To our families, friends, and colleagues without whose support this work could not have been completed.

To my wife Patricia, our children Linda and Michael, my parents Zakaria and Malak, and my brothers Hassan and Ammar.

–BK

To all those dear to me, my father Edmund and mother Janina, my brother Ed, my second mother Louise and her husband Robert, but most of all the source of all that is good in my life, Adam, my boy and Linda, my wife.

–HJK

To daughters Emily and Elizabeth; my wife Suzanne and her children Julia, Daniel, and Antoine; Julia's husband Greg; and Dan's wife Nicole and grandchildren Matthew, Hannah, and Abigail.

–RLR

Preface

Over a decade ago, the editors appreciated a need for a single textbook that would cover comprehensively all aspects of the broad field of neuromuscular disease, which ultimately led to the publication of the first edition of *Neuromuscular Disorders in Clinical Practice*. The book attempts to be comprehensive and clinically oriented with the goal of discussing all disorders of the peripheral nervous system and the techniques used to assess these disorders. It thus parallels other neurology subspecialty texts, such as those for epilepsy or cerebrovascular disease, or internal medicine subspecialty books, such as those for rheumatology, endocrinology, or cardiology.

The second edition mimics the organization of the first. The book is divided into two parts, Part one discusses the approach to neuromuscular disorders followed by Part two dedicated to specific neuromuscular disease. Part one begins with an introduction to the clinical assessment of neuromuscular disorders; though it is not meant to duplicate available monographs on neurological examination, the chapter sets the stage for the evaluation of patients with neuromuscular disease. The second chapter provides concise overview of basic anatomy and physiology of nerves and muscles. The next subsection covers investigative techniques used in evaluating neuromuscular diseases. These include laboratory studies (muscle enzymes, autoantibodies, and exercise testing) and clinical neurophysiology procedures (clinical EMG, single fiber EMG, quantitative EMG analysis, quantitative sensory testing, autonomic testing), as well as nerve and muscle pathology. The new edition adds a chapter in skin biopsy performance and evaluation. The chapter on Molecular Diagnosis and Genetic Testing is updated extensively matching the significant knowledge increase in the last 10 years in this area.

The final subsection of Part one is broad with discussions of assessment and treatment of neuromuscular disorders. Individual chapters include quantitative assessment and outcome measures, rehabilitation, immunotherapy, and critical and respiratory care in the management of patients with neuromuscular diseases.

Part two provides detailed discussions of specific neuromuscular disorders. Most chapters are organized into etiology and pathogenesis, clinical presentation, differential diagnosis, evaluation and diagnosis, treatment and management, and prognosis. This approach was used in order to highlight the clinical emphasis of the book and correlate the clinical, electrodiagnostic, pathological, biochemical, and genetic aspects of neuromuscular disorders. Part two is divided into six subparts. Section one deals with disorders of the motor neuron and dorsal root ganglia (neuronopathies). Section two covers all the peripheral neuropathies including inherited and acquired polyneuropathies, mononeuropathies, radiculopathies, and plexopathies. Section three discusses neuromuscular junction disorders. Section four reviews muscle channelopathies, with a chapter devoted to disorders of muscle membrane excitability, including the periodic paralyses, non-dystrophic myotonias and related disorders, and a separate chapter on malignant hyperthermia. Section five is devoted to the inherited and acquired myopathies. Section six is devoted to the numerous conditions that do not fit neatly into one disorder or cross boundaries to other areas of the nervous system. The section discusses disorders of nerve hyperexcitability, including myokymia, neuromyotonia, muscle cramps, and fasciculations, as well as central nervous system disorders with neuromuscular manifestations, including stiff-man syndrome, and tetanus. Miscellaneous syndromes with neuromuscular presentations are

discussed, including paraneoplastic neuromuscular disorders, weakness in the intensive care unit, the floppy infant, rhabdomyolysis/myoglobinuria, and the fasciitis syndrome. The book ends with a chapter on neuropathic chronic musculoskeletal pain.

The second edition of *Neuromuscular Disorders in Clinical Practice* is intended to serve as a comprehensive text for both novice and experienced practitioners. General neurologists as well as specialists in neuromuscular medicine and trainees in neuromuscular medicine, clinical neurophysiology, and electromyography should find this book inclusive and comprehensive, yet practical and clinically relevant. Additionally, specialists in physical medicine and rehabilitation, rheumatology, neurosurgery, and orthopedics will find the book useful in their practice.

The contributors are an internationally recognized group of clinicians and scientists specializing in neuromuscular disorders, which allows for an appreciation of not only the science but the art of patient care. It is our hope that this text will provide the reader with the true flavor of, the nuances of, and the breadth and depth of the subspecialty field of neuromuscular disorders and thus enhance the care of patients with these conditions.

Acknowledgments

We gratefully acknowledge our present and former colleagues, fellows, and residents who have taught us and encouraged us throughout our careers. In addition, we are deeply indebted to Dr. Robert B. Daroff, whose guidance, support, and inspiration have been instrumental in our roles as physicians, teachers, and writers. We also thank Maria Smilios for keeping us organized and moving throughout the entire process. We thank Richard Lansing of Springer Publishing for appreciating the value of a new edition of *Neuromuscular Disorders in Clinical Practice*.

Part I

Approach to Neuromuscular Diseases: Principles and Basics

Clinical Assessment in Neuromuscular Disorders

1

Bashar Katirji

Clinical Manifestations in Neuromuscular Disorders

Neuromuscular diseases are conditions that result from disorders or lesions of the peripheral nervous system (PNS). This include disorders of the motor unit or the sensory component including disorders of the motor neurons (anterior horn cells of the spinal cord or motor nuclei of the cranial nerves or both), dorsal root ganglia, spinal roots, cranial nerves, peripheral nerves, neuromuscular junctions, or muscles. These disorders are discussed in details in individual chapters in this textbook.

A systematic neurological evaluation is necessary to accurately localize these disorders and differentiate them from central nervous system (CNS) disorders or other systemic illnesses which do not involve the PNS [1, 2]. In general, neuromuscular disorders manifest with weakness, sensory disturbances, or reflex changes, signs which are shared by CNS disorders. However, other less common manifestations are more specific to neuromuscular disorders, including fasciculations, myokymia, myotonia, muscle cramps, muscle atrophy, or hypertrophy. Careful examination of other organ systems often provides clues to the diagnosis of a specific neuromuscular disease, such as the violaceous rash of dermatomyositis or the posterior subcapsular cataracts ("Christmas tree") seen in myotonic dystrophy.

Weakness

Weakness is the most common complaint in patients with neuromuscular disorders.

Weakness is also common in CNS lesions including cortical, subcortical, brainstem, or spinal cord lesions. Neuromuscular disorders that are due to disorders of any component of the motor unit often cause weakness. These include anterior horn cell diseases (e.g., amyotrophic lateral sclerosis), root and/or peripheral nerve disorders (e.g., Guillain-Barré syndrome), neuromuscular junction diseases (e.g., myasthenia gravis), muscle membrane disorders (e.g., periodic paralysis), or muscle diseases (e.g., inclusion body myositis). Weakness in neuromuscular disorders is the major cause of disability which, in turn, depends on its severity, distribution, and patient's lifestyle. The variable effect of weakness on disability may result in significant delay in diagnosis due to the long interval between the onset of disease and the time the patient notices the weakness. For example, a patient with shoulder girdle weakness due to facioscapulohumeral (FSH) muscular dystrophy, who has a sedentary lifestyle and profession, may function well for several years before noticing shoulder weakness. In contrast, athletes or individuals with an active lifestyle may notice leg weakness long before it becomes evident to the physician on physical examination.

Proximal weakness in neuromuscular disorders often manifest in the lower extremities before the upper ones. Common complaints of proximal pelvic girdle weakness include difficulty climbing stairs, rising from the floor, arising from a toilet seat, or stepping out of a bathtub. Patients with hip extensor weakness (gluteus maximus) often have difficulty rising from a sitting or supine position without the use of one or both of the upper extremities. Patients with quadriceps weakness more than hip weakness (such as in inclusion body myositis) have more difficulty walking down stairs or down hills than climbing up stairs. This may also result in sudden falls, mimicking drop attacks, due to knee instability. Children with pelvic girdle weakness, such as Duchenne muscular dystrophy or spinal muscular atrophy (SMA), often rise from a

Table 1.1 Predominant and typical distribution of muscle weakness in generalized neuromuscular disorders

Disorders	Proximal weakness	Distal weakness
Myopathies	Muscular dystrophies (most types)	Myotonic dystrophy I (DM 1)
	Myotonic dystrophy II (DM 2)	Facioscapulohumeral muscular dystrophy[a]
	Polymyositis	Scapuloperoneal syndromes[a]
	Dermatomyositis	Distal myopathies
	Inclusion body myositis[b]	Inclusion body myositis[b]
	Metabolic myopathies (most types)	
	Endocrine myopathies	
	Toxic myopathies	
	Congenital myopathies (most types)	
Neuromuscular junction disorders	Myasthenia gravis	–
	Lambert-Eaton myasthenic syndrome	
	Botulism	
Peripheral polyneuropathies	Acquired demyelinating polyneuropathies[c]	Axonal polyneuropathies (most types)
	Diabetic amyotrophy	Inherited demyelinating polyneuropathies (most types)
Anterior horn cell disorders	Spinal muscular atrophies	Amyotrophic lateral sclerosis[d]
	Amyotrophic lateral sclerosis[d]	

Most muscular dystrophies, including Duchenne, Becker, Emery-Dreifuss, limb-girdle, and oculopharyngeal, cause proximal weakness
[a]Facioscapulohumeral muscular dystrophy and the scapuloperoneal syndromes manifest with shoulder (proximal) girdle weakness and scapular winging with ankle dorsiflexion (distal) weakness
[b]Inclusion body myositis usually presents with quadriceps (proximal) and long finger flexor (distal) weakness
[c]Guillain-Barré syndrome and chronic inflammatory demyelinating polyneuropathy
[d]Amyotrophic lateral sclerosis often presents with unilateral or bilateral asymmetrical distal (hand or foot) weakness but is quite variable and may present with predominantly proximal or generalized weakness

supine position on the floor by first turning over onto the hands and knees, then straightening the legs and arching the back, and finally moving the hands to the knees and gradually extending the trunk by "climbing up" the thighs (*Gowers' sign*). Adults with severe proximal leg weakness rise from a sitting position by utilizing their hands for support against chairs or tables which are adaptive variations of the Gowers' maneuver. Patients with shoulder weakness often complain of difficulty carrying heavy objects or performing tasks above eye level, such as shampooing hair, or removing or placing objects on high shelves. Young patients may be aware that they are unable to shoot a basketball above their head.

Patients with distal leg weakness affecting the anterior compartment muscles often complain that they catch their toes on carpets or curbs and they cannot walk on their heels. When weakness of ankle dorsiflexors is significant resulting in foot drop, such as in peroneal palsy or facioscapulohumeral muscular dystrophy, the patient often excessively flexes the hip and knee to clear the foot, resulting in a "steppage gait." Patients with weakness of calf muscles (plantar flexors), such as with Miyoshi myopathy (Limb girdle muscular dystrophy 2B), cannot walk on their toes and lose the spring associated with normal stepping due to the inability to effectively propel the foot at the end of the stance phase. Patients with distal leg weakness, particularly those with weakness of foot eversion, are often susceptible to ankle sprains, which may be prevented with ankle-foot orthoses. Patients with distal hand weakness complain of difficulty twisting a key, buttoning buttons, or using a nail clipper. When weakness involves the long finger flexors, such as in inclusion body myositis or myotonic dystrophy, patients complain of a weak grip leading to difficulty with opening jars or turning door knobs.

Proximal weakness of hip or shoulder girdles is often due to myopathy or a neuromuscular junction (NMJ) disorder with several exceptions (Table 1.1). In contrast, distal weakness is often, but not always, due to neurogenic causes such as peripheral polyneuropathy or amyotrophic lateral sclerosis (ALS).

