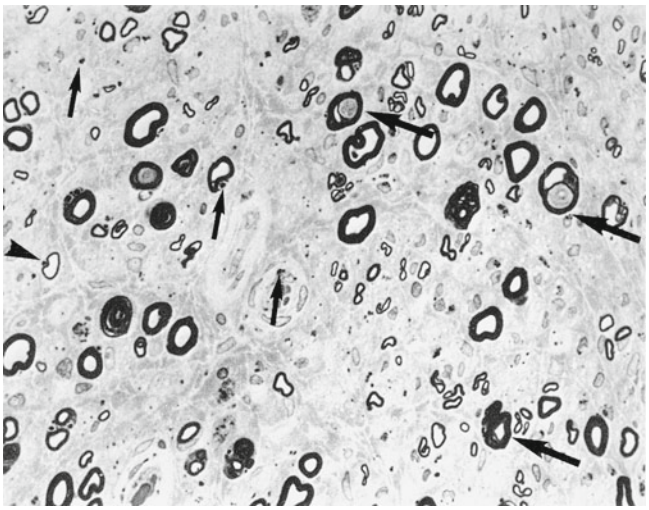

Fig. 35.7 Amiodarone neuropathy. One micrometer section of sural nerve showing a reduced density of myelinated fibers. A few degenerating fibers are seen; others show myelin abnormalities (*large arrows*). The *arrowhead* indicates an axon with an inappropriately thin myelin sheath. Some small regenerating clusters are seen. *Small arrows* point to some of the many inclusions in Schwann cells and endothelial cells. Toluidine blue ×720 (Reproduced with permission from Jacobs and Costa-Jussa [121])

suggested a causal relationship [180–182]. The incidence of peripheral neuropathy in leflunomide is unknown. In a retrospective study of 785 patients treated with leflunomide, 1.4 % were found to possibly have drug-related neuropathy by both clinical and EDX findings [183]. A prospective cohort study of 32 patients found that although 54 % of those treated with leflunomide reported symptoms of peripheral neuropathy, only 1 of the 16 in the leflunomide-treated group had an abnormal EDX study [184]. The neuropathy is predominantly a sensorimotor axonal type which usually begins between 3 and 6 months of treatment [181, 185], though it has been reported as early as 2 weeks after exposure [180]. A review of 80 cases of peripheral neuropathy in patients treated with leflunomide reported to the FDA between 1998 and 2004 found no association between age, sex, or dose of leflunomide and the time of onset of neuropathy [185]. However, a cohort study found an increased association of neuropathy in patients who were older, had concurrent diabetes, or were previously treated with neurotoxic drugs [186]. Treatment is with discontinuation of the drug. One study found that patients who stopped taking leflunomide within 30 days of symptom onset were 86-fold more likely to have symptom improvement than those who discontinued treatment after 30 days of symptom onset [185]. Furthermore, if stopped within 30 days of symptom onset, the median time to improvement or recovery was [135] days compared to 755 days if stopped after 30 days [185].

Peripheral neuropathy is a rare side effect of *gold* therapy but is usually not dose dependent. It is often difficult to determine if the gold salts or the underlying rheumatologic condition were responsible for the peripheral neuropathy [187]. Gold-induced neuropathy is associated with sensory symptoms initially, more often loss of pain and temperature sense than vibration. Distal weakness and areflexia develop later, followed by lower extremity or diffuse myokymia which can be a distinguishing feature [188–190]. Weakness is usually acute and may be profound and asymmetric [189, 191]. A Guillain-Barré-like syndrome with demyelinating polyneuropathy can occur but is uncommon [7].

EDX studies may show prolonged distal latencies and slowed conduction velocities on nerve conduction studies. On needle EMG, denervation potentials and myokymic discharges may be present [188–190]. Changes on nerve biopsy are mixed, with both axonal and segmental demyelination. Discontinuation of the drug often brings about improvement, but severely affected patients may not fully recover [189]. Cranial polyneuropathies, encephalopathy, and stroke have been reported as other neurologic complications [188].

Indomethacin (Indocin®), an anti-inflammatory/analgesic, has been implicated in sensorimotor neuropathies with the primary clinical manifestation being weakness. Paresthesias and ataxia may be seen. EDX studies show decreased motor nerve conduction velocities and normal sensory latencies. Recovery is often complete after discontinuation of the drug [192].

Miscellaneous Agents

Disulfiram (Antabuse®), used in alcoholic rehabilitation, is known to cause a sensorimotor distal axonopathy in patients taking more than 250 mg/day. Sensory symptoms are seen first in the feet [8]. Sensory loss occurs before weakness, and burning dysesthesias are common. Examination shows absent distal reflexes, a stocking-glove sensory loss, and distal weakness [3]. Axonal degeneration and loss of myelinated fibers are seen on sural nerve biopsy. In some cases, segmental demyelination [193] and neurofilament accumulations are seen [194, 195]. There is usually slow recovery after discontinuation of the drug. Optic neuropathy has been shown to occur as well [10]. The pathophysiology of the polyneuropathy is thought to involve carbon disulfide, one of disulfiram's metabolites, a known neurotoxin [196].

Nitrous oxide (N_2O) used as an anesthetic in dentistry has been shown to cause peripheral neuropathy and myelopathy, mostly commonly in vitamin B12-deficient persons [197]. Methionine synthetase inhibition may be the pathophysiologic mechanism; supplementation with methionine and folic acid has been shown to protect against the neuropathy associated with N_2O [198, 199].

Perazine, a phenothiazine derivative, has been reported to cause a "sunbath polyneuritis," in which sun exposure

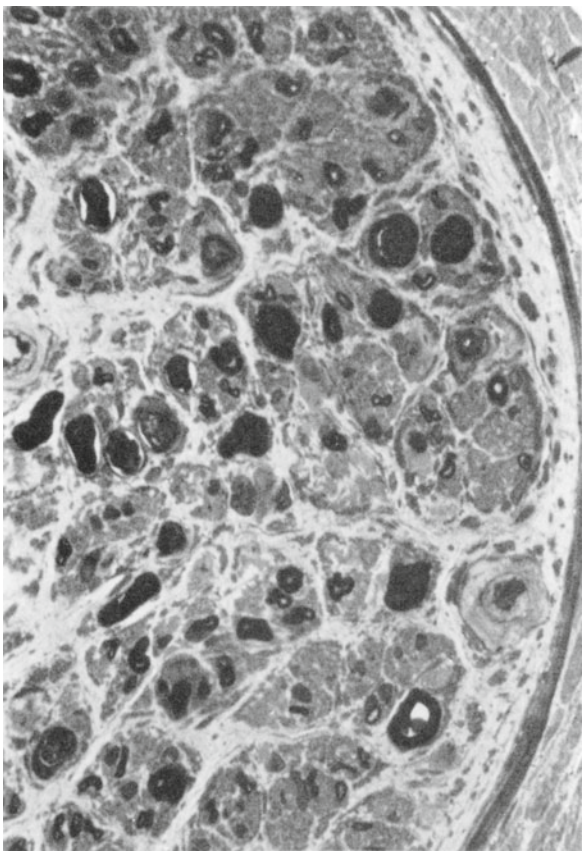

Fig. 35.8 Cross section of a sural nerve in a patient taking pyridoxine for 9 months (2 g/day). There is severe fiber loss and some myelinated fibers are undergoing degeneration (×720) (Reproduced with permission from Schaumburg et al. [202])

puts patients at risk for a sensory neuropathy. This is presumably caused by photoproduct-related cell damage via a lipid peroxidation mechanism. Three of the seven patients in one report had bilateral facial nerve palsies. Needle EMG of facial muscles showed denervation potentials [200]. Sural nerve conduction velocities are reduced, but motor nerve conduction velocities are normal [200]. All patients had a monophasic illness and near complete recovery [201].

Ironically, *pyridoxine* (vitamin B6), used to prevent INH-induced neuropathy, causes a neuropathy. This usually occurs at large doses (2–6 g/day) but may occur with as little as 50 mg/day (human requirement being 2–4 mg/day) [202, 203]. The entity is often heralded by unsteady gait and numb feet, with patients reporting difficulty using their hands; perioral numbness sometimes follows [202]. Examination shows stocking-glove sensory loss with vibration and proprioception loss, often leading to ataxia and choreoathetosis [8, 202]. Reflexes are decreased or absent. Strength is preserved. EDX shows absent SNAPs but normal motor nerve conductions and needle EMG, consistent with a sensory neuronopathy [202]. Sural nerve biopsy shows loss of large and small fibers [202, 204] (Fig. 35.8). CSF is normal [202]. Patients may improve within a few months of discontinuing the vitamin or may be left with permanent deficits [3, 202, 204].

Amphetamines can cause a necrotizing hypersensitivity angiitis with multiple mononeuropathies [10]. *Intravenous heroin* has been shown to cause nontraumatic plexopathies which are very painful and may recur in those who resume its use after a period of abstinence [10].

Dapsone, used for malaria prophylaxis, leprosy, and various skin conditions, causes predominantly a motor neuropathy when used in high doses (200–500 mg/day) for greater than 6 weeks [8, 205]. Patients treated at lower doses, as is commonly employed in leprosy, rarely develop neuropathy [86]. There may be paresthesias, but objective sensory loss is not demonstrable [21]. There is usually severe muscle atrophy, especially of the hands, and hyporeflexia or areflexia [21, 206]. Biopsy shows axonal degeneration of both sensory and motor nerves [86, 205]. Recovery is sometimes prompt [78] but is usually slow after discontinuing the drug [10]. A severe optic neuropathy can also be seen [10].

This psoriatic therapy *etretinate* (Tegison®) has been shown to cause a reversible axonal sensory polyneuropathy which on sural nerve biopsy shows axonal degeneration of small and large myelinated fibers [207].

Topical *ammoniated mercury* has resulted in a primarily axonal polyneuropathy with secondary demyelinating pathology [208, 209]. Burning dysesthesias are prominent. Examination shows decreased lower extremity reflexes and a stocking-glove sensory loss.

Podophyllin, used for topical treatment of condyloma acuminata, causes an axonal sensorimotor polyneuropathy when significant systemic absorption occurs [210]. Central nervous system depression, hallucinations, seizures, ataxia, autonomic instability, pancytopenia, and multiorgan failure have also occurred [3, 210]. Examination shows distal weakness, loss of ankle jerks, and sensory loss in a stocking-glove distribution which may persist for several months [210]. EDX study shows decreased SNAP and CMAP amplitudes, increased distal latencies, and denervation on needle EMG [210]. CSF may show elevated protein suggesting root involvement [3, 210].

Acetazolamide (Diamox®) has been reported to cause painful paresthesias and distal sensory loss, which can sometimes be disabling [7]. *Sodium cyanate*, used to prevent sickle cell crisis, causes a sensorimotor neuropathy [211]. *Stilbamidine* is known to cause facial paresthesias and other unpleasant sensations [7, 212]. *L-tryptophan*-induced eosinophilia-myalgia syndrome can be associated with a severe axonal sensorimotor polyneuropathy as a prominent feature in some patients.

Vasculitic Neuropathies and Neuropathies of Connective Tissue Diseases

36

Michael P. Collins and John T. Kissel

Introduction

The connective tissue diseases (CTDs) are a complex group of systemic autoimmune disorders linked by their propensity to involve the musculoskeletal system [1–3]. The primary CTDs (also called collagen vascular diseases) are listed in Table 36.1. While these diseases are all assumed to be autoimmune, their etiologies and mechanisms are poorly understood. They are generally felt to arise from complex interactions among heterogeneous genetic, environmental, immunologic, and endocrinologic influences.

The CTD-related neuropathies are challenging to diagnose and treat for several reasons. First, the underlying rheumatologic condition is often difficult to precisely identify. Second, most of the neuropathic phenotypes are nonspecific and can occur in all of the CTDs. Third, manifestations of treatable neuropathies, such as vasculitis, overlap with those of non-treatable neuropathies. Finally, the pathogenesis of most non-vasculitic neuropathies is obscure.

Etiopathogenic Mechanisms of Neuropathies in Connective Tissue Diseases

Neuropathies occurring in the course of a CTD may arise from several mechanisms, some independent of the immunologic disturbances of the disease. Understanding these mechanisms is of fundamental importance to managing these patients.

Vasculitis

The term vasculitis refers both to the pathologic finding of inflammatory destruction of vessel walls and to a large group of clinical conditions resulting from that process (Fig. 36.1) [1, 4]. In addition to the primary vasculitides, where vasculitis is the defining feature of the condition, essentially all CTDs can produce a secondary vasculitis that occurs as part of the disease process or is triggered by an exogenous antigen, such as an infection or drug.

Neuropathy from Organ System Failure

Organ system failure is an important but infrequent cause of neuropathy in CTDs. Most common are neuropathies resulting from renal failure in the vasculitides, systemic lupus erythematosus (SLE), systemic sclerosis (SSc), and occasionally rheumatoid arthritis (RA). The pathogenesis of uremic neuropathy is uncertain, but its improvement following transplantation suggests that a neurotoxin resulting from renal compromise is operative [5].

Entrapment Neuropathies

Clinical and animal studies indicate that most generalized neuropathies predispose patients to entrapment neuropathies [6]. Disorders like RA and SSc, which are associated with chronic inflammation and proliferation of connective tissues, may further compromise the anatomic pathways of nerves, especially the median nerve in the carpal tunnel [7]. In these conditions, the combination of mechanical pressure and ischemia results in focal demyelination, followed by axonal degeneration if the compression persists.

Neuropathy from Inflammatory Demyelination

Neuropathies clinically and electrodiagnostically identical to Guillain-Barre syndrome (GBS) [8] and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) [9] can occur in the setting of CTDs, most commonly SLE [10]. Whether the immunopathogenic mechanisms underlying these neuropathies are distinct from or identical to those occurring in patients with similar neuropathies but no CTD is unclear.

Table 36.1 Classification of the principal connective tissue disorders

Primary vasculitic syndromes
Predominantly small-vessel vasculitides
Wegener's granulomatosis (granulomatosis with polyangiitis)
Microscopic polyangiitis
Churg-Strauss syndrome (eosinophilic granulomatosis with polyangiitis)
Henoch-Schönlein purpura (IgA vasculitis)
Essential mixed cryoglobulinemia
Predominantly medium-vessel vasculitides
Polyarteritis nodosa
Kawasaki disease
Predominantly large-vessel vasculitides
Giant cell (temporal) arteritis
Takayasu arteritis
Other vasculitides (e.g., Behçet's disease)
Nonsystemic/localized vasculitides
Connective tissue diseases[a]
Rheumatoid arthritis
Primary Sjögren's syndrome
Systemic lupus erythematosus
Systemic sclerosis
Mixed connective tissue disease
Relapsing polychondritis
Seronegative spondyloarthropathies

[a]Each of these conditions may themselves predispose to an associated vasculitis

Neuropathy Due to Ganglionitis

One neuropathy with a unique immunopathogenesis is the dorsal root ganglionitis associated most closely with primary Sjögren's syndrome (pSS) [11]. This neuropathy is probably mediated in part by cytotoxic T lymphocytes (CTLs), but many pathogenic questions remain unanswered, including its etiology, antigenic triggers, and basis for targeting the sensory ganglia.

Cryoglobulinemia

Cryoglobulins occur as secondary phenomena in many CTDs [12, 13]. They are circulating immunoglobulins that precipitate at temperatures below 37 °C. Type I cryoglobulins consist of monoclonal immunoglobulins and usually occur in lymphoproliferative diseases. Type II are composed of monoclonal immunoglobulin (usually IgMκ) rheumatoid factors (anti-IgG activity) and polyclonal IgG, while type III are a mixture of polyclonal IgM rheumatoid factors (RFs) and polyclonal IgG. Types II and III are termed mixed cryoglobulins, which can be *essential* – without known cause – or *secondary* to pSS, RA, SLE, SSc, lymphoproliferative

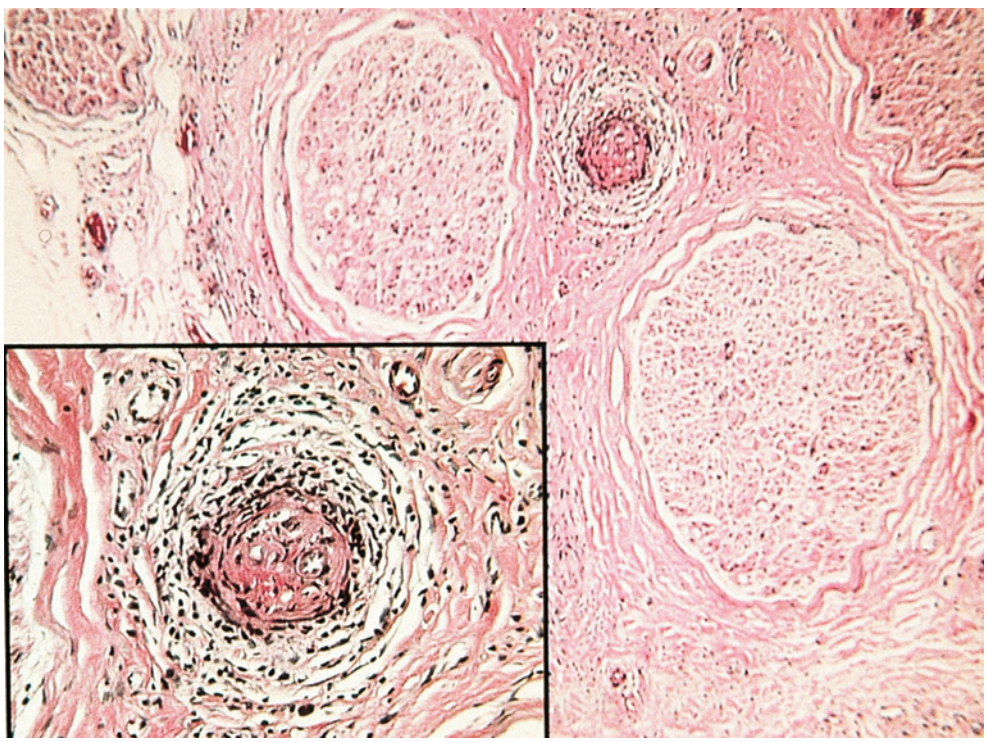

Fig. 36.1 Superficial peroneal nerve biopsy in patient with nonsystemic vasculitic neuropathy. One epineurial vessel is surrounded by perivascular inflammatory cells. Higher power view (*inset*) shows that the inflammatory cells infiltrate and disrupt the vessel wall and are associated with a recanalized thrombus (hematoxylin and eosin)

Table 36.2 Immunosuppressive drugs used for connective tissue diseases that may cause neuropathy

Drug	Rheumatic disease uses	Type(s) of neuropathy	Frequency
Chloroquine and hydroxychloroquine	RA, SLE, cutaneous lupus, SSc, pSS, dermatomyositis	Distal, axonal/demyelinating, sensorimotor; concurrent proximal vacuolar myopathy; occasional myotonic discharges; abducens palsies	Uncommon
Colchicine	Behçet's, leukocytoclastic vasculitis, morphea, SSc	Distal, axonal, sensorimotor; concurrent proximal vacuolar myopathy; occasional myotonic discharges	Uncommon
Cyclosporine	RA, SLE, SSc, polymyositis dermatomyositis, vasculitides	1. Acute, motor predominant, axonal or mixed axonal/demyelinating (GBS-like) 2. Brachial plexopathy 3. Distal paresthesias 4. Optic neuropathy	Rare, except tingling ~25 %
Dapsone	Relapsing polychondritis, RA, cutaneous lupus, Behçet's, cutaneous vasculitides	Axonal, motor-predominant, distal; occasionally upper limb predominant	Uncommon at usual doses
Gold salts	RA, psoriatic arthritis	Axonal or mixed axonal/demyelinating, sensorimotor; usually distal symmetric but can mimic GBS; often with myokymia; cranial neuropathies	Rare
Interferon-α	Essential and HCV-associated mixed cryoglobulinemia; HBV-related PAN; Behçet's; refractory CSS	1. Anterior ischemic optic neuropathy (AION) 2. Vasculitic or multifocal, sensorimotor axonal 3. Distal, symmetric, axonal, sensory/sensorimotor 4. Symmetric CIDP-like 5. Rare reports of many other phenotypes	Rare, except AION
Leflunomide	RA, maintenance of remission in ANCA-associated vasculitis	Distal, symmetric, axonal, sensory or sensorimotor Biopsy evidence of vasculitis in some cases	Uncommon
D-penicillamine	SSc, RA (rarely used anymore)	1. Motor or sensorimotor, acute or chronic demyelinating (CIDP, GBS) 2. Distal axonal with oculomotor palsies and ANAs 3. Neuromyotonia 4. Optic neuropathy	Rare
Tacrolimus (FK 506)	RA, SLE, Behçet's disease	1. Chronic demyelinating, sensorimotor, multifocal or symmetric (CIDP, LSS) 2. Acute, axonal, motor-predominant 3. Bilateral optic neuropathies 4. Distal paresthesias	Rare, except tingling ~25 %
Thalidomide	RA, SLE, cutaneous lupus, Behçet's disease	Distal, axonal, sensory	Common
TNF-α inhibitors	RA, spondyloarthropathies	1. Acute or chronic, symmetric demyelinating (GBS, CIDP) 2. Chronic, asymmetric demyelinating (MMN, LSS) 3. Vasculitic or multifocal, sensorimotor axonal 4. Distal, symmetric, axonal, sensory/sensorimotor	Rare

AION anterior ischemic optic neuropathy, *ANAs* antinuclear antibodies, *ANCAs* antineutrophil cytoplasmic antibodies, *CIDP* chronic inflammatory demyelinating polyradiculoneuropathy, *CSS* Churg-Strauss syndrome, *GBS* Guillain-Barre syndrome, *LSS* Lewis-Sumner syndrome, *MMN* multifocal motor neuropathy, *PAN* polyarteritis nodosa, *pSS* primary Sjögren's syndrome, *RA* rheumatoid arthritis, *SLE* systemic lupus erythematosus, *SSc* systemic sclerosis, *TNF-α* tumor necrosis factor-alpha

diseases, glomerulonephritis, and chronic infections. Chronic infection with hepatitis C virus underlies 80–90 % of essential mixed cryoglobulinemia [14]. Patients with mixed cryoglobulinemia may develop a neuropathy mediated by (1) immune complex-induced vasculitis [15]; (2) intravascular deposition of cryoglobulins causing an endoneurial microangiopathy [16]; (3) IgM binding to myelin, producing demyelination [17]; or (4) T cell-mediated vascular damage [18].

Neuropathy Due to Drug Toxicity

Several drugs used to treat CTDs can themselves produce a neuropathy (Table 36.2), a situation destined to create diagnostic confusion, as there is nothing distinctive about the clinical, electrodiagnostic, or pathologic features of these drug-induced neuropathies. Drugs most commonly cause a distal symmetric polyneuropathy, but more atypical patterns can be seen [19–24].

Thrombotic Vasculopathy

In vasculitides and CTDs associated with antiphospholipid antibodies, microvascular thrombosis may lead to neuropathy [25]. In the vasculitides, inflammatory damage to vascular endothelium results in the release of cytokines and other mediators that promote vasospasm, myointimal cell proliferation, and activation of clotting factors and platelets, all of which contribute to thrombotic occlusion of vessels [26].

Autoantibodies

CTDs are often associated with multiple autoantibodies, some of which may be directed against peripheral nerve antigens. Candidates include anti-ganglioside or anti-sulfatide antibodies, which can be found in patients with SLE and other CTDs and have been associated with neuropathy [27, 28].

Vasculitis

The vasculitides are diseases in which inflammatory infiltrates target and destroy vessel walls, resulting in ischemic and inflammatory injury to the involved tissues [3, 4]. Triggers include infections, drugs, and cancers, but in most patients, the inciting antigen is unknown. Vasculitis usually affects many tissues simultaneously but may be confined to a single organ, e.g., the peripheral nervous system (PNS).

Classification of Vasculitides with Neuropathy

Derivation of a uniform classification scheme for the vasculitides has always been problematic. Many classification systems have been proposed [29]. Most have distinguished the *primary* vasculitides (without known cause) from the *secondary* vasculitides (with an accepted etiology or predisposing disease). The most widely used *classification criteria* for the primary systemic vasculitides were derived by the American College of Rheumatology (ACR) in 1990 for polyarteritis nodosa (PAN), Churg-Strauss syndrome (CSS), Wegener's granulomatosis, hypersensitivity vasculitis, Henoch-Schönlein purpura (HSP), giant cell arteritis (GCA), and Takayasu arteritis [30]. In 1994, the Chapel Hill Consensus Conference (CHCC) proposed a new *nomenclature* that has also been widely accepted [31]. In the CHCC definitions, GCA and Takayasu arteritis primarily involve large vessels; PAN and Kawasaki disease affect small- to medium-sized arteries; and microscopic polyangiitis (MPA), Wegener's granulomatosis, CSS, HSP, cutaneous leukocytoclastic angiitis, and cryoglobulinemic vasculitis all predominantly involve the microvasculature, although small- to medium-sized arteries are also sometimes affected. For PAN, microvascular involvement was deemed exclusionary; as a result, it has become a rare disease in recent studies. Hypersensitivity vasculitis was excluded as a diagnostic entity. Further refinements followed in 2007, with a new consensus classification of CSS, MPA, PAN, and Wegener's granulomatosis [32].

The CHCC nomenclature was revised in 2012 [33]. Eponyms were eliminated except for disorders with ill-defined pathogeneses. Wegener's granulomatosis was renamed granulomatosis with polyangiitis (GPA), CSS was labeled eosinophilic granulomatosis with polyangitis, and HSP was recast as IgA vasculitis. In the revised nomenclature, small-vessel vasculitides are divided into those associated with sparse versus prominent vascular wall deposits of immunoglobulin and complement. The "pauci-immune" disorder are the ANCA-associated vasculitides: GPA, MPA, and CSS. The "immune complex small-vessel vasculitides" include anti-glomerular basement disease (Goodpasture syndrome), cryoglobulinemic vasculitis, IgA vasculitis (HSP), and hyopcomplementemic urticarial vasculitis. Additional entities are also incorporated into the revised nomenclature. "Variable-vessel vasculitides," which affect vessels of all sizes and types, include Behçet disease and Cogan syndrome. "Single-organ vasculitis" (also referred to as nonsystemic or localized vasculitis) affects vessels of any type in a single organ or tissue [34, 35]. Localized vasculitis has been described in almost all organs. Of greatest import, nonsystemic vasculitic neuropathy (NSVN) was identified as a unique, PNS-confined form of vasculitis by Dyck et al. in 1987 [36]. The many secondary causes of vasculitis are categorized as "vasculitis associated with systemic disease" (e.g., a CTD) or "vasculitis associated with a probable etiology" (e.g., drug- or infection-associated vasculitis).

The PNS is most commonly involved in vasculitides affecting small- to medium-sized vessels. Of the *primary* systemic vasculitides, neuropathies occur most frequently (50–70 % of patients) in CSS, PAN, and MPA [37–39]. For the *secondary* vasculitides, peripheral nerves are routinely affected in hepatitis B-associated PAN (80 % of patients) [38], hepatitis C-related mixed cryoglobulinemia (~60 %) [14, 40], and rheumatoid vasculitis (RV) (45–50 %; see below). In contrast, vasculitic neuropathies are unreported in Kawasaki disease, Takayasu arteritis and anti-glomerular basement membrane disease and very uncommon in GCA, Behçet disease, Cogan syndrome, and HSP. A consensus classification of vasculitides associated with neuropathy has been proposed by the Peripheral Nerve Society guideline group on NSVN (Table 36.3) [41].

Epidemiology of Primary Systemic Vasculitides and Vasculitic Neuropathy

Epidemiological studies have demonstrated that GCA and the primarily cutaneous vasculitides have the highest incidence rates, followed by RV, GPA, and MPA [42–45]. PAN is rare as defined by CHCC criteria. The frequency of the

Table 36.3 Classification of vasculitides associated with neuropathy [41]

I. Primary systemic vasculitides
1. Predominantly small-vessel vasculitis
(a) Microscopic polyangiitis[a]
(b) Churg-Strauss syndrome (eosinophilic granulomatosis and polyangiitis)[a]
(c) Granulomatosis with polyangiitis (Wegener's)[a]
(d) Essential mixed cryoglobulinemia (non-HCV)
(e) Henoch-Schönlein purpura (IgA vasculitis)
2. Predominantly medium-vessel vasculitis

[a]Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitides

vasculitic *neuropathies* is somewhat different due to the variable prevalence of neuropathy in these conditions and the fact that vasculitic neuropathy not infrequently occurs in isolation (i.e., NSVN). No study has determined the incidence or prevalence of any vasculitic neuropathy, but based on the best available data, the most common vasculitic neuropathies are NSVN (26 %) and those associated with MPA/PAN (25 %), RV (12 %), and CSS (10 %) [46]. Vasculitic neuropathy can develop at any age but most commonly occurs in the sixth through eighth decades [47–55]. For NSVN, the age at diagnosis ranges from 13 to 88 years, with a mean of 59.5 years [46]. Men are more frequently affected than women in PAN, MPA, RV, and HSP, while women are preferentially affected in GCA, SLE-related vasculitis, cryoglobulinemic vasculitis, and NSVN. Men and women are afflicted with roughly equal frequency in GPA and CSS [3, 45, 46].

Pathogenesis of Primary Systemic Vasculitides

Most vasculitides are assumed to result from autoimmune mechanisms, although the specific immunologic events are incompletely understood [3, 56–59]. Vasculitis begins with activation of the innate immune system by environmental or internal triggers, with subsequent self-antigen recognition by naïve autoreactive T and B lymphocytes, triggering both humoral and cellular immune responses. These processes, in turn, prime circulating leukocytes, activate endothelial cells, and upregulate antigen-presenting cells (APCs) in and around vessel walls. The primary mediators of endothelial cell activation are the pro-inflammatory cytokines TNF-α, IL-1, and IL-17. The endothelium responds by production and expression of cell adhesion molecules, tissue factors, cytokines, chemokines, inflammatory peptides, and angiogenic factors. Leukocytes then adhere to the endothelial surface, become activated, and migrate through the endothelium, an interaction that depends on a complex array of cellular adhesion molecules, cytokines, chemotactic agents, and other inflammatory regulators [60–62]. Additional effector cells are then recruited, including neutrophils, eosinophils, monocytes/macrophages, T cells, and NK cells, which damage vessel walls via various cellular and biochemical mechanisms [63–66]. The involved cells continue to release cytokines and tissue factors that stimulate coagulation, intimal cell proliferation, vessel wall fibrosis, and neovascularization [67]. Regulatory T cells and cytokines eventually downregulate the inflammatory response, leaving a fibrotic and often thrombosed or occluded vessel [58].

Cytokines are a diverse group of soluble polypeptides produced by multiple cell types that function as growth factors and hormones of the immune and hematopoietic systems [68, 69]. The term encompasses the interleukins, chemokines, interferons (INFs), and colony-stimulating factors. Subsets of CD4+ T helper (Th) lymphocytes can be distinguished by their cytokine profiles [70, 71]. The signature cytokines produced by these subsets are INF-γ for Th1 cells; IL-4, IL-5, and IL-13 for Th2 cells; and IL-17 for Th17 cells. Th1 cells activate macrophages, induce T cell proliferation, and increase production of opsonizing and complement-fixing IgG antibodies, promoting phagocyte-mediated defense against infections, granuloma formation, and T cell-mediated autoimmune diseases. Th2 cells promote IgE- and eosinophil-mediated immune responses, including allergic reactions. Th17 cells induce pro-inflammatory cytokines, chemokines, inflammatory mediators, and antimicrobial peptides; mediate recruitment of neutrophil-rich inflammatory reactions; and activate macrophages and T cells [71, 72]. They are required

Table 36.4 Pathogenic mechanisms in vasculitides

Mechanism	Implicated diseases
Circulating immune complexes	Henoch-Schönlein purpura (IgA)
	Hepatitis B-associated polyarteritis nodosa
	Mixed cryoglobulinemic vasculitis
	Other infectious vasculitides
	Some drug-induced and paraneoplastic vasculitides
	Connective tissue disease-associated vasculitides

	? Polyarteritis nodosa
	? Takayasu arteritis
	? Rheumatoid vasculitis
	? Lupus vasculitis
	? Kawasaki disease
	? Behçet's disease
Antineutrophil cytoplasmic antibodies	Granulomatosis with polyangiitis (Wegener's)
	Microscopic polyangiitis
	Churg-Strauss syndrome
Cytotoxic T lymphocytes	Allograft rejection
	? Vasculitic neuropathies
Delayed-type hypersensitivity	Giant cell arteritis
	? Granulomatosis with polyangiitis (Wegener's)
	? Churg-Strauss syndrome
Eosinophils	Churg-Strauss syndrome

? = mechanism proposed for this disease but not established

for host defense against bacterial infections but are also implicated in many autoimmune diseases [73].

Within this basic framework, several distinct immunopathogenic mechanisms have been proposed to produce vessel injury in the vasculitides (Table 36.4).

Circulating Immune Complexes

In this model, antibodies interact with circulating antigens to form antigen-antibody complexes, activate complement, and prime circulating leukocytes [56, 74–77]. Pathogenic deposition of immune complexes in vessel walls is promoted by turbulent flow, impaired clearance mechanisms, immune complexes with certain physical properties (intermediate sized and cationic), and abnormally permeable vessel walls. Deposited immune complexes activate more complement, generating chemoattractants (C3a and C5a) and C5b-9 membrane attack complex (MAC) that mediates endothelial cell lysis. The immune complexes also activate resident macrophages and mast cells via the Fc gamma receptor ($Fc_{\gamma}R$) pathway to release platelet-activating factor (PAF), eicosanoids, cytokines, bradykinin, and other inflammatory mediators. Neutrophils are recruited to the site within 24–48 h and release proteolytic enzymes and reactive oxygen species that further damage the vessel wall.

Antineutrophil Cytoplasmic Autoantibodies (ANCAs)

ANCAs are directed against cytoplasmic proteins in neutrophils and monocytes [78, 79]. They are classified as cytoplasmic cANCAs or perinuclear pANCAs based on their immunofluorescence (IF) staining pattern. In vasculitis, cANCAs usually target proteinase 3 (PR3), while pANCAs target myeloperoxidase (MPO). The three ANCA-associated vasculitides are GPA, MPA, and CSS [80–82]. ANCAs are present in 80–90 % of patients with active, generalized GPA and MPA but only 40 % of those with CSS [3, 4, 83]. PR3-cANCAs are most strongly associated with GPA, while MPO-pANCAs occur most commonly in MPA and CSS. A meta-analysis provided a weighted pooled sensitivity of 85 % and specificity of 99 % in the diagnosis of MPA, GPA, or CSS [84].

Multiple pathogenic mechanisms for ANCAs have been proposed [57, 58, 80–82]. The first involves interactions of ANCAs with primed (pre-activated) neutrophils. ANCA-activated neutrophils adhere to the endothelium, degranulate, undergo respiratory burst, and damage endothelial cells through release of reactive oxygen species, nitric oxide, serine proteases (including MPO and PR3), neutrophil extracellular traps, factors activating complement via the alternate pathway, and inflammatory mediators [57, 80, 81, 85, 86]. Released PR3 can, in turn, induce endothelial cell activation, lysis, and apoptosis. ANCAs also directly activate endothelial cells [87]. In addition, PR3 and MPO are transferred to the surface of apoptotic neutrophils, permitting interactions with their respective ANCAs [85, 88]. Although ANCAs do not activate apoptotic neutrophils, they do serve as opsonins, enhancing the recognition of these cells by phagocytic macrophages. Phagocytosis of ANCA-opsonized apoptotic neutrophils triggers production of pro-inflammatory molecules, amplifying and perpetuating the inflammatory response [85, 88, 89]. Defective clearance of PR3 and MPO on apoptotic neutrophils may be the initiating mechanism for ANCA production and subsequent development of vasculitis [85, 90].