Muscle strength in neuromuscular clinics is best evaluated by a combination of manual muscle testing and functional evaluation. Quantitative assessment of muscle strength such as dynamometry and the Tufts Quantitative Neuromuscular Examination (TQNE) are useful tools but usually limited to clinical trials. Functional rating scales are important since they measure functional ability and are discussed in detail in Chap. 15. The most widely used procedure for strength assessment is the manual muscle test (MMT). This test does not require sophisticated equipment and can be performed quickly at the bedside. Various MMT approaches and grading methods are used including the British Medical Research Council (MRC), the most widely and simple used method. This test does not require sophisticated equipment and can be performed quickly at the bedside. The MRC has several modified. However, since grade 4 encompasses a majority of patients with muscle weakness, a modified scale, in which grades 5, 4, and 3 are subdivided, is most popular (Table 1.2) [3, 4]. A composite MRC score, based on examination of ten muscles on each side, may be used in longitudinal follow-up of patients with neuromuscular disease associated with generalized weakness

Table 1.2 Medical Research Council (MRC) grading and a modified MRC grading of muscle power

MRC grading		Modified MRC grading	
5	Normal power	5	Normal power
		5–	Equivocal power, barely detectable weakness (examiner is not truly certain of weakness)
4	Active movement against gravity and resistance	4+	Slight weakness (examiner has to exert considerable effort to overcome the muscle)
		4	Moderate weakness (examiner can overcome the muscle)
		4–	Severe weakness (examiner overcome the muscle with minimal effort)
3	Active movement against gravity	3+	Active movement through full range against gravity with transient resistance with collapse
		3	Active movement through full range against gravity but no resistance
2	Active movement with gravity eliminated	2	Active movement with gravity eliminated
1	Flicker or trace of contraction	1	Flicker or trace of contraction
0	No contraction or movement	0	No contraction or movement

Table 1.3 Composite MRC score useful in longitudinal assessment of neuromuscular disorders associated with generalized weakness

Function	Right	Left	MRC score
Arm abduction	5	5	*Upper extremities 60*
Elbow flexion	5	5	
Elbow extension	5	5	
Wrist extension	5	5	
Fingers abduction	5	5	
Hand grip	5	5	
Total	*30*	*30*	
Hip flexion	5	5	*Lower extremities 40*
Knee extension	5	5	
Knee flexion	5	5	
Ankle dorsiflexion	5	5	
Total	*20*	*20*	
MRC score	*Right*	*Left*	*Total MRC score*
	50	*50*	*100*

MRC score = 0–5 (see Table 1.2). A modified score may be also used (0, 1, 2, 3, 3.5, 4, 4.5, 5)

(Table 1.3) [5]. Such scoring is not useful for examination of patients with mononeuropathy or radiculopathy, or isolated oculobulbar, hand, or foot weakness.

True muscle weakness should be differentiated from "apparent" weakness, which usually occurs when patients are unable to move a joint because of skin, tendon, or joint contractures. For example, a patient with shoulder pain who is unable to abduct his arm may have adhesive capsulitis (frozen shoulder) which limits both active and passive abduction of the shoulder. Pain in limb interferes with their ability to contract a muscle fully. Similarly, nonorganic weakness (malingering or conversion) often produces incomplete muscle contraction. The MMT in patients with limb pain or nonorganic weakness usually shows a collapsing (give-way) weakness. Patients with cachexia due to poor nutrition, malignancy, chronic systemic infection, or inflammatory disease or patients with deconditioning due to inactivity may have functional impairment with walking, climbing stairs, or household- and work-related tasks. Careful questioning of these patients often reveals that activity is limited by shortness of breath, pain, depression, or fatigue.

Contracture

Contracture is the shortening or tightening of skin, fascia, muscle, or joint capsule that prevents normal movement. It commonly develops in patients with muscle weakness, chronic limb pain, and impaired mobility. Measurement of joint range of motion and contracture could be done at the bedside including the use of goniometry. In neuromuscular disorders, the formation of muscle contractures occurs from a combination of (1) intrinsic structural changes of muscle, (2) muscle weakness that causes an inability to achieve active joint mobilization throughout the normal range, (3) imbalance of agonist and antagonist muscle strength, (4) immobility, (5) compensatory postural changes used to biomechanically stabilize joints during standing, and (6) anatomical location of the muscle especially those that cross two joints, such as hamstrings, biceps, and long finger flexors. Frequent areas for soft tissue tightness are neck flexion, shoulder adduction, elbow flexion, forearm pronation, finger adduction and extension, hip flexion and internal rotation, knee flexion, ankle plantar flexion, and foot inversion. Contractures in the lower limbs contribute significantly to the loss of ambulation, while upper extremity contractures add to the restrictions of performance of activities of daily living.

Fatigue

Fatigue that worsens at the end of the day or after exercise is a hallmark of NMJ disorders, particularly myasthenia gravis. An objective sign of fatigue in myasthenia gravis is the progressive worsening of ptosis with sustained upgaze (*curtain*

sign). Less objective signs include fatigue following climbing steps, repeated clenching of the fist, or sustained arm stretch or leg raise.

Weak muscles often fatigue abnormally; thus fatigability is a feature of most neuromuscular disorders, including ALS, muscular dystrophy, and peripheral neuropathy. In metabolic myopathy, patients are normal or slightly weak at rest but become easily fatigued with activity. In general, fatigue occurs in neuromuscular disease when many muscle fibers are damaged, nonfunctional, or denervated. The intact remaining muscle fibers are able to generate force but are often worked at their metabolic limits.

Fatigue due to neuromuscular disease may be difficult to separate from "loss of energy" and asthenia, particularly when there is no fixed weakness at rest. Fatigue is also a common feature of a variety of disorders ranging from anemia, endocrine disorders, heart disease, and multiple sclerosis to chronic fatigue syndrome and fibromyalgia.

Atrophy

Muscle atrophy is second only to weakness in importance and as the presenting complaint in patients with neuromuscular disorders. In general, muscle wasting is appropriate to the degree of weakness in myopathies, while in neurogenic disorders, particularly ALS and SMA, muscle atrophy may be an early manifestation and tends to be proportionally more severe than weakness. However, this sign may be subtle and not always useful. Also, muscle atrophy may be difficult to confirm in obese and thin patients, in women, and in children. In general, muscle wasting is easier to appreciate when it is asymmetric, when it involves the hand and foot intrinsics, and when it occurs near bony prominences (e.g., proximal humerus and scapula).

Atrophy from neuromuscular disorders should be differentiated from disuse muscle wasting which occurs following joint immobilization (such as after fractures), prolonged bed rest, medical conditions that limit movement, or cachexia. In these instances, the contour of the affected muscles, although thinner, is well preserved.

Muscle Hypertrophy

An increase in muscle bulk is common with exercise and is rarely a primary pathological phenomenon. The most striking example of abnormal generalized hypertrophy is seen in patients with myotonia congenita, giving them the appearance of professional weight lifters. These non-dystrophic myotonic disorders have no muscle weakness, and their true hypertrophy of muscle fibers is likely the result of increased spontaneous muscle fiber activity (myotonia). Focal hypertrophy may be seen in calf muscles of patients with Duchenne and Becker's muscular dystrophy as well as in patients with the limb-girdle muscular dystrophies, SMA, and some glycogen storage disorders. In these disorders, the hypertrophy is referred to as *pseudohypertrophy* since it is associated with weakness and there is substantial replacement of muscle by fat and connective tissue as well as true muscle fiber hypertrophy. Focal hypertrophy may also be seen rarely in radiculopathies, cysticercosis, amyloidosis, sarcoidosis, and focal myositis. Palpable masses in muscles may be seen with local cramps, muscle infarct, tumor (such as rhabdomyosarcoma), ruptured tendon, or muscle hernia (where muscle fibers rupture through the perimysial sheath).

Gait Disorder

A keen observation of the gait of patients with neuromuscular disease is extremely helpful in diagnosis. Gait abnormalities may point to a CNS disorder, such as a magnetic gait seen with normal pressure hydrocephalus or a shuffling gait with festination in Parkinson disease.

Typically, proximal weakness results in a *waddling gait* caused by bilateral hip abductor weakness which results in a pelvic tilt toward the swinging leg. A compensatory lumbar lordosis occurs with advanced hip and lumbar paraspinal muscle weakness, during which the upper trunk and shoulders are hyperextended to position the body's center of gravity, behind the hip joints in order to maintain upright posture. In patients with severe quadriceps weakness, such as in IBM, the knee is hyperextended (*back kneeling*) during the stance phase of gait in comparison to the slight flexion at the knee in individuals with normal quadriceps function. The knee hyperextension prevents these patients from falling and helps ambulation. Bilateral foot drop due to weakness of ankle dorsiflexors is associated with a *steppage gait* caused by excessive hip and knee flexion (in order to clear the foot of the floor). When unilateral, this is sometimes referred to as a "slap-foot." In patients with advanced lower extremity weakness (proximal and distal), hip flexion is often replaced by circumduction of a hyperextended knee to clear the toes of the floor. A patient with increased leg muscle tone, such as with spastic hemiparesis, also circumducts his leg due to weak flexors and strong extensors. When spasticity is bilateral, increased muscle tone manifests as a *scissoring gait.*

Patients with loss of position sense due to large-fiber sensory loss or dysfunction of the dorsal column of the spinal cord have a disturbance of equilibrium, often referred to as *sensory ataxia*. Such patients usually stand and walk with a broad base. They may be able to maintain the upright position while the eyes are open but often sway or fall when the eyes are closed (*Positive Romberg sign*).

Reflexes and Tone

The myotatic or deep tendon reflexes (DTRs) are extremely useful tools in the diagnosis of neurological disorders in general and in neuromuscular disorders in particular. This is especially important in the differential diagnosis during the early phases of neuromuscular disorders. In general, the DTRs are preserved in myopathies, and their loss follows closely the degree of weakness (i.e., they are only absent or depressed in severely weakened or atrophied muscles). For example, in patients with Duchenne muscular dystrophy, the knee jerks become absent relatively early, while the ankle jerks are retained well into the nonambulatory phase of the disease. In contrast to the myopathies, the DTRs are usually abolished early even in strong muscles in patients with peripheral polyneuropathy, such as Guillain-Barré syndrome (GBS) or lower motor neuron disorders such as SMA. In patients with a length-dependent polyneuropathy, the DTRs tend to be absent or depressed distally while relatively preserved proximally. Finally, the presence of brisk DTRs in atrophic and weak limbs is highly suggestive of a combined lower and upper motor neuron disorder as seen with ALS or vitamin B12 deficiency.

Apart from spasticity in wasted limbs, as seen with ALS, muscle tone is rarely important in the diagnosis of neuromuscular disorders in adults. In infants, generalized hypotonia may be due to neuromuscular disorders, but it is clear that the "floppy infant syndrome" is a nonspecific syndrome which may be caused by a variety central or peripheral nervous system disorders as well as systemic disorders (such as Ehlers-Danlos syndrome, malnutrition, and metabolic disorders).

Pain and Muscle Cramps

Myalgia is common symptom in patients with neuromuscular disorders. Muscle pain at rest is common in GBS, acute poliomyelitis, polymyositis, and acute viral myositis. Myalgia is a frequent manifestation of polymyalgia rheumatica and rheumatological disorders. It is then often associated with stiffness and arthralgia. Diffuse or focal muscle pain is also common in fibromyalgia and chronic fatigue syndrome. Muscle pain with exertion may occur with muscle ischemia (intermittent claudication with occlusive peripheral vascular disease) but is also common in neurogenic claudication associated with lumbar spinal canal stenosis. Exertional muscular pain, with or without muscle cramps, is a feature of metabolic myopathies such as McArdle's disease and other glycogenosis but may also occur in hypothyroidism and mitochondrial myopathies.

Muscle cramps consist of painful involuntary contractions involving part of or the whole muscle and lasting from seconds to minutes. Often, there is a palpable lump at the site of the contraction which disappears as the cramps ease. On needle electromyography (EMG), cramps are associated with high-frequency and slightly irregular bursts of motor unit action potentials (MUAPs). Muscle cramps are common in healthy individuals and are sometimes referred to as physiologic, benign, or common muscle cramps. They also accompany metabolic disturbances such as hyponatremia, dehydration, or uremia, and are common in pregnancy and hypothyroidism. These cramps tend to be worse in the legs, particularly the calves, and at night. Cramps are often relieved by stretching of the muscle and can be triggered by contraction of a shortened muscle such as forcibly contracting the calf muscles while pointing the toes down. Muscle cramps are common in neuromuscular diseases, particularly neurogenic disorders and metabolic myopathies. For example, patients with ALS often complain of cramps which might predate the onset of weakness. The cramps in metabolic myopathies, such as McArdle's disease, are extremely painful, often brought on by exertion, and may last up to several hours. These cramps are actually *muscle contractures* since they are associated with electrically silent needle EMG.

Neuropathic pain is often caused by damage to the peripheral nerves. Neuropathic pain may be simply divided into two

Table 1.4 Characteristics of major forms of neuropathic pain

	Dysesthetic pain	Nerve trunk pain
Descriptors	Burning, tingling, raw, searing, crawling, drawing	Aching, occasionally knifelike
Recognition	Unfamiliar, never experienced before	Familiar, "like a toothache"
Distribution	(1) Cutaneous or subcutaneous usually	(1) Deep
	(2) Distal	(2) Relatively proximal
Constancy	Variable, may be intermittent, jabbing, lancinating, shooting	Usually continuous but waxes and wanes
Better/worse	Little makes it better; worse following activity	Better with rest or optimal position; worse with movement, nerve stretch, or palpation
Basis of pain (hypothetical)	Increased firing of damaged or abnormally excitable nociceptive fibers, particularly sprouting, regenerating fibers	Increased firing due to physiological stimulation of endings of undamaged afferents from nerve sheaths themselves (nervi nervorum)
Examples	(1) Causalgia	(1) Root compression
	(2) Small-fiber neuropathy	(2) Neuralgic amyotrophy (idiopathic brachial plexitis)

Revised from Asbury and Thomas [5], with permission

types: a dysesthetic and nerve trunk pain (Table 1.4) [6]. Patients with rapidly denervating conditions, such as GBS or acute poliomyelitis, may have muscle pain and tenderness, sometimes mistaken as myalgia due to a primary muscle disorder.

Abnormal Muscle Movements

Inspection of muscle at rest, with contraction, and following percussion, is an important part of the neuromuscular evaluation. In addition to detecting muscle atrophy or hypertrophy, appreciation of abnormal spontaneous movements or abnormal muscle contraction or relaxation is extremely useful.

Fasciculations are brief, asynchronous twitches of groups or bundles of muscle fibers. They are due to involuntary contractions of motor units. Fasciculations should be looked for in muscles at rest and may be difficult to see in infants and obese patients due to subcutaneous fat. As an isolated finding, they are often of no significance since they are common in healthy individuals, particularly after exercise or the consumption of CNS stimulants, such as caffeine. They may also occur in patients receiving cholinesterase inhibitors, with hyperthyroidism, hyperparathyroidism, and hypomagnesemia, as well as with the use of CNS stimulants such as theophylline and lithium. Fasciculations are associated with neurogenic disorders such as ALS, SMA, and, less often, peripheral polyneuropathies and radiculopathies. Although fasciculations do not move large joints, as seen with myoclonus, they may result in low-amplitude asynchronous twitches of the fingers imitating chorea. Fasciculations that are observed during partial muscle contraction ("contraction fasciculations") are less specific but may occur in neurogenic disorders such as in the facial muscles of patients with bulbospinal muscular atrophy (Kennedy's disease). Contraction fasciculations are not true fasciculations but represent rapid firing of large reinnervated motor units.

Myokymia is seen clinically as involuntary, repeated, "wormlike" or writhing contractions of part of a muscle. These are very difficult to differentiate from fasciculations particularly when widespread but are easily distinguished by needle EMG (see Chap. 7). Myokymia is rare and is seen mostly in neurogenic disorders, although facial myokymia may occur in brainstem disease such as multiple sclerosis or pontine glioma. Limb myokymia is a common occurrence following radiation injury to peripheral nerve, such as delayed radiation-induced brachial plexopathy, but may be seen with GBS or nerve entrapment (such as carpal tunnel syndrome).

Myotonia is characterized clinically by failure of muscle to relax immediately after cessation of voluntary contraction. It is caused by spontaneous repetitive depolarization of muscle membrane and has a distinct characteristic appearance and sound on needle EMG (see Chap. 7). Clinical myotonia is common in myotonic dystrophies and in the non-dystrophic myotonias and may be elicited as action myotonia or percussion myotonia. Among *action myotonias*, grip myotonia (elicited by asking the patient to forcefully clench the fist and attempt to release rapidly) is the most common. With this maneuver, there is failure of relaxation which lasts 5–10 s and occasionally as long as 1 min. Lid myotonia is less common and manifests by difficulty opening the eyes after forceful eye closure. Action myotonia tends to improve with repeated contractions (warm-up phenomenon) although in paramyotonia the stiffness may worsen with repeated contractions. *Percussion myotonia* is best elicited by tapping the thenar eminence with a reflex hammer. This results in slow tonic position of the thumb with a gradual relaxation lasting up to 10 s. Less common procedures include tapping the tongue or the forearm extensors which results in contraction with delayed relaxation. With muscle percussion, a dimple (due to contraction of a strip of a muscle) might appear at the sight of the tap which may last up to 10 s.

Neuromyotonia is an extremely rare phenomenon due to continuous motor unit activity resulting in muscle stiffness. In contrast to myotonia, it is of neural origin and disappears after neuromuscular blockade. Neuromyotonia is often seen with myokymia in disorders associated with potassium channel antibodies including Isaac's syndrome (see Chap. 70) but may be encountered in neurogenic disorders such as SMA.

Myoedema is a ridgelike mounding of a portion of a muscle, occurring after percussion of muscle and lasting up to 1–3 s. Myoedema is electrically silent on needle EMG. It is an extremely rare phenomenon and is seen usually in patients with myxedema or cachexia.

Rippling muscle is another rare phenomenon associated with electrical silence on EMG. It manifests as a self-propagating rolling or rippling of muscles that is usually induced by passive muscle stretch. Muscle percussion may result in an exaggerated muscle contraction manifesting as a localized mounding (imitating myoedema) or a prolonged muscle contraction (clinically indistinguishable from myotonia).

Pseudoathetosis comprises undulating and writhing movements of the outstretched fingers, with a combination of flexion, extension, abduction, pronation, and supination. Fine tasks are often clumsy. Pseudoathetosis is more marked when the eyes are closed, which distinguishes it from athetosis. The movements are the result of deafferentation and loss of position sense in the affected limb. They are usually due to severe loss of large sensory fibers, as seen in sensory neuropathies, dorsal root ganglionopathies, and polyradiculopathies as well as in tabes dorsalis and other dorsal column disorders.

A *neuropathic tremor* may accompany peripheral polyneuropathies, particularly the demyelinating polyneuropathies. It is very similar to essential tremor, with a usual frequency of 3–6 Hz and a postural and kinetic component produced by alternating contraction of agonist and antagonist muscles. Its exact mechanism is not well understood though the loss of proprioceptive or muscle spindle inputs may explain for the tremor. The tremor is more common in

demyelinating polyneuropathies than axonal polyneuropathies, such as during the recovery phase of GBS or chronic inflammatory demyelinating polyneuropathy (CIDP) and in anti-MAG polyneuropathy. When tremor is associated with Charcot-Marie-Tooth (CMT) disease type I, it is sometimes referred to as the Roussy-Lévy syndrome.

Sensory Disturbances

Sensory manifestations are features of sensory peripheral nerve disorders or disorders of the dorsal ganglia and consist of a wide spectrum of positive to negative phenomena. *Positive symptoms* include paresthesias (pins and needles sensation and tingling), dysesthesias (uncomfortable sensation particularly to touch with various surfaces), or hyperpathia (painful response to a non-painful stimulus). *Negative symptoms* include numbness, loss of sensation, and imbalance. Sensory manifestations may follow a peripheral nerve (mononeuropathy), single root (radiculopathy or ganglionopathy), or a stocking-glove distribution (peripheral polyneuropathy). Acquaintance with peripheral nerve sensory territories as well as with human dermatomal maps, which may vary among individuals, is essential in distinguishing radiculopathy from mononeuropathy and peripheral polyneuropathy from spinal cord sensory loss (Fig. 1.1a–c).

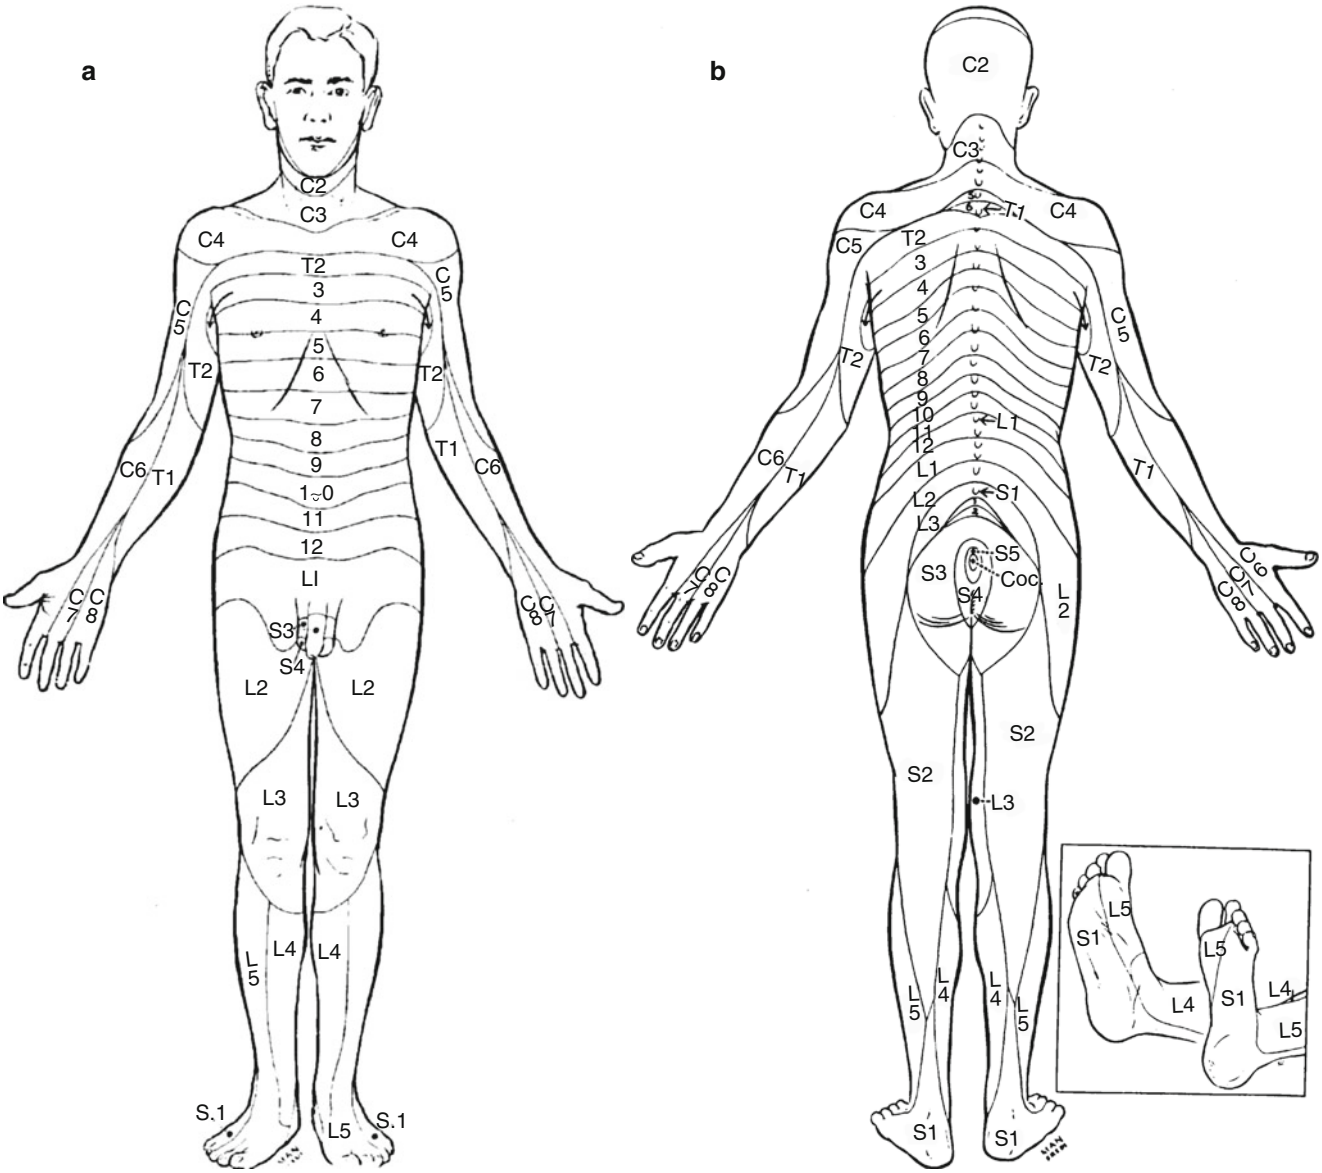

Fig. 1.1 The dermatomes after Foerster [6]). (**a**) Anterior view. (**b**) Posterior view (*inset*: foot). (**c**) Side view. *C* cervical, *T* thoracic, *L* lumbar, *S* sacral (Reprinted with permission from Haymaker and Woodhall [7])