Anti-endothelial Cell Antibodies

Anti-endothelial cell antibodies (AECAs) interact with endothelial cell antigens to form immune complexes that have the potential to produce damage via complement-dependent cytotoxicity (CDC), antibody-dependent cellular cytotoxicity (ADCC), or induction of endothelial cell apoptosis [91–95]. Target antigens could be constitutive components of the vessel wall, cryptic-induced antigens, foreign antigens, or adherent "planted" antigens. AECAs have been detected with varying prevalence in ANCA-associated vasculitides, PAN, GCA, Takayasu arteritis, RV, Kawasaki disease, Behçet's disease, HSP, and lupus vasculitis, but there is still no convincing evidence to support a causal relationship in these disorders [91, 92, 95–98]. AECAs are not unique to vasculitis, occurring in many other conditions. Studies assessing the ability of AECAs to mediate CDC or ADCC

have produced contradictory results [99–102]. There is more compelling in vitro evidence that AECAs can trigger apoptosis of endothelial cells [97].

Cytotoxic T Lymphocytes

Cellular immunity may play a pathogenic role in some vasculitides by promoting delayed-type hypersensitivity (DTH) or directly killing target cells [58, 59, 103, 104]. CTLs are activated after MHC-restricted binding to APCs such as dendritic cells and activated macrophages [66, 105]. They destroy antigen-bearing target cells by various secretory and nonsecretory pathways [66, 106–111].

Delayed-Type Hypersensitivity

Chronic DTH is an immune reaction in which T cell-dependent macrophage activation and cytokine-mediated inflammation cause tissue injury, a mechanism important in the pathogenesis of GCA. Activation of adventitial dendritic cells is an early event in GCA [112, 113]. Activated dendritic cells initiate a CD4+ Th1 cell response against an unknown antigen in the perivascular space. A separate population of dendritic cells activates a second pathogenic pathway mediated by Th17 cells [59]. Th1 and Th17 cells produce INF-γ, IL-17, and IL-32, which, in turn, induce macrophage activation [59, 114]. Activated macrophages migrate to the media and form granulomas. Macrophages, giant cells, activated T cells, and vascular smooth muscle cells produce pro-inflammatory cytokines, chemokines, matrix metalloproteinases, reactive oxygen species, nitric oxide, vascular endothelial growth factor (VEGF), and platelet-derived growth factor (PDGF) that damage the vessel wall and promote neovascularization. In other granulomatous vasculitides, such as GPA and CSS, similar mechanisms may be active [115].

Eosinophils

CSS is characterized by persistent eosinophilia and allergic phenomena resulting from a foreign or autoantigen triggering a Th2 response in genetically predisposed individuals [116, 117]. The most commonly reported association is with leukotriene antagonist use [118]. IL-5 plays the key role in inducing eosinophil maturation and activation and prolonging eosinophil survival [119]. Infiltrating eosinophils damage vessels by the release of multiple cytotoxic enzymes [120].

Pathogenesis of Vasculitic Neuropathies

The preponderance of evidence supports the view that NSVN and most systemic vasculitic neuropathies (SVNs) are mediated by direct cellular cytotoxicity and chronic DTH [121, 122]. One gene expression profiling analysis and other more directed investigations of cytokine/chemokine expression in vasculitic neuropathy revealed increased pro-inflammatory cytokines and upregulated cytokines, chemokines, and chemokine receptors active in T cell and macrophage inflammatory responses [123–128]. Pathologic studies demonstrate a marked predominance of CD4+ and CD8+ T cells and macrophages in epineurial infiltrates in sural nerve biopsies of patients with vasculitic neuropathy [54, 121, 122, 129], and many of the T cells are activated and express markers characteristic of CTLs [122, 129]. Markers of APCs are upregulated in the epineurium and endoneurium [121, 130–133]. Costimulatory molecule CD86, which interacts with CD28 on naïve T cells, is upregulated on endothelial cells in NSVN [133]. Costimulatory molecule ICOS (inducible costimulator), which is expressed preferentially by effector memory CD4+ and CD8+ cells, is upregulated on epineurial T cells, while ICOS ligand is upregulated on macrophages in areas where ICOS-expressing T cells are found, suggesting that macrophages act as APCs to restimulate activated T cells [134].

These observations support a pathogenic model wherein disease-specific, autoreactive T cells are recruited to the PNS; undergo activation by self-glycolipid or peptide antigens presented by macrophages, Schwann cells, and/or endothelial cells; and then mature into CTLs that damage target cells in epineurial vessels. However, arguing *against* this model, one investigation of T cell receptor (TCR) Vβ gene utilization in epineurial infiltrates in sural nerve biopsies of patients with NSVN revealed no clonally expanded T cells, suggesting that T cells had been nonspecifically recruited to the PNS [135].

In addition to mononuclear cells, epineurial vessel walls in vasculitic neuropathy often contain deposits of IgM, IgG, C3, and complement terminal MAC [121, 136]. Moreover, a DNA microarray analysis of nerve biopsies in vasculitic neuropathy showed immunoglobulin genes relevant to B cell selection and antigen recognition to exhibit maximally upregulated transcription [128]. Thus, immune complex deposition with subsequent activation of complement and recruitment of phagocytic cells might represent another mechanism of vascular damage. However, pointing away from immune complexes as a key mechanism, B cells and polymorphonuclear leukocytes are rarely identified [54, 121, 122].

The final common pathway of tissue damage is regional ischemia due to occlusion of the involved epineurial or nutrient vessels. In experimental models of small-vessel occlusion, the central regions of larger fascicles in proximal nerve trunks degenerate most consistently [137]. Autopsy studies of peripheral nerves in patients with vasculitic neuropathy have demonstrated that while vasculitis is diffusely distributed in the epineurium throughout the proximal and distal segments of the nerves, marked myelinated fiber loss and Wallerian-like degeneration begin in the middle segments (corresponding to the distal arm and distal thigh) [138, 139]. Likewise, the ischemic pattern of centrofascicular degeneration occurs only in proximal and middle nerve segments, while diffuse nerve loss predominates in distal sections. The spinal

cord, dorsal root and sympathetic ganglia, and ventral and dorsal roots are spared. These findings indicate that vasculitis affects peripheral nerves diffusely but produces maximal damage in a border zone vulnerable to ischemia in the proximal/midportion of the upper and lower limb nerves.

Clinical and Laboratory Features of Systemic Vasculitides Associated with Neuropathy

Small- and Medium-Vessel Primary Systemic Vasculitides

The small- and medium-vessel primary systemic vasculitides are a diverse group of potentially life-threatening diseases characterized by vasculitic involvement of multiple organs. They include PAN, MPA, CSS, GPA, and HSP. Each disorder has distinguishing anatomic, pathologic, laboratory, and clinical features (Table 36.5). The ANCA-associated vasculitides – GPA, MPA, and CSS – share a predilection for small vessels, paucity of immune deposits in vascular lesions, and potential for rapidly progressive glomerulonephritis and pulmonary capillaritis [140]. Neuropathies occur in 60–70 % of patients with PAN [38]. The incidence of neuropathy in MPA is less well defined but appears to occur in ~50 % of patients [37, 141–145]. For CSS, neuropathy develops in 2/3 of patients [142, 144, 146–152]. In GPA, neuropathies are less common than in PAN, MPA, and CSS, occurring in 15–20 % of patients [141, 142, 144, 153–157], but cranial neuropathies are more common and develop in about 15 % [144, 145, 153]. HSP is only rarely associated with neuropathy.

Predominant Large-Vessel Primary Systemic Vasculitides

GCA is a granulomatous vasculitis involving large- and medium-sized arteries, especially branches of the aortic arch and extracranial carotid arteries (Table 36.5) [158, 159]. Typical symptoms are headache, weight loss, fever, jaw claudication, and polymyalgia rheumatica (PMR), a synovitis that produces pain and stiffness in the neck, shoulders, and proximal extremities. Almost 90 % have vestibular dysfunction and 60 % report hearing loss [160]. There is a 15–20 % risk of permanent visual loss from acute ischemic optic neuropathy. Symptoms of large-vessel disease (claudication and ischemic necrosis/ulceration) affect the upper limbs in 6–8 % of patients and lower limbs in 2–7 % [161–163]. ESR and CRP are almost always elevated [164–167]. Superficial temporal artery biopsy showing granulomatous inflammation, infiltration of macrophages and T cells, and disruption of the internal elastic lamina remains the gold standard for diagnosis. In a large, population-based series of 166 GCA patients, focal/multifocal neuropathies suspicious for vasculitis were identified in 6 % of patients [168]. Over 100 cases of GCA-related, corticosteroid (CS)-responsive neuropathy have been described, to include diffuse polyneuropathies in ~40 %, focal or multifocal neuropathies (most commonly involving the distal median nerve) in ~40 %, and C5/6 radiculopathies or upper trunk plexopathies in ~20 % [169–175].

Secondary Systemic Vasculitides Associated with Neuropathy

The secondary systemic vasculitides occur in the context of an underlying systemic disease predisposing to autoimmune phenomena or a specific etiologic trigger, such as an infection, drug, or malignancy. In addition to the autoimmune CTDs (see below), systemic diseases sometimes accompanied by vasculitic neuropathies include mixed cryoglobulinemia (see Table 36.5), infections, sarcoidosis, inflammatory bowel diseases, and cancers.

Localized Vasculitides

Nonsystemic Vasculitic Neuropathy

Many patients with vasculitic neuropathy exhibit no systemic involvement despite long-term follow-up, i.e., NSVN [36]. Although initially considered rare, NSVN is the most commonly reported vasculitic neuropathy [36, 48, 54, 55, 176–178]. A Peripheral Nerve Society guideline group derived consensus diagnostic criteria for NSVN [41]. Patients are first required to have pathologically definite or clinicopathologically probable vasculitic neuropathy. The diagnosis is excluded by such systemic features as clinical evidence of other organ involvement, angiogram-revealed visceral aneurysm, ANCAs, ESR ≥100 mm/h, cryoglobulins, pathologic evidence of vasculitis in non-neuromuscular tissues, infection underlying the vasculitis, or medical condition/drug predisposing to vasculitis. Constitutional symptoms, diabetes mellitus, and muscle vasculitis are still compatible with NSVN.

NSVN Variants/Subtypes

Several syndromes described by other names represent variants of NSVN. The first is vasculitis restricted to nerves and skin [179]. The best characterized entity is cutaneous PAN, a disorder that affects small- to medium-sized arteries in the dermis and panniculus [180–184]. The disease is mediated by immune complex deposition with complement activation via the classical pathway. The salient skin lesions are recurrent, painful nodules in the lower legs that often ulcerate; other manifestations include livedo racemosa, gangrene, urticaria, and bullae. The disease is characterized by multiple episodes of reactivation and resolution. Constitutional symptoms are common. Approximately 45 % of patients develop a multifocal or distal symmetric neuropathy in the lower limbs [46, 183, 185, 186].

A second variant is diabetic radiculoplexus neuropathy (DRPN), a distinct syndrome that occurs in 1 % of diabetics, especially older men with type 2 diabetes [187–195]. Most patients first develop pain in their hip/thigh, with weakness

[a]All may be associated with leukocytoclastic vasculitis in skin

emerging days to weeks later. Proximal muscles are more commonly affected than distal muscles, but weakness routinely spreads to other segments of the same limb, involving more than nerve. Pain and weakness usually begin unilaterally and spread contralaterally in 80–90 %. Most patients lose weight. Upper limb involvement occurs in ~10 %. Laboratory workup reveals mildly elevated ESR in ~20 % and elevated CSF protein in 85 %. Symptoms typically worsen over several weeks to months (median 4 months) and then slowly improve over many months (median 15 months), but 10–15 % of patients relapse. Nerve biopsies reveal T cell-predominant perivascular/vascular inflammation involving epineurial and, to a lesser extent, endoneurial microvessels, accompanied by changes suggestive of vasculitis, including asymmetric fiber loss, neovascularization, hemosiderin deposition, focal perineural thickening, injury neuroma, and complement deposition in vessel walls [189, 191–195]. *Necrotizing* vasculitis is rare. These findings suggest that DRPN is a PNS microvasculitis, characterized by proximal lower limb involvement and self-limited course. A painless form of DRPN has also been described with slower progression, increased symmetry, greater upper limb involvement (75 %), and distal (rather than proximal) predominance (55 %) [196]. An analogous syndrome is "non-diabetic lumbosacral radiculoplexus neuropathy," an entity considered a subtype of NSVN [197, 198].

Wartenberg's migrant sensory neuritis features episodic, migratory attacks of purely sensory symptoms in the distribution of individual cutaneous nerves [199–204]. Transient stabbing, tingling, or burning pain is followed by persistent sensory loss. Limb nerves are routinely affected, but in 30–40 % of patients, the trigeminal or truncal nerves are also involved [204]. Symptoms typically remit after 6 weeks to several months, but infrequently, numbness persists indefinitely. The clinical course is benign but can extend over years. Cutaneous nerve biopsy findings suggest that some patients with this phenotype have a benign, purely sensory form of NSVN [200, 201, 203, 205].

Clinical Features of Vasculitic Neuropathy (NSVN and SVN)

The clinical presentation of peripheral nerve vasculitis depends on the distribution of affected neural vessels, severity of the vasculitic process, and spectrum of extra-neurologic involvement [36, 47–55, 126–128, 142, 145, 198, 206–218]. Multiorgan involvement is indicative of a systemic vasculitis or underlying CTD (Table 36.5). The most commonly affected organs with systemic vasculitides involving the PNS are the skin, mucous membranes, and ENT tissues [145]. Patients with NSVN, by definition, have no extra-PNS involvement. Constitutional symptoms such as fever, weight loss, fatigue, myalgias, and arthralgias occur in 70 % of patients with a SVN and 30–40 % of patients with NSVN.

Vasculitic neuropathy has a characteristic clinical picture whether occurring alone or as part of a systemic vasculitis. Symptoms typically evolve over weeks to months, with delay from symptom onset to diagnosis ranging from 2 to 8 months in most series [49, 52, 54, 55, 176, 177, 198, 210, 215]. Some patients present fulminantly, mimicking GBS [219], while others follow an indolent course and are not diagnosed for several years [55, 177, 220]. Most patients experience at least one acute attack, but one-third have a slowly progressive course [36, 55, 177]. The most distinctive presentation is a *multifocal neuropathy* or *multiple mononeuropathy*, resulting from ischemic insults to individual nerves. Patients develop pain, weakness, and sensory loss in a stepwise fashion in the distribution of individual nerves. In other patients, individual mononeuropathies overlap, creating an *asymmetric polyneuropathy*. The distribution most difficult to recognize as vasculitic is a *distal*, *symmetric polyneuropathy*, a statistically improbable outcome for a pathologically multifocal process. The reported relative prevalence of these patterns is 45 % multifocal neuropathy, 35 % asymmetric polyneuropathy, and 20 % distal symmetric polyneuropathy [41].

In practice, the most commonly affected nerves are a diffuse mixture of lower limb nerves derived from the lumbosacral plexus [177]. The most frequently affected individual nerve is the common peroneal or peroneal division of the distal sciatic nerve [36, 40, 55, 177]. In the arms, the ulnar nerve is most commonly involved. Neurologic deficits are almost always distally accentuated, but proximal involvement is not uncommon. Cranial neuropathies occur in 10 % of patients [54, 55, 177].

Vasculitis generally affects mixed or purely sensory nerves rather than anterior horn cells or sensory/autonomic ganglia [139]. Most patients develop mixed sensory and motor deficits, but 10 % have predominantly sensory findings [36, 49, 52, 54, 55, 145, 177, 207, 214, 216, 218]. Sensory dysfunction usually involves all modalities, but exceptional patients have small-fiber predominance [55]. Pure motor or autonomic presentations are rare. Eighty percent of vasculitic neuropathies are painful [41].

Differential Diagnosis of Multifocal /Asymmetric Neuropathy

Although vasculitic neuropathy is not common, the differential diagnosis includes other multifocal neuropathies (Table 36.6) that are generally even more uncommon, such as multifocal, acquired, demyelinating sensory and motor (MADSAM) neuropathy (Lewis-Sumner syndrome); DRPN; neuralgic amyotrophy; sarcoidosis; Lyme disease; leprosy; hereditary neuropathy with liability to pressure palsies

Table 36.6 Differential diagnosis of multifocal/asymmetric neuropathy

A. Ischemic neuropathies
1. Peripheral nerve vasculitis (see Table 36.3)
2. Livedoid vasculopathy
3. Sickle cell anemia
4. Cholesterol emboli syndrome
5. Atrial myxoma
6. Diffuse intravascular coagulation
7. Essential thrombocythemia
8. Antiphospholipid antibody syndrome

B. Inflammatory/immune-mediated neuropathies
1. Sarcoidosis[a]
2. Multifocal acquired demyelinating sensory and motor neuropathy (Lewis-Sumner syndrome)
3. Multifocal motor neuropathy
   (a) Idiopathic
   (b) Associated with tumor necrosis factor-alpha inhibitors
   (c) Paraneoplastic (lymphomas)
4. Multifocal acquired motor axonopathy
5. Multifocal variants of Guillain-Barre syndrome
6. Idiopathic brachial or lumbosacral plexopathy (neuralgic amyotrophy)[a]
7. Neuropathy with eosinophilia[a]
   (a) Idiopathic hypereosinophilic syndrome
   (b) Eosinophilic fasciitis
   (c) Eosinophilia-myalgia syndrome
   (d) Kimura disease
8. Neuropathy with gastrointestinal conditions (Crohn disease, ulcerative colitis, celiac sprue)[a]
9. Chronic graft-versus-host disease
10. Wartenberg's migrant sensory neuritis (inflammatory cases)[a]
11. Disialosyl antibody-related neuropathy (e.g., CANOMAD)
12. Sensory perineuritis
13. Hashimoto thyroiditis
14. Toxic oil syndrome
15. Multiple sclerosis with multifocal demyelinating neuropathy

C. Infectious/toxic neuropathies[a]
1. Leprosy
2. Lyme disease
3. Viral (human immunodeficiency virus, human T cell lymphotropic virus type I, varicella zoster virus, cytomegalovirus, Epstein-Barr virus, parvovirus B19, West Nile virus, measles)
4. Diffuse infiltrative lymphocytosis syndrome
5. Infective endocarditis
6. Tuberculosis
7. Sporotrichosis
8. Meningococcemia
9. Other (Group A β-hemolytic streptococcus, leptospirosis, hepatitis A, Mycoplasma pneumoniae, Salmonella typhi, Pseudomonas aeruginosa, trichinosis, ascaris, Plasmodium falciparum, scrub typhus, Coxiella burnetii, relapsing fever)

D. Drug-induced neuropathies[a]
1. Antibiotics (penicillin, sulfonamides, minocycline, vancomycin, macrolides)
2. Cromolyn
3. Thiouracil
4. Allopurinol
5. Amantadine
6. Interferon-α
7. Naproxen
8. Montelukast and other leukotriene receptor antagonists
9. Tumor necrosis factor-alpha inhibitors
10. Valacyclovir
11. Leflunomide
12. Gasoline sniffing (? n-hexane)
13. Drugs of abuse (amphetamines, cocaine, heroin)
14. Statins (?)

E. Genetic neuropathies
1. Hereditary neuropathy with liability to pressure palsies
2. Hereditary neuralgic amyotrophy
3. Porphyria
4. Familial amyloid polyneuropathy (transthyretin)
5. Tangier disease
6. Krabbe disease
7. Mitochondrial disorders

F. Mechanical neuropathies
1. Multiple peripheral nerve injuries
2. Multifocal entrapments not related to a genetic disorder
3. Postoperative neuropathies
4. Compartment syndromes
5. Intermittent pneumatic compression (bilateral common peroneal)
6. Gluteal lipoaugmentation (bilateral sciatic)
7. Burns
8. Wartenberg's migrant sensory neuritis (mechanical cases)
9. Heterotopic ossification

G. Neuropathies related to neoplastic diseases
1. Direct infiltration of nerves by tumor
   (a) Lymphoma (neurolymphomatosis)
   (b) Leukemia
   (c) Multiple myeloma
   (d) Intraneural metastases
2. Paraneoplastic (vasculitic and non-vasculitic)[a]
3. Multifocal peripheral nerve mass lesions with external/internal compression (e.g., neurofibroma, Schwannoma, intraneural perineurioma)
4. Neurofibromatosis type 2 (Schwann cell proliferation/dysfunction)
5. Lymphomatoid granulomatosis[a]
6. Intravascular lymphoma
7. Neoplastic meningitis
8. Primary systemic AL amyloidosis
9. Non-amyloid light chain or IgM deposition
   (a) Waldenström's macroglobulinemia
   (b) IgM monoclonal gammopathy of undetermined significance

H. Intraneural hemorrhage
1. Idiopathic thrombocytopenic purpura
2. Acute leukemia
3. Hemophilia
4. Vasculitic neuropathy

[a]Conditions occasionally or routinely associated with vasculitis

Table 36.7 Recommendations for laboratory investigation of suspected vasculitic neuropathy [41]

A. Routinely indicated studies: Complete blood count, eosinophil count, chemistry panel, urinalysis, glycosylated hemoglobin and/or 2-h glucose tolerance test, erythrocyte sedimentation rate, C-reactive protein, antinuclear antibodies, rheumatoid factor, antineutrophil cytoplasmic antibodies, serum protein immunofixation electrophoresis, complement (C3, C4, total), cryoglobulins, hepatitis B surface antigen, hepatitis C antibodies, and chest X-ray
B. Occasionally indicated studies: SSA/SSB antibodies, other antibodies against extractable nuclear antigens, double-stranded DNA antibodies, cyclic citrullinated peptide antibodies, angiotensin-converting enzyme, lysozyme, vascular endothelial growth factor, beta2-microglobulin, human immunodeficiency virus antibodies, Lyme antibodies, hepatitis C RNA, cytomegalovirus antigen or DNA, paraneoplastic autoantibodies, lactate dehydrogenase, high-density lipoprotein cholesterol, porphyria screen, DNA for PMP22 deletion associated with hereditary neuropathy with liability to pressure palsies, DNA for transthyretin gene, chest CT, gallium-67 scan, visceral angiography, salivary gland biopsy, lumbar puncture, and other body imaging for malignancy

(HNPP); amyloidosis; paraneoplastic or pSS-related sensory neuronopathy; neoplastic meningitis or neural infiltration; and porphyria. Electrodiagnostic testing permits differentiation of the demyelinating features of Lewis-Sumner syndrome, HNPP, and leprosy from the axonal pattern of vasculitic neuropathy. Laboratory studies and nerve biopsy are also often required for accurate diagnosis of these patients.

For patients with pathologic evidence of vasculitic neuropathy, the differential diagnosis includes all conditions associated with PNS vasculitis, including the primary systemic vasculitides, CTDs, hepatitis B, HIV infection, hepatitis C, cryoglobulinemia, sarcoidosis, cancers, and–rarely–other infections or drugs. For the primary systemic vasculitides, consideration of the non-neurologic features and laboratory findings usually permits an accurate diagnosis.

Electrodiagnostic and Laboratory Features of NSVN and SVN

Laboratory evaluation of a patient with suspected vasculitis should assess for systemic organ involvement, markers of inflammation, autoantibodies, and specific causes of multifocal or vasculitic neuropathy. In the guideline on NSVN, consensus was reached on laboratory tests to be considered in a patient with an unexplained neuropathy suspicious for vasculitis (Table 36.7) [41]. Laboratory studies predictive of biopsy-confirmed vasculitic neuropathy include elevated ESR, CRP, RF, β2-microglobulin, MPO-ANCAs, and plasma VEGF [41].

In NSVN, an elevated ESR is found in 50 % of patients; other laboratory markers of inflammation or immune activation (e.g., ANA, RF, anemia, leukocytosis, and hypocomplementemia) are abnormal in less than 25 % of patients [46]. ANCAs occur in only 3 % of patients [55, 221]. For patients with neuropathies caused by a *systemic* vasculitis, laboratory abnormalities are more common: elevated ESR in 85 %, leukocytosis in 75 %, anemia in 45–50 %, RFs in 45 %, decreased complement in 30 %, and ANAs in 30 % [47, 49, 50, 52, 54, 55, 206, 208–214, 216, 218]. Spinal fluid examination is not helpful because CSF pleocytosis is uncommon (~5 %) and mild-to-moderate CSF protein elevation occurs in 30 % of patients with both NSVN and SVN [36, 49, 50, 52, 54, 55, 177, 208, 211, 212]. The best laboratory predictors of an underlying systemic vasculitis are ANCAs and ESR ≥100 mm/h [41].

Electrodiagnostic studies are useful for documenting non-length-dependent features of the neuropathy, excluding a primary demyelinating process, and identifying which nerve to biopsy [222–225]. Findings reflect multifocal axonal damage to motor and sensory fibers. Nerve conduction studies reveal low-amplitude or non-reproducible sensory nerve action potentials (SNAPs) and compound muscle action potentials (CMAPs), while conduction velocities are normal or mildly reduced and distal latencies normal or mildly prolonged. H reflexes and F waves are often impersistent or unevocable with normal or mildly prolonged latencies. "Pseudo" or "axon non-continuity" conduction blocks occur in 10–25 % of patients, resulting from acute Wallerian-like degeneration [36, 226]. If nerve conductions are repeated in 2 weeks, pseudo-conduction blocks disappear due to degeneration of the distal stumps [227, 228]. True demyelinating partial motor conduction blocks are rarely seen [229, 230], possibly caused by due to axonal swelling and attenuation with secondary segmental demyelination, structural changes at the nodes of Ranvier, reperfusion-induced segmental demyelination, and inactivation of nodal voltage-gated sodium channels [231–234].

Needle EMG examination reveals fibrillation potentials in ~70 % of patients and decreased recruitment of motor unit potentials (MUPs) in clinically weak muscles [41]. Long-duration MUPs are found in 20–50 % of patients (those with long-standing disease or preexisting conditions) [41, 226]. Short-duration MUPs suggestive of concomitant myopathy occur in 10–15 % of patients with systemic disease [47, 55, 211, 212] but not in those with NSVN [55, 212, 226]. Sufficiently extensive electrodiagnostic studies usually show evidence of a multifocal or asymmetric neuropathy.

Pathologic Features of VN

Since axons are more vulnerable to ischemia than Schwann cells, perineurial cells, and fibroblasts, nerve biopsies in SVN and NSVN usually reveal changes indicative of a

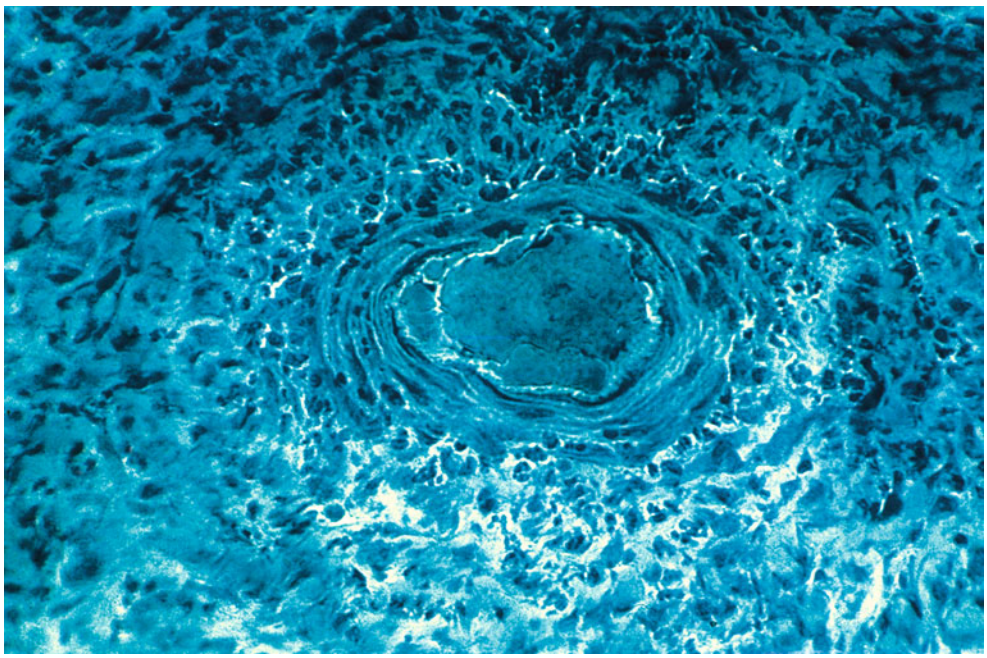

Fig. 36.2 This superficial peroneal nerve biopsy in a patient with nonsystemic vasculitic neuropathy shows an epineurial arteriole infiltrated and surrounded by an inflammatory infiltrate. The vessel is occluded by an acute thrombus (Modified Gomori trichrome)

primary axonal process [49, 51, 53, 54, 176, 235, 236]. Affected fascicles show decreased myelinated nerve fiber density, abundant Wallerian-like degeneration, regenerating axonal clusters, and inconspicuous demyelinating/remyelinating changes. In fulminant vasculitis, all cellular elements are lost. Axon loss tends to be centrofascicular in proximal watershed areas but becomes multifocal in distal parts of the nerve due to intermingling of descending fibers [137–139, 235]. Cellular infiltrates in vasculitic neuropathy are perivascular and predominate in the epineurium [36, 54, 124, 135]. They are composed primarily of T cells and macrophages. B cells are uncommon and NK cells and polymorphonuclear leukocytes rare [54, 121, 122]. Peripheral nerve vasculitis has a predilection for epineurial vessels with diameters of 50–300 μm [36, 48, 49, 54, 235, 237, 238]. NSVN tends to involve smaller vessels (<100 μm) within this range but is not limited to microvessels [54, 178]. Direct IF (DIF) shows deposits of IgM, fibrinogen, C3, and/or C5b9 in epineurial vessel walls in 55–80 % of patients [49, 121, 136, 176].

Diagnostic Criteria: Pathologically Definite and Pathologically Probable

The pathologic diagnosis of *definite active* vasculitic neuropathy requires inflammation within the vessel wall *and* signs of vascular damage such as fibrinoid necrosis, endothelial disruption, fragmentation or loss of the internal elastic lamina, degeneration or loss of smooth muscle cells in the media, hemorrhage, or acute thrombosis [41, 235] (Fig. 36.2). Perivascular or mural inflammation alone, without associated structural damage, is nonspecific. A diagnosis of *definite chronic* vasculitis requires vascular inflammation and signs of healing/repair, such as intimal hyperplasia, fibrosis of the media or adventitia, or chronic thrombosis with recanalization [41, 224] (Fig. 36.1).

Many investigators have attempted to increase pathologic sensitivity by defining alterations "suggestive" or "suspicious" for "probable" vasculitic neuropathy in specimens lacking definite vasculitis [52, 55, 176, 194, 224, 235, 238]. Most of these criteria require perivascular or vascular inflammation and one or more changes predictive of definite vasculitis, e.g., active Wallerian-like degeneration [177], asymmetric nerve fiber loss [177, 239, 240], hemosiderin deposits [239–241] (Fig. 36.3), myofiber necrosis/regeneration in peroneus brevis muscle biopsy [177], and DIF for vascular immune deposits of IgM, complement, or fibrinogen [136, 242]. Endoneurial hemorrhage, epineurial neovascularization, focal perineurial degeneration/thickening, and injury neuroma might also be supportive features, but their specificity for vasculitis is not established [194, 238].

Nerve Biopsy: Indications, Sensitivity, and Specificity

Because the differential diagnosis of a multifocal/asymmetric neuropathy is broad (Table 36.6), most patients with suspected vasculitic neuropathy should undergo nerve biopsy, usually of the sural or superficial peroneal nerve (SPN). SPN biopsy is combined with a peroneus brevis muscle (PBM) biopsy through a single incision in the lower leg [48, 52]. For patients in whom the sural nerve and SPN are not clinically involved, the superficial radial, lateral

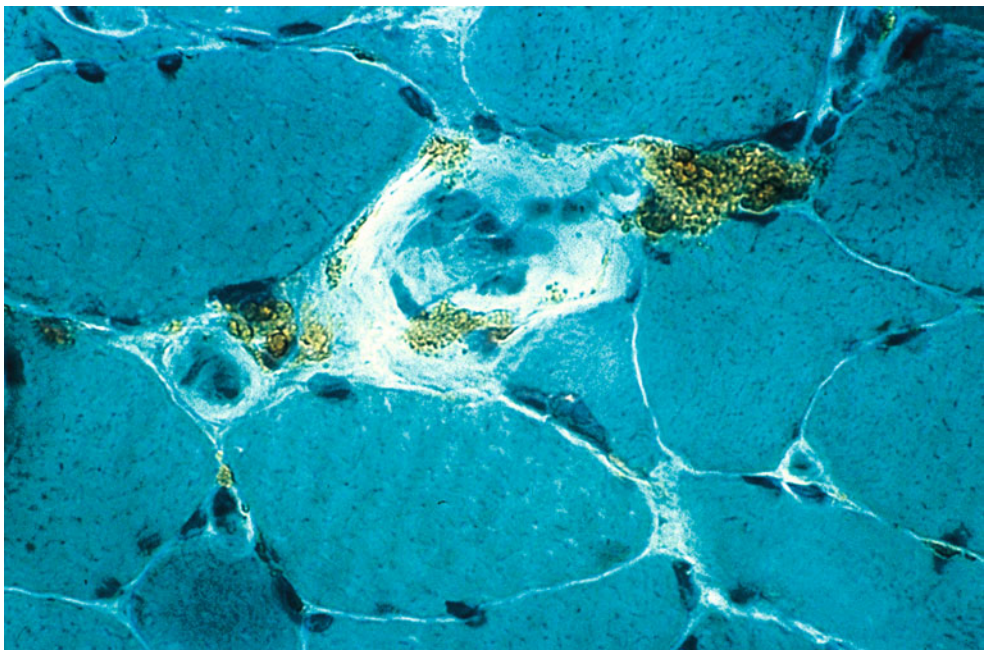

Fig. 36.3 Peroneus brevis muscle biopsy from a patient with nonsystemic vasculitic neuropathy. Hemosiderin deposits are seen surrounding a single endomysial vessel. This finding is suggestive but not diagnostic of vasculitis (Modified Gomori trichrome)

antebrachial cutaneous, intermediate femoral cutaneous, or saphenous nerves are alternatives. Although nerve is more commonly diagnostic than muscle in cases of suspected vasculitic neuropathy, concomitant muscle biopsy increases the yield by 15 % [243].

Not all patients with a cryptogenic neuropathy require nerve biopsy for vasculitis. In patients with an unexplained distal symmetric polyneuropathy, the yield of nerve biopsy for vasculitis is <5 % [214, 244, 245]. This yield is enhanced if the patient has an asymmetric/multifocal pattern [124, 225, 244, 246], pain [240], acute-onset [246], progressive clinical course [240], ANCAs [247], elevated ESR/CRP [240, 246], elevated beta2-microglobulin [246], or increased VEGF [248]. In the absence of an independent gold standard, the true sensitivity of nerve biopsy for vasculitic neuropathy is unclear. However, in patients who lack nerve biopsy evidence of definite vasculitis, clinically probable vasculitic neuropathy can be diagnosed by clinical and pathologic criteria [41]. Assuming these clinically probable cases truly have vasculitic neuropathy, the estimated sensitivity for definite vasculitis is 55–60 % with sural nerve [36, 53, 55, 176, 177, 224] and 60–65 % with SPN/PBM [41, 52, 214, 225] or sural nerve/gastrocnemius muscle biopsy [217].

Treatment

Although many randomized controlled treatment trials (RCTs) have been conducted in the vasculitides over the past 20 years, there is still little data relevant to treatment of any type of vasculitic *neuropathy*. For all vasculitides, treatment begins with a search for precipitating factors, such as drugs, infections, or neoplasms. If present, the triggering condition should be eliminated or treated. Examples of this approach include the use of pegylated INF-α or oral antiretroviral drugs (e.g., lamivudine, adefovir, entecavir, tenofovir, telbivudine) in patients with chronic hepatitis B-associated PAN [249], pegylated INF-α plus ribavirin in hepatitis C-associated vasculitic neuropathy [250], antiretroviral therapy in HIV-related vasculitis [251], and ceftriaxone in Lyme disease-induced vasculitic neuropathy [252], sometimes accompanied by plasma exchange. However, no inciting or perpetuating antigen can be identified in most vasculitides (including NSVN), necessitating immunosuppressive therapy (Table 36.8).