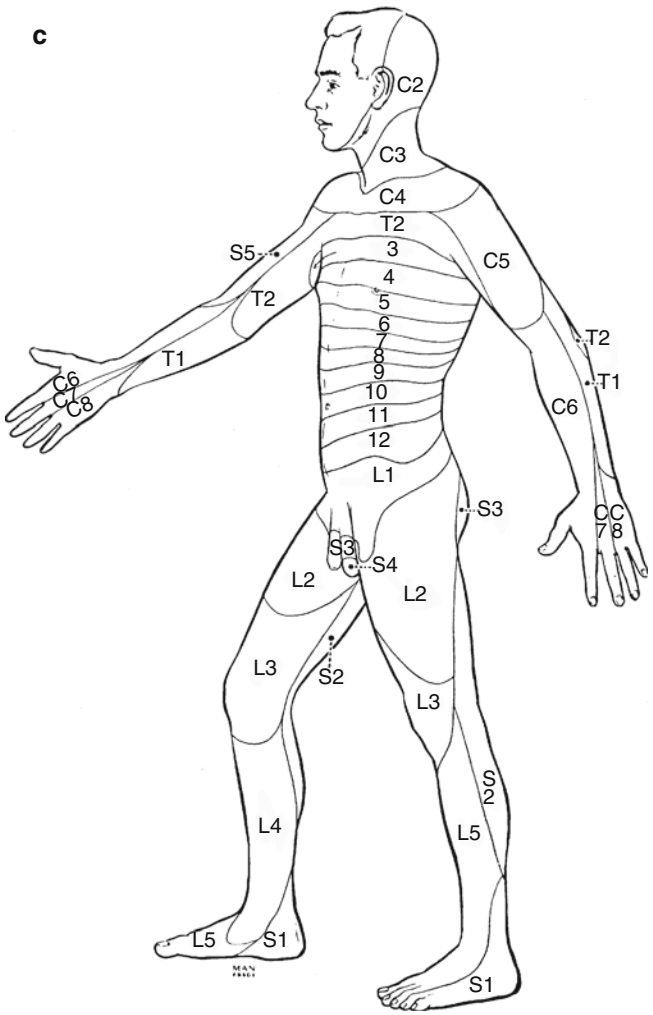

Fig. 1.1 (continued)

Temperature and pain sensation, as well as autonomic functions, are mediated by the small myelinated and unmyelinated fibers, while proprioception and vibration sense, as well as the afferent limb of the muscle stretch reflex, are mediated by the large myelinated fibers. Touch is conducted by both types of fibers. In typical dying back axonal peripheral polyneuropathy, the large fibers, small fibers, or both types of sensory fibers may be affected. In small-fiber neuropathies, there is diminished or loss of pain and temperature sensation, which may be accompanied by dysesthesia, hyperpathia, or dysautonomia. Examples include amyloid neuropathy and small-fiber diabetic neuropathy. In contrast, large-fiber polyneuropathies result in sensory ataxia, areflexia, and loss of position sense. Although tingling and dysesthesia may occur in large-fiber neuropathy, pain is not a common feature of these disorders.

Percussion of peripheral nerves with a reflex hammer or finger may elicit a Tinel's sign, an electrical sensation in the distribution in the percussed nerve. This clinical phenomenon reflects reinnervation of sensory fibers. It is seen at or distal to the site of peripheral nerve damage and may progress distally in regenerating nerves. However, a Tinel's sign may be also elicited in normal individuals with more vigorous percussion of peripheral nerves such as the ulnar nerve at the ulnar groove or the median nerve at the carpal tunnel.

Quantitative measures of sensory functions are useful. These include sensory nerve conduction studies (see Chap. 7), which evaluate the large sensory fibers; autonomic testing which assesses cardiac, sudomotor and vasomotor small nerve fibers (see Chap. 10); and quantitative sensory testing which examines cooling (small-fiber) and vibration (large-fiber) functions (see Chap. 11).

Peripheral Nerve Enlargement

Palpation of peripheral nerves is an important tool in the neuromuscular examination. *Nodular* expansions of peripheral nerves may occur in leprosy or neurofibromatosis, while *diffuse* enlargement of nerves is more common in chronic demyelinative polyneuropathy such as CMT disease type I, Dejerine-Sottas disease, CIDP, or Refsum's disease and in infiltrative polyneuropathy such as in amyloidosis. The following nerves may be easily palpated at the bedside: (1) the greater auricular nerve in the posterior neck, (2) the ulnar nerve in the ulnar groove, (3) the superficial radial sensory nerve as it crosses the extensors to the thumb distal to the wrist, (4) the sural nerve lateral to the Achilles tendon or behind the lateral malleolus, (5) the common peroneal nerve around the fibular neck, and (6) the digital nerves over the dorsum of the fingers.

Common Presentations of Weakness in Neuromuscular Disorders

Rapidly Progressive Quadriparesis

Quadriparesis progressing over days to weeks is a relatively common neurological presentation. Usually, the history is one of an ascending paresis beginning in the lower limbs and progressing cephalad to the trunk and upper limb and often weakening the respiratory, bulbar, and ocular muscles. Descending weakness, progressing in the opposite direction, may occur but is less common.

Causes of rapidly progressive quadriparesis are best discussed using the neuraxis as an anatomical guideline. Disorders presenting with this presentation are usually to spinal cord or peripheral nervous system dysfunction including any element of the lower motor neuron. Hence, it is useful to address the differential diagnosis based on the different elements of the motor unit (Table 1.5). In the western hemisphere with the exception of spine trauma

Table 1.5 Causes of rapidly progressive quadriparesis

Muscle disorders
Polymyositis
Dermatomyositis
Rhabdomyolysis
Critical illness myopathy
Muscle membrane disorders
Familial periodic paralysis
Secondary hypokalemic paralysis
Neuromuscular junction disorders
Myasthenia gravis (myasthenic crisis)
Botulism
Drug-induced neuromuscular blockade
Toxic
Tick paralysis
Organophosphate poisoning
Black widow spider
Snake venoms
Nerve gas
Metabolic
Hypermagnesemia
Hypophosphatemia
Peripheral nerve and/or root disorders
Guillain-Barré syndrome
Acute intermittent porphyria
Diphtheritic polyneuropathy
Critical illness polyneuropathy
Vasculitic neuropathy
Heavy metal acute poisoning (thallium, arsenic)
Diffuse polyradiculopathy (infectious, neoplastic)
Anterior horn cell disorders
Acute poliomyelitis (including West Nile myelitis)
Spinal cord disorders
Transverse myelitis
Cord compression (disc herniation, fracture/dislocation, epidural malignancy)
Cord infarction (anterior spinal artery syndrome)
Brainstem disorders
Central pontine myelinolysis
Pontine infarct (basilar artery thrombosis)

and weakness in the intensive care setting, GBS and transverse myelitis are the most common (Table 1.6). The following is a general guide to the evaluation of patients with rapidly progressive quadriparesis, and the reader should refer to the chapters dealing with specific neuromuscular disorders for a detailed discussion.

Clinical Findings

Distribution and Temporal Progression of Weakness

The neurological examination is most useful in guiding the diagnosis during the early phases of these disorders. The final outcomes of the majority of disorders that lead to generalized weakness are fairly uniform and include severe quadriparesis, hyporeflexia, or areflexia, with or without respiratory failure and bulbar or ocular weakness, thus producing in the later stages of illness. Obtaining a detailed history and/or observing the progression and distribution of the weakness is essential in the formulation of the differential diagnosis. For example, the first symptom of botulism is often asymmetrical ptosis or double vision, followed rapidly by dysphagia, dysarthria, and, finally, respiratory failure and limb weakness. In contrast, in classical GBS, symptoms often begin with symmetrical bilateral leg weakness with imbalance and numbness, followed by trunk and upper limb weakness, which may progress into respiratory failure, and, sometimes, facial diplegia or diplopia.

Deep Tendon Reflexes

Evaluating the deep tendon reflexes (DTRs) is among the most important signs in patients with rapidly progressive quadriparesis. In general, disorders of peripheral nerve are often associated with early hyporeflexia, the DTRs are usually spared in neuromuscular junction disorders and myopathies prior to severe quadriparesis, and they are often absent in any neuromuscular disorder associated with severe weakness. For example, the DTRs in botulism are normal until significant limb weakness develops, while they are often depressed or absent in mildly weak limb(s) early in the course of GBS.

Symmetry of Weakness

Asymmetrical weakness is also an important finding early in the course of illness since most scenarios, if untreated, go on to generalized symmetrical paralysis. In general, subacute polyneuropathies and myopathies are symmetrical from the outset. However, subacute NMJ disorders, polyradiculopathies, and anterior horn cell diseases are often asymmetrical early in the course and sometimes as recovery begins. For example, in GBS, polymyositis, and periodic paralysis, the weakness is often symmetrical from the outset, while in botulism, myasthenia gravis, carcinomatous polyradiculopathy, and acute paralytic poliomyelitis, ocular, bulbar, and limb muscle weakness are often asymmetrical. However, there are many exceptions. For example, the weakness in vasculitic neuropathy is often asymmetrical and may be restricted to peripheral nerve distributions (mononeuropathy multiplex), while tick paralysis typically causes a rapid symmetrical quadriparesis.

Extraocular Muscle Weakness

Extraocular muscle abnormalities are common in neuromuscular junction (NMJ) disorders, particularly botulism and myasthenia gravis. They are rarely found in polyneuropathies and do not occur in subacute myopathies or anterior horn cell disorders. In contrast to ocular findings, bulbar muscle manifestations, particularly dysphagia, are common to most neuromuscular disorders.

Table 1.6 Differential diagnosis of nontraumatic rapidly progressive quadriparesis (listed in anatomical order)

Disorder	Characteristic clinical manifestation	Typical diagnostic findings
Pontine infarction due to basilar artery occlusion	History of transient ischemic attack is common	MRI often reveals brainstem infarct
	Symptoms are sudden in onset, though may be stuttering	MRI often may show basilar artery occlusion or stenosis
	Somnolence is common	
	Brisk reflexes are common but may be delayed	
	Babinski sign(s) is usually present	
	Ocular and bulbar findings are common, often asymmetrical, but vertical eye movements are usually spared	
Central pontine myelinolysis	Alcohol abuse or critical illness (transplantation, severe burn) is common	MRI of brain reveals central tegmental, mostly pontine, T2-weighted signal abnormality
	Rapid correction of hyponatremia is often detected	
	Ocular muscles are usually spared	
	Hyperreflexia and Babinski signs may be delayed	
	Sensory manifestations are rare	
Transverse myelitis	Sphincteric disturbance is common	MRI of spinal cord may reveal abnormal signal or enhancement in cervical or thoracic cord.
	Discrete sensory level on trunk may be evident	CSF pleocytosis and increased IgG production are common
	Brisk reflexes or Babinski signs are common but may be delayed till after spinal shock stage	
	No cranial nerve involvement	
Acute paralytic poliomyelitis	Wild polio virus is extremely rare	CSF lymphocytic pleocytosis is common
	Usually associated with oral polio vaccine or other enteroviruses, coxsackie, and echoviruses	EDX studies reveal asymmetrically low CMAPs with preserved SNAPs, with active denervation in segmental distribution
	Muscle pain and fever are common	Rise in serum antibody titers is common
	Weakness is almost always asymmetrical	Viral culture from CSF or gut is of low yield
	Reflexes are preserved in strong limbs	
	No sensory or sphincteric symptoms	
Neoplastic/infectious polyradiculopathy (leptomeningeal disease)	Radicular pain is common	EDX studies show segmental denervation with intact SNAPs
	Asymmetrical limb weakness, sensory loss, and cranial nerve palsies are the hallmark of disease	MRI of brain or spine may reveal meningeal enhancement
	Deep tendon reflex loss may be patchy	High CSF protein, pleocytosis, and low glucose are often present
	Cognitive changes, headache, or seizures are common	CSF cytology may be detect neoplastic cells
	History of solid tumor, lymphoma, leukemia, HIV, or other immunocompromised state may be present	
Guillain-Barré syndrome	Prodromal flu-like symptoms are common	CSF albuminocytologic dissociation is common
	Areflexia or hyporeflexia in weak limbs is early	Slowing of F waves or motor or sensory NCSs is common but may be delayed
	Sensory manifestations are often subjective only	
	Bilateral facial weakness is not uncommon	
Acute intermittent porphyria	History of abdominal pain, psychiatric disease, or confusion is common	EDX studies reveal subacute axonal sensorimotor polyneuropathy is evident on
	Precipitating factors (drugs, infections) are common	CSF protein is usually normal or mildly elevated
	Autonomic manifestations are very common	Urinary porphobilinogen increases during attack
	Weakness may start in arms	Low-level erythrocyte uroporphyrinogen I synthetase confirms the diagnosis
	Distal sensory loss is usually dense	

Table 1.6 (continued)

Disorder	Characteristic clinical manifestation	Typical diagnostic findings
Vasculitic neuropathy	Onset is often abrupt with stepladder progression	Elevated ESR is common
	Asymmetrical weakness/sensory losses are the usual findings	ANA, RF, and ANCA titers may be elevated
	Findings may be restricted to multiple mononeuropathies	EDX studies often reveal an asymmetrical axonal polyneuropathy or multiple mononeuropathies
	History of connective tissue disorder may be present	Nerve or muscle biopsy often confirms the presence of arterial wall infiltration by inflammatory cells with or without fibrinoid necrosis
	Systemic manifestations (fever, arthralgia, skin rash, etc.) may coexist	
Acute diphtheritic polyneuropathy	Is very rare in developed countries	CSF is similar to GuillainBarré syndrome
	History of fever, severe pharyngitis, membranous exudate over tonsils, and cervical adenopathy few weeks earlier	EDX studies often show signs of demyelinative polyneuropathy similar to Guillain-Barré syndrome
	Palatal weakness and paralysis are always present	
	Quadriparesis is usually descending and may progresses over few months	
Myasthenia gravis (myasthenic crisis)	Oculobulbar weakness is common, often fatigable	Tensilon test may be positive
	Weakness may be descending	Slow repetitive nerve stimulation reveals CMAP decrement, particularly from proximal muscles
	Deep tendon reflexes are usually preserved	Acetylcholine receptor antibody is elevated in the majority
	No sensory loss or bladder involvement	
Tick paralysis	Affects mostly young girls but extremely rare	CSF is normal
	Rapid progression into quadriparesis and areflexia	NCSs show low CMAPs but normal SNAPs and no slowing
	Mimics Guillain-Barré syndrome	Finding and removing the tick (usually near hairline) results in rapid recovery
Botulism (food-borne botulism)	Rapid weakness is almost always descending	Tensilon test may be positive
	Early oculobulbar weakness is the rule	Moderate increment on rapid repetitive nerve stimulation
	Pupillary dilatation is common but may be delayed	Abnormal serum assay is common
	Late ileus and urinary retention are common	
Periodic paralysis	Family history is common	Serum potassium is often abnormal
	The first attack is usually in the first or second decade	EDX studies during paralytic attack show low CMAPs, decrease insertional activity, and short-duration, low-amplitude, and polyphasic MUAPs
	Onset of quadriparesis is rapid, usually overnight	Needle EMG, between attacks, reveals myotonic discharges in hyperkalemic form only
	Cranial nerve involvement and respiratory failure are rare	
Acute rhabdomyolysis (myoglobinuria)	Onset is with severe muscle pain	CK is markedly elevated (up to 1,000 folds)
	Deep tendon reflexes and sensation are normal	Myoglobin is almost always detected in urine
	History of drug or toxin intake, infection, or exercise is often present	Needle EMG may be normal in the acute phase
Polymyositis-dermatomyositis - necrotizing autoimmune myopathy	Myalgia is common	CK is often markedly elevated
	Heliotrope rash in dermatomyositis is characteristic	Short-duration, low-amplitude, and polyphasic MUAPs, with fibrillation potentials, are usually seen on needle EMG
	Neck weakness is common and early	Degenerating and regenerating myofibers with or without inflammatory infiltrate is often seen on muscle biopsy
	Dysphagia is the only cranial involvement	
	Deep tendon reflexes are often preserved	
	May be associated with connective tissue disorder

Sensory Manifestations

The presence of sensory symptoms or signs excludes all subacute myopathies, NMJ, and anterior horn cell disorders, unless accompanied by a peripheral neuropathy, such as in paraneoplastic disorders. Sensory symptoms and signs are very common in polyneuropathies and polyradiculopathies. They are usually symmetrical in the former and asymmetrical in the latter.

Autonomic Findings

A part from Lambert-Eaton myasthenic syndrome and botulism, where both nicotinic and muscarinic nerve terminals are targeted by the toxin, autonomic findings are a feature of polyneuropathies and polyradiculopathies. These findings include orthostatic hypotension, tachyarrhythmias, ileus, urinary retention or incontinence, and pupillary abnormalities.

Laboratory Investigations

Serum Electrolytes and EKG

Serum electrolytes are easy to measure and may suggest a specific diagnosis. Serum potassium, magnesium, and phosphorus should be obtained promptly in all patients with rapidly progressive quadriparesis. Measuring serum potassium is particularly important in a young patient with a family history of quadriparesis, suggestive of periodic paralysis. Also, secondary hypokalemic periodic paralysis should be considered, if there is a history of thyrotoxicosis, malabsorption, barium salt poisoning, or abuse of diuretics, laxatives, or licorice. The EKG usually is abnormal with hypokalemia (prolonged QT interval, flat T wave, and prominent U wave), with hyperkalemia (peaked T waves), and, sometimes, in hypermagnesemia. The latter may occur in patients with toxemia of pregnancy treated with parenteral magnesium or with the use of magnesium-containing antacids or cathartics, particularly when associated with impaired renal function. Hypophosphatemia is usually associated with parenteral hyperalimentation, the use of phosphate-binding antacids, acute alcohol intoxication, and severe respiratory alkalosis.

Serum Creatine Kinase

Elevated serum creatine kinase (CK) often suggests a primary muscle disorder (see Chap. 3). When acute rhabdomyolysis leads to severe weakness, the CK is markedly elevated, reaching up to 1,000–2,000 folds of the normal level. In polymyositis, dermatomyositis, and, sometimes in critical illness myopathy, the CK is often elevated, reaching usually up to 100–200 folds of the normal value. CK may be elevated modestly in other neuromuscular disorders causing subacute quadriparesis, particularly GBS and acute paralytic poliomyelitis. Caution should be taken in patients with severe quadriparesis and bed confined where CK may be elevated due to muscle crush injury and not due to the primary cause of the weakness.

Cerebrospinal Fluid

Abnormalities seen in the cerebrospinal fluid (CSF) are generally supportive of a diagnosis, but not pathognomonic. In general, all myopathies and NMJ disorders are associated with normal CSF, while the CSF is often abnormal in subacute peripheral polyneuropathies, radiculopathies, and anterior horn cell disorders. Elevated CSF protein is among the most common abnormality seen, followed by pleocytosis. The latter is usually dominated by lymphocytes except in infectious disorders where there is often early polymorphonuclear pleocytosis. CSF glucose is sometimes lowered in infectious, carcinomatous, or lymphomatous polyradiculopathies (leptomeningeal disease). In these disorders, CSF cultures and cytology are required for diagnosis.

Electrodiagnostic Tests

Nerve conduction studies (NCSs), repetitive nerve stimulation, and needle EMG are invaluable aids in the diagnosis of patients presenting with acute or subacute quadriparesis. Details are discussed in Chap. 7 on clinical electromyography and in individual chapters dealing with the above disorders.

Despite their common utility in the evaluation of patients with suspected subacute neuromuscular disorders, there are many limitations to the use of EDX studies in these subacute settings. In general, NCSs and repetitive nerve stimulation are more useful than needle EMG in the acute phase of these disorders. Although normal NCSs suggest disorders of muscle, neuromuscular junction, spinal roots, or anterior horn cell, many patients with acute axonal polyneuropathies may have normal NCSs during the first week or two of illness. In contrast, compound muscle action potential (CMAP) amplitudes may be low in botulism, drug-induced neuromuscular blockade, severe myasthenia gravis, or severe necrotizing myopathies. Sensory nerve action potentials (SNAPs) are usually abnormal in patients with subacute neuropathies, but this may be delayed also. Although it is intuitive to conclude that NCSs are sensitive in confirming demyelination such as in Guillain-Barré syndrome, these studies often reveal abnormalities that are not specific of primary demyelinating polyneuropathy during the early phases of the disease.

Foot Drop

Foot drop is defined as severe weakness of ankle dorsiflexion with intact plantar flexion. It should not be confused with a *flail foot* in which there is no or minimal ankle or foot movement in all directions, including severe weakness of ankle dorsiflexion, plantar flexion, and intrinsic foot muscles (Fig. 1.2). In contrast to a flail foot, voluntary movement at or distal to the ankle occurs in foot drop due to intact plantar flexion and intrinsic foot muscles. Many patients with severe peripheral polyneuropathy, such as CMT disease, are often

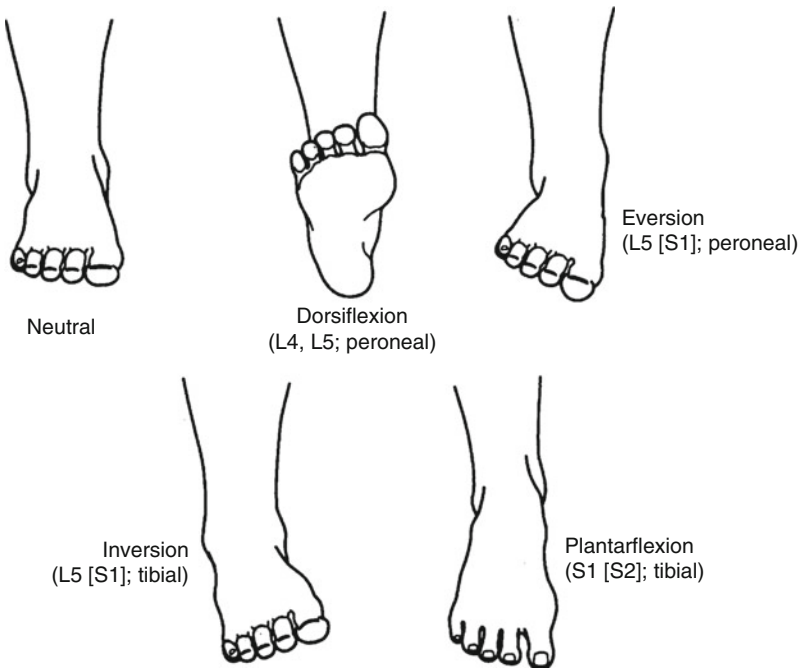

Fig. 1.2 Directions of foot movements. Note that the *L5* root is, in part, responsible for foot dorsiflexion, eversion, and inversion, while the common peroneal nerve is responsible for dorsiflexion only

[b]Extremely rare causes

mislabeled as having bilateral foot drop, while careful examination reveals foot and ankle weakness in all directions, compatible with bilateral flail foot.