Immunosuppressive Therapy of Primary Small- to Medium-Vessel Vasculitis

The traditional immunosuppressive regimen for the primary small- and medium-vessel systemic vasculitides – PAN, MPA, CSS, and GPA – involves a combination of CS and cyclophosphamide (CYC), a regimen that has never been validated in a RCT [253]. Prednisone is started at 1 mg/kg/day for 2–4 weeks, tapered to 60 mg every other day over 1–2 months, and then more gradually tapered over 12 months. The CYC dose is 2 mg/kg/day continued for 1 year after complete remission and then tapered by 25 mg every 2–3 months. While effective in controlling most vasculitides, long-term follow-up studies have revealed standard therapy-treated GPA and NSVN to be chronic, relapsing diseases with a high incidence of drug-related morbidity [177, 254, 255]. For example, in one cohort of 158 GPA patients,

Table 36.8 Immunosuppressive medications used in treating vasculitis

Agent	Route	Typical dose	Side effects	Monitor
Prednisone	Oral	1.0 mg/kg/day	Infections, osteoporosis, hyperglycemia, hypertension, cataracts, glaucoma, mood changes, insomnia, confusion, aseptic joint necrosis, weight gain, edema, fat redistribution, myopathy, delayed wound healing, gastric ulcers, hypokalemia, skin atrophy	Glucose, electrolytes, blood pressure, eyes, bone density
Methotrexate	Oral or IV	15–25 mg/week	Hepatotoxicity, leukopenia, infections, alopecia, mucositis, nausea, abdominal pain, pneumonitis, nodulosis, neoplasia	CBC, LFTs, creatinine
Cyclophosphamide	Oral IV	1.5–2.0 mg/kg/day 600–700 mg/m^2 or 15/mg/kg every 2–3 weeks	Leukopenia, infections, hemorrhagic cystitis, pneumonitis, alopecia, neoplasia, nausea, vomiting, diarrhea, SIADH, infertility, rash	CBC, UA
Azathioprine	Oral	1.5–2.5 mg/kg/day	Leukopenia, infections, hepatotoxicity, nausea, diarrhea, drug fever, pancreatitis, mucositis, alopecia, neoplasia	CBC, LFTs
IVIg	IV	2.0 g/kg	Fevers, chills, headache, aseptic meningitis, myalgias, back pain, chest pain, nausea, acute renal failure, rash, anaphylaxis with IgA deficiency, leukopenia, hemolytic anemia, thromboembolic events, blood-borne infections	Blood pressure, pulse, CBC, creatinine
Mycophenolate mofetil	Oral	2–3 g daily	Leukopenia, infections, diarrhea, nausea, abdominal pain, GI hemorrhage, PML	CBC
Rituximab	IV	375 mg/m^2/week ×4 weeks	Immune hypersensitivity reaction, infections, leukopenia, lymphopenia, anemia, rash, nausea, diarrhea, abdominal pain, edema, headache, arthralgia, myalgia, dysrhythmia, PML	CBC, blood pressure, pulse, cardiac rhythm

CBC complete blood count, *GI* gastrointestinal, *IV* intravenous, *IVIg* intravenous immunoglobulin, *LFTs* liver function tests, *PML* progressive multifocal leukoencephalopathy, *UA* urinalysis

treatment-associated side effects included ovarian failure (57 %), serious infections (46 %), hemorrhagic cystitis (43 %), cataracts (21 %), fractures (11 %), diabetes mellitus (8 %), avascular hip necrosis (3 %), bladder cancer (3 %), and myelodysplasia (2 %) [254]. Compared to the general population, there was a 2.4-fold increase in malignancies, with a 33-fold increase in bladder cancers and 11-fold increase in lymphomas. Other studies have confirmed an increased risk of bladder, skin, and hematologic malignancies in GPA patients treated with CYC [256, 257]. These findings have provided a strong impetus to (1) reduce patient exposure to CYC and (2) more rapidly taper CS.

Over the past 20 years, treatment has evolved to a more individualized approach tailored to the patient's age, extent and severity of disease, and prognostic factors. Current strategies minimize exposure to CYC by use of non-CYC-based maintenance regimens or by replacement of CYC in the induction phase for patients with less severe disease. As outlined in consensus guidelines, patients with localized or mild, generalized ("early systemic") disease characterized by normal or mildly abnormal renal function and no other organ-threatening manifestations are treated with high-dose CS and methotrexate (MTX) 15–25 mg/week [258, 259]. The guidelines recommend starting prednisone at 1.0 mg/kg/day for 1 month and tapering to 10 mg/day by 6 months. It is then stopped or continued at low doses (5.0–7.5 mg daily) to reduce relapses [260]. MTX is discontinued after 18–24 months. Patients with moderate-to-severe, generalized disease (including progressive neuropathies) are treated with CYC and prednisone. CYC can be administered orally at 2.0 mg/kg/day or in the form of IV pulses, e.g., 15 mg/kg or 0.60–0.70 g/m^2 every 2–3 weeks [261, 262]. The dose needs to be reduced in the elderly and those with chronic kidney disease. CYC is stopped once the patient remits, generally in 3–6 months, replaced by an agent to maintain remission, usually azathioprine (AZA) 1.5–2.0 mg/kg/day or MTX 20–25 mg/week. Leflunomide 20 mg/day is a second-line option. Mycophenolate mofetil (MMF) has also been used for maintenance of remission, but in one open-label RCT, it was inferior to AZA in preventing relapses in ANCA-associated vasculitis [263]. Remission maintenance therapy is continued for at least 18–24 months. In patients with severe renal disease (creatinine >5.6 mg/dl) or alveolar hemorrhage, CS/CYC is augmented with plasma exchanges [264]. Based on the results of two recent RCTs, rituximab is now a first-line alternative to CYC for induction of remission in newly diagnosed MPA or GPA [265–268].

Immunosuppressive Treatment of SVN and NSVN

There are no RCTs of treatment for vasculitic neuropathy associated with any type of vasculitis. In the absence of evidence, vasculitic neuropathies occurring in the primary small- to medium-vessel systemic vasculitides are generally managed in the same manner as the underlying systemic

vasculitis. While none of the controlled trials in these vasculitides had *primary* neuropathic endpoints, the implication from published studies is that vasculitic neuropathies generally improve hand in hand with the non-neurologic manifestations [41, 269].

Treatment trials in patients with primary small- to medium-vessel systemic vasculitides cannot be directly extrapolated to NSVN. Several studies have suggested that NSVN is clinically and pathologically milder than a SVN, suggesting that less aggressive therapy may be indicated [54, 55, 238]. Although no RCTs of therapy in NSVN have been performed, two class III retrospective cohort surveys involving 73 patients have provided limited evidence, suggesting that combination therapy is more effective than CS monotherapy in inducing sustained remission and improving disability in NSVN [176, 177].

A Peripheral Nerve Society guideline on NSVN offers several consensus-driven good practice points on treatment of NSVN [41]. CS monotherapy is considered first line. Prednisone is started at 1.0 mg/kg/day, tapered to 10 mg/day at 6 months, and continued at low doses for another 6–18 months. Combination therapy is recommended for rapidly progressive NSVN and patients progressing on CS alone. First-line immunosuppressive options are CYC, MTX, or AZA, with CYC preferred for severe neuropathies. CYC is generally administrated in IV pulses (as above) to decrease the cumulative dose and side effects. MTX is started at 15 mg/week and titrated to 25 mg/week over 1–2 months. AZA dose is 2.0–2.5 mg/kg/day. Once remission is achieved, maintenance therapy for 18–24 months is recommended to reduce relapses. First-line options are AZA 1.0–2.0 mg/kg/day or MTX 20–25 mg/week. In patients refractory to the initial regimen, CYC should be used if not already done. In patients refractory to CYC, unproven treatment options based on extrapolation from RCTs in the small- to medium-vessel primary systemic vasculitides include IVIg, plasma exchange, and rituximab [264–266, 270].

Supportive Care

Effective management of vasculitic neuropathy also incorporates aggressive supportive care, including pain management, rehabilitation, counseling, and education. For most patients, pain control is a fundamental issue, mandating the use of tricyclic antidepressants, gabapentin, pregabalin, serotonin-norepinephrine reuptake inhibitors, carbamazepine, valproate, tramadol, topical lidocaine, topical capsaicin, and scheduled narcotics [271]. With rare exceptions, pain control alone is *not* an indication to continue high-dose CS. Physical therapy helps maintain strength and range of motion, prevent contractures, limit osteoporosis, and counteract CS myopathy. Occupational therapy helps to maximize function, especially for activities of daily living (ADLs), sometimes facilitated by appropriate bracing. Walking aids (e.g., cane, wheeled walker, or crutches) or a wheelchair may be required to maintain mobility. The value of psychological support cannot be overemphasized. Because of physical limitations, chronic pain, exposure to high doses of CS, prolonged recovery, and uncertain prognosis, patients with vasculitic neuropathy are at high risk for depression and other psychological reactions [272, 273]. The treating physician must maintain a high index of suspicion and be prepared to provide pharmacologic support or psychiatric referral for patients who become depressed.

Prognosis of SVN and NSVN

The prognosis of untreated vasculitic neuropathy associated with the primary systemic vasculitides is variable and unpredictable [206, 274, 275]. Similarly, the natural history of NSVN is unknown because nearly all reported patients have received immunosuppressive agents. However, based on rare reports of untreated patients and reported patients' clinical courses prior to treatment, NSVN may follow a monophasic course with complete or near-complete recovery, slowly progress for as many as 40 years, slowly progress for several years prior to stabilizing or subacutely worsening, progress in a fulminant fashion to quadriparesis or death in weeks to months, or spontaneously relapse and remit [41].

Treated NSVN appears to have a better prognosis than treated SVN. Five-year survival rates in two studies of NSVN were 85 and 87 %, contrasting with ~75 % in modern systemic vasculitis cohorts [48, 177, 276, 277]. NSVN has low risk for systemic dissemination, provided no symptoms, signs, or serologic features of a systemic vasculitis are identified, and immunosuppressive therapy is implemented. In the largest NSVN cohort, only 6 % of patients developed signs of vasculitic involvement in non-neuromuscular tissues during median follow-up of 63 months, and in these patients, spread was limited to the skin [177]. More common than systemic spread is the appearance of relapsed neuropathy symptoms following a sustained treatment response in one-third of patients [46]. Relapses tend to occur in patients whose therapy has been stopped or reduced to low doses of CS, suggesting the need for more extended maintenance therapy. In long-term survivors of NSVN, 60 % of patients have no or mild symptoms, ~20 % have mild-to-moderate impairment with independent ambulation, and ~20 % are dependent in some ADLs (e.g., requiring assistance with ambulation) or nonambulatory [176, 177]. This compares favorably to neurologic morbidity in surviving patients with SVN: 40 % no or mild symptoms, ~35 % mildly to moderately impaired, and ~25 % dependent in walking or ADLs [49, 52, 207, 216]. While most NSVN patients have mild or no neurologic deficits at end of follow-up, chronic pain ensues in 60 % [177].

Connective Tissue Diseases

Rheumatoid Arthritis

Definition/Epidemiology

RA is a chronic disorder characterized by inflammation of the synovium and secondary damage to articular cartilage and underlying bone in peripheral joints in a symmetric distribution [278, 279]. It is the most common CTD, affecting 0.2–1.1 % of adults [280]. Annual incidence ranges from 10 to 50 new cases per 100,000 and increases with age. Women are affected three times more commonly than men [278]. Most patients develop symptoms between the ages of 35 and 50 years.

Etiology/Pathogenesis

The cause of RA is unknown [278, 279, 281–284]. One hypothesis holds that the disease occurs in genetically susceptible individuals as an exaggerated immune response against an infectious agent, but no convincing etiologic link with any organism has been established [279, 281]. Smoking is the main environmental risk factor [279]. Alternatively, repeated inflammatory insults mediated through Toll-like receptors (TLRs) and other specialized receptors that recognize microbial products in a genetically susceptible individual might contribute to the breakdown of immune tolerance [281]. Genetic factors explain up to 60 % of disease susceptibility [285, 286]. Genome-wide association studies have identified more than 30 genetic loci associated with RA, most in genes encoding proteins implicated in regulation of the immune response [285, 287]. The so-called shared epitope in the third hypervariable region of the HLA-DRB1 gene is the major genetic risk factor. With aging, defects in homeostatic control of the T cell population may lead to the loss of tolerance to neoantigens, such as citrullinated peptides. Citrullination refers to the posttranslational conversion of arginine to citrulline [288, 289]. In RA, citrullination occurs in the inflamed synovium. The specifically citrullinated proteins vary but include many normal constituents, such as vimentin, fibrinogen, fibronectin, and collagen. Immunoglobulins targeting these proteins are then produced, the anti-cyclic citrullinated peptide (CCP) antibodies [283, 290].

The earliest pathologic changes in the synovium are microvascular injury and hyperplasia of synovial lining cells, followed by perivascular inflammatory cell infiltration and angiogenesis [281, 291]. The predominant infiltrating cells are CD4+ memory T lymphocytes, most of which differentiate into Th1 cells, but IL-17 is the chief T cell-derived cytokine in the synovium [292]. Polyclonal immunoglobulins, RFs, and anti-CCP antibodies are produced within the synovium, resulting in immune complex deposition and complement activation [281, 293]. Products of complement activation and chemokines attract neutrophils to the synovial fluid. Synoviocytes (fibroblast-like and macrophage-like), chondrocytes, osteoclasts, and mesenchymal stromal cells are then activated. Macrophages and fibroblast-like synoviocytes are the primary sources of pro-inflammatory cytokines, such as TNF-α [281, 294]. The synovial membrane enlarges to from a pannus that invades cartilage and bone, resulting in bone erosions and periarticular osteoporosis [295]. In RV, AECAs and deposition of immune complexes produced within the synovium and entering the circulation may participate in the pathogenic cascade [296, 297].

Clinical Presentation

RA presents with the insidious onset of pain, stiffness, and swelling in multiple joints over weeks to months, often accompanied by fatigue, myalgias, anorexia, and weight loss [2, 279, 298, 299]. Commonly affected joints are the wrists, hands, feet, knees, ankles, elbows, and shoulders. Joint involvement is classically symmetric. Morning stiffness lasting more than 1 h is a nearly constant feature. As the disorder progresses, a chronic erosive synovitis develops with compromise of joint space integrity and secondary joint deformities and contractures (Fig. 36.4). Extra-articular involvement occurs in up to 40 % of patients, especially those with advanced disease and high RF titers [279, 299, 300]. Manifestations are vasculitis, rheumatoid nodules, serositis, pulmonary nodules, interstitial lung disease, keratoconjunctivitis sicca, lymphadenopathy, Felty syndrome (RA, splenomegaly, neutropenia), amyloidosis, neuropathy, two- to fourfold increased risk of lymphoma, and accelerated atherosclerosis [301, 302].

Vasculitis

RV develops most commonly in patients with long-standing disease, history of smoking, high RF levels, decreased circulating C3, joint erosions, subcutaneous nodules, cryoglobulins, Felty syndrome, and HLA-DRB1 *shared epitope* genotypes [299, 303–306]. Autopsy series have revealed vasculitis in 20 % of patients [307–311], most of which was subclinical. In prospective clinical studies, vasculitis develops in 4–5 %. The incidence of RV has decreased over the past two decades, possibly due to more aggressive treatment of RA [312–314]. Skin involvement is the most frequent (75 % of cases) and often initial feature [304, 306]. Neuropathies are next most prevalent, occurring in 45–50 % of patients [303, 307, 311, 315–317]. Clinical involvement of other organs is uncommon. Laboratory findings are similar to those in the primary systemic vasculitides, but CCP antibodies are a distinguishing feature [318].

Evaluation and Diagnostic Criteria

The diagnosis of established RA depends on a characteristic clinical picture, radiographic findings of periarticular osteopenia and bony erosions, inflammatory synovial fluid,

Fig. 36.4 Hands from a 56-year-old man with a 20-year history of rheumatoid arthritis who presented with a right foot drop and symmetric distal sensory loss. There is severe joint involvement of the wrist, metacarpophalangeal, and proximal interphalangeal joints producing swelling and joint deformity with slight radial deviation at the wrist and ulnar deviation of the digits. Note the relative sparing of the distal interphalangeal joints

and abnormal serologic studies. The 1987 ACR revised classification criteria for RA are 91–94 % sensitive and 89 % specific for RA in a control population consisting of other types of CTDs, but they do not discriminate new-onset RA from other inflammatory arthropathies [319]. New classification criteria devised in 2010 focused on early features of the disease predictive of persistent or erosive RA (Table 36.9) [320].

ESR and CRP are elevated in almost all patients with active disease [298]. About 25 % of patients develop normocytic anemia secondary to chronic inflammation. ANAs are present in 20–30 % of patients. Complement levels are normal or increased. ANCAs occur in 20–50 % of patients, but they are not consistently associated with RV [321, 322]. RFs have only moderate sensitivity (70 %) and specificity (79 %) for RA [323]; they can be detected in many other conditions (including all CTDs), 1–5 % of the general population, and 10 % of elderly individuals [324, 325]. High titers of RFs are predictive of a more severe clinical course with erosive disease and extra-articular manifestations. Anti-CCP antibodies are more specific (96 %) and equally sensitive (67 %) [323]. They are found in 1–2 % of normal individuals, 5–10 % of patients with other chronic inflammatory diseases, and 34 % of patients with tuberculosis [326, 327]. Titers of RF and anti-CCP antibodies are not useful in monitoring disease activity.

Treatment/Prognosis

In decades past, patients with indolent disease were managed with nonsteroidal anti-inflammatory drugs (NSAIDs) alone, while those with more aggressive disease received CS or one of the disease-modifying antirheumatic drugs (DMARDs), such as MTX, sulfasalazine, or hydroxychloroquine [279, 328, 329]. Because early treatment with DMARDs improves clinical/radiographic outcomes compared to delayed treatment, initiation of DMARD therapy within 3 months of diagnosis has been the established best practice since the 1990s [279, 328–334]. Most patients are initially treated with MTX rapidly escalated from 7.5–15 to 20–25 mg/week. When MTX is contraindicated, sulfasalazine and leflunomide are alternatives. Patients with persistent disease activity despite use of MTX are treated with a TNF-α inhibitor (etanercept, infliximab, adalimumab, golimumab, or certolizumab pegol) [335]. Combination therapy with MTX and a TNF-α inhibitor yields better clinical outcomes and reduced radiographic progression than MTX or TNF-α monotherapy in patients with early RA. Those who fail MTX combined with a TNF-α inhibitor can be treated with another TNF-α inhibitor, rituximab (CD20 monoclonal antibody), tocilizumab (IL-6 receptor antagonist), or abatacept (CTLA-4 fusion protein) [336]. In patients with high disease activity and poor prognostic factors, initial treatment with both MTX and a TNF-α inhibitor is recommended [332, 333]. The addition of low-dose CS to DMARDs in RA also retards radiographic progression [337]. The optimal treatment approach for systemic RV is unknown, but in practice, combined CS and CYC is the mainstay of treatment [338–340]. Patients with milder disease are often managed with CS combined with AZA or MTX [306]. For patients refractory to or intolerant of CYC, class IV evidence suggests a role for the TNF-α inhibitors and rituximab [341, 342]. There are also case reports of efficacy for abatacept and tocilizumab [343, 344].

Although about 10 % of patients with early RA undergo spontaneous remission without residual disability, most patients have progressive disease [278, 279]. About 65 % of

[a]The criteria are aimed at classification of newly presenting patients. In addition, patients with erosive disease typical of RA with a history compatible with prior fulfillment of the 2010 criteria should be classified as having RA. Patients with long-standing disease, including those whose disease is inactive (with or without treatment), who, based on retrospectively available data, have previously fulfilled the 2010 criteria should be classified as having RA

[b]Large joints refer to shoulders, elbows, hips, knees, and ankles

[c]Small joints refer to the metacarpophalangeal joints, proximal interphalangeal joints, second through fifth metatarsophalangeal joints, thumb interphalangeal joints, and wrists

patients have radiographic evidence of erosive arthritis within 3 years of disease onset [345]. Disability increases by an average of 0.6 % per year and joint damage by 2.0 % per year [346]. Mortality rates in patients with RA are 1.5–1.6-fold higher than in the general population [347, 348].

Neuropathies

Polyneuropathies have been identified in ~15 % of patients with RA in prospective studies employing clinical criteria and ~30 % in electrodiagnostic investigations (data from 17 clinical and 10 EMG studies) [349–354]. Approximately 45 % of these neuropathies are asymmetric or multifocal. About 50 % of RA-related neuropathies are "sensory" in clinical series, but most involve both sensory and motor fibers in electrodiagnostic studies [354, 355].

Vasculitic Neuropathy

As previously noted, neuropathies evolve in 45–50 % of patients with RV, suggesting that up to 10 % of all patients with RA will eventually develop a vasculitic neuropathy. Vasculitic neuropathy usually occurs in patients with long-standing, seropositive, nodular disease but can be a heralding feature of the illness. Signs and symptoms are similar to those of other vasculitic neuropathies, except for a larger proportion (~50 %) of predominantly sensory neuropathies [42, 51, 303, 317, 356–359]. The laboratory and electrodiagnostic features have already been discussed above.

Distal Sensory or Sensory-Motor Polyneuropathy

About 10 % of patients with RA develop a distal sensory or sensory-motor polyneuropathy. Patients present with slowly progressive distal paresthesias, numbness, and sometimes pain; typically minor motor involvement; and modest pan-modality sensory loss [360, 361]. Electrodiagnostic studies usually reveal axonal motor involvement, even when clinical findings are primarily sensory [354, 355]. Asymmetries should prompt consideration of an overlapping vasculitic neuropathy. Information on nerve pathology is sparse and conflicting, but some biopsies or postmortem examinations have revealed vasculitis, healed arteritis, or findings predictive of vasculitis [51, 349, 352, 360, 362–365].

Entrapments

Carpal tunnel syndrome and ulnar neuropathy at the elbow develop in 15–20 % of patients with RA based on clinical, nerve conduction, or sonographic criteria [352, 353, 355, 366–369]. Proliferating synovium, joint deformities, synovial cysts, and rheumatoid nodules are predisposing factors. There are also numerous reports of posterior interosseous nerve entrapments, generally attributed to synovitis or synovial cysts at the elbow [370]. Tibial, femoral, common peroneal, digital, proximal median, and distal ulnar nerve entrapments are more rarely encountered [7, 371–373].

Other Phenotypes

There are rare reports of CIDP [352]; GBS [357]; trigeminal sensory and other cranial mononeuropathies [374]; lumbar radiculopathies caused by intraspinal extradural rheumatoid nodules [375], lumbar pachymeningitis [376], facet joint pannus [377], or rheumatoid diskitis [378]; and amyloid neuropathies [352]. Secondary or reactive amyloid A (AA) amyloidosis occurs in many chronic inflammatory diseases, including RA, due to increased synthesis of serum amyloid A (SAA), an acute-phase reactant [379, 380], but neuropathies are rare [381, 382].

Treatment/Prognosis

No RCT of treatment in RA-associated neuropathies has been reported. Patients with indolent neuropathies are usually managed supportively. Patients with entrapments can be splinted or treated with local CS injections. Surgical release is reserved for those with progressive deficits or severe symptoms. Many patients require treatment for neuropathic pain. Biopsy-proven vasculitic neuropathies should be treated with CS monotherapy or CS combined with a cytotoxic agent (see above). Although no prospective studies have addressed the prognosis of rheumatoid neuropathy, one retrospective analysis of patients with vasculitic rheumatoid neuropathy demonstrated a 5-year survival of 57 % [51]. Cutaneous vasculitis, neuropathy affecting three or four limbs, and reduced C4 level were independent predictors of mortality in this study. Sustained remission occurred in 55 % of patients and 25 % relapsed.

Sjögren's Syndrome

Definition/Epidemiology

Sjögren's syndrome is an autoimmune disease characterized by lymphocytic infiltration of exocrine glands, especially the lacrimal and salivary glands, producing the primary clinical manifestations of dry mouth (xerostomia) and dry eyes (keratoconjunctivitis sicca) [383–385]. The disorder has an estimated prevalence of 0.5–1 % in adults [386, 387]. It can develop at any age, but onset in the fourth and fifth decades is typical; 90 % of cases occur in women. The term *primary* Sjögren's syndrome (pSS) is applied when the disorder occurs in isolation; *secondary* Sjögren's (sSS) refers to cases developing in conjunction with another autoimmune CTD, most commonly RA. The primary and secondary forms of SS occur with approximately equal prevalence [388].

Etiology/Pathogenesis

The etiology of pSS is unknown, but environmental factors may trigger chronic inflammation in genetically susceptible individuals [383, 385, 389, 390]. One theory holds that immunologically activated and apoptotic glandular epithelial cells expose autoantigens in genetically predisposed patients, thereby driving an injurious immune response [390–392]. For example, the disease may result from an aberrant immune response to a virus latently infecting the epithelial cells of salivary and other exocrine glands [383, 389, 390]. The genetic aspects of pSS have not been as well investigated as those of RA [393, 394]. The strongest associations are those between the HLA-DQA1*0101, *0301, *0201, and *0501 alleles and subsets of autoantibodies, not the disease itself [390]. The glandular cellular infiltrate consists primarily of activated T cells, with less frequent B cells, plasma cells, macrophages, and NK cells [385, 388]. CD4+ Th2 cells predominate in early stages of the disease, while Th1 and Th17 cells take precedence in later stages [388, 390, 395]. Germinal center-like structures are found in 17–28 % of minor salivary gland biopsies [390, 391, 396]. They are presumed to be sites of helper T cell-dependent B cell proliferation and maturation. B cell activation is evidenced by circulating immune complexes, multiple autoantibodies, cryoglobulinemia, RFs, hypergammaglobulinemia, oligoclonal B cell expansions, and increased risk of B cell lymphoma [397]. Autoantibodies are directed against such antigens as Ro/SSa, La/SSB, α-fodrin (constituent of the epithelial cell cytoskeleton), M3R muscarinic receptors, carbonic anhydrase II, and proteasomal subunits [398]. pSS is most closely linked to antibodies against Ro/SSA and La/SSB. Microarray analyses of minor salivary gland tissue and peripheral blood mononuclear cells from patients with pSS show enhanced levels of type I IFN-inducible gene expression, i.e., a type I IFN *signature* [389, 399]. Type I IFN consists of five classes of molecules: IFN-α, IFN-β, IFN-ε, IFN-κ, and IFN-ω. Most cells make small amounts of type I INF, but the principal producer is the plasmacytoid dendritic cell. Type I IFN has many immunomodulatory effects, all of which have the potential to perpetuate an autoimmune disease.

Clinical Presentation

pSS presents in an indolent fashion over years to decades, manifesting with slowly evolving symptoms of dry eyes and dry mouth [383–385, 388, 400–405]. Unilateral or bilateral, chronic or recurrent salivary gland enlargement occurs in 25–50 % of patients, usually involving the parotid gland (Fig. 36.5). Dental caries, accelerated periodontal disease, and oral candidiasis are common. Other exocrine glands may also be affected, resulting in dryness of the skin and mucosal surfaces of the upper respiratory tract, GI tract, and vagina. Dysphagia develops in 75 % of patients, caused by mucosal dryness, reflux, and esophageal dysmotility. Chronic cough secondary to tracheitis occurs in 40–50 % of patients.

Some 50 % of patients with pSS develop a multisystem disorder heralded by fatigue, fever, myalgias, and arthralgias [383–385, 388, 400–405]. Symptoms result from lymphocytic invasion of organ epithelia (e.g., interstitial nephritis, autoimmune hepatitis, and interstitial pneumonitis) or immune complex disease (e.g., vasculitis, arthritis, and glomerulonephritis). Manifestations include nonerosive arthritis (~50 % of patients), skin involvement (~50 %), Raynaud's phenomenon (15–50 %), autoimmune thyroid disease (~35 %) [406], lymphadenopathy (10–30 %), neuropathy (~20 %), CNS disease (6 %, except cognitive impairment in 20–50 %) [407, 408], interstitial lung disease (10 %), distal renal tubular acidosis (5–10 %), glomerulonephritis (1–2 %), autoimmune hepatitis (2–4 %), primary biliary cirrhosis (5–10 %), and polymyositis (1–2 %). Some patients develop extra-nodal, mantle zone, B cell, mucosa-associated lymphoid tissue-type lymphoma or Waldenström's macroglobulinemia [409].

Table 36.10 Revised international classification criteria for Sjögren's syndrome [419]

Criterion	Definition
I. Ocular symptoms	Dry eyes every day for more than 3 months, recurrent sensation of sand or gravel in the eyes, or use of tear substitutes more than three times a day
II. Oral symptoms	Daily feeling of dry mouth for more than 3 months, recurrent or persistently swollen salivary glands as an adult, or use of liquids to aid in swallowing dry food
III. Ocular signs	Abnormal Schirmer's I test (≤5 mm in 5 min) or rose bengal score (≥4 according to van Bijsterveld's scoring system)
IV. Histopathology	Focus score ≥1 in a minor salivary gland biopsy
V. Salivary gland involvement	Positive result in one of the following tests: salivary scintigraphy, parotid sialography, salivary flow (≤1.5 ml in 15 min)
VI. Autoantibodies	Antibodies to Ro (SS-A) or La (SS-B) antigens
Primary Sjögren's syndrome:	(a) Any 4 of 6 items present (including IV or VI); or (b) 3 of 4 objective items present (III, IV, V, VI)
Secondary Sjögren's syndrome:	(a) Another well-defined connective tissue disease (b) Item I or II present plus 2 items from among III, IV, and V
Exclusion criteria:	Past head or neck radiation treatment Hepatitis C infection Human immunodeficiency virus infection Preexisting lymphoma Sarcoidosis Graft-versus-host disease Use of anticholinergic drugs

Vasculitis

Vasculitis develops in 10 % of patients with pSS [400, 403, 404, 410–412]. Nearly all patients with vasculitis have skin manifestations, notably recurrent purpura. Neuropathies occur in 35 % of patients [403, 410, 413, 414]. Other involved organs include the joints, kidneys, GI tract, lungs, and CNS. Vasculitis is associated with ANA, RF, anti-Ro antibodies, hypocomplementemia, and cryoglobulinemia [414, 415].

Evaluation and Diagnostic Criteria

The diagnosis of pSS can be challenging for several reasons. First, the clinical manifestations may be subtle and attributed to normal aging. Second, in patients with more pronounced symptoms, it may be difficult to document objective exocrine gland dysfunction. Finally, other disorders can present with chronic sicca symptoms, including sarcoidosis, IgG4-related disease, chronic graft-versus-host disease, amyloidosis, lymphoma, primary biliary cirrhosis, Vogt-Koyanagi-Harada syndrome, and HCV, HIV, and HTLV-1 infections [383, 385, 416, 417]. An American-European Consensus Group revised the 1993 European classification criteria for pSS in 2002 (Table 36.10) [418, 419]. In addition to sicca symptoms, these criteria require objective evidence of keratoconjunctivitis sicca or xerostomia plus positive histopathology (minor salivary gland biopsy) or serology (SSA or SSB antibodies).

Objective evidence of keratoconjunctivitis sicca can be obtained by the Schirmer's I test or rose bengal dye staining [420–422] (Fig. 36.6), but the new standard for assessing keratoconjunctivitis sicca in SS combines fluorescein staining to grade the cornea with lissamine green staining to grade the conjunctiva [423]. Objective evidence of salivary gland involvement requires abnormal parotid gland sialography, salivary scintigraphy, sialometry (unstimulated salivary flow), or labial salivary gland biopsy [383, 385, 418, 419, 424]. Sialography is not usually performed because of its invasiveness and potential to induce flares of glandular pain and swelling [385, 424]. Unstimulated salivary flow <1.5 ml

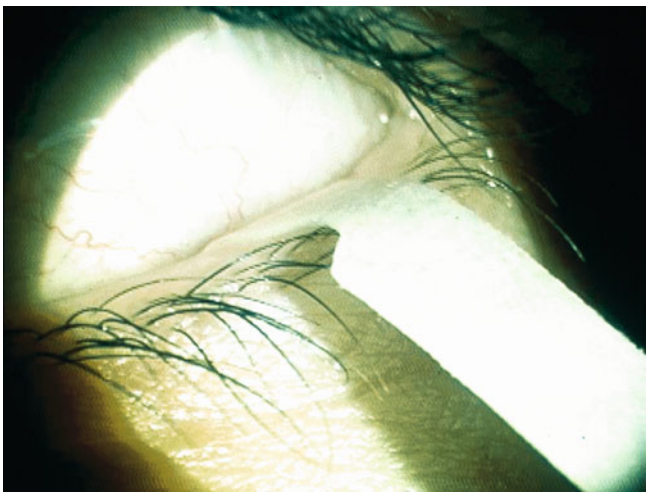

Fig. 36.6 Patient with Sjögren's syndrome undergoing Schirmer's testing. A strip of filter paper has been placed in the lower conjunctival sac. After 5 min, only 3 mm of paper has been moistened by spontaneous tear production (*grayish* paper), compared with a normal value of >5 mm (Photograph courtesy of Dr. Tom Mauger)

in 15 min is abnormal. Salivary gland scintigraphy shows delayed uptake, reduced concentration, and/or reduced excretion of the tracer, but neither the test protocol nor its interpretation is standardized [425]. In a labial salivary gland biopsy, abnormal histopathology is defined by a focus score of ≥1, where the focus score is the number of lymphocytic collections adjacent to normal mucous acini with >50 cells per 4 mm^2 of tissue (Fig. 36.7) [426]. There are several limitations to the assessment, including poor inter-examiner reliability among pathologists [427] and lack of specificity for pSS. Some 10–20 % of specimens from unaffected postmortem subjects and healthy living controls have focus scores ≥1 [428–430], and many patients with CTDs and myasthenia gravis have focal lymphocytic infiltrates [431]. Thus, labial salivary gland biopsies need to be interpreted in light of the patient's clinical picture and pathologist's experience.

The sensitivity of anti-Ro/SSA and anti-La/SSB antibodies is about 60 and 40 %, respectively [400–405]. These antibodies should thus not be used as screening tests. Moreover, they are not specific for pSS and occur in ~35 and 15 % of patients with SLE. Other laboratory abnormalities include elevated ESR in 80–90 % of patients, RFs in 40–60 %, ANAs in 85 %, hypergammaglobulinemia in 50 %, hypocomplementemia in 10–25 %, cytopenias in 15–20 %, cryoglobulinemia in 15–20 % [383–385, 388, 400–405], pANCAs in 6–26 % [432–435], and CCP antibodies in 4–10 % [402, 411, 436]. IgG and IgA antibodies against α-fodrin also occur in patients with pSS [398, 437]. A meta-analysis showed IgG α-fodrin antibodies to have low sensitivity (40 %) but relatively high specificity (82 %) [438]. They might be considered in patients with an appropriate clinical phenotype who are negative for Ro/La antibodies.

Treatment/Prognosis

pSS without extra-glandular manifestations is a relatively benign entity. Treatment is supportive and includes the use of artificial tears, lubricating ointments, cyclosporine ophthalmic emulsion, pilocarpine tablets, cevimeline capsules, punctual plugs, or lacrimal duct cauterization for dry eyes, and meticulous dental care, frequent oral fluids, sugar-free gums and lozenges, artificial saliva, lubricating gels and mouthwashes, maltose lozenges, mucin-containing oral products, pilocarpine, cevimeline, or sorbitol-/xylitol-containing lozenges for dry mouth [383–385, 388]. The secretagogues pilocarpine and cevimeline (an M3 receptor agonist) have both been shown to be effective for dry mouth and eyes in RCTs [439, 440]. Topical cyclosporine has also been evaluated in RCTs with demonstrated efficacy in the treatment of keratoconjunctivitis sicca [441, 442]. Musculoskeletal symptoms are often treated with CS and hydroxychloroquine, but a RCT of hydroxychloroquine showed no significant benefit for myalgias, arthralgias, or fatigue [443]. CS and hydroxychloroquine have no effect on exocrine gland symptoms. RCTs of infliximab and etanercept demonstrated no benefit [444, 445]. A small RCT of rituximab revealed significant improvements in the primary and secondary endpoints, but larger confirmatory studies are ongoing [446]. Patients who develop systemic vasculitis are treated in the same fashion as patients with primary small- and medium-vessel vasculitides.

The long-term prognosis of pSS is good, except for increased risk of lymphoma. Longitudinal studies have revealed salivary and lacrimal function to remain relatively stable [447]. Most patients show no progression or systemic spread after 10 years of follow-up [400]. Mortality rate is not significantly increased compared to that of the general population [448]. Purpura, decreased C4, cryoglobulinemia, persistent parotid gland swelling, splenomegaly, vasculitis, and CD4+ lymphocytopenia are adverse prognostic factors, increasing the risk for multisystem disease and B cell lymphoma [448].

Neuropathies

Neuropathies are more common in pSS than other CTDs due, in part, to the fact that the disorder targets not only exocrine glands but also dorsal root and autonomic ganglia. The reported prevalence of neuropathy in pSS is highly variable, but in prospective studies, mean neuropathy prevalence is ~20 % [407, 449–454]. In ~70 % of patients, neuropathy precedes the diagnosis of pSS by a median of 24 months [246, 455–459]. Almost any pattern of neuropathy can occur in pSS, including a length-dependent sensory or sensory-motor polyneuropathy, ataxic sensory neuronopathy, painful small-fiber-predominant neuropathy, multifocal neuropathy, polyradiculoneuropathy, or cranial neuropathy. Approximately 60 % of neuropathies are predominantly or

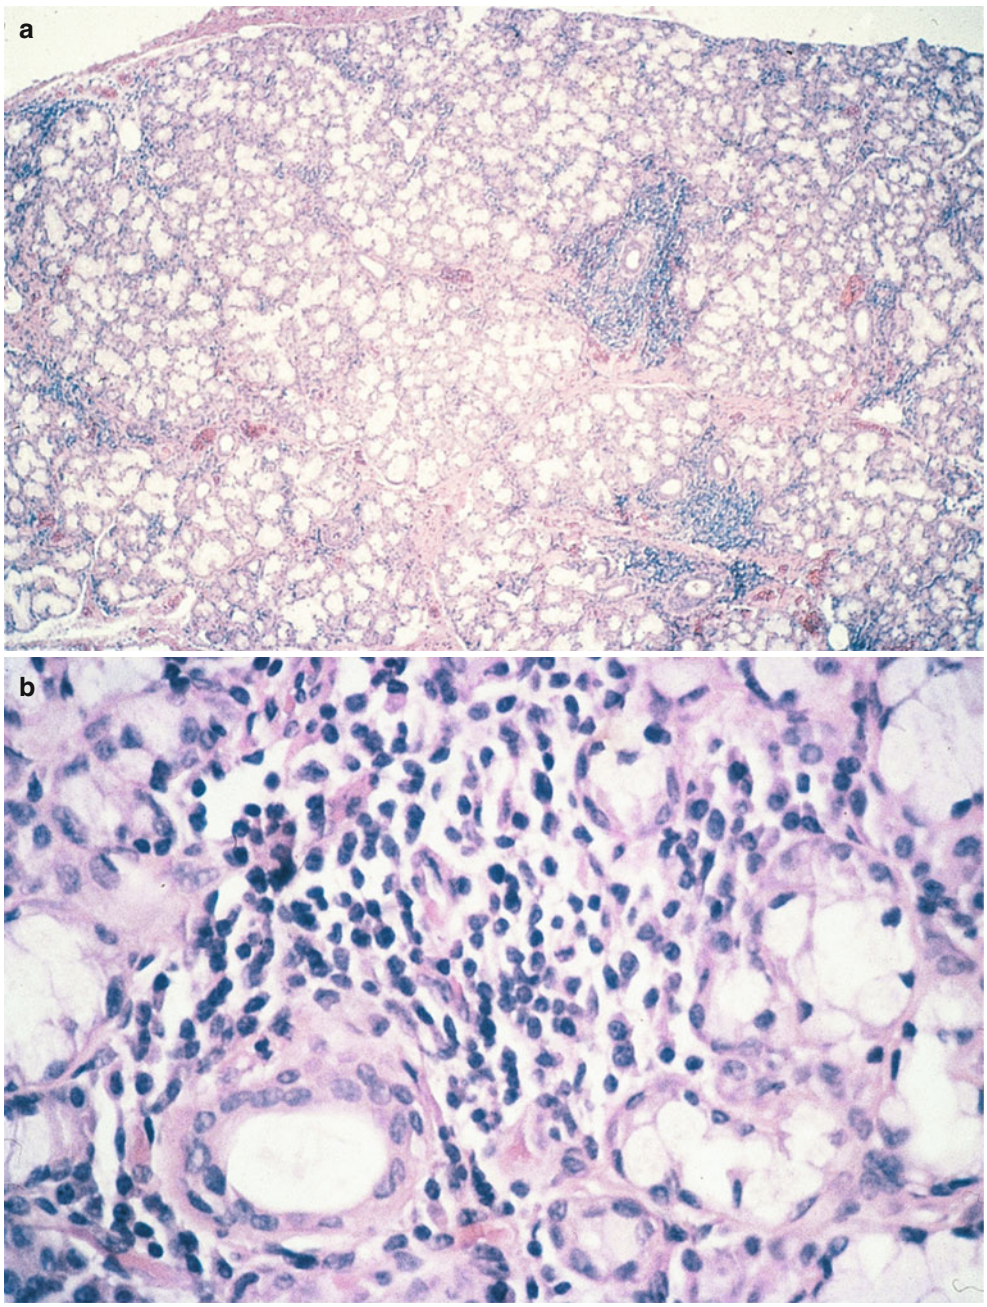

Fig. 36.7 Minor salivary gland biopsy from patient with Sjögren's syndrome. A higher power view (**b**) shows that the cells surround and distort the salivary gland lobules (hematoxylin and eosin) (Photographs courtesy of Dr. Carl M. Allen)

purely sensory, and 40 % are asymmetric [451, 455, 456, 458, 460–464]. In patients with a pSS-related neuropathy, the prevalence of anti-Ro/SSA and anti-La/SSB antibodies is 50–55 and 20 %, respectively [412, 455, 459].

Vasculitic Neuropathy

Most patients with a pSS-related multiple mononeuropathy have PNS vasculitis. Multifocal neuropathies occur in 4 % of patients and constitute 15 % of pSS-associated neuropathies [451, 452, 456, 458–460, 462, 464, 465]. From a different perspective, since systemic vasculitis develops in 10 % of pSS patients, and 1/3 have a neuropathy, it can be inferred that vasculitic neuropathy will occur in 3–4 % of Sjögren's patients. The clinical presentation, electrodiagnostic features, and biopsy findings of vasculitic neuropathy are similar to those in any other vasculitis [459]. Clinical predictors of vasculitic neuropathy are acute-onset (1 month), multifocal pattern, sensory-motor involvement, constitutional symptoms, elevated CRP, RF, decreased complement, and elevated β2-microglobulin [246].

Ataxic Sensory Neuronopathy

Ataxic sensory neuronopathy is a distinctive but uncommon pSS-related neuropathy, occurring in 2–3 % of patients and

accounting for up to 15 % of all neuropathies in the disease [412, 449–451, 456, 458, 462, 463, 466]. The mean age of onset is 56 years [11, 459, 466–469]. The neuronopathy develops before sicca symptoms in 50 % of patients. Patients usually present with chronically progressive numbness and paresthesias in the limbs, trunk, and face in an asymmetric/non-length-dependent pattern, associated with unsteady gait and loss of proprioception in the extremities, resulting in ataxic limb movements. The onset is acute or subacute in 15 % of patients. Only 50 % of patients have pain. Face and truncal regions are affected in 40–45 % each. Examination reveals prominent large-fiber sensory loss, sensory ataxia, pseudoathetosis, diffuse hypo-/areflexia, and milder impairment of small-fiber modalities. Strength is preserved. Autonomic dysfunction occurs in 40–50 % of patients, resulting in tonic pupils, anhidrosis, orthostatic hypotension, facial flushing, and constipation/diarrhea.

Electrodiagnostic studies reveal absent or low-amplitude SNAPs in affected limbs with normal or mildly reduced conduction velocities [11, 459, 466–468, 470]. SNAP abnormalities have non-length-dependent features, such as interside asymmetries, greater upper limb than lower limb involvement, and lower amplitude proximal than distal SNAPs. H reflexes are typically absent. In patients with trigeminal involvement, blink reflexes and masseter cutaneous silent period are usually absent or abnormal, while the masseter reflex is spared, indicative of trigeminal ganglion dysfunction [471, 472]. Motor studies and F waves are preserved. EMG examination is usually normal, but minimal denervation can be seen.

Laboratory findings include positive ANA in 85 %, Ro/SSA antibodies in 55 %, La/SSB antibodies in 15 %, RFs in 40 %, and decreased complement in 20 %. CSF is normal except for mildly to moderately elevated protein in 20 %. Cervical spine MRI shows high signal abnormalities in the dorsal columns in 75 % of patients, reflecting degeneration of the central afferent projections of the dorsal root ganglion neurons [459]. Distal cutaneous nerve biopsies reveal preferential loss of large myelinated nerve fibers, Wallerian-like degeneration, and scant regenerating axonal clusters, consistent with the presumptive cell body source of pathology. While epineurial perivascular inflammation is not uncommon (35 % of biopsies), vasculitis was noted in only one large series, occurring in 20 % of patients [11, 459, 468, 469]. Despite the widely held conviction that this syndrome is caused by dorsal root ganglionitis, the pathologic evidence behind this conclusion is limited [11], and one autopsy study showed the pathologic process to be more diffuse, targeting not only the sensory/sympathetic ganglia but also peripheral nerves, with some vasculitic involvement [459].

Non-ataxic Sensory Neuropathy

The other pSS-associated polyneuropathies are more common but less well characterized. As previously noted, about 60 % of pSS-related neuropathies affect only sensory nerves. Since 15 % of these sensory neuropathies are ataxic sensory neuronopathies, the other 45 % should be non-ataxic small-fiber-predominant sensory disorders, consistent with pooled data from five series [412, 456, 463, 473, 474]. This would thus appear to be the most common pSS-related polyneuropathy.

Patients usually present with distally accentuated pain, numbness, and tingling [459, 463, 473, 475, 476], but many patients also manifest non-length-dependent features [459, 463]. The onset is typically insidious, but acute presentations with total-body pain have been described [459]. Neurologic examination is normal except for impaired pain/thermal sensation, allodynia, and hyperpathia, but in some patients, milder large-fiber sensory loss is demonstrated. Muscle stretch reflexes are preserved. The majority have autonomic signs and symptoms, especially anhidrosis and orthostasis [360].

In patients with small-fiber neuropathies, standard electrodiagnostic testing is normal. A minority of patients have low-amplitude or non-reproducible distal SNAPs, but SNAP abnormalities are not as severe or pervasive as those in the ataxic sensory neuronopathy syndrome. ANAs are often positive, but less than half have anti-Ro/La antibodies [459, 476]. Cervical spine MRIs sometimes reveal increased T2 signal in the dorsal columns [459]. Sural nerve biopsies show predominant small myelinated and unmyelinated fiber loss, Wallerian-like degeneration, essentially no axonal sprouting, no vasculitis, and rare perivascular inflammation [459, 475]. Skin biopsies reveal decreased epidermal nerve fiber density [463, 476]. The pathology of this small-fiber syndrome is unknown, but it probably represents a sensory ganglionopathy predilected for smaller ganglion cells.

Distal Sensory-Motor Polyneuropathy

Distal sensory-motor polyneuropathies constitute about 25 % of pSS-related neuropathies. Patients present with slowly progressive numbness, tingling, and pain in the feet [455, 458, 461, 465, 470, 474]. Sensory deficits typically involve all modalities. Weakness is usually mild, distal, and often restricted to the toes. Ankle jerks are depressed or absent. Autonomic symptoms are uncommon. Electrodiagnostic studies are characteristic of a length-dependent axonal process, with decreased sensory nerve and compound muscle action potential amplitudes in the distal lower limbs, normal or mildly reduced sensory-motor conduction velocities, and distal-predominant active and chronic partial denervation in the needle EMG examination. The mechanisms underlying distal sensory-motor polyneuropathies in pSS are enigmatic, but in patients with subacute or acute progression and asymmetries, PNS vasculitis should be suspected. For patients with symmetric signs and symptoms, some biopsy studies have revealed definite or probable vasculitis [413, 455, 461], while others have not [407, 451, 458, 470].

Other Phenotypes

Polyradiculoneuropathies or polyradiculopathies occur rarely in pSS and are more commonly axonal than demyelinating [452, 456, 458, 459, 474, 477]. There are also rare reports of GBS and acute inflammatory polyradiculopathy [478, 479]. The axonal polyradiculoneuropathies generally produce subacutely or chronically progressive, distally accentuated, large- to small-fiber sensory loss, often accompanied by proximal and distal weakness. Reflexes are depressed or absent, and CSF protein is elevated. MRIs of the lumbar spine can show enhancement of the cauda equina and dorsal roots [459]. Sural nerve biopsies reveal variably decreased myelinated nerve fiber density, mildly increased demyelination/remyelination, no vasculitis, and perivascular inflammation. Pure motor neuronopathies or axonopathies are also rarely described. In patients not responding to immunosuppressive therapy, the development is likely by chance [480–482], but rare patients with ALS, brachial amyotrophic diplegia, or primary lateral sclerosis have improved or stabilized when treated, suggesting that immunopathogenic mechanisms might be operative in some cases [407, 482, 483].

Entrapments

Entrapment neuropathies are uncommon in pSS. Carpal tunnel syndrome occurred in 8 % of patients in 14 studies; ulnar nerve entrapment at the elbow was diagnosed in 5 % in two series [484, 485].

Cranial Neuropathies

Cranial neuropathies occur in approximately 5 % of patients with pSS, with the trigeminal nerve most commonly affected [407, 412, 449, 450, 452, 456, 461, 462, 464, 465, 485, 486]. Patients with trigeminal sensory neuropathies present with subacutely or chronically progressive numbness in the second and third divisions of this nerve; occasionally, all three divisions are affected [461]. Symptoms commence unilaterally but become bilateral in 40 % of patients [459, 461, 487]. Facial pain is uncommon. These neuropathies sometimes develop as part of a more generalized sensory neuronopathy. The pathogenesis is probably lymphocytic infiltration of the trigeminal sensory ganglion. All other cranial nerves are less commonly affected, with predominant seventh or eight nerve involvement. A potentially self-limited, occasionally recurrent, acute or chronic cranial polyneuropathy is rarely encountered [456, 459, 488].

Treatment/Prognosis

Only class IV data is available to inform treatment decisions in patients with pSS-related neuropathies. Patients with mild neuropathy are generally managed with supportive care. Those with proven or suspected vasculitic neuropathy are treated with an immunosuppressive regimen as discussed above. Of all the Sjögren's-related neuropathies, a multifocal vasculitic neuropathy is the only condition that routinely responds to immunosuppression [246, 459]. Uncontrolled data suggests that 80 % of these neuropathies improve with CS monotherapy, CS combined with various immunosuppressive agents, pulse IV CYC, or rituximab [246, 457–459, 461, 489]. The cranial polyneuropathy is also reported to be CS responsive [459, 488, 490], but this syndrome is often self-limited without treatment [491, 492]. No treatment has been shown to be consistently effective in patients with the pSS-related sensory neuropathies, but for the ataxic sensory neuronopathy, favorable responses to CS monotherapy or IVIg have been reported in 15–25 % of patients [459, 493]. Infrequent ataxic patients improve with plasma exchange or immunosuppressive agents such as AZA or CYC. Isolated patients have responded to D-penicillamine [494], interferon-α [495], infliximab [496], and rituximab [497]. Patients with a pSS-related, painful, small-fiber neuropathy do not generally improve with CS [246, 457–459, 476] but may respond to IVIg [493, 498, 499]. There is little data on treatment of the trigeminal sensory neuropathy [459, 461, 493]. Based on limited data, the chronic axonal and demyelinating polyradiculoneuropathies associated with pSS may respond better to IVIg than CS [459].

There is little information on the long-term prognosis of the various pSS-related neuropathies. Most patients with the ataxic sensory neuronopathy and trigeminal sensory neuropathy continue to progress indefinitely, but spontaneous stabilization and improvement occur in a minority of patients [11, 466]. In the non-ataxic painful neuropathy, symptoms persist and slowly spread over time, with evolution of sensory ataxia in less than 20 % of patients [459].

Systemic Lupus Erythematosus

Definition/Epidemiology

SLE is a multisystem disorder characterized clinically by exacerbations and remissions and immunologically by production of multiple autoantibodies, activation of complement, immune complex generation, and altered cellular immunity [500–502]. It is the third most common CTD, with a prevalence of 20–70 cases per 100,000 [503]. The incidence of SLE peaks between 15 and 40 years, but it can develop at any age. Women are preferentially affected. The female/male ratio decreases from 12:1 during childbearing years to 2:1 in children and those older than 45 [504].

Etiology/Pathogenesis

SLE is a disorder in which multiple genetic, environmental, and hormonal influences produce abnormalities of the innate

and adaptive immune systems, resulting in breakdown of B and T cell tolerance to self-antigens normally sequestered in the cell nucleus [502, 505, 506]. Key aberrations include reduced clearance of apoptotic cells by macrophages; persistent exposure of self-antigens (nucleosomal DNA/protein, RNA/protein, and others) in surface blebs of apoptotic cells; activation of myeloid dendritic cells by viral RNA or self-DNA/RNA complexed to adjuvant proteins; activation of autoreactive T helper cells by mature dendritic cells; selection of germinal center B cells with self-reactivity against nuclear antigens exposed in the apoptotic blebs; T cell-dependent affinity maturation and isotype switching of these activated B cells with subsequent production of autoantibodies to epitopes on the nuclear antigens; binding of these anti-DNA antibodies to DNA to form immune complexes that, in turn, activate plasmacytoid dendritic cells to produce INF-α; and deposition of circulating DNA-anti-DNA immune complexes in various tissues with ensuing injury [502, 505–509]. Similar to pSS, the type I IFN system is fundamental in perpetuating autoimmunity in SLE [510]. Another key cytokine is IL-17 [511].

Genome-wide association studies have revealed more than 30 confirmed or candidate genes associated with SLE [512, 513]. The implicated genes have functional roles in antigen presentation, B and T cell signaling, T helper cell regulation, type I INF signaling, TLR-7/9 signaling, immune complex clearance/processing, apoptosis, and DNA methylation. Two environmental risk factors for SLE are well established: exposure to UV light and gender [502, 506]. Viral infections (e.g., EBV) are believed to be another important precipitating environmental factor. The majority of autoantigens in SLE can be grouped into one of three categories: DNA/protein complexes derived from the nucleosome, small nuclear RNPs (snRNPs) derived from the spliceosome, and hYRNA-Ro/La (see pSS) [514, 515]. Double-stranded (ds) DNA antibodies are the pathogenic hallmark of SLE. The primary RNA-associated autoantigens involve the U1 snRNP complex, which contains 8 Smith (Sm) proteins and the U1 snRNP-specific proteins U1-70, U1-A, and U1-C. Anti-Sm antibodies occur infrequently, but they are highly specific for SLE. Other autoantigens include cardiolipins, cell surface molecules (e.g., on erythrocytes, lymphocytes, and platelets), and complement components.

The clinical disease phase of SLE is characterized by autoantibody-mediated tissue injury [505, 506, 514]. Lupus vasculitis is probably mediated by deposition of circulating immune complexes, possibly augmented by AECAs.

Clinical Presentation

The clinical spectrum of SLE is diverse (Table 36.11) [500, 501, 516, 517], and essentially any organ can be affected. The hallmark of the disease is its protean clinical manifestations and fluctuating clinical course. Most patients experience

Table 36.11 Clinical manifestations of systemic lupus erythematosus

Constitutional symptoms (95 %)
Fatigue, weight loss, fever, anorexia
Musculoskeletal symptoms
Arthralgias/myalgias (95 %)
Arthritis (80 %)
Fibromyalgia (20–30 %)
Myositis (5 %)
Osteonecrosis (5–15 %)
Hematologic disorders
Anemia of chronic disease (40–60 %)
Autoimmune hemolytic anemia (5–20 %)
Leukopenia (40–50 %)
Thrombocytopenia (20 %)
Thrombotic thrombocytopenic purpura (rare)
Antiphospholipid antibodies (10–30 %)
Lymphadenopathy (25 %)
Skin lesions (80 %)
Malar butterfly rash (50–55 %)
Subacute cutaneous lupus (10 %)
Alopecia (40 %)
Discoid lupus (20–25 %)
Photosensitivity (70 %)
Oral and nasal ulcers (35–40 %)
Raynaud's phenomenon (30–40 %)
Nervous system complications
Seizures (10–20 %)
Psychosis (5–10 %)
Acute confusional state (rare)
Cognitive impairment (up to 80 %)
Strokes (5–20 %)
Chorea (1–5 %)
Aseptic meningitis (1–5 %)
Myelopathy (<1 %)
Optic neuritis/multiple sclerosis-like (rare)
Neuropathy (15–20 %)
Kidney involvement (50 %)
Mesangial proliferative lupus nephritis (class II)
Focal or diffuse proliferative lupus nephritis (classes III, IV)
Membranous glomerulonephritis (class V)
Sclerotic nephritis (class VI)
Ocular lesions (15–20 %)
Sicca syndrome (10–15 %)
Cotton wool spots
Conjunctivitis, episcleritis
Retinal vasculitis
Pulmonary involvement
Pleuritis (30 %)
Acute lupus pneumonitis (1–5 %)
Interstitial lung disease (5–10 %)
Diffuse alveolar hemorrhage (1–5 %)
Pulmonary artery hypertension (11–43 %)

periods of disease quiescence interrupted by "flares" [518]. Fatigue, fevers, weight loss, anorexia, and nausea are prevalent at onset and during exacerbations. The most common sites of initial involvement are the joints and skin. Almost all patients experience musculoskeletal pain, while 60–80 % develop nonerosive arthritis. Skin manifestations are next most frequent (Fig. 36.8). Other commonly affected organs are the kidneys, blood, CNS, lungs, and heart. Nephritis is one of the most serious manifestations of SLE and a leading cause of death [519]. The most common cardiac lesion is pericarditis, but patients also have a seven- to tenfold increased risk of vascular events because of accelerated atherosclerosis [501]. The leading pulmonary manifestation is pleurisy. Anemia and lymphopenia are common but do not require treatment.

Many CNS and PNS syndromes are associated with SLE. To standardize reporting, an ACR Ad Hoc Committee published case definitions and diagnostic criteria for 19 neuropsychiatric manifestations [520]. Excluding headaches, which occur at a rate similar to the general population [521], the most common CNS manifestations are cognitive dysfunction (75–80 % of patients), psychiatric disturbances, seizures, strokes, chorea, and aseptic meningitis [522, 523].

Vasculitis

Biopsy studies have indicated that vasculitis occurs in approximately 20 % of SLE patients [517, 524–527]. The most commonly affected organ is the skin (80–85 % of patients), followed by the PNS (10–15 %), which suggests that 2–3 % of patients with SLE will develop a vasculitic neuropathy at some time in their life [42, 524, 525]. GI involvement (especially mesenteric vasculitis) is the most prevalent visceral manifestation (5–10 % of patients) [524, 525, 528, 529]. Renal, retinal, and pulmonary vessels are less frequently involved. As compared to SLE without vasculitis, cutaneous vasculitis does not increase mortality, but survival is decreased in visceral SLE vasculitis [524].

Evaluation and Diagnostic Criteria

The differential diagnosis of SLE is broad, especially early in the course of the disease when only a few organs are affected. The ACR classification criteria for SLE are widely applied as a guide to diagnosis (Table 36.12) [530]. These criteria reflect the major clinical and laboratory features of the disease. In patients presenting with isolated nervous system involvement, the diagnosis can be challenging. Positive ANA is detected in greater than 95 % of patients and is thus an ideal screening test, but it is not specific to SLE and can be seen in other autoimmune diseases, drug reactions, infections, and healthy individuals (including 10–35 % of individuals older than 65) [500]. More specific to SLE are antibodies against dsDNA and the Sm antigen. Up to 70 % of patients have dsDNA antibodies, while anti-Sm antibodies occur in 15–20 % [500, 527]. dsDNA antibodies increase and circulating levels of C3 and C4 decrease in patients with active disease, especially glomerulonephritis [501, 531]. Antiphospholipid antibodies are found in about one-third of patients; of these patients, 20–50 % develop thromboembolic events [532]. A clue to the presence of SLE is lymphopenia, which occurs in 50 % of patients [501]. Another characteristic feature is an elevated ESR with a concomitantly normal CRP [533].

Treatment/Prognosis

For SLE, the goals of therapy are to control acute symptoms, prevent exacerbations, and limit systemic spread with resulting end-organ dysfunction. Patients with mild disease are managed with NSAIDs, topical CS for rashes, hydroxychloroquine, and/or low-dose oral CS [500, 501, 534]. Clinically significant cytopenias are treated with CS [535]. Nonrenal manifestations can also be managed with MMF, AZA, or MTX [501]. Glomerulonephritis is typically treated with high-dose CS combined with IV pulses of CYC or oral MMF [501, 536, 537]. Calcineurin inhibitors are an option for patients with resistant lupus nephritis [538]. There are no large RCTs analyzing treatment responses for life-/organ-threatening manifestations other than lupus nephritis, but class IV evidence supports the efficacy of IV CYC/CS for

Table 36.12 Revised criteria for the classification of systemic lupus erythematosus [530]

Criterion	Definition
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by physician
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	(a) Pleuritis – convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion; *or* (b) Pericarditis – documented by ECG or rub or evidence of pericardial effusion
7. Renal disorder	(a) Persistent proteinuria greater than 0.5 g/day or greater than 3+ if quantification not performed; *or* (b) Cellular casts – may be red cell, hemoglobin, granular, tubular, or mixed
8. Neurologic disorder	(a) Seizures – in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance; *or* (b) Psychosis – in the absence of offending drugs or known metabolic derangements; e.g., uremia, ketoacidosis, or electrolyte imbalance
9. Hematologic disorder	(a) Hemolytic anemia – with reticulocytosis; *or* (b) Leukopenia – less than 4,000/mm^3 total on two or more occasions; *or* (c) Lymphopenia – less than 1,500/mm^3 on two or more occasions; *or* (d) Thrombocytopenia – less than 100,000/mm^3 in the absence of offending drugs
10. Immunologic disorder[a]	(a) Anti-DNA: antibody to native DNA in abnormal titer; *or* (b) Anti-Sm: presence of antibody to Sm nuclear antigen; *or* (c) Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
11. Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome

Criteria of *American College of Rheumatology*: four or more criteria mandatory for diagnosis
[a]Modified from Hochberg [682]

alveolar hemorrhage, vasculitis, neurologic disease, severe thrombocytopenia, and severe dermatological manifestations [500]. Rituximab has been used off label in SLE patients for several years but is of questionable efficacy based on two RCTs [539, 540]. Belimumab, a human monoclonal antibody that blocks binding of B cell-activating factor (BAFF) to its B cell receptor, significantly improved the SLE Responder Index at 52 weeks in two RCTs [541–543].

Patients with SLE still have a two- to fivefold increased risk of death compared to the general population, to include significantly increased rates of death from cardiovascular disease, infection, cancers, and kidney disease [544]. Survival rates are about 95 % at 5 years, 91–93 % at 10 years, and 80 % at 15 years [503, 544]. Patients with SLE are at increased risk of developing hematologic (especially non-Hodgkin lymphoma), lung, and hepatobiliary malignancies [545]. Remissions lasting more than 1 year occur at an annualized rate of 28 % and often persist for multiple years [546].

Neuropathies

The reported frequency of neuropathy in SLE is highly variable, but in prospective studies devoted to neuropathy, they occurred in 15–20 % of patients by clinical criteria [28, 408, 522, 523, 547–551] and 30 % when nerve conduction criteria were employed [28, 547–549, 552–557]. Unlike pSS, most SLE-related neuropathies evolve in the setting of established disease. In one study, the mean age of onset of the neuropathy was 45 years, corresponding to a mean SLE disease duration of 8 years [10]. Neuropathies in SLE are associated with SLE disease activity but not SLE-related serologic and clinical manifestations. The most common phenotypes are a distal symmetric or asymmetric sensory-motor polyneuropathy, multifocal/presumably vasculitic neuropathy, and inflammatory demyelinating neuropathy. Electrodiagnostic studies usually reveal evidence of a predominantly axonal, sensory-motor, distal-predominant process, but 20 % of neuropathies were demyelinating in one series [10, 549, 556, 557]. Skin biopsy may reveal significantly decreased intraepidermal nerve fiber density in the leg [548, 549]. Most of these patients had no symptoms or nerve conduction abnormalities.

Vasculitic Neuropathy

Approximately 15 % of SLE-related PNS disorders are discrete or overlapping multifocal neuropathies, characteristic of vasculitis [10, 408, 522, 547, 550, 551, 557]. Given the 15–20 % incidence of SLE-related neuropathies, some 2–3 % of patients are predicted to develop a vasculitic neuropathy. In SLE patients with pathologically proven or suspected vasculitic neuropathy, 75–80 % have an asymmetric or multifocal neuropathy [42, 47, 210, 524, 558–560]; 10–15 % a symmetric sensory-motor polyneuropathy [560–562]; 5–10 % an acute, GBS-like disorder [563]; and 2 % a lumbosacral polyradiculopathy [564]. Electrodiagnostic studies reveal asymmetric, predominantly axonal, sensory-motor changes. Nerve biopsy reveals changes typical of necrotizing vasculitis.

Distal Sensory-Motor Polyneuropathy

A more common phenotype is that of a distally accentuated, axonal, sensory-motor polyneuropathy, a pattern that accounts for 75–80 % of SLE-related neuropathies. The initial symptoms are usually distal tingling, numbness, and pain that spread proximally over weeks to months [552, 560, 565, 566]. In 1/3 of patients, mild to severe distal weakness also emerges [10]. About 40 % are asymmetric [10]. The signs and symptoms usually progress slowly over years [567]. Electrodiagnostic studies demonstrate predominantly axonal features, with reduced or absent SNAPs and normal or mildly reduced motor conduction velocities and amplitudes [28, 552, 556, 560]. Needle EMG examination reveals chronic partial denervation in distal muscles with only rare fibrillation potentials [552]. Nerve biopsy should be considered when vasculitis is suspected because of an asymmetric onset, stepwise clinical course, acute/subacute progression, or greater-than-expected motor involvement. Only a few nerve biopsies have been reported in patients with SLE and a distal symmetric polyneuropathy. These biopsies revealed mild vasculitis or changes suspicious for a vasculitic neuropathy, but this data is insufficient to generalize to others with this phenotype [560, 566].

Inflammatory Demyelinating Polyradiculoneuropathies

Inflammatory demyelinating neuropathies are another PNS manifestation of SLE. Many case reports have documented the occurrence of chronic progressive or relapsing demyelinating neuropathies reminiscent of CIDP [568–573]. If the number of published reports is an indication, CIDP occurs more commonly in SLE than any other CTD, with approximately half of the cases developing concurrently with SLE [569, 570, 572, 573]. The clinical and electrodiagnostic picture is indistinguishable from idiopathic CIDP. Although GBS is now one of the reportable SLE-related neuropsychiatric syndromes, reported GBS frequencies range from 0 % (multiple studies) to 5 %, suggesting that an acute demyelinating polyradiculoneuropathy is *not* a pathogenically related SLE syndrome. Since lupus patients exhibit multiple autoantibodies, it is appealing to postulate that "anti-nerve" autoantibodies might initiate the neuropathy in some patients, but no study has established a clear relationship between any autoantibody and inflammatory demyelinating neuropathies in SLE.

Entrapments

There is sparse information on the prevalence of entrapment neuropathies in SLE due, in part, to the fact that "mononeuropathy or mononeuropathy multiplex" is an ACR neuropsychiatric syndrome but not carpal tunnel syndrome or any other nerve entrapment. Several prospective clinical and electrodiagnostic investigations have revealed signs, symptoms, and/or nerve conduction evidence of carpal tunnel syndrome in 10 % of SLE patients [523, 547, 552, 554].

Cranial Neuropathies

Cranial neuropathy develops in ~3 % of SLE patients (data from 19 series). The most commonly affected nerves are the optic and cochlear. Optic neuropathies occur in about 1 % of patients and are often bilateral [574–576]. In case–control studies, sensorineural hearing loss has been identified with increased frequency in patients with SLE (16–21 %) compared to healthy controls [577, 578]. There are many reports of isolated cochlear, abducens, or vagal neuropathies (especially recurrent laryngeal nerve palsies) and less frequent cases of trigeminal sensory, oculomotor, and facial neuropathies [579–584]. The presumed mechanism is vasculitis-related ischemia, but optic neuritis can also ensue from CNS demyelination.

Other Phenotypes

There are rare reports of SLE-associated acute or chronic sensory ataxic neuronopathy [585, 586], neuromyotonia [587], bilateral phrenic nerve palsies [588], and motor neuron disease [589].

Treatment/Prognosis

Treatment of PNS involvement in lupus is tailored to the pathogenesis, severity, and tempo of the neuropathy. No controlled trials have been performed. Vasculitic neuropathies are usually managed with combination therapy [558, 561, 590]. Whereas prednisone monotherapy has been ineffective in the majority of reported cases of SLE-related vasculitic neuropathy [559, 560, 563, 564], CYC or CYC/CS produced complete or partial remission in almost all reported patients. Inflammatory demyelinating neuropathies are managed identically to the idiopathic cases. Acute cranial mononeuropathies are generally treated with CS. Symptoms usually improve or resolve, but recovery is more unpredictable for optic neuropathies, recurrent laryngeal nerve palsies, and sudden hearing loss [584]. Some patients with acute deafness have responded to plasma exchange [584]. For SLE-related optic neuropathies, treatment with IV methylprednisolone followed by high-dose prednisone is recommended [576].

Treatment decisions are most difficult for patients with the common distal symmetric polyneuropathy. Patients with this pattern of neuropathy who exhibit acute or subacute progression and nerve biopsy evidence of definite or probable vasculitis should be treated akin to the primary small- and medium-vessel systemic vasculitides. For patients who undergo nerve biopsy with a finding of nonspecific perivascular inflammation, a trial of high-dose CS alone is an acceptable but unproven option. Most patients with SLE who develop an indolent or nonprogressive distal polyneuropathy are treated symptomatically without undergoing nerve biopsy.

Systemic Sclerosis

Definition/Epidemiology

SSc (or scleroderma) is a complex disorder of unknown etiology characterized by alterations of the microvasculature, disturbances of the humoral and cellular immune system, and massive proliferation of collagen and extracellular matrix proteins, resulting in fibrosis of the skin, visceral organs, or both [591–593]. Scleroderma is classified as *localized* if restricted to the skin and *systemic* if other organs are affected [594]. The localized forms are rarely associated with neuropathy and will not be further discussed. SSc is, in turn, subdivided into *limited* and *diffuse cutaneous* forms [595]. Limited cutaneous SSc is defined by skin involvement that does not extend proximal to the knees or elbows. If both proximal and distal limbs and the trunk are affected, the disorder is termed diffuse cutaneous SSc. Facial involvement occurs in both types. Many patients with limited cutaneous SSc fulfill diagnostic criteria for CREST syndrome (*c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasia) [596], but these findings may also occur in diffuse cutaneous SSc. The prevalence of SSc generally ranges from 50 to 300 cases per 1,000,000 and its annual incidence from 2 to 23 cases/million, excepting geographical/ethnic clusters [597, 598]. It affects all ages but is uncommon in children. The peak age of onset is the fifth decade. Women are three times more commonly affected than men [597].