Foot drop is a direct effect of tibialis anterior muscle weakness. It is often associated with weakness of toe extension due to weakness of the extensor hallucis and extensor digitorum longus and brevis. Unilateral foot drop is caused by disorders distinct from those leading to bilateral foot drop, with some overlap (Tables 1.7 and 1.8). In general, most cases of bilateral foot drop are caused by lumbar spine disorders such as bilateral L5 radiculopathies or more generalized disorders such as a motor neuron disease, polyneuropathy, or myopathy. In contrast, unilateral foot drop is often due to a focal disorder such as a mononeuropathy or radiculopathy.

Peroneal neuropathy or L5 radiculopathy are by far the most common causes of foot drop. They often result in unilateral foot drop which may occasionally be bilateral. The weakness in peroneal neuropathy is restricted to ankle dorsiflexion, toe dorsiflexion, and ankle eversion. Ankle eversion

Table 1.9 Differential diagnosis of common neuromuscular causes of unilateral foot drop

	Peroneal neuropathy	L5 radiculopathy	Lumbar plexopathy (lumbosacral trunk)	Sciatic neuropathy (mainly peroneal)
Common causes	Compression (weight loss, perioperative, or iatrogenic), blunt and open trauma	Disc herniation, lumbar spinal stenosis	Prolonged labor (short women and/or large infants), pelvic fracture	Hip surgery, injection injury, coma
Ankle inversion	Normal	Weak	Weak	Normal or mildly weak
Toe flexion	Normal	Weak	Weak	Normal or mildly weak
Plantar flexion	Normal	Normal	Normal	Normal or mildly weak
Ankle jerk	Normal	Normal (unless with S1)	Normal (unless with S1)	Normal or depressed
Sensory loss	Distal 2/3 of lateral leg and dorsum of foot	Poorly demarcated, predominantly big toe	Well demarcated to L5 dermat ome	Entire lateral leg and dorsum of foot and, often, the sole
Pain	Rare, deep	Common, radicular	Common, may be radicular	May be severe

is usually stronger than dorsiflexion, since the superficial peroneal nerve is often less involved than the deep peroneal nerve. In L5 radiculopathy, there is additional weakness of ankle inversion and toe flexion. Foot dorsiflexion weakness is not uncommon with L4 radiculopathy although quadriceps, iliopsoas, and thigh adductor weakness is usually more pronounced. Occasionally, a selective L4 radiculopathy may result in severe ankle dorsiflexion weakness leading to foot drop. This is probably related to the myotomal variability of the tibialis anterior muscle; in most individuals, this muscle is innervated by the L5 root predominantly but receives a major contribution from the L4 root. It is likely that in those patients with foot drop due to L4 radiculopathy, the majority of tibialis anterior segmental innervation is via the L4 root. Unilateral conus medullaris lesion involving the L5 segment may rarely cause a foot drop that is difficult to distinguish from an L5 root lesion.

Partial sciatic neuropathy usually affects the lateral division (peroneal nerve) more than the adjacent medial division (tibial nerve). This often presents as a foot drop and poses a diagnostic challenge since it imitates a distal selective peroneal nerve injury due to compression at the fibular head (Table 1.9).

Injury to the lumbosacral trunk of the lumbosacral plexus, such as occurring mostly during labor in short women delivering large infants, is relatively rare. It often present with foot drop with variable buttock pain and numbness in the lateral leg and dorsum of the foot. The neurological findings include not only weakness of ankle and toe dorsiflexion and ankle eversion but also ankle inversion and toe flexion. There is variable weakness of the glutei and hamstring muscles. A lumbosacral trunk lesion imitates clinically an L5 radiculopathy, and careful EDX studies are often essential for final diagnosis.

Anterior compartment syndrome of the leg often results in foot drop since the anterior compartment contains all muscles which function as ankle and toe evertors (tibialis anterior, extensor hallucis, and extensor digitorum longus), in addition to the deep peroneal nerve. Dysfunction of any of these structures (muscles with or without nerve) results in weakness of foot and toe dorsiflexion. There is usually leg pain out of proportion to what is anticipated from the clinical situation, particularly if it occurs after a time interval from the primary etiological event. The pain is worsened by passive flexion of toes and plantar flexion of ankle, and there is often tenseness of the anterior compartment fascia.

Bilateral foot drop is less common and is usually due to cauda equina, conus medullaris, or generalized neuromuscular disorders (Table 1.8). A significant number of the distal myopathies have a predilection for the muscles of the anterior compartment of the leg. In fact, ankle eversion weakness and foot drop are common presentations in the limb girdle muscular dystophies which present as distal myopathies (see Chap. 57). In some of them, the disorder may start with weakness in the hands, followed by bilateral foot drop. Bilateral, often asymmetrical, weakness of foot dorsiflexion, often leading to foot drop, is a common finding in patients with FSH muscular dystrophy and the scapuloperoneal syndromes (SPS). Almost all patients have associated winging of the scapulae and shoulder girdle weakness. Facial weakness is also very common. Multifocal motor neuropathy often presents with asymmetrical intrinsic hand muscle weakness, wristdrop, or foot drop. The latter is the most common manifestation in the lower extremity, usually caused by peroneal neuropathy manifesting with a demyelinative conduction block. The lack of significant atrophy and sensory loss are characteristic findings. Foot drop due to peroneal neuropathy at the fibular head may also occur in patients with hereditary neuropathy with liability to pressure palsy (HNPP). In the sporadic form of ALS, limb weakness often precedes bulbar symptoms, and the arms tend to be affected earlier than the legs. Occasionally, foot drop is an early manifestation of ALS and may pose a diagnostic challenge. In these patients, the weakness often involves all the distal L5 innervated muscles, resulting in weakness of ankle inversion (tibialis posterior) and toe flexion (flexor digitorum longus). Most patients go on to develop diffuse foot weakness, resulting in a flail foot, along with weakness in other myotomes in the same or in other limbs. Hyperreflexia, hypertonia, atrophy, and fasciculations are useful diagnostic features.

Table 1.10 Causes of unilateral atrophy and weakness of intrinsic hand muscles

All intrinsic hand muscles
Combined ulnar neuropathy and carpal tunnel syndrome
Lower brachial plexopathy (including neurogenic thoracic outlet syndrome)
C8 radiculopathy
Amyotrophic lateral sclerosis
Focal motor neuron disease (monomelic amyotrophy)
Cervical syringomyelia
High cervical or foramen magnum spinal cord compression
Peripheral polyneuropathy
Distal myopathy
All intrinsic muscles excluding the thenar muscles
Ulnar neuropathy at the elbow
Ulnar neuropathy at the wrist (Guyon's canal)
All intrinsic muscles excluding the thenar and hypothenar muscles
Ulnar neuropathy at the wrist (distal Guyon's canal or pisohamate hiatus)
Limited to the thenar muscles
Carpal tunnel syndrome
High median neuropathy (including the pronator syndrome)
Neurogenic thoracic outlet syndrome
T1 radiculopathy

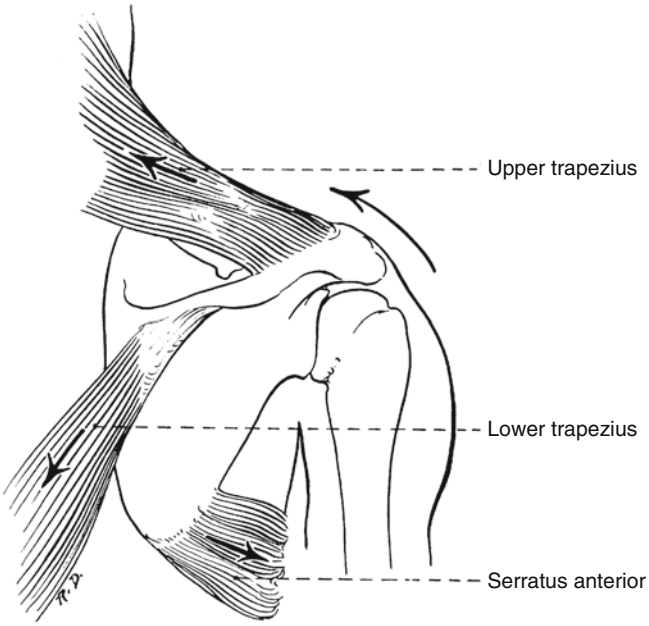

Fig. 1.3 Scapular rotators during abduction (Reprinted from Hollinshead [8], with permission)

Hand Atrophy

Patients who present with hand atrophy, often associated with weakness, may harbor a variety of neuromuscular or intrinsic cervical spinal cord disorders. It is important to distinguish whether the atrophy involves the thenar eminence, hypothenar eminence, the interossei, or all three muscle groups (Table 1.10). Interossei atrophy results in deep grooves between the metacarpal bones, best appreciated over the dorsum of the hand with the fingers extended. With ulnar nerve lesions, there is often clawing of the ring and little fingers (*benediction posture*). In this posture, weakness of the third and fourth lumbricals results in hyperextension of the metacarpophalangeal joints (due to unopposed action of long finger extensors) and flexion of the proximal and distal interphalangeal joints. With weakness of abduction of the little finger (due to weakness of the third palmar interosseous muscle), patients may catch their little finger when trying to put their hand in their pocket (*Wartenberg's* sign). With weakness of the opponens pollicis, the thumb may rotate and face the same direction as the other fingers (*simian hand*). Associated sensory manifestations, such as in the lateral hand in carpal tunnel syndrome and in the medial hand in thoracic outlet syndrome or ulnar neuropathy across the elbow, are useful signs in sorting out the cause of atrophy. Patients with hand atrophy and weakness without sensory involvement present more of a diagnostic challenge. EDX studies with detailed needle EMG are often necessary for accurate diagnosis.

Scapular Winging

During shoulder movements, the scapula maintains its position by the support of multiple muscle groups, termed the scapular fixators or stabilizers. Among them, the serratus anterior, trapezius, levator scapulae, and rhomboids muscles play the major role.

The serratus anterior is essential in synchronizing scapular movements associated with shoulder flexion or abduction and during forward pushing. During forward flexion, the serratus anterior keeps the scapula close to the thoracic wall, while during abduction, it rotates the scapula laterally and forward. The trapezius muscle works mostly during shoulder abduction by maintaining the vertebral border of the scapula vertically and rotating the scapula laterally along the vertical axis (Fig. 1.3). The rhomboids and levator scapulae muscles are antagonists to the serratus anterior. They rotate the scapula medially and backward and maintain the upper part of the scapula close to the vertebral spine during abduction.

The trapezius muscle is innervated by the spinal accessory nerve (cranial nerve XI). In addition, the lower part of the muscle receives branches from the C3 and C4 nerve roots which join the motor nerve to the trapezius distal to the takeoff of the sternocleidomastoid branch. The serratus anterior receives its motor supply exclusively from the long thoracic nerve which originates from the anterior primary rami of the C5, C6, and C7 roots. The rhomboids (major and minor) and levator scapulae are innervated by the dorsal scapular nerve which arises from the anterior primary ramus of C5. The

Nemaline myopathy
Centronuclear myopathy
McArdle's disease

Table 1.12 Differential features of scapular winging due to trapezius or serratus anterior weakness

Muscle	Trapezius weakness	Serratus anterior weakness
Innervation	Spinal accessory nerve	Long thoracic nerve
Scapular winging at rest	Prominent	Mild
Shoulder sagging at rest	Obvious	Subtle
Levator scapulae at rest	Prominent (with chronic weakness only)	Not visible
Relation to midline at rest	Lateral translocation	Medial translocation
Winging is accentuated by	Shoulder abduction	Shoulder forward flexion or protraction (pushing) against resistance

levator scapulae receives additional and substantial motor supply from the primary rami of C3 and C4, while the rhomboids rarely are supplied from the C4 root.