Etiology/Pathogenesis

The etiology of SSc is unknown [592]. Environmental risk factors include CMV and parvovirus B19 infections and exposure to silica, polyvinyl chloride, epoxy resins, toluene, and trichloroethylene [591, 598]. As in the other CTDs, multiple weakly contributing genetic susceptibility loci are involved 603]. Most of the associated genes play a role in innate or adaptive immunity. Genetic factors may underlie not only disease susceptibility but also the predisposition to develop specific clinical phenotypes and specific SSc-associated autoantibodies. For example, the associated HLA genes primarily influence anti-centromere or anti-topoisomerase I antibody production, not the disease itself [591, 599].

The three cardinal pathogenic features are microangiopathy, cellular and humoral autoimmunity, and progressive visceral and vascular fibrosis [591, 600, 601]. The earliest pathologic change is damage to small arteries and microvessels in the skin and viscera. Endothelial injury results in dysregulated production of vasodilatory and vasoconstrictive factors, increased expression of adhesion molecules, enhanced permeability, activation of prothrombotic and fibrinolytic pathways, and proliferation/fibrosis of all layers of the vessel wall, resulting in widespread capillary loss and obliterative vasculopathy. Despite the diffuse microvascular loss, compensatory vasculogenesis is dysregulated and does not occur [602]. Skin biopsies in early stages of the illness show infiltration of CD4+ T cells and macrophages, suggesting that SSc may result from a primary immune microvasculopathy [591, 600, 601]. The activated CD4+ cells secrete Th2 and other pro-fibrotic cytokines [603]. B cells are also activated in lesional tissues, signified by the presence of multiple autoantibodies, polyclonal hypergammaglobulinemia, cryoglobulinemia, and increased RFs [591, 600, 604]. Autoantibodies directed against cell surface antigens and secreted proteins may play a pathogenic role in the disease, e.g., antibodies against fibroblasts (stimulatory), endothelial cells, PDGF receptor (stimulate fibroblasts), fibrillin-1 (activate fibroblasts), MMP-1,3 (inhibitory), and Nag-2 (induce endothelial cell apoptosis and activate fibroblasts) [603, 604].

Other antibodies are directed against ubiquitous autoantigens with no established pathogenic role [515, 592, 605]. Several mutually exclusive autoantibodies are specific markers of SSc and have strong associations with disease phenotype and HLA haplotypes. Examples include antibodies against Scl-70 or topoisomerase I (associated with diffuse cutaneous SSc, interstitial lung disease, severe cardiac involvement, increased mortality), centromere proteins CENP-A through F (limited cutaneous SSc, digital ischemia, isolated pulmonary arterial hypertension, calcinosis, decreased risk of death and pulmonary fibrosis), RNA polymerases I and III (diffuse cutaneous SSc, extensive skin involvement, renal crisis, increased mortality), U3 RNP/fibrillarin (diffuse cutaneous SSC, pulmonary arterial hypertension, interstitial lung disease, renal crisis, severe heart disease, myositis), and Th/T0 (limited cutaneous SSc, pulmonary fibrosis, pulmonary arterial hypertension, renal crisis) [515, 592, 605].

Fibrosis is triggered by and eventually replaces the inflammatory vascular phase [601, 603, 606, 607]. The primary mediator of fibrosis is deregulated TGF-β. It stimulates fibroblast proliferation, migration, differentiation, and production of collagen and matrix proteins. It also enhances PDGF and connective tissue growth factor (CTGF) production from fibroblasts, vascular smooth muscle cells, and endothelial cells. Activated by TGF-β, CTGF, PDGF, Th2 cytokines, IL-1/IL-6, stimulating autoantibodies, chemokines, tissue hypoxia, endothelin-1, and reactive oxygen species, fibroblasts then proliferate and secrete increased collagen, fibronectin, and other extracellular matrix proteins. The net result is an obliterative vasculopathy with dense fibrosis replacing the normal tissue architecture [606].

Clinical Presentation

Patients with SSc present with a sensation of tightness in the fingers associated with soft tissue swelling, pruritus, and hyperpigmentation [591–593, 608–611]. Joint pains, reduced range of motion, and a nonerosive inflammatory arthritis

(15 % of patients) are common accompaniments [612]. Onset is usually indolent in limited cutaneous SSc and more rapidly progressive in diffuse cutaneous SSc. In the ensuing weeks to years, the inflammatory edematous stage is superceded by a fibrotic phase, characterized by bilaterally symmetric skin thickening, hair loss, xerosis, hypohidrosis, and finger flexion contractures (Fig. 36.9). In diffuse cutaneous cases, similar skin changes and joint contractures emerge in the proximal limb. The affected skin eventually becomes atrophic and may ulcerate, especially on the dorsal PIP joints, fingertips, elbows, and malleoli. In the limited cutaneous form of the disorder, small areas of fingertip necrosis are common and autoamputation or acro-osteolysis may ensue. Telangiectasias and calcinosis also occur in the limited cutaneous form of the disease. In one-third of cases, the face is involved, resulting in a tight, shiny, featureless, masklike appearance (Fig. 36.10). Raynaud's phenomenon occurs in virtually every patient (>95 %). Patients with limited cutaneous SSc generally have severe Raynaud's for many years before the other clinical manifestations appear. In the diffuse cutaneous variant, Raynaud's usually appears coincident with the skin disease.

Virtually every organ is affected in SSc. Diffuse cutaneous SSc is associated with earlier and more prominent internal organ involvement than limited cutaneous SSc. The GI tract is affected in 80–90 % of patients, causing esophageal dysfunction (dysphagia, GERD), gastroparesis, gastric antral vascular ectasia with recurrent GI bleeding, lower GI bleeding from telangiectasia, fecal incontinence, and intestinal hypomotility with secondary bacterial overgrowth, malabsorption, vitamin B12 and D deficiency, pseudo-obstruction, constipation, diarrhea, and diverticular perforation [613]. Oral mucosal involvement produces xerostomia, dental caries, and periodontal disease. Myositis develops in 10–20 % of patients, but pathologic confirmation is often lacking. Up to 25 % develop hypothyroidism [593].

Serious pulmonary, renal, and cardiac manifestations may also occur. Pulmonary disease is the leading cause of death [614]. The two main types of pulmonary involvement are fibrosis-related interstitial lung disease and pulmonary arterial hypertension. Fibrosis is more common in diffuse cutaneous SSc. Interstitial lung disease occurs in 80–90 % of patients, but only 40 % develop symptoms. Pulmonary arterial hypertension emerges in about 10 %. Renal involvement develops in ~20 % of patients and predisposes to hypertension and proteinuria [615]. Scleroderma renal crisis, resulting from obliterative microvasculopathy of the kidneys, occurs in 10–15 % of patients with diffuse cutaneous SSc, manifesting with malignant hypertension and acute renal failure. Risk factors include extensive skin involvement, exposure to CS, and RNA polymerase I/III antibodies. Clinically important cardiac disease develops in 10 % of patients, with atrial and ventricular tachycardia, heart block, other cardiac conduction defects, pericarditis, myocarditis, valvular incompetence, and congestive failure [616].

Fig. 36.9 This is a 32-year-old man with systemic sclerosis whose hands exhibit the characteristic skin changes of the disease, including hyperpigmentation, sclerodactyly, atrophy, and calcinosis, with secondary finger flexion contractures

Vasculitis

Vasculitis occurs uncommonly in SSc (1–7 % of patients in clinical reports and 9 % in one autopsy series) [608, 617–619]. MPO/PR3-ANCAs appear to be markers of systemic vasculitis in this disorder [620–622]. MPO or PR3-ANCAs occur in about 5 % of patients with SSc [623, 624]. Mean age of onset is 57 years. Patients with diffuse cutaneous SSc are more commonly affected than those with limited cutaneous SSc. Scl-70 antibodies occur in 70–75 % of patients. Most of the ANCAs target MPO. The most common clinical feature is rapidly progressive glomerulonephritis in 85 % of patients. Other manifestations include GI involvement (55–60 %), fever (40 %), alveolar hemorrhage (25 %), limb ischemia (10–15 %), skin vasculitis (10–15 %), and neuropathy (5 %) [625–628]. The most important differential diagnosis is

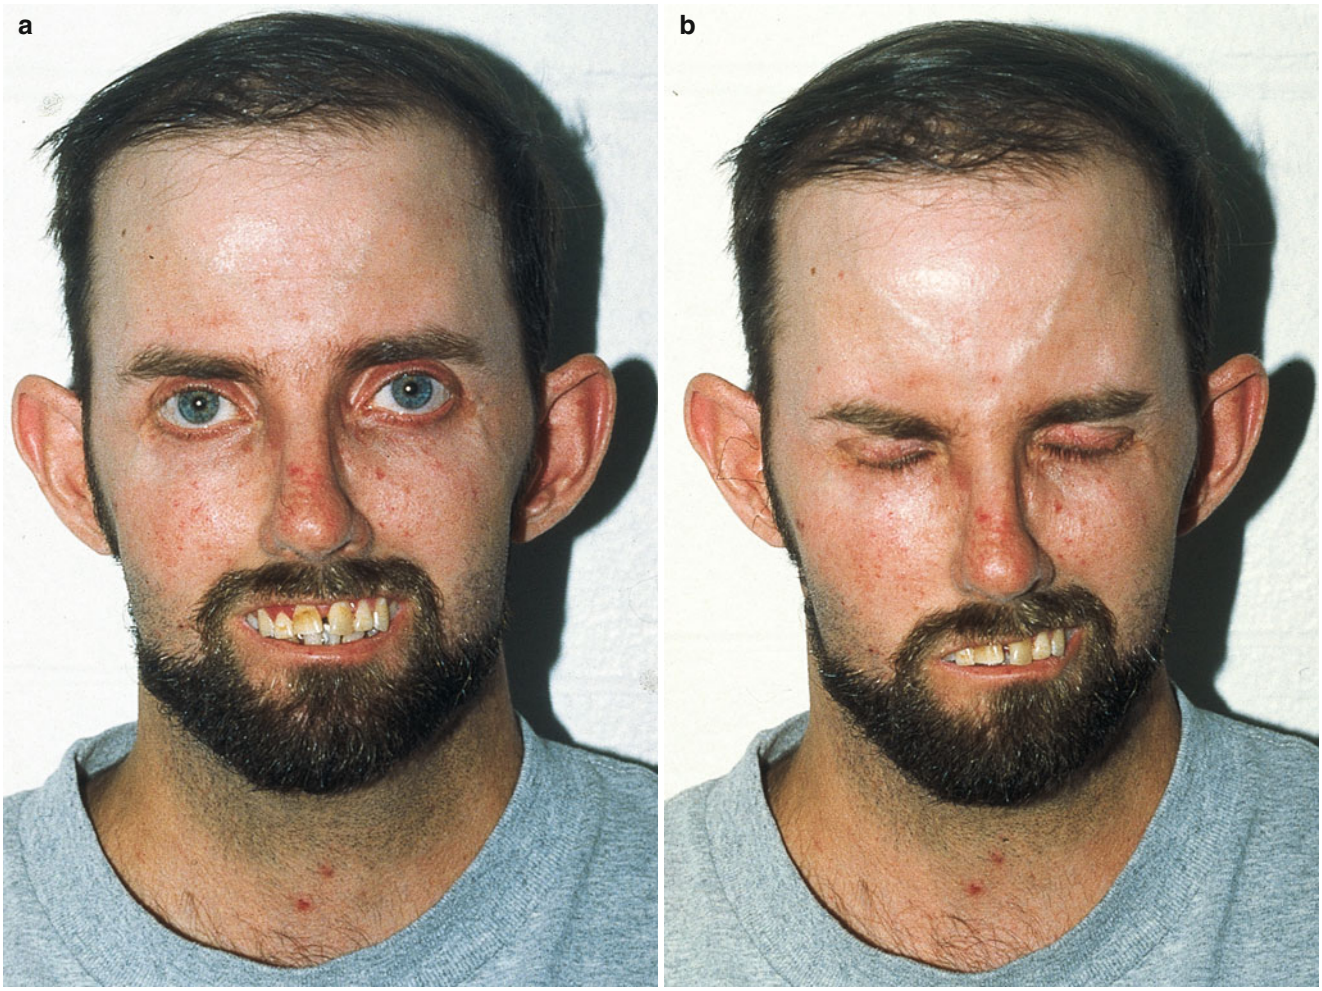

Fig. 36.10 These facial views of the same patient shown in Fig. 36.11 demonstrate the tight, drawn, masklike appearance typical of severe systemic sclerosis (**a**). This patient developed a right facial nerve palsy (**b**), which had partially resolved when this picture was taken

scleroderma renal crisis. In SSc patients with rapidly progressive renal failure, factors suggesting vasculitis are normotension, fever, elevated ESR, active urinary sediment, normocytic nonhemolytic anemia, alveolar hemorrhage, MPO-pANCAs, Scl-70 antibodies, and renal biopsy evidence of necrotizing, crescentic glomerulonephritis with small-vessel vasculitis.

Evaluation and Diagnostic Criteria

The clinical picture of SSc is sufficiently distinctive that the diagnosis is usually straightforward. In patients with mild disease, the differential diagnosis includes other CTDs that can be associated with Raynaud's phenomenon, environmental exposures that can cause scleroderma-like illnesses, and other scleroderma-like skin diseases such as scleredema, diabetic scleredema, scleromyxedema, stiff skin syndrome, chronic graft-versus-host disease, eosinophilic fasciitis, eosinophilia-myalgia syndrome, POEMS syndrome, nephrogenic systemic fibrosis, paraneoplastic sclerodermiform syndrome, amyloidosis, sarcoidosis, myxedema, and acromegaly [591, 593]. The ACR diagnostic criteria require either the one major criterion – proximal scleroderma (skin tightness, thickening, and non-pitting induration proximal to the MCP or MTP joints in the extremities or involving the face, neck, or trunk) – or two or more of the three minor criteria: (1) sclerodactyly, (2) digital pitting scars of fingertips or loss of substance of distal finger pad, or (3) bibasilar pulmonary fibrosis [629].

ANAs occur in 90–95 % patients [591, 593, 608, 611, 612]. Two mutually exclusive autoantibodies – anti-centromere and anti-topoisomerase I (Scl-70) – are highly specific (99 %) for SSc. Anti-topoisomerase I antibodies are found in 30–40 % of all patients with the disorder, 40–55 % of those with diffuse cutaneous SSc, and 15–25 % of those with limited cutaneous disease [605, 608, 611, 612, 630]. Anti-centromere antibodies are found in 30 % of all patients with SSc, 45–50 % of those with limited cutaneous disease, and only 5 % of those with the diffuse cutaneous subtype. Antinuclear antibodies directed against RNA polymerase III (5–20 % incidence) and Th/T0 (2–5 % incidence) are also highly specific for SSc [591, 605, 631]. In contrast to most

Fig. 36.11 This patient with known CREST syndrome (limited cutaneous systemic sclerosis) presented with distal sensory loss and slight weakness of left ankle dorsiflexion (**a**). She had characteristic small telangiectasias over her face (**b**)

CTDs, ESR is usually normal (mildly elevated in 25 % of patients) [592, 608]. Low-titer RFs occur in 25 % of patients [593, 608]. A mild anemia due to chronic inflammation is uncommonly present [593]. Chronic GI bleeding may result in iron-deficiency anemia, while macrocytic anemia can emerge with B12 or folate deficiency. Microangiopathic hemolytic anemia is a signature of renal crisis. Other cytopenias are uncommon.

Treatment/Prognosis

Treatment is generally symptomatic [591, 592, 632, 633]. Although no intervention has been proven to modify the natural history of the disease, autologous hematopoietic stem cell transplantation has emerged as a possible treatment for severe SSc [634]. In a 1-year RCT of oral CYC versus placebo for SSc-related interstitial lung disease, CYC was associated with modest but significant improvements in lung function, dyspnea, skin scores, and quality of life [635], but apart from a sustained impact on dyspnea, all of these effects were no longer apparent at 24 months [636, 637]. CS can be used for inflammatory joint symptoms, early edematous skin disease, serositis, myositis, and tenosynovitis, but they do not influence the progression of the disease [591]. Because high-dose CS increase the risk of renal crisis, CS should only be used in low doses for short periods of time. Other immunomodulatory agents have not been adequately studied, but MTX is sometimes used for skin involvement [633, 638]. Arthralgias can be treated with NSAIDs. There is no established anti-fibrotic treatment. Patients with Raynaud's phenomenon respond to calcium channel blockers, 5-phosphodiestease inhibitors, angiotensin II receptor antagonists, alpha$_1$-receptor blockers, serotonin reuptake inhibitors, topical nitroglycerin, and botulinum toxin A [639]. For digital ischemic ulcers, the endothelin-1 receptor antagonist bosentan reduces new ulcer development [640]. Short-acting ACE inhibitors are the drugs of choice for renal crisis. Proton pump inhibitors are used for reflux. Promotility agents can be tried for gastroparesis. Bacterial overgrowth responds to short courses of rotating antibiotics. Options for pulmonary artery hypertension include bosentan, sildenafil, and the prostacyclin analogues epoprostenol or treprostinil [641].

In patients with established disease, prognosis depends on the severity and extent of the cutaneous and visceral involvement [592, 593]. Patients with limited cutaneous disease and anti-centromere antibodies have a more favorable prognosis, characterized by indolent progression, less common visceral involvement, and 10-year survival of 75 % [609]. On the other hand, their skin manifestations do not usually regress, and progressive pulmonary artery hypertension can emerge late in the clinical course (10–15 %). In contrast, patients with diffuse cutaneous SSc and anti-Scl-70 antibodies exhibit

more rapid progression, increased internal organ involvement, and 10-year survival of only 55 % [609]. In patients with this form of the disease, cutaneous fibrosis usually plateaus after 2–4 years. Paradoxically, skin thickening then slowly regresses, to the extent that patients with late-stage disease often have soft and atrophic skin. Internal organ involvement almost always evolves in the first 4 years of the illness. Age- and gender-adjusted standardized mortality rates (SMRs) are two to five times higher than the general population [642]. Survival has improved in recent decades, but the SMR has not significantly changed [642, 643]. Death usually results from pulmonary causes. Patients with SSc are also at mildly increased of developing a malignancy, most commonly a lung or breast cancer [644].

Neuropathies

Traditionally, PNS involvement has been considered rare in SSc [608–610, 645]. However, in neurologically focused studies, clinical or electrodiagnostic examination evidence of a polyneuropathy has been demonstrated in 15–20 % of patients [646–648]. Skin biopsy studies suggest a much higher incidence of subclinical neuropathy, especially in the later stages of the illness [649, 650].

Vasculitic Neuropathy

Vasculitic neuropathy occurs in ~5 % of cases of ANCA-associated vasculitis/SSc overlap. The incidence of vasculitic neuropathy in all SSc patients is under 1 % [618, 651, 652]. Of reported patients with SSc and vasculitic neuropathy, 80 % had CREST syndrome or limited cutaneous SSc (Fig. 36.11) [618, 625–628, 651–656]. An asymmetric/multifocal, distally accentuated, sensory-motor neuropathy is almost always observed.

Distal Sensory-Motor or Sensory Polyneuropathy

Sensory-motor and sensory polyneuropathies in SSc often begin asymmetrically, but more than 50 % evolve into a distal, symmetric pattern [646–648, 651, 652, 657–661]. These neuropathies can be either motor or sensory predominant [660, 661]. Electrodiagnostic studies typically demonstrate axonal features. Although the asymmetric onset in many patients suggests vasculitis, there are few nerve biopsy-proven cases of vasculitis [618, 626, 652–654, 656]. In non-vasculitic cases, nerve biopsies have revealed myelinated nerve fiber loss and axonal atrophy; endoneurial, perineurial, and epineurial fibrosis; and endoneurial microangiopathy [659, 660, 662]. In these patients, the neuropathy may have resulted from a chronic noninflammatory vasculopathy or endoneurial connective tissue proliferation.

Other Phenotypes

Isolated reports have described SSc patients with a slowly progressive ataxic sensory neuronopathy [663]; progressive, painful, asymmetric/non-length-dependent, sensory axonal neuropathy or neuronopathy with mixed or small-predominant involvement [661, 664]; acute or chronic progressive brachial plexopathy [648, 665, 666]; or distal acquired demyelinating symmetric (DADS) neuropathy with anti-myelin-associated glycoprotein antibodies [667].

Entrapments

Somewhat surprisingly, symptomatic carpal tunnel syndrome has been reported in only 5 % of patients with SSc [647, 658, 668, 669], but prospective nerve conduction studies have revealed asymptomatic carpal tunnel syndrome in 10 % [646, 650, 670, 671]. Pressure palsies of other nerves are more rarely reported, to include ulnar mononeuropathies at the wrist and elbow, meralgia paresthetica, and median nerve entrapment in the forearm caused by thickened fascia [670–674].

Cranial Neuropathies

Trigeminal sensory mononeuropathy is the most common cranial neuropathy in SSc, affecting 3 % of patients [646–648, 656, 657, 669, 675–677]. Its features are identical to the trigeminal sensory neuropathy associated with pSS and SLE. It occurs bilaterally but asymmetrically in 60 % of cases. In a minority of patients, trigeminal sensory mononeuropathy is but one manifestation of a more widespread, multifocal sensory neuropathy or neuronopathy [661, 676]. It can be accompanied by facial nerve involvement [676]. This disorder is assumed but not proven to result from an inflammatory ganglionitis of the trigeminal sensory ganglia. There are also rare reports of optic, trochlear, and recurrent laryngeal mononeuropathies [678–680]. Audiovestibular involvement is reported more commonly [681].

Treatment/Prognosis

No treatment has been shown to consistently improve the sensory-motor polyneuropathy or trigeminal sensory neuropathy in these patients. Entrapment neuropathies can be managed with NSAIDs, splinting, or surgical release. Patients with vasculitic neuropathy can be treated with the combination regimen discussed above. Patients with asymmetric sensory neuropathies or neuronopathies and brachial plexopathies sometimes respond to IVIg, CS and CYC, or CS alone [663–666].

Conclusion

Neuropathy in the setting of a CTD usually occurs in patients with a previously diagnosed condition. In these patients, the neurologist's primary goal is to determine whether the neuropathy is due to immunologic injury or some other process, such as entrapment or medication effect. Less commonly, neuropathy is the predominant or presenting feature in a patient with no known CTD. In these cases, the clinician must integrate the neurologic findings with other clinical and laboratory data to

formulate a diagnosis that explains all the patient's manifestations and can be confirmed through further testing or biopsy. A fundamental goal must always be to determine if vasculitis is the cause of the neuropathy; as such, a diagnosis has a profound effect on therapy.

Compartment Syndromes

Introduction

Although various subgroups of what are now designated compartment syndromes (CSs) were first well described during the latter half of the nineteenth century, apparently the term was not used until 1963. Moreover, it was only in the 1960s and 1970s that modern concepts regarding these disorders evolved, when it became apparent that a considerable number of what had appeared to be diverse clinical entities actually were merely different manifestations of a common underlying pathophysiology [1–4].

A CS can be "… defined as a condition in which the circulation and function of tissues within a closed space are compromised by increased pressure within that space" [5]. Characteristically, the structures at risk are muscles, usually accompanied by major peripheral nerves, which are injured when their blood supply (i.e., their capillary perfusion) is reduced below a level required for tissue viability [6–9].

Established CSs generally have four components: (1) a closed space formed by a limiting envelope, which may consist of fascia alone, fascia and bone, epimysium, skin, or various external boundaries (e.g., circumferential bandages); (2) pressure elevation within that space due to an increase either in its volume or contents, usually resulting from fluid accumulation (e.g., interstitial or intracellular fluid) or a restriction of its size; (3) reduced perfusion of the muscles and nerves within the compartment because their microcirculation is compromised by the elevated pressure; and (4) progressive ischemic damage of the intracompartmental structures if the pressure is not reduced rather promptly. Noteworthy is that normal compartment pressures typically range from 0 to 8 mm Hg. Consequently, most injurious elevated pressures usually are much less than mean arterial pressure at approximately 100 mm Hg [4, 6, 10–12].

Approximately 50 different compartments have been described in humans, and all can be sites of CSs (Table 37.1). However, only a relatively few of these are of significance to physicians in other than a few surgical specialties, because only they compromise major muscles or neural structures or occur with any appreciable frequency [4].

Relatively few of the compartments contain solely nerve fibers (i.e., no muscles) [4, 8, 9, 13]. The CSs involving these have been designated "neurovascular injuries" or "hemorrhagic compressive neuropathies." "Acute carpal tunnel syndrome" often refers to abrupt median nerve compression within the carpal tunnel [14–16]. However, this term is highly inaccurate and misleading, since neither the clinical nor the electrodiagnostic (EDX) features seen with it are similar to the classic presentation of carpal tunnel syndrome (CTS) (i.e., chronic compression of the median nerve beneath the transverse carpal ligament) [17].

The CSs are divided into two general types: (1) acute and (2) chronic, the former has by far the most serious potential medical consequences [18–20].

Acute CSs (ACSs) result from a number of traumatic and nontraumatic conditions. Their pathophysiology is rather well established, and typically, they require prompt treatment to prevent irreparable damage, principally to muscles, nerves, and sometimes even limbs. They are one of the few "surgical emergencies" in the field of neuromuscular disorders; hence, they fall primarily in the realm of emergency,

Table 37.1 Elements of seven of the major compartments

Compartment	Boundaries	Structures Compromised
Forearm volar	Antebrachial fascia, ulna, radius, interosseous membrane	*Muscles*: flexor carpi ulnaris, palmaris longus, flexor carpi radialis, pronator teres (superficial group), flexor digitorum superficialis, flexor digitorum profundus, flexor pollicis longus, pronator quadratus (deep group) *Nerves*: median, ulnar, anterior interosseous
Medial brachial fascial	Medial brachial fascia	*Muscles*: none *Nerve*: components of infraclavicular brachial plexus, especially median
Anterior of leg	Crural fascia, anterior intermuscular septum, fibula, tibia, interosseous membrane	*Muscles*: tibialis anterior, extensor digitorum longus, extensor hallucis longus, peroneus tertius *Nerve*: deep fibular (peroneal)
Deep posterior of leg	Transverse intermuscular septum, fibula, tibia, interosseous membrane	*Muscles*: tibialis posterior, flexor digitorum longus, flexor hallucis longus *Nerve*: posterior tibial
Psoas	Psoas major epimysium, psoas fascia	*Muscle*: psoas major *Nerve*: lumbar plexus
Iliacus	Psoas major, psoas minor, iliacus fascia	*Muscle*: iliacus *Nerve*: femoral[a]
Gluteal (3 separate compartments)	Fascia lata	*Muscles*: gluteus maximus, gluteus medius and minimus, tensor fascia lata *Nerves*: sciatic,[a] inferior gluteal, superior gluteal

[a]Not actually within the involved compartment but may be compromised by swelling of nearby muscle

orthopedic, and vascular physicians. Although ACSs may affect any compartment, the majority involve those in the leg (especially the anterior compartment) and those in the forearm (especially the volar compartment). In contrast to ACSs, *chronic CSs* (CCSs) are due almost entirely to exercise and overuse, many aspects of their pathophysiology are debated, they do not require urgent operative treatment (unless they convert to ACSs, a relatively rare occurrence), they generally resolve spontaneously with rest, and the majority are managed by sports medicine physicians [6, 18]. The majority of CSSs affect solely the compartments of the leg, especially the anterior and the posterior compartments.

Some terms require definition. Those ACSs that are evolving or developing are referred to as "incipient," whereas those that are full blown are labeled "established." Frequently, CCSs are referred to as "exertional," "exercise induced," "recurrent," or "intermittent" [6, 7, 18–21]. Two severe complications of ACSs, both of which result from irreversible damage to the muscles within the affected compartment(s), merit specific names: Volkmann's ischemic contracture and crush syndrome. *Volkmann's ischemic contracture (Volkmann's contracture, Volkmann's ischemia)*, which is an old term, is the end-stage clinical manifestation of an ACS in which marked tissue (muscles, nerves, etc.) necrosis has evolved into muscle fibrosis and resultant contractures; it is most commonly used to describe the limb deformities resulting from a volar forearm ACS. *Crush syndrome (Bywaters syndrome)* concerns the systemic manifestations that follow ACS-induced massive rhabdomyolysis: myoglobinuria, acidosis, hyperkalemia, and third-space fluid loss, which can produce renal failure, shock, and cardiac arrhythmia. Typically, this entity results from multiple ACSs or involvement of a large muscle mass within a single compartment (e.g., gluteal ACS) [1, 2, 22, 23].

Etiology and Pathogenesis

A considerable number of specific causes for ACSs have been described. Most result from an increase in compartment contents (volume), including: (1) post-ischemic edema (e.g., following arterial injuries, thrombosis, or embolism; vascular surgery; tourniquet application; and prolonged immobilization with limb compression), (2) blood accumulation (e.g., anticoagulation, bleeding disorders, and infiltrating transfusions), and (3) combinations of edema and blood accumulation (e.g., following fractures and soft tissue injuries). The less common mechanism of ACS production is boundary restriction, which reduces compartment size and thereby decreases the amount of swelling necessary to cause elevated intracompartmental pressure. It results from casts, splints, circumferential dressings, eschars from burns, and closure of fascial defects.

An underrecognized and potentially treatable form of ACS is the medial brachial fascial compartment (MBFC) syndrome that follows injury to the axillary or brachial artery (e.g., after axillary angiography, axillary regional block during which the axillary artery is punctured, or local trauma) [24, 25]. The

MBFC is formed by tough brachial fascia that extends from the axilla to the elbow and contains the axillary sheath, which in turn envelopes the axillary vessels and infraclavicular brachial plexus, including the terminal nerves. Puncturing the axillary vessels can lead to hematoma or pseudoaneurysm formation within the MBFC – and not just within the axillary sheath, which is friable and ruptures at relatively low pressure – and sufficiently elevated intracompartmental pressure leads to injury of the median, ulnar, radial, musculocutaneous, axillary, and suprascapular nerves (in descending order of frequency) [24, 25]. Various combinations of terminal nerve injury also occur, and most commonly involve the median and ulnar nerves, followed by the median, ulnar, and radial nerves [24, 25]. The MBFC syndrome is thus a form of "neurovascular injury" that differs from other forms of ACS in that the MBFC solely contains blood vessels and nerves and, thus, does not involve muscle necrosis.

Overall, the most common causes for ACSs are fractures, soft tissue injuries, arterial injuries, prolonged limb compression, and burns; muscle exertion, in contrast, seldom produces ACSs [6, 11, 26, 27]. Regardless of etiology, ultimately one mechanism is responsible for all ACSs: elevated intracompartmental pressure, which decreases the arterial-venous (A-V) pressure gradient across the capillary circulation, thereby lessening tissue perfusion. If untreated, ischemia results and may produce irreversible changes, depending upon the degree and duration of the elevated pressure (i.e., pressure and time thresholds) [5, 6, 10].

Concerning CCSs, there is essentially only one etiology: exertion/overuse. Nonetheless, the exact cause (e.g., increased contents vs. decreased space) in a particular patient often is unclear, and the pathogenesis is less well understood. Various theories have been proposed to explain why repeated contraction of the muscles within the compartment causes the intracompartmental pressure to rise to a point that symptoms are produced [6, 7, 18–21].

Clinical Presentation

The first symptom of ACS, which may appear many hours after the inciting event, is pain, localized to the involved compartment. Typically, it is deep, out of proportion to what would be expected based on the clinical situation, persistent, and increasingly severe over time. When the compartment is more superficially located (e.g., anterior compartment of leg), it may appear swollen, as well as tense and tender to palpation. As the process evolves, paresthesias, hypesthesias, and then anesthesia appear in the distribution of nerves that traverse the affected compartment. Ultimately, the muscles within the compartment and those innervated by nerves that traverse the compartment become paretic and, if the process is unrecognized or untreated, paralyzed [4, 6, 11, 27].

In contrast to most forms of ACS, symptom onset in the context of the MBFC syndrome can occur within minutes or hours but on occasion may be delayed for days or even a few weeks. This time lapse is due to slow accumulation of blood within the compartment or, alternatively, to the time it takes for pseudoaneurysm formation of the axillary or brachial vessel to occur. In either event, the lag in symptom onset may contribute to a delay in recognition of the disorder [24, 25]. As with other forms of "neurovascular injury," the MBFC syndrome is not accompanied by signs of arterial occlusion (i.e., pallor or pulselessness); furthermore, the degree of ecchymosis overlying the site of puncture or trauma and the presence or absence of a palpable hematoma do not correlate with the amount of compression that occurs within the MBFC [24, 25].

With CCS, typically the only symptom is pain localized to the involved compartment (or, occasionally, more general in distribution) and that is provoked by exercise, relieved by rest, and, often, that progressively worsens with exercise over time. Muscle tenderness or tenseness may be present, and rather infrequently, there may be paresthesias in the distribution of nerves that traverse the compartment or weakness of muscles within the compartment. All these symptoms regress with cessation of exercise, but, at times, a CCS converts to an ACS [6, 18–21].

Differential Diagnosis

The clinical presentations of both ACS and CCS are similar in various respects to many other disorders. For ACS, these include primary arterial injury, deep venous thrombosis, cellulitis, and primary nerve injury (particularly when a limb fracture coexists) [10, 11, 27]. For CCS, these include vascular claudication, various strains and sprains, stress fractures, tendonitis, and periostitis. Moreover, lower limb CCS may be confused with shin splints and tenosynovitis of the anterior tibial or peroneal muscles, whereas the symptoms of upper limb CCS may mimic the referred pain caused by cardiac abnormalities [10, 18–21].

Evaluation and Diagnosis

The early recognition of an ACS is crucial because irreversible damage may be prevented with prompt treatment. Generally, the diagnosis is based on the clinical presentation; formal pressure measurements may or may not be necessary. The clinician must possess a high index of suspicion whenever conditions favorable for the development of an ACS are encountered. Pain, more severe than anticipated from the primary problem, usually is the first and most important symptom of a developing ACS. When it is absent, nearly always

there are coexisting central or peripheral nervous system disorders that mask it. The first objective finding, which may be difficult to confirm in many patients and not detectable at all in others, is a palpably tense, swollen compartment accompanied by tenderness along the extent of the compartment, rather than being localized to the site of injury. Often, there is pain with passive stretch of the muscles within the compartment. Sensory deficits are the first signs of concomitant nerve ischemia. Typically, decreased sensation to pain and light touch is demonstrated in the distal sensory distribution of the nerve or nerves that traverse the involved compartment. Weakness of muscles within the compartment, or of muscles innervated by nerves that traverse the compartment, is a late finding with ACS; it indicates that, unless intracompartmental pressure is promptly reduced, irreversible damage to muscles and nerves is imminent. A critical point worth reiterating is that ACSs characteristically are not associated with substantial impairment of the distal limb circulation (except in the presence of a major arterial injury). Consequently, absent pulses, poor capillary filling, and skin pallor generally are not seen. This is because the elevated intracompartmental pressure, although substantial enough to collapse capillaries and thereby cause ischemia of the contents within the compartment, typically is well below the mean arterial pressure and, therefore, does not restrict blood flow in major arteries that pass through the affected compartment [10–12, 27].

Actual measurements of the intracompartmental pressure can be performed at the bedside. Various techniques for doing so have been described by different investigators. Currently, the two most commonly used are the slit catheter and the miniature transducer-tipped catheter [6, 11]. Unfortunately, there is no general agreement on what pressure value is critical to trigger decompression, in part because the pressure threshold depends on the patient's blood pressure. The most widely quoted pressures, in this regard, are those above 30–45 mm Hg (in absolute terms) and those within 4–10 mm Hg of diastolic blood pressure [6, 10, 11, 28]. Noteworthy is that in a recent article, two of the leading investigators in the field recommended that "… when possible, physicians should weigh clinical signs more heavily than (intra-compartmental pressures) when diagnosing compartment syndromes" [6]. This admonition stems mainly from the fact that substantial pressure gradients may be present within an affected compartment, presumably due to local hematomas. As a result, pressure measurements obtained at one site may be quite misleading [6]. If the differential diagnosis includes arterial injury, then arteriograms and Doppler blood flow studies may be required. Similarly, in the appropriate clinical situations (e.g., severe or multiple ACSs), plasma creatine kinase (CK) levels and urinalysis for myoglobinuria are also helpful. When abnormal, these changes typically reflect the presence of an established, rather than an incipient, ACS [11, 28].