Scapular winging is a descriptive term, generally referring to translocation of the scapula from its normal position. This may be apparent at rest or accentuated or improved by certain shoulder movements. Scapular winging may be unilateral or bilateral. Bilateral scapular winging is usually caused by diffuse weakness of the scapular fixators from generalized neuromuscular diseases, particularly FSH and SPS. Other neuromuscular disorders, associated occasionally with scapular winging, are listed in Table 1.11. Unilateral winging is most often caused by weakness of the trapezius or serratus anterior muscles usually due to isolated mononeuropathies of the spinal accessory or long thoracic nerves, respectively. Isolated dorsal scapular mononeuropathy, leading to weakness of the rhomboids muscle or levator scapulae, is extremely rare. Bilateral scapular winging from isolated mononeuropathies is unusual.

Patients with scapular winging often present with shoulder weakness, pain, or both. Sometimes, the patient complains of a droopy shoulder or scapular dislocation. At times, a family member notices the scapular winging, or the physician detects it during the neurological examination. Shoulder weakness is in all planes of movement but is primarily appreciated with tasks requiring shoulder abduction or forward flexion. The pain is usually deep and poorly localized to the shoulder and scapula. It is often exacerbated by activity and improved following rest. Adhesive capsulitis of the shoulder joint (frozen shoulder), a common complication of chronic winging of the scapula, often worsens the pain and shoulder weakness.

Distinguishing weakness of the trapezius from the serratus anterior may be a challenge to the clinician (Table 1.12). Although weakness of either muscle results in scapular winging with medial deviation of the inferior angle of the scapula (due to the unopposed action of the rhomboids and levator scapulae on the upper scapula), certain characteristics prevail with each. Often, two steps are required on the neurological examination to secure a diagnosis. First, observing the shoulder and scapular position *at rest* is extremely important (Fig. 1.4a, b). In trapezius weakness, the winging is striking, the shoulder is significantly sagged, and the scapula is displaced laterally from the midline. In chronic lesions, the levator scapulae is very prominent due to atrophy of the overlying upper trapezius and, possibly, compensatory hypertrophy of the levator scapulae. In contrast, with serratus anterior weakness, there is little change in the appearance of the shoulder girdle at rest, and the scapular translocation is medial. The second step in diagnosis is to watch the scapula during *specific active shoulder movements*. Shoulder abduction accentuates scapular winging with trapezius weakness, while forward flexion of the shoulder (particularly to 45° below horizontal) or protraction against resistance worsens the scapular winging with serratus anterior weakness. Occasionally, even with these steps, the clinician may not be able to determine the weak scapular fixator muscle, and needle EMG of the shoulder fixators is needed for a definitive diagnosis.

In FSH and SPS, scapular winging is often bilateral but may be asymmetrical. The weakness involves most scapular fixators but particularly the serratus anterior, rhomboids, and lower trapezius. Characteristically, the winged scapulae in FSH and SPS are laterally displaced at rest. With forward flexion, winging is accentuated with a characteristic upward protrusion of the scapulae (due to preferential weakness of the lower trapezius

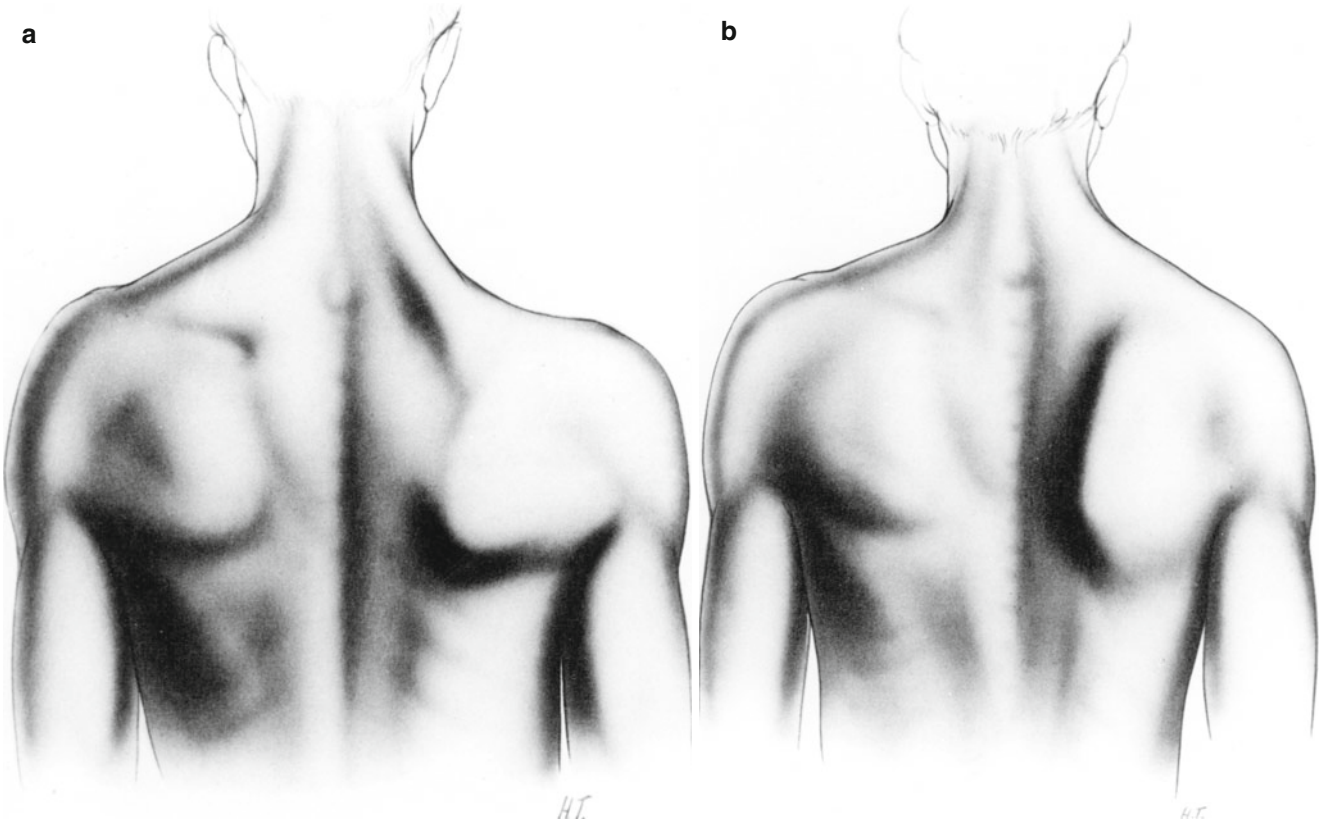

Fig. 1.4 Comparison of shoulder and scapula at rest following isolated weakness of trapezius (spinal accessory neuropathy) (**a**) and serratus anterior (long thoracic neuropathy) (**b**). Note the lateral translocation of the scapula, striking winging, droopy shoulder, and prominent levator scapulae in a and medial translocation, milder winging, and minimal depression of shoulder in (b) (Reprinted from Liveson and Spieholz [9], with permission)

muscles). Winging also worsens with shoulder abduction. Associated bilateral facial paresis; weakness of biceps, triceps, and tibialis anterior; a positive family history; and genetic studies often help in establishing the diagnosis of FSH or SPS.

Dropped Head

Severe weakness of head extension may result in the inability to hold the head up. Weakness of the cervical paraspinal muscles (neck extensors) is usually an early presentation of a generalized neuromuscular disorder, such as myasthenia gravis, polymyositis, or ALS (Table 1.13), but may also occur in isolated neck extensor or trunk extensor myopathies (paraspinous myopathies, see Chap. 66). It also may occur in patients with advanced neuromuscular diseases such as FSH or myotonic dystrophy type I or II. Dropped head may also be associated with parkinsonism and multiple system atrophy, and this may represent an association between these disorders and isolated neck extensor myopathy. It is important to distinguish dropped head syndrome due to neck extensor weakness from cervical dystonia resulting in anterocollis and from severe cervical spondylosis, particularly when associated with spondylolisthesis.

Table 1.13 Common disorders presenting with or manifesting with prominent head drop

Myopathies
Polymyositis
Dermatomyositis
Facioscapulohumeral muscular dystrophy
Myotonic dystrophies
Inclusion body myositis
Nemaline myopathy
Multicore myopathy

Nerve and Muscle: Basic Concepts

2

Francisco H. Andrade

Introduction

Reflex and voluntary motor activity results from the integration of multiple and continuous stimuli. The hierarchical division of motor behavior reflects its particular goal. Thus, short interneuron arcs in the spinal cord mediate simple reflexes, and complex motor activities involve central processors, such as motor cortex, cerebellum, and basal ganglia. Regardless of complexity, motor activity always involves nerves and muscles as the final pathway for the production of force and movement. This chapter presents the basic aspects of neuromuscular biology: how neural signals initiate the contractile process, and how it is regulated.

Excitable Cells

Neurons and muscle cells are *excitable*, that is, an appropriate stimulus will change their electrical potential difference with the environment. Motor systems depend on this property of excitable cells to transmit information, eventually leading to force and movement.

Plasma Membrane

Cells are surrounded by a lipid-protein membrane that creates intra- and extracellular compartments, the cytoplasm and extracellular space, respectively. The plasma membrane serves as a barrier between the compartments, limiting the movement of molecules in and out of the cell; therefore, the cytoplasmic and extracellular concentrations of ions, proteins, fatty acids, and carbohydrates may be very different. In addition to being a mechanical barrier, the plasma membrane contains receptors, channels, and transporters that mediate the interactions between the cell and its environment.

The plasma membrane consists mostly of lipids and proteins in proportions that vary depending on the cell type, plus a small amount of carbohydrates, mostly in membrane glycolipids or glycoproteins [1]. The membrane lipids are mainly phospholipids containing choline (lecithins and sphingomyelins) or amino groups (phosphatidylserine, phosphatidylethanolamine), other phospholipids (phosphatidylglycerol, cardiolipin), and cholesterol. The phospholipid molecules have polar hydrophilic head groups and two nonpolar hydrophobic hydrocarbon tails. Because of this, membrane lipids are arranged to form a fluid bilayer, with the polar groups facing to the outside (cytoplasm and extracellular space) and the nonpolar groups facing inside. The proteins are found embedded in this bilayer, either exposed to only one of the surfaces (peripheral membrane proteins) or crossing the whole span of the membrane (integral membrane proteins) [2]. This is not a rigid structure: the lipids and proteins are in constant motion (parallel to the membrane's plane) in a process called *lateral diffusion*. The fluidity of the membrane is adjusted by cholesterol and limited by cytoskeletal elements that interact with membrane components, restricting their motility [3, 4]. Because cholesterol is a bulky, weakly amphipathic molecule, it stiffens the membrane, blurring the distinction between the gel and fluid states [5].

The plasma membrane controls the movement of substances between the cell and its environment. In general, passive transport across biological membranes is by diffusion: for any given substance, the rate of diffusion across a membrane is given by its lipid solubility, the concentration gradient between the compartments, and the thickness of the membrane. These factors restrict movement across a membrane to small, nonpolar molecules. The diffusion rate of charged substances is orders of magnitude less. An exception to this rule is the diffusion of water. For unknown reasons, cellular membranes show a surprisingly high permeability to water.

Table 2.1 Typical ionic composition of mammalian skeletal muscle

	Extracellular (mM)	Intracellular (mM)	E_{ion} (mV)
Na^+	145	12	+67
K^+	4	155	−98
Cl^-	123	4	−91
Ca^{++}	1.5	$<10^{-4}$	+129

Diffusion alone is not sufficient to fulfill cellular exchange requirements. Other mechanisms exist to facilitate the transport of selected substances across the plasma membrane. Specific integral membrane proteins may act as channels or carriers (transporters) in a process called *mediated transport* (proteins *mediate* the transmembrane movement of molecules). Mediated transport is faster than diffusion and may be specific for a particular ion or compound. It may saturate (i.e., transport rate reaches a peak when all the transporters are occupied). Mediated transport may be passive, via transport proteins that do not require the expenditure of energy (facilitated transport), or active, when the movement of molecules is coupled to the release of energy, usually from ATP (active transport). In practical terms, facilitated transport follows concentrations gradients between the intra- and extracellular compartments, and active transport works ("pumps") against them. The channels and transporters that mediate these processes have distinguishing structural characteristics.