It is imperative that the MBFC syndrome be immediately recognized on clinical grounds alone since the likely period for reversible peripheral nerve injury appears to be less than 4 h [24, 25]. The role of ancillary diagnostic tests (e.g., CT, MRI, Doppler blood flow studies, and compartment pressure measurements) is less well defined, and their routine use is not recommended unless they can be performed within the 4-h "golden period" from the time of symptom onset.

Identifying ACSs based on clinical findings, however, is particularly difficult in those patients who are uncooperative (e.g., children), are obtunded, or have known peripheral nerve deficits from other causes in the affected limbs. In these situations, compartment pressure measurements often are critical for diagnosis as long as they do not substantially delay treatment [11, 24, 29].

The majority of CCSs can be diagnosed solely by the history. In marked contrast to ACSs, there typically are no clinical findings, although swelling over the involved compartment, particularly immediately after exercise, has been reported. The diagnosis must be confirmed (and the specific compartment involved identified) by direct measurement of intracompartmental pressures. Although techniques are available for continuous pressure monitoring before, after, and, particularly, during exercise, there is no consensus regarding what results are crucial for diagnosis. Various investigators have championed: (1) comparing pre-exercise and intraexercise pressure measurements, (2) intraexercise absolute pressure measurements, (3) the value of pressure drops during the intraexercise relaxation phase, and (4) postexercise pressure measurements [4]. This marked divergence of opinion most likely results from the lack of understanding of the underlying pathophysiology of CCS [18–21]. Some elaborate laboratory procedures may ultimately prove to be more helpful for diagnosis; thus, thallous chloride scintigraphy with single-photon emission computed tomography (SPECT) scanning, near-infrared spectroscopy, and methoxyisobutyl isonitrile (MIBI) perfusion imaging has impressed some investigators [20, 30]. In contrast, magnetic resonance imaging (MRI) has not proven itself to be particularly helpful, although, along with venograms, triple-phase bone scans, and bone X-rays, it may assist in excluding some of the disorders included in the differential diagnosis [18–21].

Treatment and Management

Developing and early established ACSs generally are surgical emergencies requiring decompression of the affected compartment by operative means, usually fasciotomies. In the case of the MBFC syndrome, immediate puncture site exploration is indicated to identify and remove the compressive hematoma or repair the pseudoaneurysm within the compartment. Occasionally, however, depending upon the

cause, elevated compartmental pressure can be reduced nonoperatively. Examples of the latter include preventing limb elevation, which reduces the mean arterial pressure, thereby causing decreased blood flow to the compartment and removing constricting structures (e.g., casts, dressings) that are serving as external inelastic envelopes [10, 11, 27]. Decompression of a compartment will only result in symptom reversal if it is performed within a certain time period. Unfortunately, this is dependent upon many unknown factors (e.g., exactly when in the course the pressure became elevated and the exact degree of elevation throughout the time period) [6]. Consequently, only general guidelines are applicable. Nonetheless, the sooner the compartmental pressure is lowered, the more likely recovery is to follow. Operations performed within eight, and especially four, hours after neurological symptoms have appeared frequently are successful. Conversely, operations performed after 12 or more hours seldom have any beneficial effect [4, 10, 11, 13, 24, 25].

The only two major ACSs for which the most appropriate treatment is debated are those that compromise the lumbar plexus and the femoral nerve (psoas and iliacus ACSs, respectively). Some investigators believe that these can be managed conservatively [4, 15].

There are a variety of treatments for CCS. In many instances, because the condition is self-limited, patients elect to merely stop or reduce the activity that causes symptoms (e.g., long-distance running), rather than seek active therapy. Correction of factors thought to contribute to the development of CCSs (e.g., inappropriate footwear, running on hard surfaces, excessive foot pronation, and increased activity) is advocated, although none of these have been shown scientifically to be detrimental. Conservative treatments include rest, ice, heat, physiotherapy, steroid injections, analgesics, and antiinflammatory medications. While these may reduce the symptoms to varying degrees, they do not actually cure the underlying condition. Even complete rest for prolonged periods is ineffective in this regard. In general, the only means of successfully treating a CCS is elective fasciotomy, although the more recent development of minimally invasive techniques (e.g., endoscopic compartmental release) appears to offer an alternative and at least equally effective therapy compared to conventional open fasciotomy [18–21, 31].

Prognosis

With ACS, the ultimate outcome depends on whether the elevated intracompartmental pressure is reduced before the muscles and nerves within the compartment sustain irreversible damage. With successful decompression, all symptoms usually promptly resolve. Conversely, with no or unsuccessful treatment, the results usually are grave, often permanent, and sometimes life-threatening. These include muscle fibrosis with resulting contractures, permanent nerve deficits, limb deformities (including abnormalities of limb growth in children), and, when muscle necrosis is extensive, renal failure, sepsis, shock, and hyperkalemia [7, 10, 11, 23].

Generally, the prognosis following fasciotomy for CCS is very good, although it may vary somewhat, depending upon the specific compartment affected. Thus, in one study, anterior leg compartment decompression had much more satisfactory results, overall, than did deep posterior leg compartment decompression. Whether elective surgery in these instances is successful may also depend on the management in the immediate postoperative period. The effects of fasciotomies are maximized if limb mobilization occurs at the earliest possible moment, to prevent the healing fascia from reverting back to its original size [18–21].

Ischemic Monomelic Neuropathy

Introduction

Ischemic monomelic neuropathy (IMN) is a relatively rare ischemic neuropathy in which nerve damage occurs in the more distal portion of a limb because of compromised blood flow in a major artery of the limb located more proximally, either by noncompressive occlusion or diversion. Often, the ischemic event is relatively short-lived (e.g., few hours at most) [32]. Both upper and lower limb IMN occur (UL-IMN and LL-IMN, respectively), which differ somewhat in several respects. UL-IMN is less common, invariably unilateral, and nearly always iatrogenic in nature. In contrast, LL-IMN is more common, occasionally bilateral, and iatrogenic or noniatrogenic in nature. A feature characteristic of every IMN, regardless of etiology or limb affected, is that the clinical and EDX changes are most severe in the most distal portion of the limb and shade proximally (i.e., they demonstrate a marked distal-to-proximal gradient). Moreover, at any given limb level, nerve fibers composing different peripheral nerves are affected in a uniform manner. This is more obvious with UL-IMN, wherein the amount of involvement of median and ulnar nerve fibers in the hand invariably is very similar, if not identical, as judged both by severity of motor and sensory nerve conduction study (NCS) amplitude reduction and by the amount of fibrillation potentials and motor unit action potential (MUAP) loss on needle electromyography (EMG) [32, 33].

Etiology and Pathogenesis

Nearly all the reported cases of UL-IMN have occurred following placement of A-V shunts in the antecubital fossa or proximal arm for dialysis purposes in patients with end-stage

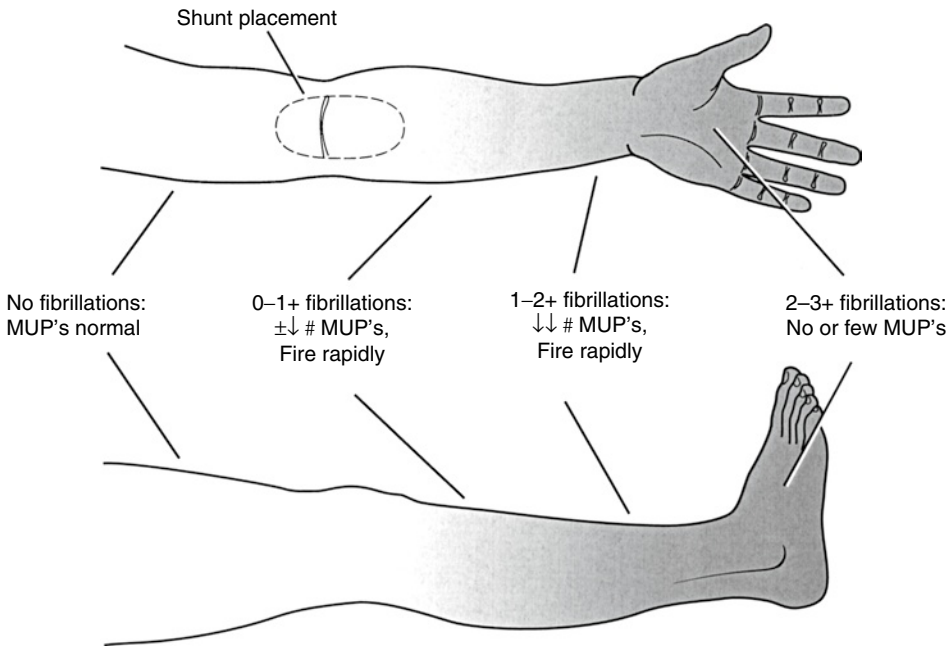

Fig. 37.1 The distal-to-proximal gradient of needle EMG examination changes characteristically seen with ischemic monomelic neuropathy (Modified with permission from Wilbourn and Levin [4])

diabetic nephropathy [34–37]. Conversely, LL-IMN has had several reported causes initiated by compromise of the following arteries: the proximal popliteal (embolus), the superficial femoral (intra-aortic balloon pump placement, cardiopulmonary bypass cannulation, and thrombosis), the iliofemoral (thrombosis), and the aortoiliac (embolus) [32, 33]. At least two patients reportedly have developed LL-IMN (one unilateral, one bilateral) following the use of either ergotamine tartrate or a semisynthetic ergot alkaloid, methysergide [38, 39]. However, in both patients, some features – clinical, EDX, or both – were inconsistent with IMN, particularly in regard to the requisite distal-to-proximal gradient of abnormalities (see below).

The etiologic factor common to all cases of IMN is a sudden decrease in arterial blood flow to the more distal portion of the limb. This produces limb ischemia which, although severe enough to damage distal nerve fibers and their associated symptoms and signs, is too brief or otherwise insufficient to cause muscle or skin damage. The underlying pathology with IMN is axon loss. Its striking distal-to-proximal distribution and its marked uniformity at any given limb level are demonstrated most convincingly during the needle electromyography (EMG) portion of the EDX assessment (Fig. 37.1) [32]. One group of investigators has suggested that, very early in its course, UL-IMN may present as multifocal ischemic conduction block in the forearm, principally or solely along the median nerve. Using motor NCS, they demonstrated such lesions in three patients (all diabetic, two immediately following A-V shunt placement, and one with sudden occlusion of the brachial artery in the upper arm). All showed rather rapid resolution of these conduction blocks following treatment [40]. One major problem with this concept is that similar conduction blocks, to the same degree and at the same limb level, were not demonstrated along the motor fibers of the ulnar nerves in the affected limbs. Yet, by definition, with UL-IMN, the distal median and ulnar nerves (as well as the distal radial nerve) consistently are damaged to the same degree.

Clinical Presentation

The cardinal symptom of IMN is pain – usually deep and burning in character, constant, and persistent – in the hand or foot, sometimes with coexisting paresthesias. Certain patients, particularly those with UL-IMN, also complain of distal sensory deficits. Weakness of intrinsic hand and foot muscles invariably is present, usually accompanied by wasting with lesions of more than several weeks duration; this is much more clinically obvious with UL-IMN. The symptoms usually appear promptly after the inciting event, but they often do not reach maximal intensity for several days [32, 33].

On neurological examination, there is impairment of all sensory modalities in a prominent distal-to-proximal gradient. Generally, no sensory changes are detectable proximal to the midforearm or midcalf. Weakness, and sometimes atrophy, is evident in the more distal limb muscles and is always most severe in, if not limited to, the intrinsic hand and foot muscles. Signs of ongoing vascular insufficiency (coolness, pallor, atrophic skin or hair changes, absent pulses) or muscle infarction (induration, tenderness, contractures) are not usually present.

Differential Diagnosis

Delays in diagnosis and treatment are common with IMN. Frequently, it is confused with other disorders, such as psychogenic limb pain and peripheral nerve injuries caused by malpositioning on the operating table. In addition, LL-IMN has been mistaken for lumbosacral radiculopathy, sciatic nerve infarction, and intermittent claudication, whereas UL-IMN symptoms have been attributed to plexopathies resulting from axillary blocks, to CTS, and, particularly, to "steal syndrome" ("venous sink") [32–35, 37, 41]. Concerning the latter, a "steal phenomenon" exists to some degree distal to most A-V fistulas. In the arterial segment distal to the fistula, a major drop in pressure occurs, which can be alleviated to some degree by collateral arterial circulation. However, if the decrease is severe enough, blood flow through the artery distal to the fistula may actually reverse, producing distal ischemia. Hye and coworkers view A-V fistula formation as producing two distinct clinical syndromes: (1) the typical "steal syndrome," in which distal limb ischemic changes (nonhealing wounds, impending tissue loss) overshadow mild distal neurological changes (rest pain, sensory loss), and (2) IMN, in which severe neurological dysfunction in the distal limb occurs with little to no evidence of concurrent ischemic tissue damage. These two syndromes are readily distinguished from one another by clinical examination, EDX studies, and digital arterial pressure indices [37].

Evaluation and Diagnosis

The laboratory test of most value in the diagnosis of IMN is the EDX examination. Unfortunately, these are usually conducted well after the optimal time period for symptom reversal (e.g., surgical correction) has lapsed. On NCSs, the sensory and motor responses, recording distally, typically are low in amplitude or unelicitable, with the sensory NCSs the most severely affected. Latencies and conduction velocities, when obtainable, characteristically are within normal limits unless a generalized polyneuropathy, customarily diabetic, coexists. If NCSs are performed using more proximal recording sites, the recorded amplitudes are either less effected or normal. On needle EMG, fibrillation potentials and MUAP dropout are prominent in the intrinsic hand or foot muscles while less severe, in a graded manner, in progressively more proximal muscles. Also, there is no evidence of coexisting ischemic muscle damage (i.e., the MUAPs that can be activated do not show suggestive "myopathic" configurational changes). In summary, the EDX changes with IMN are identical to those seen with a dying back axon loss polyneuropathy, except that they usually involve only a single limb. Advanced age, a concurrent axon loss polyneuropathy, and coexisting mononeuropathies (particularly CTS with UL-IMN) can render the EDX results less definite [32, 33]. In certain instances, arteriograms, digital artery pressure measurements, and other vascular tests are of value, primarily for excluding other disorders [37, 41, 42].

Treatment and Management

Any ongoing ischemia should be promptly rectified, if possible. This typically is the case with UL-IMN, in which shunt ligation is indicated [32, 34, 36, 37, 41]. With the majority of LL-IMN, however, the arterial compromise already has been corrected by the time the patient is assessed. The pain of IMN may be helped by a variety of neuropathic pain medications; sympathectomies have yielded variable results [32, 33]. Concerning UL-IMN, Hye and coworkers have recommended preventive measures, such as awareness of the disorder developing following A-V shunt placement, avoiding the dominant limb, and performing careful postoperative assessments [37]. Valji and coworkers have noted that, with IMN-induced hand pain, arteriograms are of no value and should not be performed [42]. Of importance is that a correct diagnosis not only results in appropriate therapy but also, given the many iatrogenic cases, often prevents inappropriate litigation.

Prognosis

A variable outcome is seen among patients with IMN. In some, the symptoms are only partially relieved by treatment and, thus, persist indefinitely, whereas in others, the pain ceases spontaneously after several months, even when there is no clinical or EDX evidence of axon regeneration [32, 33, 35]. Regarding UL-IMN, there are several reports of substantial improvement, both clinically and electrically, occurring within several months of graft ligation [36, 37, 41].

Acute Ischemic Mononeuropathy/Plexopathy

Introduction

Most mononeuropathies and plexopathies resulting from acute ischemia are due to small vessel disease (e.g., vasculitis), acute compression, or ACS. Occasional cases of abrupt onset ischemic mononeuropathy result from large vessel atherosclerotic disease, either directly or indirectly (i.e., their surgical repair), as well as from several miscellaneous causes [43, 44]. Thus, these entities are both iatrogenic and noniatrogenic in nature. Typically, either the lumbosacral plexus or various lower extremity nerves (e.g., femoral, sciatic, common peroneal) are affected. In many reports, however, the exact location of the lesion is unclear (e.g., lumbosacral

plexus vs. cauda equina, femoral nerve vs. lumbar plexus, sciatic nerve vs. sacral plexus) [45–47].

Etiology and Pathogenesis

Among those cases resulting from atherosclerotic disease or its surgical treatment, the blood vessels characteristically involved are the distal aorta, the common iliac artery, the internal and external iliac arteries (particularly the former), and the branches of the internal iliac artery. Noteworthy is that the cauda equina and at least the sacral plexus, if not the lumbar plexus as well, receive their principal blood supply from branches of the internal iliac artery [46, 48]. The neural structures most often reported to have sustained ischemic damage are the lumbosacral plexus and the femoral nerve [44–55]. Immediate causes for the ischemia have varied in these instances, but probably the single most common is abdominal aortoiliac surgery, usually for ruptured aneurysms and less often for infected grafts and graft failures [44–60]. Nonsurgical etiologies include atherosclerotic stenosis or occlusion of the iliac arteries or branches arising from them (e.g., the superficial femoral artery), radiation therapy to the pelvic region, the use of intra-aortic balloon pumps, and intra-arterial injections of various medications into the iliac or gluteal arteries [45, 48, 55].

The immediate cause for the nerve fiber ischemia – specifically, why it occurs in a few of the many patients who have the same vascular problems and undergo the same surgical procedures – often is unclear but is thought to be multifactorial, including significant periods of hypotension, emboli, failure to heparinize, and, particularly, cross clamping of the major vessels [47, 53]. Attempts to correlate the level of vascular compromise with the particular neural structure damaged by ischemia have met with limited success; for example, isolated ischemic femoral neuropathies have resulted not only from common iliac artery occlusion but also from cross clamping of the aorta [52, 53]. Wohlgemuth et al. described a series of patients who experienced intermittent ischemia of the lumbosacral plexus due to stenosis of the common iliac and internal iliac arteries related to muscular effort [48]. Sciatic neuropathies and common peroneal neuropathies resulting from ischemia have also been reported. The former, in one series, all resulted from lesions of the common iliac artery [45, 56].

Diabetic lumbosacral radiculoplexus neuropathy (*DLRPN*), known by many other names, including the Bruns-Garland syndrome, diabetic lumbosacral radiculopathy, and diabetic amyotrophy, is one form of noniatrogenic lower limb ischemic neuropathy [57]. The pathophysiology of DLRPN is postulated to be an immune attack resulting in microvasculitic-induced ischemic nerve injury. This condition is clinically and pathologically indistinguishable from nondiabetic lumbosacral radiculoplexus neuropathy (LRPN) [57].

Clinical Presentation

With atherosclerotic disease, sensory loss and weakness typically appear abruptly in the distribution of the affected neural structures, or, when they result from various vascular reconstructive procedures, the features first become apparent in the postoperative period. The changes present prior to such surgery often have been overshadowed by symptoms of acute vascular insufficiency (cold, painful, pulseless limb with persistent resting pain) or by progressive limb claudication [52, 53]. The rare patient who has exercise-induced ischemia of the lumbosacral plexus presents with pain in the buttocks and leg, sometimes accompanied by hypesthesias and less often weakness, following muscular exertion (e.g., walking) [48]. With DLRPN, the typical presentation is sudden or subacute onset pain and weakness in an asymmetric distribution. The weakness often has an initial predilection for proximal nerve fiber segments (e.g., roots) and quickly spreads to adjacent segments and the contralateral side (i.e., territorial extension) so that by the time of evaluation the disorder often is bilateral and widespread and may appear symmetric [57, 58]. All patients with DLRPN should be specifically queried about preceding weight loss as approximately two-thirds will have an associated weight loss of greater than 10 lbs. There appears to be a correlation of DLRPN with the earlier stages of type 2 diabetes (compared to the more indolent and less painful form of polyneuropathy associated with long-term disease). In summary, DLRPN tends to affect diabetics with better glycemic control, lower body mass index, and less long-term complications of diabetes (e.g., retinopathy or nephropathy) [57, 58].

Differential Diagnosis

Lumbosacral plexopathy must be distinguished from conus medullaris and cauda equina lesions. Ischemic femoral neuropathies can be confused with psoas and iliacus ACSs, which also compromise femoral nerve fibers. Sciatic neuropathies must be differentiated from incomplete cauda equina lesions and sacral plexopathies, as well as from IMN [32, 43, 45, 53].

Evaluation and Diagnosis

Determining the level of the lesion – that is, the exact neural structure affected – often is difficult. A detailed neurological examination, typically supplemented with EDX and neuroimaging studies, is required. Lumbosacral plexopathies usually can be distinguished from distal spinal cord and cauda equina lesions because frequently (but not always) they are unilateral, and they do not cause urinary incontinence. They are distinguished from proximal peripheral nerve lesions because

their motor and sensory deficits and reflex abnormalities are outside the distribution of an individual peripheral nerve. With lumbosacral plexopathies, neuroimaging techniques may show abnormalities in the plexus but not in the spinal cord or lumbosacral roots. The classic EDX presentation of a lumbosacral plexus lesion is low amplitude or unelicitable sensory responses and low or normal motor responses on NCS in the affected limb. On needle EMG, there are fibrillation potentials and MUAP loss in limb muscles innervated by multiple roots or peripheral nerves but sparing the ipsilateral lumbosacral paraspinal muscles. The NCS profile in DLRPN and nondiabetic LRPN likewise reflects low amplitude or unelicitable sensory and motor amplitudes, but, in contrast to pure lumbosacral plexus lesions, fibrillation potentials are frequently identified in the paraspinal muscles, and the overall EDX abnormalities tend to be much more widespread than the clinical deficits [58]. Unfortunately, in some patients, definite EDX localization remains elusive. For example, when the sensory NCS responses are unelicitable bilaterally, the patient has an underlying polyneuropathy, is of advanced age, or has some other potential explanation for the absent sensory responses. In addition, although the presence of paraspinal muscle fibrillation potentials excludes an isolated plexopathy, their absence does not exclude an intraspinal canal lesion [43, 46]. Quantitative sensory and autonomic testing in patients with DLRPN and nondiabetic LRPN shows unequivocal sensory abnormalities in the foot, leg, and thigh, as well as moderate to severe autonomic dysfunction [58].

Exercise-induced ischemia of the lumbosacral plexus has characteristic clinical features. Typically, patients are asymptomatic and have normal neurological examinations when inactive but developing pain and progressive sensory and motor deficits in the distribution of the plexus during exertion. Buttock pain is a common manifestation and may be the first symptom to appear with exercise [48]. Ischemic femoral neuropathies are diagnosed clinically by the presence of weakness, sensory loss, and reflex changes limited to the femoral nerve distribution. Pertinent negative findings include the absence of a groin mass, groin tenderness, and pain on hip flexion (all of which characteristically are seen with iliacus ACS). On EDX studies, the femoral NCS response typically is very low in amplitude or unelicitable, and, on rare occasions, a saphenous NCS response may be unelicitable on the affected side while present in the contralateral, uninvolved limb. On needle EMG, there are fibrillation potentials and MUAP loss in the quadriceps muscles but not the thigh adductors or ipsilateral lumbar paraspinal muscles [43, 45].

Although both components of the lumbosacral plexus (i.e., lumbar and sacral) may be damaged simultaneously by ischemia, each component can be injured in isolation. Whenever this occurs, lumbar plexopathies must be distinguished from femoral neuropathies, and sacral plexopathies must be differentiated from high sciatic neuropathies.

Most ischemic sciatic neuropathies present with motor and sensory deficits in the distribution of the common fibular (peroneal) and tibial nerves (i.e., all abnormalities are distal to the knee). Thus, they apparently affect the sciatic nerve distal to the motor branches supplying the hamstring muscles. Consequently, the latter, as well as more proximally situated muscles innervated by the same roots (e.g., glutei and lumbosacral paraspinal muscles), appear normal [43]. When assessed within a few months after onset, either by clinical or EDX examination, ischemic sciatic neuropathies are readily separated from lower extremity IMN because, unlike the latter, they manifest a definite line of demarcation, separating abnormal from normal. However, as time passes, and the more proximally located muscles are reinnervated via collateral sprouting, these sciatic neuropathies exhibit a distal-to-proximal gradient of abnormalities that appear very similar to those seen at the onset of IMN [32].

Treatment and Management

Only supportive therapy is available for established iatrogenic ischemic plexopathies and most ischemic peripheral neuropathies. This includes analgesics, physical therapy, and orthotics (if necessary). Similarly, there is no proven treatment for DLRPN or nondiabetic LRPN; the best evidence to date suggests that pain, but not sensorimotor function, may improve with intravenous methylprednisolone. Results from an ongoing randomized, double-blind, placebo-controlled study comparing high- and low-dose intravenous immunoglobulin against placebo in patients with DLRPN are not yet available [59]. Unfortunately, preventive measures for these disorders are essentially unknown [43]. Intermittently appearing lumbosacral plexopathies resulting from exercise can be treated with interventional radiological therapy (e.g., stent placement in the common or internal iliac arteries) [48].

Prognosis

Unlike ischemic lower spinal cord and cauda equina lesions, established ischemic lumbosacral plexopathies and patients with DLRPN and nondiabetic LRPN may recover, although many show delayed and only partial recovery [43, 46, 49, 59]. In contrast to the uncertain prognosis of ischemic plexopathies, femoral nerves damaged by ischemia typically improve considerably with the passage of time. For example, one patient who presented with virtual paralysis of the quadriceps muscles had an "excellent return of function" 1 year after onset [52, 53]. Although definitive information is sparse, ischemic sciatic neuropathies probably would also improve substantially.

Chronic Limb Ischemia

Chronic limb ischemia, characteristically involving one or both lower extremities, is almost invariably caused by atherosclerotic occlusion of the arterial vascular system, also known as peripheral arterial disease (PAD). For more than a century, investigators have attempted to demonstrate – first using clinical and pathological studies and later supplementing them with EDX studies – an association between the chronic ischemia in these limbs and damage to peripheral nerve fibers. Unfortunately, despite the great number of reports on the subject that have appeared over the years, no consensus has been achieved. Instead, far too often, the published results have been contradictory. Controversies include (1) whether the ischemia itself results in definite clinical abnormalities and, if so, what these consist of; (2) whether nerve damage caused by ischemia can be demonstrated pathologically; and (3) whether EDX changes unequivocally attributable to nerve ischemia can be found and, if so, how they present [4, 43, 44, 60]. The term "ischemic neuritis" aptly illustrates the problem. Although it has been used for decades to describe the lower extremity pain (burning, often diffuse, and particularly severe at night) and hyperpathia reported by patients with peripheral vascular disease, "In fact, there is no direct evidence to relate these symptoms in patients with arteriosclerotic occlusive disease to nerve fiber damage" [60].

There are cogent reasons for the controversies surrounding PAD and the peripheral nerve fiber injury that may or may not result from it. First, chronic limb ischemia is not stereotyped in its presentation. Rather, it varies greatly in degree from one limb to another. Thus, the clinical, pathological, and EDX manifestations of PAD are on a continuum. At one extreme is asymptomatic PAD, demonstrable only with various diagnostic vascular studies. At the opposite extreme is the severely compromised limb manifesting persistent rest pain and impending distal gangrene. Between these two extremes is the limb that is normal at rest, which exhibits intermittent claudication with exercise [44]. Second, "… in comparison to the extensive physiologic and pathologic investigations of impaired circulation of the brain, such studies of peripheral nerve have been meager and monotonously incomplete" [60]. Many of the reported EDX studies on the subject, for example, consisted of only one or two NCSs, often with only conduction velocities reported (no response amplitudes), or needle EMG of only one or two muscles [4]. Third, many of the reports have lacked adequate controls. Fourth, patients with diabetes mellitus were included in the study population in some investigations [4, 44, 60]. Finally, several of the reported studies focused on strictly unilateral PAD, with the contralateral, uninvolved limb serving as a control. Unfortunately, in many of these patients, the limb temperatures differ, with the affected limb being cooler; these temperature differences alone often could explain the relatively slight NCS differences reported between them [4].

Even though the evidence is conflicting, it appears likely that at least some patients with PAD develop nerve damage in the affected limb(s) because of the chronic ischemia present. This view is supported by two relatively recent reports on the topic. England and coworkers, after having previously observed histologic evidence of denervation in gastrocnemius biopsies from the symptomatic limb in patients with unilateral PAD, detected both histologic and EDX evidence of such changes in another series of patients [61]. All six of the patients in the latter group were considered to have unilateral "mild-to-moderate" PAD, presenting as stable intermittent claudication with no neurological changes in the symptomatic limbs. On EDX studies, they found significant abnormalities only on the needle EMG, specifically suggestive chronic neurogenic MUAP changes in several muscles assessed distal to the knee. These were confirmed by quantitative EMG studies performed on the gastrocnemius muscles in the symptomatic and asymptomatic limbs. The authors concluded that either the "distal motor axons or motor nerve twigs in or near the denervated muscles" had been compromised by ischemia that occurred during the bouts of intermittent claudication that their patients had experienced. This nerve damage, in turn, leads to chronic denervation and reinnervation in the affected muscles [61]. Papapetropoulou and coworkers performed clinical and EDX studies on 40 patients with more severe unilateral PAD. Nearly half (45 %) of their patients had neurological abnormalities on clinical assessment, consisting of depressed Achilles tendon reflexes, distal sensory abnormalities, or, less often, slight muscle weakness. On routine needle EMG, the authors found no evidence of chronic partial denervation. However, on bilateral quantitative EMG analysis of the tibialis anterior and medial gastrocnemius muscles, they detected MUAP changes (increased mean duration and mean amplitude) in the symptomatic, but not the contralateral and asymptomatic, limbs. Moreover, they noted that even though several of the NCS results in the symptomatic limbs were still within normal limits in absolute terms, they were significantly different from those in the control limbs. They concluded that routine EDX studies simply are not sensitive enough for detecting neuromuscular changes caused by PAD, although mild abnormalities are present [62].

The treatment of the ischemic nerve damage in these instances essentially is similar to the symptomatic therapy provided for any painful polyneuropathy [43]. Noteworthy is that these nerve alterations may not be alleviated by restoration of the blood supply of the affected limb. Thus, Hunter and coworkers performed EDX studies on ischemic lower extremities both before and after operative revascularization [63]. They found that the postoperative results were either unchanged or worse than the preoperative ones. Their data suggest that ischemic polyneuropathies resulting from PAD have a poor prognosis. Unfortunately, this conclusion can neither be confirmed nor refuted by clinical

studies, because none has been reported that documents prognosis over a long time period [43].

Frostbite

The human body can sustain both local and systemic cold-induced injuries (referred to as frostbite and hypothermia, respectively) [64]. Frostbite is defined as localized tissue injury resulting from exposure to temperatures below the freezing point of intact skin [6, 65, 66]. All actual frostbite entails some – at least minimal – tissue destruction; the term "frostnip" is applied to the transient numbness and blue-white discoloration that affects the face or fingertips after cold exposure, that promptly resolves with rewarming, and that leaves no evident tissue damage [67, 68]. Historically, most reports of frostbite concerned military personnel. More recently, however, frostbite occurring in rural and urban civilian populations has been described [65, 66]. Pertinent risk factors include homelessness, increased participation in outdoor winter recreational activities, alcohol consumption, illicit drug use, psychiatric illness, and vehicular trauma or failure (leaving occupants with inadequate protection from the elements). Psychiatric illnesses were so prominent in certain urban frostbite studies that some medical centers now advocate psychiatric screening in all such patients [65, 66, 69]. At present, adult males between 30 and 49 years of age constitute the highest risk group (men outnumber women by a ratio of 10 to 1 or more) [66]. The distal extremities, particularly the feet, account for more than 90 % of reported frostbite injuries. Less often, the ears, nose, cheeks, and penis are frostbitten [66, 70].

The pathogenesis of frostbite is quite complex. It can be divided into direct and indirect injury with three phases. Surprisingly, the direct injury at which most therapy is aimed at limiting or preventing is probably of relatively limited clinical significance compared to the indirect injury [65–67]. Direct injury occurs during the prefreeze phase and a portion of the freeze-thaw phase. During the prefreeze phase, superficial tissue cooling results in microvascular vasoconstriction and endothelial leakage. This occurs when the skin temperature is below 10 °C (but not yet at or below freezing, 0 °C) [65, 67]. During the freezing phase, large ice crystals form in the extracellular fluid, causing increased extracellular osmotic pressure. This, in turn, produces fluid shifts from the intracellular space to the extracellular space that results in intracellular dehydration and in membrane lipoprotein complex denaturation. When approximately one-third of the cellular volume is lost, the cells collapse and die [65, 67, 70]. The amount of permanent damage resulting from direct injury is linked to the total duration of freezing, and, unfortunately, there is no effective therapy for this component of frostbite except rewarming [65, 70]. The indirect injury portion of frostbite occurs during the thaw portion of the freeze-thaw phase and during the vascular stasis and progressive ischemia phase that manifests during rewarming [65, 67]. The majority of tissue destruction takes place during, or immediately after, the thaw phase and is "possibly preventable and potentially reversible" [65]. The vascular stasis and progressive ischemia stage, which occurs during the first few hours after tissues are thawed, is characterized by progressive microvascular collapse, affecting first venules and then arterioles. These result from a number of adverse events occurring near simultaneously, including (1) intense cold-induced local microvascular constriction, (2) intravascular thrombosis resulting both from vascular endothelial damage with platelet clots forming at the damaged regions and from increased blood viscosity that causes red blood cells to form clumps and occlude small blood vessels, and (3) arteriovenous shunting. Due to these processes, failure of capillary wall integrity occurs, and plasma protein leaks into the extracellular space, with resultant edema formation and more cell destruction, which produces histamine release and more edema. Because of the endothelial damage, the hypoxia, and the local thrombosis, inflammatory mediators are released, particularly prostaglandin F_2 and thromboxane A_2. These, in turn, trigger vasoconstriction, platelet aggregation, and blood vessel thrombosis, leading to further ischemia. Their release peaks during rewarming [65, 67, 70].

The clinical features of frostbite are rather stereotyped [70]. In the *prefreeze stage*, the first symptoms are sensory nerve dysfunction, consisting of cutaneous sensory loss (numbness). Clinical examination at this point reveals abnormalities in light touch, pain, and temperature. These are due to vasoconstrictive ischemia and neurapraxia involving the nerve fibers, which are very susceptible to cold, similar to muscles and much more than connective tissue [64, 65, 67, 70]. These changes usually are accompanied by edema. At this stage, patients often complain of the hands or feet being "clumsy." During the *freezing stage*, the direct injury of frostbite occurs and is divided into two groups: superficial and deep. *Superficial frostbite* causes minimal, if any, tissue loss. On examination, before rewarming, the damaged areas appear painful but supple (i.e., the skin indents to pressure), and sensation is intact on formal testing. After thawing, either no blisters appear or large ones develop that contain only clear fluid. With *deep frostbite*, there is usually significant tissue loss. On examination, the area is anesthetic, has a blue-gray skin discoloration, and does not indent (i.e., feels "wooden"). After thawing, small hemorrhagic blisters appear, the skin continues to feel wooden, and a black dry eschar may develop [65–67, 70]. If partial tissue destruction occurs, intermittent pain may appear during ongoing cold exposure.

The optimal treatment of frostbite injury is quite complicated, and its details are beyond the scope of this chapter. It can be divided into three phases. In the "pre-thaw field phase," the

most important factor is to prevent uncontrolled or partial rewarming during transport, which can be disastrous in regard to tissue loss. It is much preferable, in general, to maintain the tissue in the frozen state until proper thawing can occur. The "rewarming phase," for anything but relatively minor frostbite, should occur in a hospitalized setting, preferably in a specialized center, such as one devoted to burns. During this phase, rigid protocols are followed, with rewarming achieved by the limb(s) being placed in a water bath containing a mild antibacterial agent (povidone-iodine or chlorhexidine). More recent recommendations are for a lower water bath temperature at 37–39 °C for 15–30 min (water temperatures outside this narrow range can increase tissue damage) [71]. Significant pain usually occurs during rewarming as tissue perfusion is reestablished. Commonly, an initial dull, continuous ache is present that evolves into severe throbbing pain 48–72 h after rewarming; this can persist for weeks (until demarcation occurs) [67, 68, 70]. During the "post-thaw phase," one of the most difficult tasks is to determine the extent of tissue loss that will ultimately occur. Consequently, most authorities recommend avoiding amputation until demarcation of nonviable tissue is evident. It has been noted that "the amount of tissue eventually salvaged often exceeds even optimistic initial estimates" [67]. Consequently, the adage usually followed in this regard is "frostbite in January, amputate in July" [65, 66]. Early surgical intervention, in the form of fasciotomies, in the immediate "post-thaw" scenario, is required for ACS [71]. The role of adjunctive therapies, including hyperbaric oxygen, vasodilators, tPA, and sympathectomy, is reviewed elsewhere [71]. Even when tissue loss is not prominent, long-term residuals are common. In one series, 65 % of patients manifested such problems. Most of them are due to direct nerve fiber damage or to one of its complications: residual abnormalities in sympathetic tone [67]. These consist of residual pain ("ischemic neuritis"), sensory loss, vasomotor dysfunction, cold intolerance, hyperhidrosis, pigment changes, and skin atrophy [65, 67, 70].

Hand-Arm Vibration Syndrome

That vibration can be one of the occupational causes of secondary Raynaud's phenomenon was first reported in 1911, although the most influential article on the subject appeared in 1918. Initially caused by the use of pneumatic drills and referred to as "vibration white finger," the disorder was renamed "hand-arm vibration syndrome (HAVS)" in 1985 by international consensus [70–74].

HAVS is reported to have three components: (1) a circulatory disturbance (i.e., vasospasm with finger blanching [secondary Raynaud's phenomenon] which is invariably present), (2) sensorineural changes (principally limited to the fingers), and (3) various hand and forearm abnormalities (mainly skeletal) [72, 73].

The majority of attention initially was focused on the vascular disturbances, because they were the most obvious clinical manifestations. Thus, workers using a handheld vibrating tool experience attacks of finger blanching on exposure to cold, usually accompanied by numbness and decreased sensitivity of the affected finger(s). Initially, only the tip of one or more fingers is affected, particularly the most exposed finger (e.g., the index finger that holds the "trigger" of the vibration tool). Eventually, however, as this disorder progresses, all fingers may be affected throughout their length. Generally, the palms are not involved. Each attack lasts anywhere from 1 to 60 min, and they are especially common in the morning, particularly during the winter months. With continued exposure to vibration, the attacks become more frequent and prolonged. They cease when the hands are warmed but then are replaced by hyperemia and pain [72]. In addition to the vascular problems, sensory disturbances occur with HAVS. Initially, these consist of paresthesias, numbness, and sometimes pain of the fingertips that are experienced during, and immediately after, each use of vibration tools and also during blanching attacks. Soon, decreased sensitivity and a loss of temperature perception are noted in the affected fingers. With continued vibration exposure, these intermittent sensory complaints become constant. Ultimately, they are joined by motor changes, resulting in decreased strength and manual dexterity of the intrinsic hand muscles [72]. With prolonged use of pneumatic percussive tools that vibrate at a low frequency (less than 40 Hz), wrist and elbow osteoarthrosis can develop [72].

Vibration tools known to cause HAVS include pneumatic drills and hammers, electric grinders and polishers, and petrol-driven chain saws. These tools are used in mining, foundries, road construction, tree cutting, and in many manufacturing plants [73]. Typically, there is a latent period between the initial exposure to vibration and the onset of symptoms. This latent period is variable and depends upon the tool vibration frequency, the total time of exposure, handgrip strength, climatic conditions, and individual susceptibility [72]. In general, HAVS does not occur until patients have had more than 1,000 h of exposure to vibration tools [72]. Once present, the symptoms increase with the intensity of the vibration exposure and the exposure time [73]. In England, it was recently estimated that approximately one out of 25 (4 %) workers exposed to vibration has moderate to severe HAVS [72].

Finger biopsies of patients with HAVS have shown (1) substantial thickening of the muscular layers of the arterial walls; (2) demyelination of peripheral nerve fibers; and (3) an increase in the amount of connective tissue, resulting in both perivascular and perineural fibrosis [72].

In regard to the neural component, several types of mechanoreceptors in the skin respond to vibration and may suffer vibration damage. These consist of fast-adapting receptors

(FA-1, Meissner's corpuscles; FA-2, Pacini's and Golgi-Mazzoni corpuscles), which react solely to skin deformation, and slowly adapting receptors (SA-1, Merkel's cell neurite complexes; SA-2, spindle-shaped Ruffini's nerve endings), which respond both to constant skin deformation and to moving stimuli [75]. Initially, only the FA-2 receptors are injured, but with more severe sensory loss, deterioration of both FA-1 and SA-1 receptors also occurs. In addition, much of the vascular phenomenon presumably is due to autonomic nervous system dysfunction. This is thought to be on a central level, due to sympathetic hyperactivity and parasympathetic depression [72].

The diagnosis of HAVS depends on a history of exposure to vibration, coupled with suggestive symptoms in the absence of other possible causes. A number of laboratory procedures, most of which assess the status of the vascular system, can be performed in an attempt to confirm the clinical diagnosis. These include motor and sensory NCS, measures of distal sensory appreciation (vibration, thermal, two-point perception), cold provocation testing, vibrotactile thresholds, thermal thresholds, grip strength, aesthesiometry, and both two-point and depth perception [72, 73, 76]. However, these are not standardized, and many are reported to be of "questionable reliability" [76].

The differential diagnosis of HAVS includes, for the vascular symptoms, primary and secondary Raynaud's phenomenon and, for the neurological symptoms, CTS. The exact relationship between HAVS and CTS is quite controversial. The basic source of the dispute revolves around the question of whether the finger pain and paresthesias experienced by patients with HAVS simply are due to coexisting CTS – some investigators consider HAVS to be a specific predisposing factor for CTS – or result from a separate abnormality of peripheral nerve fibers (e.g., injuries to the receptors or digital nerves in the fingertips and injury to nerve fibers within the carpal canal but caused by vibration, not compression) [74, 75, 77, 78]. The debate is of more than academic importance since, according to many investigators, CTS caused by HAVS responds poorly to conservative therapy and only temporarily to surgical release [74, 75].

The paramount aspect of treatment for HAVS is stopping all exposure to vibration. If this occurs in the early stages, there is improvement in both the subjective and objective findings. If it does not occur until the process is more advanced, some changes may persist. In regard to specific disturbances, the vasospastic problems, which often progress with continued exposure, tend to stop or regress when exposure to vibration ceases. Conversely, the neural symptoms may not regress, even when exposure ceases [79]. Suggestive preventive measures include avoiding medications that cause peripheral vasoconstriction, maintaining body temperature while working, and fitting tools with antivibratory mechanisms [72].

Infectious and Granulomatous Peripheral Neuropathies

38

Susan C. Shin, Sonja Schütz, Anthony P. Geraci, Enrique A. Wulff, and David M. Simpson

Introduction

The infectious and granulomatous neuropathies constitute a variety of inflammatory conditions, often termed "neuritis." In some, the infectious agent or its neurotoxic products are known such as botulism, syphilis, leprosy, Lyme disease, diphtheria, and herpes. In others, the pathogenesis is uncertain or indirect, as in tuberculosis, HIV infection, sarcoidosis, and brucellosis (insert Table 38.1). Peripheral nerve involvement in these disorders may manifest clinically as mononeuropathy, mononeuropathy multiplex, polyneuropathy, and polyradiculopathy. As a group, these disorders are the world's most common causes of neuropathy and, in general, are treatable or preventable. Nerve pathology may result from the inflammatory reaction induced by the infection and from the host's immunological reaction. An infectious organism is considered an etiologic agent when (1) the inflammatory reaction occurs during serologically proven infection, (2) other causes are excluded, and (3) nerve histology demonstrates the infectious organism [1].

HIV-Associated Neuropathies

Introduction

The earliest descriptions of neurological complications of acquired immune deficiency syndrome (AIDS) include multiple peripheral nervous system (PNS) disorders [2–5]. More than one-third of AIDS patients are estimated to have a peripheral neuropathy [5, 6]. Human immunodeficiency virus (HIV) neuropathy may affect proximal and distal components of the motor, sensory, and autonomic PNS, from the neuronal cell body to terminal nerve fibers. Since other AIDS-related neurological conditions, such as myelopathy, myopathy, and dementia, may coexist, the diagnosis of neuropathy may be particularly complicated and challenging.

A wide range of potential etiologies underlies peripheral neuropathy in HIV-infected patients (insert Table 38.2). Inflammatory demyelinating polyneuropathy (IDP) also occurs, particularly in early HIV infection [7, 8]. Distal symmetrical polyneuropathy (DSP) generally occurs in patients with advanced immunosuppression and is also a neurotoxic effect of certain antiretroviral medications [9–13]. Opportunistic infections, such as cytomegalovirus (CMV), can affect nerve roots [14], as does cancer in lymphomatous meningitis [15]. Autoimmune disorders occur in HIV-infected patients and may manifest as IDP or mononeuropathy multiplex (MM) [16]. In addition, noninfectious causes of polyneuropathy such as diabetes mellitus, uremia, alcoholism, and vitamin B12 deficiency must be considered.

Highly active antiretroviral therapy (HAART) has changed the natural history of AIDS. As patients live longer, the incidence and prevalence of neurological complications are likely to increase. The prevalence of HIV-associated sensory neuropathy is reported to be 57.2% in the era of combination antiretroviral therapy [17]. Prompt recognition and treatment of neuropathy may significantly benefit a patient's quality of life. Traditional, symptomatic therapy for neuropathy coupled with new pathogenesis-based treatments may offer pain relief and improve motor function for patients with HIV neuropathy.

Table 38.1 Non-HIV-associated infectious and granulomatous neuropathies

Diagnosis	Etiology	Presenting symptoms	Neurological signs	Diagnostic studies	Treatment
Leprosy	*Mycobacterium leprae* bacillus	Rash, numbness Decreased sweating	Anesthesia w/in areas of rash Cranial neuropathy Autonomic neuropathy	Lepromin skin test – + >5mm Skin biopsy NCV – segmental demyelination EMG – denervation	Dapsone 100mg/day Rifampin 600mg/day Clofazimine 300mg/day
Lyme disease	*Borrelia burgdorferi* spirochete	Drooling, xerophthalmia; LE weakness, incontinence, confusion, HA	Facial palsy, cranial neuropathy Paraparesis, meningismus, ataxia	Elisa/Western blot serology, PCR CSF – pleocytosis, ↑ prot. EMG – axonal neuropathy, radiculopathy	Cetriaxone 2g/day IV Cefotaxime 6g/day IV Doxycycline 200mg/day
Zoster neuropathy	*Varicella zoster* virus	Painful rash, weakness (incl facial) Radicular pain (w/o rash)	Meningismus, vesicular eruption, cranial neuropathy, dermatomal sensory loss	Exam – vesicular rash CSF PCR for VZV EMG – denervation (if weakness)	Acyclovir 300mg/5× day Valaciclovir, famciclovir TCA's, opioids, topical lidocaine High-concentration capsaicin dermal patch
Diphtheria	*Corynebacterium diphtheriae*	Sore throat, weakness (all extremities) Hoarseness, SOB	Cranial neuropathy, quadraparesis, ↓ pulmonary function tests	Pharyngeal culture for C. diphtheriae EMG/ NCV – demyelination	Penicillin Erythromycin
Botulism	*Clostridium botulinum* toxin	Blurred vision, diplopia, dysphagia, weakness, SOB	Loss of convergence, ophthalmoplegia, flaccid paralysis, ↓ PFTs	Clinical exam and history, diagnosis of exclusion	Gastric lavage, botulinum antitoxin
Syphilis	*Treponema pallidum* spirochete	Lancinating pains, incontinence, paresthesias	Ataxia Loss of DTRs in lower extremities	CSF: VDRL +, pleocytosis	Penicillin, doxycycline
Brucellosis	*Brucella suis*, *B. melitensis*, *B. abortus* bacteria	Weakness, incontinence, diplopia	Cranial neuropathy, paraparesis	Serum and CSF serology and culture Clinical exam	Rifampin, doxycycline, streptomycin, sulfa
Tuberculosis	*Mycobacterium tuberculosis*	Diplopia, HA, confusion.	Cranial neuropathy, paraparesis	PPD + >5–10mm CSF – lymphocytic pleocytosis AFB culture	Isoniazid, ethambutol, rifampin, etc.
Tick paralysis	Tick bite – Dermacentor species	Weakness after tick bite	Ascending paralysis, ↓ DTRs in legs	Normal CSF Exam for ticks on skin	Removal of tick, supportive care
Sarcoidosis	Unknown	HA; weakness, numbness in any distribution, confusion	Meningismus, hydrocephalus, motor/ sensory neuropathy	↑ ACE level in serum/ CSF, nerve or muscle biopsy (granulomas)	Corticosteroids, cyclosporine

Etiology and Pathogenesis

The etiologies of HIV-associated neuropathy are diverse, and a broad range of mechanisms may cause PNS dysfunction (Table 38.3) and include cytotoxic effects due to direct HIV infection, cytokine dysregulation, opportunistic infections, neoplastic processes, autoimmune disorders, metabolic abnormalities, and toxic effects of medications.

Direct and Indirect Effects of HIV

Although the direct pathogenesis of HIV-associated degeneration of peripheral nerve fibers is unknown, investigators have suggested that peripheral neuropathy in AIDS is due to direct HIV infection [18]. Ho et al. was able to culture HIV from sural nerve homogenates of two AIDS patients who did not have symptomatic peripheral neuropathy [16, 19]. De la Monte et al. also proposed that direct infection of the peripheral nerve caused AIDS neuropathy [20]; this was based on the observation of perineural mononuclear infiltration, suggesting a cell-mediated response against the virus. Another report provided electron microscopic evidence of HIV infection of the sural nerve [21]. However, initial attempts to demonstrate HIV in dorsal root ganglion cells, nerve roots, or peripheral nerves were unsuccessful [20, 22–24]. While in vitro studies demonstrated neurotropism of certain HIV

isolates [25–27] through a CD4-independent mechanism (apparently mediated by the gp120 glycoprotein) [28–31], autopsy and biopsy material revealed HIV only in macrophage-derived cells and endothelium of the central and peripheral nervous systems [32–36]. Using improved molecular techniques, HIV-1 nucleic acid may be identified in a small percentage of astrocytes and neurons of advanced AIDS patients [37, 38]. Up to a quarter of neurons from the dorsal root ganglion of some AIDS patients have HIV-1 nucleic acid detected by in situ hybridization [39]. Acharjee et al. reported that transcripts and proteins from an HIV accessory protein, viral protein R (Vpr), were detected in dorsal root ganglion and peripheral nerves of HIV-infected patients. Furthermore, retraction of neurites was seen in HIV-infected human dorsal root ganglion cultures. Dorsal root ganglion neuronal damage is theorized to occur via Vpr-related cytosolic calcium activation and changes in the cytokine system [40]. Ultimately, HIV infection of glia and neurons may not be pathogenic but may prove to be a viral reservoir [41].

Widespread functional and pathological damage to the PNS and the absence of significant in vivo infection of neurons suggest indirect mechanisms, such as cytokine dysregulation and immunologic dysfunction, as etiologic factors. Elevations of several proinflammatory cytokines in chronic HIV infection are associated with clinical manifestations including wasting syndrome, aphthous ulcers, chronic diarrhea, and dementia [42]. Similarly, elevation of tumor necrosis factor alpha (TNF-α), interleukin-1, and interleukin-6 occurs in peripheral nerve and dorsal root ganglia of AIDS patients [43–45]. Low level HIV-1 replication through cytotoxic T lymphocytes may induce cytokine expression and consequent degeneration of sensory neurons of the dorsal root ganglion [45]. This process may be mediated by the HIV glycoprotein gp120, which activates T lymphocytes [42] and binds to sensory ganglion neurons [28]. Proposed mechanisms of neuronal injury include oligodendrocyte injury by TNF-α, quinolinic acid-induced neurotoxicity via the N-methyl-D-aspartate receptor [46], and complement-dependent or calcium-mediated injury triggered by gp120 binding [28, 46]. Apoptotic macrophages and neurons are observed in the sensory ganglia of AIDS patients, [47] and DNA breaks, suggestive of apoptosis, are found in dorsal root ganglion cells [48]. Therefore, AIDS-associated peripheral neuropathy may be a final common pathway of apoptosis mediated by global dysfunction of the immune and cytokine systems.

Paraproteinemic neuropathy may be another indirect mechanism that causes DSP in AIDS patients. In one study, IgM and IgG reactivity against myelin proteins was detected in 25 sera of 35 HIV-infected patients, but none of the 48 controls [49]. However, the seropositive patients in this cohort did not have clinical neuropathy, and a causal relationship is presumptive.

Drug Toxicity

Some therapies for HIV infection are neurotoxic, and the neuropathy that develops is usually clinically and electrophysiologically indistinguishable from DSP. Certain adjunctive therapies for AIDS-related conditions and at least

Table 38.3 Diagnosis of HIV-related peripheral neuropathies

Diagnosis	CD4+ (cells/mm^3)	Presenting symptoms	Neurological signs	Diagnostic studies
DSP	<200	Distal numbness, paresthesias, pain	Stocking-glove sensory loss, ↓ ankle reflexes	EMG: distal axonopathy
IDP	>500, <50	Progressive weakness, paresthesias	Weakness, areflexia, mild sensory loss	CSF: ↑WBC, ↑↑ protein EMG: demyelination
MM	>500, <50	Facial weakness, foot drop, wrist drop	Multifocal cranial and peripheral neuropathies	EMG: multifocal axonal Neuropathy CSF: CMV cultures, PCR Nerve bx: inflammation, vasculitis, CMV inclusions
PP	<50	Lower extremity weakness, paresthesias, urinary dysfunction	Flaccid paraparesis, saddle anesthesia, ↓ reflexes, urinary retention	CSF: ↑↑ PMNs, CMV culture, PCR, EMG: polyradiculopathy

Table 38.4 Commonly used neurotoxic medications in patients with HIV infection

Drug	Indication	Neuropathy type
Didanosine (ddI)	Antiretroviral	Sensory, axonal
Zalcitabine (ddC)	Antiretroviral	Sensory, axonal
Stavudine (d4T)	Antiretroviral	Sensory, axonal
Thalidomide	Aphthous ulcers	Sensory, axonal
Dapsone	Pneumocystis carinii pneumonia (PCP) prophylaxis	Motor>sensory, axonal
Isoniazid	Tuberculosis	Sensorimotor, axonal
Pyridoxine (vitamin B6)	Supplementation with isoniazid	Sensory neuronopathy; worse in slow acetylators
Metronidazole	Antimicrobial (anaerobic infections)	Sensory, axonal
Vincristine	Lymphoma	Sensory, axonal
Etoposide	Kaposi's sarcoma	Sensory, neuronopathy
Chloramphenicol	Antimicrobial (salmonella infections)	Sensory, demyelinating; related to B12 metabolism
Ethambutol	Mycobacterial infections	Sensorimotor, axonal; may precede optic neuritis

three antiretroviral agents are neurotoxic (see below and Table 38.4). Isoniazid for tuberculosis, particularly when not supplemented with pyridoxine [50, 51], and vincristine and etoposide chemotherapy for lymphoma and Kaposi's sarcoma produce DSP [52, 53]. Thalidomide, a long-known cause of sensory axonal neuropathy, [54–56] is used to treat HIV-associated aphthous ulcers and may cause DSP; [57] however, controlled trials suggest a low incidence [58]. Neuropathy is caused by high-dose pyridoxine [59, 60] and the widely used antimicrobials, metronidazole, dapsone, and chloramphenicol [61–66]. Finally, the commonly abused neurotoxin, ethanol, may be the cause of neuropathy in some AIDS patients.

The dideoxynucleoside analogues didanosine (ddI), zalcitabine (ddC), and stavudine (d4T) possess dose-dependent neurotoxicity [11, 67]. Peripheral neuropathy may occur in 20% of patients taking ddI for at least 10 months, but neuropathic symptoms may resolve after discontinuation of ddI and most patients tolerate rechallenge with half the initial dose [68]. The incidence of neuropathy in Phase I and II studies of ddI and ddC ranges from 25% to 66% [69–71]. Neuropathic manifestations were more common in patients taking higher daily ddC doses (27.2mg/kg vs. 13.9mg/kg). Patients generally improve after withdrawal of the neurotoxic agent, although some worsen for several weeks before improvement, a phenomenon known as "coasting." Some patients may not improve after drug discontinuation and may have coexistent DSP related to primary HIV infection.

Stavudine (d4T) and ddI have similar neuropathic effects, although the incidence of neuropathy appears lower as compared with ddC. In a phase I trial of d4T at a maximum tolerated daily dose of 2.0mg/kg, neuropathy occurred in 55% of patients [72]. Larger studies using lower daily doses of 0.5mg/kg and 1.0mg/kg documented neuropathy in 6–21% of patients [11]. Similarly, ddI is linked with neuropathy in 12–34% of patients in phase I studies [73]. Severe immunosuppression of advanced HIV disease, low hemoglobin, and history of neuropathy are associated with nucleoside analogue-associated DSP [11, 74, 75]. Longer survival with combination antiretroviral therapy, higher CD4+ counts, and better overall health may prolong use of these agents with lower cumulative side effects. A controlled study evaluating ddI and ddC in patients with CD4+ counts between 200 and 500 cells/mm^3 confirms this prediction, with neuropathy rates between 3 and 6% [76]. While neurotoxic d-drug ARV use is now infrequently used in the USA, Europe, and other industrialized countries, its use in the developing world remains common, as is the frequency of neurotoxic neuropathy.

The mechanism of nucleoside analogue neurotoxicity is unknown. A few studies suggest that ddC may be cytotoxic by causing defective mitochondrial DNA replication, possibly by reversible inhibition of DNA gamma-polymerase [76–79].

Autoimmune Mechanisms

Patients infected with HIV may develop acute inflammatory demyelinating polyneuropathy (AIDP), although it is not clear that the incidence is greater than that in the general population. AIDP most often occurs early in HIV infection. Seropositive and negative patients with AIDP have similar clinical and electrophysiological features. The autoimmune pathogenesis of AIDP is likely similar to patients without HIV infection [6, 7]. The HIV genome is not detectable in Schwann cells or perineural cells by in situ hybridization, indicating that direct HIV infection of peripheral nerve is not responsible for the syndrome [6]. Immune dysregulation is supported by detection of anti-myelin antibodies with titers that decrease with convalescence [80] and increased cerebrospinal fluid (CSF) levels of soluble CD8 and neopterin [81, 82]. The treatment of IDP in HIV infection is similar to that in HIV-uninfected patients, including IVIg and plasmapheresis, although there are no controlled trials.

Mononeuropathy multiplex (MM) has clinical and electrophysiological similarities to AIDP, but its pathology is restricted to single or multiple nerves. When MM occurs early in HIV infection, autoimmune mechanisms are likely responsible, and improvement occurs with corticosteroids or intravenous immunoglobulin. Early MM may also remit spontaneously and has a relatively good prognosis [83, 84].

Metabolic Abnormalities

As HIV infection progresses to AIDS, some patients become malnourished from several causes. Dementia can decrease appetite and compromise swallowing, candida esophagitis produces odynophagia, and wasting syndrome leads to cachexia. Some investigators compare AIDS-related DSP to that of other chronic illnesses. [85] In a series of 251 patients, worsening nerve conduction values correlated with low serum albumin, low hemoglobin, and weight loss [10].

Although vitamin B12 deficiency is not a common cause of DSP in AIDS patients, it is treatable and therefore, prudent to screen for B12 deficiency in all patients with neurologic complaints. One small study showed that 29% of HIV-seropositive patients with abnormal vitamin B12 metabolism (serum level or Schilling test) had DSP [86], but others could not confirm this observation [2, 10, 20, 87]. No difference in vitamin B12 levels was found in 153 HIV-seropositive patients compared to 57 HIV-seronegative controls, but the cohort included only 15 patients with AIDS [87].

Although malnutrition, weight loss [2, 5, 85, 87], and wasting syndrome [5, 10] are common among patients with AIDS and DSP [88], they are also common in advanced AIDS patients *without* neuropathy. Therefore, a causal relationship may not be present between DSP and malnutrition except when associated with discrete vitamin deficiency or other systemic illnesses known to cause neuropathy.

Opportunistic Infections

Most opportunistic infections involve the central nervous system (CNS), and not the PNS, with the major exception of CMV infection. Some patients with progressive polyradiculopathy (PP) have overt or subclinical evidence of widespread CMV infection (e.g., retinitis, gastroenteritis). Almost all autopsy cases show signs of CMV in peripheral nerve [16]. A causal relationship between PP and CMV is supported by necrosis and inflammation of nerve roots with polymorphonuclear and mononuclear infiltrates and positive immunocytochemistry for cytomegalic inclusions [89–92]. CMV DNA may be detected by polymerase chain reaction (PCR) in CSF of patients with MM and advanced AIDS [93].

Clinical Presentation

AIDS patients present with a variety of PNS syndromes. These include inflammatory demyelinating neuropathy (acute and chronic), mononeuropathy multiplex (MM), progressive polyradiculopathy (PP), autonomic neuropathy, and a rare sensory ataxic neuropathy due to ganglioneuronitis [93]. Weakness or paresthesias may be acute, subacute, or chronic. With the exception of cranial neuropathies and some cases of MM, lower extremity complaints predominate.

Distal Symmetrical Polyneuropathy (DSP)

A painful, peripheral neuropathy occurs in 30% of AIDS patients. In the original description, 7 of 50 patients had neuropathy characterized by painful dysesthesias, a moderate, symmetrical, distal sensory loss involving large and small fibers in a stocking-and-glove distribution, and absent or depressed ankle reflexes [2]. Since this original description, the clinical features of DSP has been well characterized [3, 5, 20, 21, 24, 88, 94–97].

The cardinal feature of DSP is pain. Patients complain of numbness, burning, and paresthesias of the feet with pain usually beginning in the toes and soles of the feet. Symptoms may become severe that patients develop an antalgic gait and are unable to tolerate light contact with clothing or bedsheets. Often, the degree of pain appears disproportionate to objective findings on neurological examination. The most common, and often only, signs of DSP are depressed or absent ankle reflexes [5, 9, 10, 88, 95]. Relatively normal ankle reflexes together with hyperactive knee reflexes, in particular in the presence of Babinski sign, suggest coexistent myelopathy. Sensory examination typically reveals increased

vibratory thresholds and reduced pinprick and temperature in a stocking-and-glove distribution. However, joint position sense is usually relatively normal [5, 16]. The arms may become involved later in the disease. Weakness is not a prominent feature of DSP but if present is usually restricted to distal muscles [5].

Inflammatory Demyelinating Polyneuropathy (IDP)

HIV-infected patients with IDP present similarly to patients with IDP without HIV infection. AIDP produces rapidly progressive weakness of two or more limbs, often starting in distal muscles. Areflexia or hyporeflexia is an essential, diagnostic feature. Patients may have only minor sensory complaints and occasionally have facial diparesis. AIDP is usually monophasic that progresses rapidly over 4 weeks [98]. The most serious complications are autonomic instability and respiratory failure from diaphragmatic weakness [7, 99, 100]. CIDP may be associated with more prominent sensory complaints and is characterized by a relapsing-remitting course and a spectrum of disability from weakness [7, 101–106].

Mononeuropathy Multiplex (MM)

MM is an inflammatory neuropathy that affects single or multiple nerves causing asymmetric motor and sensory complaints. Patients typically complain of weakness or dysesthesias in the distribution of cutaneous nerves, mixed nerves, and nerve roots [83]. Characteristically, tendon reflexes are depressed in the distribution of affected nerves. Cranial neuropathies are frequently present [16, 95, 100]. MM is often self-limited when presenting early in HIV infection. In one study, eight of ten HIV patients with MM improved after 1 year without treatment [84]. In more advanced HIV disease, particularly when CD4+ counts are below 50/mm^3, confluence of neurologic deficits in peripheral nerves may simulate IDP or progressive polyradiculopathy [84, 95, 100]. Severe immunosuppression predisposes to systemic CMV infection, which may be an etiology of MM [107].

Progressive Polyradiculopathy (PP)

PP presenting as a rapidly, progressive cauda equina syndrome was described by Eidelberg and associates in 1986 [91]. Leg weakness and difficulty walking are the usual presentation [14]. Other symptoms include bladder and bowel dysfunction, low-back pain, and leg paresthesias. Flaccid paraparesis is accompanied by depressed or absent deep tendon reflexes. Pan-sensory loss is usually present [14, 89, 91, 93]. A characteristic distribution of numbness in the S4 and S5 dermatomes occurs in about 10% of patients [14], and urinary retention is present in over two-thirds [92]. Arm involvement may occur late in PP, and cranial nerves may be involved in severely immunosuppressed patients [89]. PP may simulate confluent, progressive MM [108], although sphincter dysfunction is a differentiating feature. CMV is detected in peripheral nerves of almost all autopsy cases [16]. Rare HIV patients may have syphilitic or lymphomatous PP.

Cranial, Autonomic, and Ganglio Neuropathies

Cranial neuropathies in HIV disease may herald serious illness and must be evaluated promptly. In a study of 2,370 HIV-infected patients, cranial neuropathies occurred in 98 (4.1%) [109]. These neuropathies may be relatively benign, as in facial neuropathy in relatively immunocompetent patients, or may be manifestations of lymphomatous meningitis or severe opportunistic infections, such as CMV encephalitis or cryptococcal meningitis. Occasionally, cranial neuropathies are caused by primary CNS lymphoma, non-Hodgkin's lymphoma, or brain stem glioma [110].

Orthostatic hypotension and lightheadedness with abnormal autonomic testing may occur in AIDS patients [111, 112]. Early reports involved small numbers of end-stage AIDS patients with other causes of hypotension, such as diarrhea and dehydration. However, larger series documented up to a 50% incidence of abnormal sympathetic and parasympathetic system functions [113–115]. Identification of autonomic denervation in the jejunal mucosa of HIV-infected patients further supports autonomic pathology [116].

Rarely, a sensory ataxic neuropathy occurs. One patient was reported with neuronal loss in the sensory ganglia [94]. The clinical picture of sensory ataxia is similar to tropical ataxic neuropathy, associated with HTLV-1 infection [117].

Differential Diagnosis

The differential diagnosis of HIV neuropathy is large and challenging including many treatable conditions (Table 38.2). While more than 30% of AIDS patients can be diagnosed with DSP, many confounding neurological disorders can lead to an incorrect diagnosis. Among patients with DSP, other common causes of distal polyneuropathy such as vitamin B12 deficiency, ethanol abuse, neurotoxic medications, uremia, and diabetes must be considered. A rare cause of painful peripheral neuropathy known as diffuse infiltrative lymphocytosis syndrome (DILS) can occur in some patients with CD8+ hyperlymphocytosis resulting in a Sjögren-like syndrome. The painful symptoms can be similar to those found in DSP, but the symptom onset is often more acute, motor involvement is frequent, and findings may be asymmetric or only restricted to the arms [118–120]. Although the cause of DILS is unclear, HIV-mediated immune dysregulation, rather than monoclonal T-lymphocyte expansion, is likely [121, 122].

Progressive polyradiculopathy is among the most serious PNS manifestations of HIV infection. Empiric therapy with ganciclovir is indicated in most severely immunosuppressed

patients [90, 92, 123–125]. If improvement does not occur, other causes, such as lymphomatous meningitis, syphilis, or degenerative disc disease, must be considered [15, 126, 127]. Similarly, CMV infection should be considered with rapidly progressive MM, especially in patients who do not respond to immunomodulatory therapy.

Evaluation and Diagnosis

The first and most important step in the evaluation of an AIDS patient with neuropathy is a thorough history and physical examination. Symptom duration, pain location, distribution of weakness, medication use, and concurrent illness should guide diagnosis. Ancillary tests, such as nerve conduction studies (NCS), needle electromyography (EMG), autonomic testing, and blood, CSF, and neuroradiological studies, are often confirmatory (Table 38.4).

NCS characterize the physiology of nerve involvement and identify subclinical nerve pathology. The most common NCS abnormality in DSP is reduced or absent sural sensory nerve action potentials (SNAPs) [2, 10, 88, 128]. Although sensory complaints predominate, motor fibers are often affected . In a small study, all patients had abnormal peroneal and tibial motor conduction studies [88]. Generally, motor nerve conduction velocities are mildly reduced compared to amplitude reduction [2, 88, 128], consistent with axonopathy. Median and ulnar sensory and motor amplitudes may be reduced [2, 10, 88]. Rarely, NCS may be normal [2, 88, 96, 97]. F-wave and H-reflex latencies may be prolonged [10, 21, 96]. The electrophysiologic abnormalities in drug-induced and HIV-related DSP are indistinguishable [70].

The NCS findings in inflammatory demyelinating polyneuropathies are similar to those of patients without HIV infection [129, 130]. They are characterized by reduced motor conduction velocities in two or more nerves, occasional conduction block between proximal and distal nerve stimulation sites, and prolonged distal latencies. If axonal degeneration is present or distal conduction block occurs, reduced compound muscle action potential (CMAP) amplitudes may be observed. Differentiation of CIDP from AIDP by electrophysiologic parameters is often difficult. AIDP is usually an acute, monophasic illness, whereas CIDP is subacute and marked by progression or fluctuating symptoms. Electrophysiological abnormalities are more pronounced in CIDP than in AIDP [7, 101].

Typically, MM produces reduced CMAPs, SNAPs, and mild slowing of motor or sensory conduction velocities. NCS abnormalities are multifocal and asymmetric [96]. Rapidly progressive and confluent MM may have findings similar to IDP and PP. However, since PP is restricted to lumbosacral nerve roots producing a proximal axonopathy, preserved SNAPs, reduced CMAP amplitudes, and diffuse denervation of multiple proximal and distal muscles in the legs and lumbar paraspinal muscles can help differentiate PP from other neuropathies [7]. F-wave latencies may be prolonged, whereas distal conduction velocities are usually only mildly affected [92].

Needle EMG is most valuable in the diagnosis of HIV myopathy but may assist in neuropathy evaluation. Denervation on EMG may discriminate among PP, DSP, and MM. Active or chronic partial denervation with reinnervation in distal leg muscles can be demonstrated in some DSP patients [21, 88, 96, 97]. Needle EMG evaluation of lumbosacral paraspinal muscles in PP patients will often demonstrate denervation. AIDP and CIDP patients have reduced motor unit recruitment patterns, which is usually caused by conduction block rather than axonal degeneration [7, 101].

Autonomic function testing has limited clinical applications. Lightheadedness and syncope are not unusual in the severely ill AIDS patient. Dehydration, anemia, and cardiomyopathy must be excluded before ascribing symptoms to dysautonomia. Autonomic nervous function tests include orthostatic blood pressure measurements, provocative tests such as Valsalva maneuver and tilt table, the cold pressor test, and the quantitative sudomotor axon reflex test (QSART). Plasma catecholamine levels may be inappropriately low, but this is not a consistent finding [111–113, 115, 131–133].

Certain clinical situations warrant lumbar puncture. Examples include any neuropathy associated with encephalopathy or myelopathy, constitutional symptoms (e.g., fever, weight loss), rapid symptom progression, or a history of lymphoma or CMV disease. However, interpretation of CSF values in HIV-infected, asymptomatic individuals must be done with caution. CSF abnormalities are found in 60%–90% of infected persons without neurological abnormalities or opportunistic infections [134, 135]. A predominantly lymphocytic CSF pleocytosis is present in 18%–65% of asymptomatic HIV-infected patients [136–139].

The character of the pleocytosis can help in diagnosis of peripheral neuropathies in AIDS patients. In contrast to HIV-seronegative patients with AIDP, HIV patients usually have a lymphocytic pleocytosis of up to 50 cells/mm^3. [7] CSF protein is elevated, as in seronegative patients. A nonspecific, mild, mononuclear pleocytosis is not unusual in DSP and MM patients [83, 138, 140–142]. A pronounced polymorphonuclear pleocytosis with elevated protein and hypoglycorrhachia is a discriminating feature of PP caused by CMV. CSF pleocytosis to 2,000/mm^3, protein concentrations as high as 1,000 mg/dl, and glucose often below 40 mg/dl occur [90, 123]. A mononuclear pleocytosis raises the concern for lymphomatous meningitis, especially if CSF leukocyte counts are less than 200/mm^3 [126].

CSF glucose concentration is often normal in HIV patients [3, 143, 144], and a very low concentration suggests an opportunistic infection or neoplasm. Elevated CSF protein is common [137, 139, 145] and generally not useful in diagnosis

unless well above normal. PCR detection of CMV DNA in the CSF may provide a more specific diagnosis in suspected PP or MM [93, 146], since CSF cultures for CMV are positive in only half of HIV-infected patients with PP [90, 92, 123].

Exhaustive laboratory investigations for reversible causes of neuropathy in AIDS patients are usually uninformative. Serum vitamin B12 levels, folate, erythrocyte sedimentation rate, antinuclear antibodies, fasting blood glucose, liver enzymes, creatinine, thyroid function tests, and serum protein electrophoresis are usually normal [2, 5, 21]. In most patients, neuroimaging does not add to evaluation of HIV-related neuropathy. Patients with cranial neuropathy should have magnetic resonance imaging (MRI) or computed tomography (CT) of the brain to exclude CNS pathology, such as toxoplasmosis encephalitis, cryptococcal meningitis, or lymphoma. Lumbosacral spine imaging may exclude abscess or neoplasm in suspected cases of PP. In PP caused by CMV, lumbosacral spine MRI often demonstrates enhancement of the thecal sac, leptomeninges, and cauda equina [122, 147, 148].

Nerve biopsy is rarely necessary in AIDS patients with neuropathy. Diagnosis is usually made by clinical and laboratory examinations. The most common nerve biopsy finding in DSP is axonal degeneration of myelinated and unmyelinated fibers [20, 21, 24], which is indistinguishable from other toxic axonopathies. Nonspecific, mild epineural and endoneurial mononuclear inflammation may be observed [24, 29, 83]. While demyelination occurs with DSP [20, 21], this appears not to be segmental [21, 24]. The diagnosis and etiology of MM may be facilitated by nerve biopsy. CMV virions are detected in mononuclear, endoneurial, and endothelial cells [149]. Cytomegalic inclusion bodies were identified in eight peroneal nerve biopsies of MM patients, who improved with ganciclovir [93]. Necrotizing arteritis occurs in some patients with progressive sensorimotor neuropathy, and in these patients, muscle biopsy may be a more sensitive diagnostic test compared to nerve biopsy [150].

Recently, skin biopsy has been utilized to evaluate patients with symptoms of small fiber neuropathy (SFN). Symptoms of SFN include numbness, burning, paresthesias, and painful dysesthesias. Skin biopsy is a minimally invasive procedure that can be used to assess the epidermal nerve fiber density (ENFD), which is reduced in small fiber neuropathies. The sensitivity and specificity of the test has been reported to be 88.4% and 96%, respectively [151–155]. A longitudinal study conducted by Herrmann et al. reported serial measurements of ENFD in HIV patients and found a 14-fold greater risk of developing symptomatic HIV-associated DSP in 6–12 months with ENFD <10 fibers/mm versus HIV patients with >10 fibers/mm who did not develop symptomatic DSP [151]. Skin biopsy can be a useful test to demonstrate peripheral nerve pathology when symptoms occur in the setting of normal electrodiagnostic studies.

Treatment

The treatment of HIV-related peripheral neuropathy depends on etiology. The rationale for therapy is based on four objectives: antiviral treatment, immunomodulation, treatment of underlying causes, and symptom reduction.

Antiviral Therapy

Anecdotal cases report treatment responses with zidovudine for DSP [156] and HIV-related vasculitis [157], but nucleoside analogue antiretroviral therapy does not play a major role in the treatment of neuropathy. Emerging reports suggest that combination therapy may decrease DSP incidence, but it remains to be determined if HAART with combination regimens including protease inhibitors will have an impact on the natural history of DSP [158].

Ganciclovir is a nucleoside analogue that is effective for treating CMV retinitis and can benefit PP, and some MM patients. Severely immunosuppressed patients with MM, unresponsive to plasmapheresis and corticosteroids, may benefit from empiric ganciclovir treatment. Ganciclovir may be effective for MM in AIDS patients with CMV DNA in the CSF [93, 108, 159]. Ganciclovir should be initiated in AIDS patients with PP, particularly those with a CSF polymorphonuclear pleocytosis [14, 123]. Improvement often occurs within 2–4 weeks, but a therapeutic effect may take several months, and lifelong maintenance therapy is recommended [92, 123, 160]. Patients with severe paraparesis who are not treated for more than 3 weeks are unlikely to improve [90]. For patients who deteriorate despite early treatment initiation, drug resistance should be considered [161], and an alternative antiviral agent, such as foscarnet or cidofivir, may be warranted [90, 125, 160, 162, 163]. A study of antiviral therapy for HIV-associated CMV disease was halted because of a markedly reduced CMV incidence in the current era of HAART.

Immunotherapy

Corticosteroids are useful in the treatment of inflammatory neuropathy associated with HIV infection. While controlled studies are not available, case series indicate that prednisone is often effective in treating CIDP, although relapse is common when therapy is stopped [7, 107, 164]. Prolonged corticosteroid treatment leads to further immunosuppression and increased risk of opportunistic infection, which further complicates treatment of AIDS patients. In some patients with early MM and delayed or incomplete recovery, corticosteroids may be beneficial [101]. Plasmapheresis and intravenous immunoglobulin are effective in CIDP [7, 97, 101, 164] and MM [101]. However, improvement is often transient, and frequent, regular treatments may be required. Immunotherapy is not effective in the treatment of DSP [83, 101]. Immunomodulating therapies await placebo-controlled trials in HIV patients with peripheral neuropathy [107, 165].

Other Treatments

DSP is among the most painful and debilitating neurologic complications of AIDS. Current therapy is largely symptomatic. Other possible causes of DSP should first be treated, for example, vitamin B12 replacement, diabetic management, withdrawal of offending drugs, and alcohol abuse treatment.

Mild symptoms of DSP may improve with nonsteroidal anti-inflammatory agents or acetaminophen [11, 164]. Tricyclic antidepressants, such as amitriptyline or desipramine, at doses up to 150mg/day, and anticonvulsants, such as carbamazepine and phenytoin, often moderate neuropathic pain [11, 99, 166]. New anticonvulsants may also be of benefit. Lamotrigine reduced pain compared to placebo in 42 patients; [167] this positive effect was also seen in a large placebo-controlled study of 92 patients [168]. To avoid rash, lamotrigine must be titrated slowly. Gabapentin, which has a favorable pharmakokinetic profile and sparse drug-drug interactions, has been used successfully in other neuropathic conditions [169, 170], but reports of its effectiveness in HIV-associated DSP are anecdotal [171]. A placebo-controlled study demonstrated that pregabalin was not superior to placebo in the treatment of painful HIV neuropathy [172].

For refractory pain, adjunctive treatment with topical lidocaine 5% and capsaicin 0.075% may be beneficial [11, 166]. A double-blind controlled multicenter study showed significant improvement in 307 HIV patients with DSP using a high-concentration capsaicin dermal patch. However, a second similar study could not replicate these results [173]. The treatment was shown to be safe and symptomatic relief lasted for up to 12 weeks [174]. However, some patients with DSP may have severe and debilitating pain that requires narcotic analgesia [11, 164]. Antiarrhythmic medications that block sodium channels, such as mexiletine, have been used without success [175]. A controlled trial of mexiletine and amitriptyline did not demonstrate a difference compared to placebo [176]. Efficacy of alternative therapies have not held up to rigorous scientific scrutiny. A controlled trial of acupuncture was not superior to sham acupuncture for HIV neuropathy [177].

Laboratory data and studies of animal models suggest that recombinant human nerve growth factor (rhNGF) as a potential treatment of peripheral neuropathy, in particular diabetic and HIV-related neuropathies [178]. In a placebo-controlled trial of 270 patients with painful HIV neuropathy, subcutaneously administered rhNGF produced significant pain reduction [179]. However, most secondary measures of nerve regeneration, including quantitative sensory tests and epidermal skin biopsies, did not show improvement and the future of rhNGF therapy is uncertain.

Prognosis

Currently, there is no cure for AIDS or most HIV-related PNS disorders. Many opportunistic infections can be treated, but the response is often transient or incomplete. In a study of sixteen PP patients treated with ganciclovir, six improved, three stabilized, and the remainder died shortly after treatment initiation [160]. In the current era of HAART, a dramatic increase in survival has occurred. The Multicenter AIDS Cohort Study (MACS) demonstrates that the incidence of sensory neuropathy between 1985 and 1992 has increased, perhaps as a result of longer survival [9]. However, as therapies evolve and more AIDS patients benefit from viral suppression, combination antiretroviral therapy may improve the prognosis of AIDS-related neuropathies [158].

Leprous Neuropathy

Introduction

In 1873, Dr. Gerhard Henrik Armauer Hansen identified that the acid-fast bacillus, *Mycobacterium leprae* caused a chronic infectious disease that affects skin and peripheral nerve [180]. Since then leprosy is also known as Hansen's disease. The prevalence of leprosy has fallen greatly in developed countries and is seen only rarely in immigrants from endemic areas [181]. The vast majority of patients are found in the tropic and subtropic regions [182] due to *M. leprae*'s maximal reproduction at 26–30 °C [183]. This characteristic also accounts for its predilection for cooler areas of the body such as the nose, skin, testes, anterior portions of the eye, and superficial nerves. HLA-linked genes, through immune regulation [184] and by T lymphocytes [185], play an important role in leprous clinical manifestations. The host's cellular immunity dictates the peripheral nerve sequelae of leprosy.

Etiology and Pathogenesis

M. leprae is an acid-fast, gram-positive bacillus and an obligate intracellular parasite with a generation time among the longest of all bacteria [186]. The *M. leprae* genome contains 72 loci [187], and identification of coding sequences for heat shock and superoxide dismutase genes make possible PCR detection of bacteria in skin and nerve biopsy specimens [188]. The pathogenesis and transmission of leprosy are not understood well. The viability of *M. leprae* outside the body varies from 7 to 46 days [189] and the incubation period ranges from 2 to 7 years [190]. The main mode of transmission is via the upper respiratory tract. *M. leprae* exist in the nasal mucosa in up to 50% of untreated patients [180, 191], and the bacilli are found in breast milk of infected mothers [192].

The clinical manifestations of leprosy depends on the host's immune response to *M. leprae*. Indeterminate leprosy refers to early stadium of disease with one or several cutaneous lesion and irregular and asymmetrical nerve involvement.

At this stage, spontaneously healing is possible, or progression into one of the manifestations along the clinical spectrum of leprosy. The Ridley-Jopling classification is most commonly used to classify the clinical manifestations of leprosy along a continuum between two poles (*lepromatous and tuberculoid*) with several subdivisions that fall in-between those two extremes (borderline lepromatous, borderline, borderline tuberculoid) [182]. Lepromatous type, or the malignant form, is a stable form that is negative to the Mitsuda skin reaction test (described below). Tuberculoid type, or the benign form, is positive to skin testing. The most common type and group are lepromatous and borderline. The age-related incidence is bimodal, with peaks during preadolescence and adulthood (30–60 years) [193].

In the lepromatous type, the bacilli multiply unchecked and, with an abnormal cell-mediated immune response, can disseminate hematogenously [194]. In the tuberculoid type, preserved cell-mediated immunity prevents disease dissemination [195]. With skin lesion development, peripheral nerves in the cooler areas of the body are damaged in a diffuse, bilateral and generally symmetrical fashion. In these forms, the host is unresponsive to circulating mycobacterial antigens found within polymorphonuclear leukocytes, circulating histiocytes, and monocytes [193, 194]. The balance between CD4+ and CD8+ lymphocytes and cytokine production [196] determines the pathological lesions of the different forms of leprosy. Elevations of cytokines including interleukin (IL)-2 and gamma interferon (gamma-IFN) [197] are found in tuberculoid lesions and high levels of cytokines IL-4 and IL-10 in lepromatous lesions [198].

The lepromatous type is characterized in the early stages of infection of Schwann cells of myelinated fibers by the *M. leprae* and a sparse inflammatory response with few foamy macrophages. In general, nerve architecture is well preserved; however, in more advanced stages, an extensive inflammatory reaction in the epineurium and perineurium produces nerve enlargement. Some nerve fascicles have an "onion skin" hypertrophic appearance from multiple episodes of demyelination and remyelination. Segmental demyelination and axonal degeneration in clustered nerve fibers are also seen in advanced stages [199]. Scarring from intense fibroblast infiltration and increased collagen synthesis may hamper growth of regenerating fibers [200]. In the tuberculoid type and borderline group, leprosy is characterized by total disruption of nerve architecture and an intense inflammatory granulomatous reaction [201].

Clinical Presentation

Sensory loss due to intracutaneous nerve damage is the hallmark of leprous neuropathy. Early involvement of unmyelinated and small myelinated nerve fibers is responsible for the pain, temperature, and sweat loss observed in skin lesions [202]. Histopathologic type and group dictate the clinical presentation, as follows:

Lepromatous type: Early stages may be asymptomatic due to the absence of significant neuronal inflammation [195]. The initial skin lesions may be small individual macules, papules, or nodules or a symmetric rash of the face, forearms, buttocks, and knees. Loss of pain and temperature sensation first appears on the dorsum of the hands and feet, ears, lateral leg, and forearms. At pressure points, perforating skin ulcers may appear. Progressive autonomic and cranial nerve damage produce destruction of nasal bones, lateral eyelid loss, atrophy or hypertrophy of forehead skin, iritis, and alopecia responsible for the "leonine face." [203] In advanced stages, hoarseness, orthostatic hypotension, Raynaud's phenomenon, respiratory stridor, testicular atrophy, systemic amyloidosis, concurrent infection, and renal failure may occur.

Tuberculoid type: The clinical features are isolated to anesthetic skin plaques with central hypopigmentation and erythematous borders on the extensor surfaces of the face, buttocks, and extremities [195]. Generally, only one or two lesions are present over the entire body.

Indeterminate group: This disease form is seen during early immunological reaction. Single or few hypopigmented skin lesions (macules) without sensory loss are present. The lesions usually resolve spontaneously, although some may progress to more extensive disease [204].

Borderline group: This group represents the intermediate cases between the lepromatous and tuberculoid types. The borderline lepromatous group is marked by poorly defined skin lesions of variable shape and size with a tendency to progress to a confluent rash. Patients in the borderline tuberculoid group generally have smaller and less numerous lesions [204].

Novel manifestations, known as "leprosy reactions," may arise secondary to host immune responses during therapy. The type I reaction, also known as the reversal or upgrading reaction, is usually seen in the borderline group caused by heightened cell-mediated immunity. Fever, malaise, swelling, and exacerbation of preexisting skin and nerve lesions characterize the reaction appearing during the first year of dapsone monotherapy in up to 50% of patients [205]. The type II reaction, or erythema nodosum leprosum (ENL), is almost exclusively seen in the lepromatous type caused by antigen-antibody complex deposition (Arthus phenomenon) at multiple sites throughout the body because of massive death of *M. leprae* secondary to therapy. This reaction affects about half of patients during the first year of therapy [206] and is characterized by fever, arthritis, acute peripheral nerve damage, myalgias, and iridocyclitis. Tumor necrosis factor alpha (TNF-alpha) and IL-1 are important in the reaction's incidence and severity [207].

Clinical Presentation

To assess a patient's immune response to *M. leprae* antigen and classify the leprosy subtype, the lepromin skin test is used in endemic areas. The lepromin antigen consists of killed *M. leprae* from infected armadillos (lepromin A) given intradermally as a 0.1ml solution (equivalent to 35 million *M. leprae* bacilli/ml) [208]. The skin response, or Mitsuda reaction [209], is observed at the injection site after 3–4 weeks. In lepromatous type, there is minimal or no reaction, but in the tuberculoid type and borderline tuberculoid group, a positive reaction of greater than 5 mm of induration at the injection site occurs. False-positive reactions are observed with previous subclinical infection, Bacille Calmette-Guérin (BCG) vaccination, or as a response to a nonspecific stimulus.

The diagnosis is supported by a skin biopsy that demonstrates granulomas in skin lesions even if no *M. leprae* bacilli are present. Using Fite stain, skin and nasal smears may have detected the acid-fast *M. leprae* [195]. Nerve biopsy is generally reserved for differential diagnosis of other infectious neuropathies and evaluation of treatment [210].

Electrodiagnostic studies demonstrate axonal degeneration and segmental demyelination in affected nerves. Slow motor nerve conduction velocities can be seen in clinically affected and asymptomatic nerves. SNAP amplitudes usually are reduced, and needle EMG demonstrates denervation with positive sharp waves, fibrillation potentials, and large polyphasic motor unit action potentials in affected muscles [211].

Treatment and Prognosis

The goal of treatment for leprous neuropathy is eradication of *M. leprae*. Therapy for the tuberculoid type and borderline tuberculoid group is dapsone 100mg/day and rifampin 600mg/day for 6 months. The patient should be monitored for 2 years after treatment cessation. In lepromatous type, dapsone 100mg/day with clofazimine 300mg/day for a minimum of 2 years is given and continued until skin smears are negative. Upon completion of therapy, observation for at least 5 years is necessary. New, effective agents include clarithromycin, ofloxacin, pefloxacin, sparfloxacin, and minocycline [212].

Treatment of immune-mediated "reaction states" is focused primarily on early recognition and prevention of disability. In mild reactions with only skin manifestations, oral nonsteroidal anti-inflammatory agents and analgesics are recommended. In more severe cases, high-dose corticosteroids (prednisone 40–120 mg/day) are indicated. Symptoms usually improve in 72 h, but high doses should be continued until the reaction subsides [213]. In severe cases, other agents including clofazimine, thalidomide, plasmapheresis, intravenous immunoglobulin, and cyclosporine have been added to prednisone [214].

The management of leprous neuropathy includes prevention of injury to anesthetic areas, attention to foot hygiene, and reconstructive plastic surgery. The prognosis for neuropathy depends on the type of leprosy, the time of diagnosis, chemotherapeutic response, and reactive states.

Lyme Neuropathy

Introduction

Lyme disease was first recognized in the United States in 1975 in Old Lyme, Connecticut, with outbreak of a disease characterized by recurrent attacks of large joint arthritis in patients with an antecedent tick bite and typical annular skin lesions [215]. In 1982, Burgdorfer et al. isolated a treponema-like spirochete from the *Ixodes dammini* tick that bound serum immunoglobulins from Lyme disease patients [216]. The spirochete was classified in 1984 as a species of the genus *Borrelia* and was named *Borrelia burgdorferi* to honor Willy Burgdorfer [217]. A similar syndrome was observed in Europe in 1922 and recognized as Bannwarth's syndrome since 1944 [218].

Etiology and Pathogenesis

Lyme disease is the most common tick-borne disease in the United States [219]. It is transmitted by tick vectors which include *Ixodes dammini*, *Ixodes scapularis,* and *Ixodes pacificus* in North America and *Ixodes ricinus* in Europe [220]. *B. burgdorferi* is a the gram-negative spirochete that causes Lyme disease. The pathogenesis of Lyme disease is not clear. Different pathogenic mechanisms have been proposed, including direct tissue infection (from the skin via hematogenous spread), indirect effects due to autoimmune responses (autoantibodies to axonal proteins, gangliosides, and myelin), and continuous inflammation (histopathologic changes, vasculopathy) [221]. Peripheral nerve damage may be mediated by B-cell-induced cytokines, such as IL-1, IL-6, and TNF-alpha [222]. Monoclonal antibodies against *B. burgdorferi* epitopes cross-react with PNS axons, Schwann cells, myelin, and other autoantigens [223].

Clinical Presentation

The incubation period ranges from 3 to 30 days, after which the illness follows three clinical stages. Stage I (early localized disease) is characterized by rash (*erythema chronicum*

migrans) at the tick bite site and 3–4 weeks of constitutional symptoms [224]. Neurological complications may appear at stage II (early disseminated disease) and stage III (late disseminated disease) .

Lymphocytic meningitis is the most common finding and lymphocytic meningoradiculitis (LMR) is characteristic in early neuroborreliosis. Patients with LMR usually have variable motor and sensory involvement of multiple nerves, and symptoms may wax and wane over several months [222]. Focal and multifocal peripheral and cranial nerve involvement is observed in half of patients [222]. Facial nerve paralysis is the most common sign with facial diplegia seen in half of patients [225]. Vestibulocochlear, optic, oculomotor, and trigeminal nerves may be affected. In Europe, neuroborreliosis usually presents as a meningoradiculoneuritis, characterized by severe radicular pain with or without paresis [226, 227].

Late neuroborreliosis is marked by peripheral neuropathy and encephalomyelitis [221, 228]. Polyneuritis is seen in a symmetrical, distal pattern [229], and in general, the PNS abnormalities of this stage last for weeks to months. A predominantly sensory neuropathy may be seen in up to two-thirds of untreated patients. Physical signs are uncommon. Weakness is rare, tendon reflexes are preserved, and most patients do not have sensory loss [221].

Stage III is characterized by an asymmetric oligoarthritis, cardiac involvement, and a variety of CNS syndromes including subacute encephalitis, demyelinating disease, cognitive impairment, ataxia, spastic paraparesis with bladder dysfunction, cerebral vasculitis, and dementia [225]. Myositis is reported in some patients [229]. Acrodermatitis chronica atrophicans (Herxheimer) is a late skin manifestation seen in European borreliosis that is associated with a sensory neuropathy [230].

Evaluation and Diagnosis

Serological screening for *B. burgdorferi* is of limited diagnostic value because of seroprevalence of 3% to 10% in the general population [231]. A low pretest probability is likely to lead to a false-positive result. A two-test protocol for the diagnosis of Lyme disease is recommended by the US Centers for Disease Control and Prevention: the whole cell extract enzyme-linked immunoabsorbant assay (ELISA) and the Western blot, which can be performed on serum and CSF [232]. In patients with suspected early or late neuroborreliosis, the demonstration of intrathecal spirochetal antibody production by Western blot, immunoglobulin G and M index, and the spirochetal CSF titer index all support the diagnosis of Lyme disease [221]. The diagnosis of neuroborelliosis is supported by CSF lymphocytic pleocytosis, protein elevation, and elevated immunoglobulin [233]. In inconclusive situations, serology can be repeated in 3–4 weeks or CSF PCR using a variety of borrelial specific primers may be employed. The specificity of PCR approaches 100%, although its sensitivity may not be as high [221]. Electrodiagnostic studies show an axonal neuropathy [234].

Treatment and Prognosis

PNS complications of Lyme disease are treated by Borrelia eradication. Oral doxycycline (200mg/day) and intravenous cefotaxime (6g/day), ceftriaxone (2g/day), or penicillin G (20 million units/day) are recommended [222]. Corticosteroids for pain management is controversial, although prednisolone 50mg/day for 3 days may treat severe pain [235]. Neurological manifestations carry a good prognosis after antimicrobial therapy. Cranial neuropathy recovers within weeks to months, and symptoms of radiculopathy usually abate in 2–16 weeks. Antibiotic therapy also aids in rapid pain resolution and improvement of peripheral neuropathy [222], although neuropathy associated with acrodermatitis chronica atrophicans may be less responsive to treatement [236].

Herpes Zoster Neuropathy

Introduction

Approximately 95% of the United States population is infected with varicella zoster virus (VZV), the causative agent of chicken pox. Latent, lifelong infection persists in sensory nerve ganglia and can reactivate to cause zoster neuropathy, or "shingles." [237]

Etiology and Pathogenesis

Herpes zoster neuropathy results from reactivation of latent virus or from a primary infection. Transmission is by inhalation of infectious particles or direct contact with active lesions. The typical vesicular exanthem of chickenpox develops 10–21 days after infection. VZV is distinguished from herpes simplex by deep dermal invasion producing infarctive necrosis and scar formation. VZV infection is more commonly recurrent and chronic in AIDS and cancer patients receiving chemotherapy and radiotherapy [237]. VZV migrates from sensory nerve fibers into the skin and subcutaneous tissues, producing local tissue damage and inflammation with secondary nociceptor sensitization leading to spontaneous local pain and hyperalgesia. Failure of sensitized nociceptors to normalize after tissue damage and inflammation, collateral local reinnervation, and changes in

central pathways of pain perception play important roles in development of postherpetic neuralgia (PHN) [238].

Clinical Presentation

The most common PNS manifestations of VZV infection include PHN, radiculopathy, zoster sine herpete (zoster without rash), and cranial nerve palsies [239]. Three distinct pain syndromes occur in PHN in the involved dermatomal distributions: (1) an electric shock-like, knifelike, lancinating pain; (2) a monotonous, continuous burning and aching sensation; or (3) pain produced by normally innocuous stimulation (allodynia) [240]. In patients with radicular involvement, motor impairment occurs with sensory abnormalities and local pain in the dermatome of the vesicular rash and follows the corresponding myotome [241]. Patients with motor involvement have an increased incidence of malignancy [242]. Some patients may experience radicular pain, often prolonged, without zosterform rash, known as zoster sine herpete. This entity must be considered in the differential diagnosis of long-standing radicular pain, which also includes diabetic radiculopathy, and carcinomatous or lymphomatous nerve root infiltration [242]. One third of patients with herpes zoster ophthalmicus develop cranial nerve abnormalities [242]. Other HSV cranial neuropathies are most commonly partial or complete oculomotor palsies, optic neuritis, facial palsy, and vestibulocochlear dysfunction (Ramsay-Hunt syndrome) [243].

Evaluation and Diagnosis

The diagnosis of VZV neuropathy largely depends on neurological manifestations and characteristic skin eruptions, which may be biopsied to confirm diagnosis. CSF pleocytosis and elevated protein occurs in up to 50% of patients [239]. PCR for VZV DNA in the CSF may provide confirmation [242]. Segmental denervation is evident by EMG in patients with weakness.

Treatment and Prognosis

Vaccines are available for the prevention of chicken pox in children and for risk reduction of zoster and PHN in adults [244]. Antiviral treatment with acyclovir, valaciclovir, and famciclovir may reduce the duration of an acute attack, provide prophylaxis against recurrent episodes, and decrease the incidence of HSV. Antidepressants, such as amitriptyline, desipramine, and nortriptyline, may relieve pain associated with PHN, but side effects limit their use [245]. Anticonvulsants are of limited value in the management of neuritic pain. Opioids are the most effective therapeutic agents for severe neuritic pain [246]. Recent trials of topical lidocaine 5% in gel and patch form show some effectiveness and may provide a useful adjunctive therapy [247]. Nerve blocks, skin infiltration, transcutaneous electrical nerve stimulation, and intravenous lidocaine may also provide relief of severe pain in some PHN patients [246]. In 2010, the FDA approved a high-dose (8%) capsaicin dermal patch, trade name Qutenza, for the treatment of postherpetic neuralgia. This patch was studied in a randomized, double-blind, multicenter controlled study comparing the high-concentration patch (8%) versus a low-dose capsaicin patch (0.04%). Patients received a single 60-min application and found significant reduction in pain symptoms that was maintained over a 12-week period [248]. The prognosis for recovery in PHN is generally good, although when PHN symptoms become chronic a multidimensional approach to pain therapy will help patients manage their symptoms.

Other Infectious Neuropathies

There are several other causes of infectious neuropathy (Table 38.4). Diphtheria is a rare disease in the United States, generally encountered in developing countries. Diphtheritic neuropathy may be confused with Guillain-Barré syndrome unless a history of pharyngitis is elicited. Oropharyngeal and diaphragmatic weakness occur 5–7 weeks after infection. A demyelinating sensorimotor polyneuropathy involving the trunk and extremities develops 2–3 months after infection [249]. Because the toxin produced by *Corynebacterium diphtheriae* (the causative agent of diphtheria) does not easily cross the blood–brain barrier, myelin damage of cranial and peripheral nerves is limited [250].

Brucella neuropathy is the result of infection by *Brucella suis*, *B. melitensis*, or *B. abortus*. This blood-borne infection involves nerve roots and cranial nerves by a granulomatous meningeal reaction. Diagnosis is based on clinical manifestations, positive serum and CSF serology, and culture of the organism. Treatment requires combination therapy with rifampin, doxycycline, streptomycin, and trimethoprim-sulfamethoxazole [251].

The granulomatous basal meningitis of tuberculosis may involve cranial nerves and nerve roots. Cranial nerves II, III, VI, and VIII are the most commonly affected. Certain therapies for tuberculosis, such as isoniazid, may also precipitate peripheral nerve injury. In HIV-infected patients, *M. tuberculosis* rarely causes acute lumbosacral polyradiculopathy [252].

Finally, tick paralysis is an easily overlooked form of ascending paralysis that presents similarly to AIDP. In North America, *Dermacentor andersoni* (the Rocky Mountain wood tick) and *variabilis* (the common dog tick)

cause most cases. Patients present with weakness and absent lower extremity deep tendon reflexes. Bulbar or respiratory paralysis may occur and prove fatal. Diagnosis and treatment involve finding and removing the offending tick. EMG may show repetitive compound muscle action potentials with a single stimulus. The specific pathophysiology is unknown [253].

Sarcoid Neuropathy

Introduction

Sarcoidosis is a multisystem granulomatous disorder that affects young adults and is manifested clinically with bilateral hilar adenopathy, pulmonary infiltration, and reticuloendothelial system, ocular, and cutaneous involvement. The Johns Hopkins Hospital Sarcoidosis Clinic reported in 1985 that approximately 5% of patients with sarcoidosis develop nervous system complications, and of these, the PNS is affected in approximately 85% of patients [254]. Subsequent studies suggested that the prevalence of neurosarcoidosis is may be as high as 10%. [255]

Etiology and Pathogenesis

The etiology of sarcoidosis and the pathophysiology of nerve fiber damage is unknown. A mixture of vascular compromise and localized granulomatous infiltration probably plays important roles in the pathogenesis of neuropathy. Noncaseating granulomas occur within the endoneurium of peripheral nerves, spinal nerve roots, and cranial nerves. In the absence of angiopathy, some investigators consider that neuropathy is the result of compression of fibers by granulomatous infiltration [256, 257]. Others report granulomas only in the epineurium and perineurium without evidence of direct compression of nerve fascicles but coexisting with varying degrees of angiopathy [258, 259]. Signs of demyelination and remyelination along with small and large fiber loss are usually seen [257, 259].

Clinical Presentation

Sarcoid neuropathy can affect large nerve fibers or small nerve fibers. Large fiber neuropathy presents as cranial neuropathy, mononeuropathy multiplex, radiculopathy, or symmetric polyneuropathy. Any nerve, motor or sensory, may be involved. Cranial neuropathy is most common and often involves the facial nerve, which may be bilateral [254, 260, 261]. Other nerves occasionally involved include the vestibulocochlear nerve and the optic nerve. Patients with eighth-nerve involvement may present with either sensorineural hearing loss or vestibular dysfunction. Papilledema or scotomata in a patient with known sarcoidosis may indicate optic nerve involvement [4, 254]. Patients may complain of diplopia due to meningeal or intraorbital involvement of ocular motor nerves. Horner's syndrome is also reported [254].

Intradural and extradural granulomatous masses may cause radiculopathy. Cauda equina syndrome and arachnoiditis occur [254]. Peripheral neuropathy is seen in up to 14% of patients in some series [256, 257]. Neuropathy may be predominantly sensory with paresthesias and posterior column dysfunction [256] or a more generalized sensorimotor neuropathy or mononeuropathy multiplex [254, 256, 258]. Patients with mononeuropathy multiplex often demonstrate a fluctuating pattern of sensory and motor deficits which may include large areas of anesthesia on the trunk, a distribution referred to as "intercostal neuritis." [260]

Small fiber neuropathy may present with restless leg syndrome or periodic leg movement disorder [261]. Other symptoms include sensory disturbances, such as pain (which can be disabling), numbness, burning, dysesthesias, sheet intolerance, electric-shock-like sensations, as well as autonomic disturbances, such as changes in sweating pattern, sicca syndrome, facial flushing, sexual dysfunction, and bowel/bladder dysfunction [262–264]. On neurologic examination, patients may demonstrate loss of pinprick and temperature sensation as well as allodynia.

The diagnosis of sarcoid neuropathy is straightforward, if the patient is known to have sarcoid. In patients presenting with the clinical syndromes described above and no other potential etiologies, a high degree of suspicion should be maintained and an evaluation for systemic sarcoid initiated when indicated. Tuberculosis and certain forms of leprosy may also be characterized by granulomatous nerve damage, but their clinical features can usually differentiate these forms of neuropathy.

Evaluation and Diagnosis

The diagnosis of sarcoid neuropathy is straightforward when accompanied by recognized systemic involvement. The presence of a recurrent or bilateral facial nerve paralysis suggests the diagnosis of neurosarcoidosis in a patient with established disease [254]. Electrodiagnostic studies help to clarify the type of peripheral nerve involvement in large fiber neuropathy. Motor nerve amplitudes are often markedly reduced, and sensory responses may be absent or of reduced amplitude. Conduction velocities are slowed but conduction block is unusual. Needle EMG may show evidence of denervation [256, 257, 259]. CSF analysis shows a nonspecific mild lymphocytosis and elevation of protein [254].

In patients with mononeuropathy multiplex, muscle biopsy is more likely to demonstrate noncaseating granulomas than sural nerve biopsy.

In small fiber neuropathy, skin biopsy shows reduced intraepidermal nerve fiber density [262, 263, 265]. Autonomic testing such as quantitative sudomotor axon reflex test (QSART), has a sensitivity of approximately 72% [263] and is often used in conjunction with skin biopsy.

Treatment and Prognosis

In spite of their potential side effects, corticosteroids remain the mainstay of therapy. Abdogu et al [260]. reported good response with cyclosporine in 75% of patients with neurosarcoidosis, although most of the patients relapsed after discontinuation of therapy. In certain refractory cases, radiation therapy has some benefit [259, 260, 266]. Lower et al. reported that methotrexate is well tolerated, has minimal side effects, and controlled disease in 61% of 28 patients studied [267]. Case reports suggest that intermittent, intravenous cyclophosphamide may produce symptomatic improvement in some patients [260, 268]. Sarcoid facial nerve paralysis is a short-term complication of the disease, and the prognosis is generally good in patients whose only manifestation of disease is cranial neuropathy. However, less than half of patients with eighth-nerve involvement have good recovery of hearing [254]. Treatment with intravenous immunoglobulins and infliximab appears to be effective in small fiber neuropathy [269, 270].

Peripheral Nerve Injury

39

Amparo Gutierrez and John D. England

Introduction

Injuries to peripheral nerves constitute a large and increasing medical and public health problem and are a frequent accompaniment to other bodily trauma. Although many of these injuries result from accidents involving motor vehicles, motorcycles, etc., an unfortunately increasing number are due to acts of violence, especially gunshot wounds. Among all patients admitted to level I trauma centers, peripheral nerve injury is estimated to occur in 2–3% of patients. If plexus and root injuries are also included, the incidence is close to 5% [1]. Peripheral nerve injuries occur most commonly in young adults between the age of 18 and 35 years.

Early recognition of patients with peripheral nerve injury is crucial to optimize evaluation and management. These patients are best evaluated and treated in specialized centers which have the expertise to provide all levels of care, including prompt intervention if warranted or careful sequential monitoring to ensure the best possible outcome. The indications and timing of surgical therapy for peripheral nerve injuries are complex and best made by experienced peripheral nerve experts. Even in the best of hands, recovery from peripheral nerve injuries can be disappointing. Understanding the molecular factors involved in nerve regeneration is undoubtedly the key to improving functional recovery after peripheral nerve injury. Current research is focused upon promising new agents which have the potential to stimulate and guide axonal regeneration. Within the next few years, some of these agents may become part of the standard treatment for peripheral nerve injuries.