Channel proteins in mammalian plasma cells are basically membrane pores, composed of α-helical bundles packed together around a single axis, in a way that forms the permeation pathway (or channel) for ion conductance [6, 7]. Some channels are gated: they can switch from a closed to an open configuration and back in response to chemical, physical, or electrical events [6, 8, 9]. Moreover, their activity may be modified by intra- or extracellular conditions [10]. Transporters move molecules across the plasma membrane with a conformational shift that physically moves the molecules from one side of the membrane to the other [11]. By modulating the activity of different channels and transporters, cells have multiple control points for the regulation of their internal milieu.

Membrane Potential

Animal cells are polarized, that is, they have an electrical potential. Being a barrier to diffusion, the plasma membrane creates differences in the ionic concentration between the cytoplasmic and extracellular compartments, giving rise to a chemical potential difference (Table 2.1). For example, substance *X* tends to diffuse from the compartment where it is at a higher concentration to the other. Thermodynamically, this is shown by

$$\mu_x = \mu_0 + RT \ln[X] \tag{2.1}$$

where μ_x is the chemical potential for substance *X*, μ_0 is the reference electrochemical potential for *X* under standard conditions (usually 1 M and 20 °C), *R* is the gas constant (8.314 J degree^{-1} mol^{-1}), *T* is the absolute temperature, and [*X*] is the concentration of *X*. When *X* is an ion with charge *z*, a term for electrical potential must be added:

$$\mu_x = \mu_0 + RT \ln[X] + zFE \tag{2.2}$$

where *F* is Faraday's constant (96,500 C mol^{-1}) and *E* is the electrical potential (*V*). When ion *X* is at equilibrium, the electrochemical potentials inside and outside the cell must be equal:

$$\mu_{out} = \mu_{in} \tag{2.3}$$

Then, the electrical potential difference across the plasma membrane given by the distribution of ion *X* is

$$\frac{RT}{ZF} \ln \frac{[X]_{out}}{[X]_{in}} = (E_{in} - E_{out}) \tag{2.4}$$

This is the *Nernst equation* and is important for understanding that differences in the ionic composition of the intra- and extracellular compartments are partly responsible for the electrical potential of cells. The Nernst equation shows that the equilibrium potential for an ion varies linearly with temperature and logarithmically with its concentration ratio. For ions at equilibrium, the electrical potential difference given by this equation equals the resting membrane potential. In other words, the gradient created by a difference in the concentration of an ion is opposed by its electrical potential difference, resulting in no net ionic flux. Therefore, if the plasma membrane is selectively permeable to one ion (e.g., Cl^-) and it is in equilibrium across the membrane, the potential difference calculated by the Nernst equation for the $[Cl^-]_{out}$ and $[Cl^-]_{in}$ would equal the resting membrane potential.

Plasma membranes are permeable to numerous ions (mostly K^+, Na^+, Cl^-); however, the membrane's conductance (*g*) for each ionic species is different. The effect of *g* on the membrane potential is shown by the Goldman-Hodgkin-Katz equation [12, 13]:

$$E_M = \frac{RT}{F} \ln \frac{g_K [K]_o + g_{Na} [Na]_o + g_{Cl} [Cl]_i}{g_K [K]_i + g_{Na} [Na]_i + g_{Cl} [Cl]_o} \tag{2.5}$$

where the potential difference across the plasma membrane (E_M) becomes a function of the concentration ratios of the

ions present and their conductances. In more general terms, E_M is an average of the equilibrium potentials of Na^+, K^+, and Cl^-, weighted by their relative conductances:

$$E_M = \frac{(g_K E_K) + (g_{Na} E_{Na}) + (g_{Cl} E_{Cl})}{g_K + g_{Na} + g_{Cl}} \quad (2.6)$$

As the Goldman-Hodgkin-Katz equation shows, cells that have an unequal distribution of ions also have an electrical potential difference across the plasma membrane. Most animal cells are polarized in such a way that the cytoplasm is negative with respect to the extracellular space. This potential difference localizes to the plasma membrane (resting E_M), and it is largely due to the selective permeability of the membrane to the ions that are present at different concentrations in the cytoplasm and the extracellular space.

While the permeability to Na^+ is very low under resting conditions, there is a large electrochemical gradient driving a small Na^+ current (I_{Na}) into the cell. This excess of positive charges would eventually depolarize the cell, dissipating an important factor for excitability, active transport, and volume regulation. To counteract the Na^+ influx, a specialized transporter, the Na^+-K^+ ATPase (or "pump"), extrudes Na^+ from the cytosol, against its electrochemical gradient, in exchange for K^+. Reflecting its importance for cell function, about half of the ATP provided by oxidative metabolism in the brain is used to power the Na^+-K^+ pumps [14]. The Na^+-K^+ ATPase is an $\alpha 2\beta 2$ tetramer with a molecular weight of approximately 270 kD. The α-subunits contain ATP and cardiac glycoside binding sites and are responsible for transport activity. The β-subunits are glycopeptides whose function is not clear: they may serve for proper folding of the α-subunits in the plasma membrane or as an adhesion element in cell-cell interactions [15].

Because the stoichiometry of the Na^+-K^+ ATPase reaction is 3 mol Na^+, 2 mol K^+ per mol ATP hydrolyzed, this pump is electrogenic: it generates a net positive charge efflux and a greater potential across the membrane (more negative E_M). Although the outward current generated by this pump is usually small, its activity may result in large changes in excitability.

Action Potentials

In most cells, E_M has been harnessed to store and transmit information. The resting E_M changes in response to particular stimuli: chemical, electrical, and mechanical. The modality is specific to the cell type. E_M may become less (depolarization) or more negative (hyperpolarization) in response to a stimulus. These changes in the resting E_M are mediated by gated ion channels and may be divided into two general classes: slow potentials and action potentials.

Slow potentials are graded changes in E_M that occur in response to highly localized transducing mechanisms and may be the initiators of subsequent action potentials (e.g., see section "Neuromuscular Transmission"). Their amplitude and duration are determined by the intensity and duration of the stimulus being transduced. Slow potentials lose amplitude as they spread distally from their origin but may sum temporally and spatially with other slow potentials.

Neurons, skeletal muscle fibers, and other excitable cells can generate action potentials, very rapid, pulse-like membrane depolarizations that are triggered when E_M is depolarized past a threshold. Once triggered, action potentials have constant amplitude and duration, not affected by distal spread. This phenomenon is known as an *all-or-none response*. In other words, once stimulus intensity reaches the threshold, an action potential is triggered. Augmenting the stimulus does not change the shape of the action potential. Because action potentials have constant speed, amplitude, and duration, the information transmitted by them is coded by their timing.

The origin of an action potential is easier to grasp if one considers some rules that govern electrical evens. The most fundamental is Ohm's law, the relationship between voltage or potential difference (E), current (I, amperes), and resistance (R, ohms):

$$I = \frac{E}{R} \quad (2.7)$$

Because resistance is the inverse of conductance (g, siemens),

$$I = gE \quad (2.8)$$

In other words, current equals the potential difference between two points times the conductance of the medium. In a cell, the potential difference is the electrical potential for a particular ion as calculated by the Nernst equation (Eq. 2.4), and the conductance is proportional to the permeability of the membrane to the ion. When E_{ion} is not equal to E_M, there is a gradient for the movement of ion (and its charge) across the membrane. The magnitude of the resulting current (I) is determined by the membrane conductance for the ion (g).

The plasma membrane is a lipid bilayer that behaves as a capacitor, a good insulator that separates two conductors, the cytoplasm and the extracellular fluid. Potential difference (E) requires separation of charge, and capacitance (C, farads) measures how much charge (Q, coulombs) has to move from one side of the capacitor to the other for a given potential:

$$C = \frac{Q}{E} \quad (2.9)$$

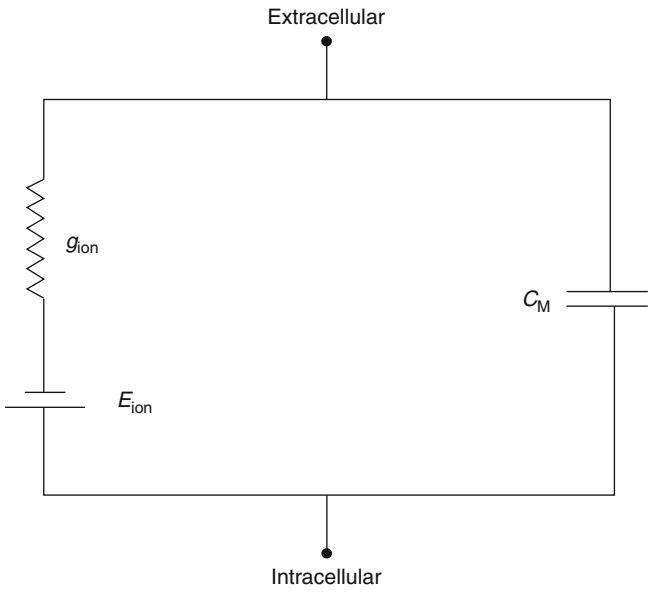

Fig. 2.1 A simplified electrical circuit equivalent of the plasma membrane showing the membrane capacitance (C_M), the potential difference (a battery) produced by ionic gradients (electrochemical potential, E_{ion}), and ionic conductance (g_{ion}, reciprocal of resistance)

Ion channels make the membrane a leaky capacitor, but their density is low and capacity is relatively high, approximately 1 μF/cm^2 of membrane area. For a spherical cell of 60 μm diameter and $E_M = -70$ mV, the amount of charges separated by the membrane's capacitance would be 46×10^6 ions, a very small fraction (less than 1/200,000) of the total number of ions in the cytoplasm. Therefore, the bulk of the cytoplasm and extracellular fluid is electroneutral, and changes in E_M do not require the movement of large numbers of ions. This fact is important for the production of action potentials.

The plasma membrane of excitable cells is basically an electric circuit: the membrane is a capacitor (C_M), and the permeability and electrochemical gradient for an ion are its conductance (g_{ion}) and a battery (E_{ion}, its electrochemical potential given by the Nernst equation) (Fig. 2.1). To include the three major ion species (Na^+, K^+, Cl^-), specific conductances (g_{Na}, g_K, g_{Cl}) and batteries (E_{Na}, E_K, E_{Cl}) are included in the circuit. Usually Na^+ and K^+ are not at equilibrium at the resting E_M, resulting in small inward (Na^+) and outward (K^+) currents that are offset by the Na^+-K^+ ATPase, included in our circuit as a current generator that gives a net flow of positive charges (I_+) from the cytosol to the extracellular fluid ($I_{Na} > I_K$) (Fig. 2.2). The Goldman-Hodgkin-Katz equation (Eq. 2.5) predicts that the potential difference measured across the plasma membrane (E_M) will change if the conductance, the ionic concentration ratio, or the function of the Na^+-K^+ ATPase is altered. Because E_M depends on the ionic concentration ratio, and the electrogenic effect of the Na^+-K^+ ATPase is relatively small, membrane potential follows changes in ionic conductance. In the resting state, the permeability to K^+ is two orders of magnitude greater than the permeability to Na^+, and E_M is closer to E_K (−70 to −90 mV) (Table 2.1). At the peak of an action potential, the permeability to Na^+ is 10–20 times greater than the permeability to K^+, bringing the membrane potential closer to E_{Na} (50 mV or higher) (Figs. 2.2 and 2.3a).

The sudden changes in ionic permeability characteristic of action potentials are due to voltage-gated channels. These ion-specific channels share certain traits: an ion-permeant pore, a voltage sensor, and a gate to open or close the pore [16–18]. Voltage-gated ion channels have motifs with six membrane-spanning α-helices (four for Na^+ and Ca^{2+} voltage-gated channels, one for K^+ channels); one helix in each motif includes seven repeats of arginine or lysine residues followed by two hydrophobic amino acids. The movement of these positively charged amino acids in response to changes in E_M is the gate that opens the channel pore [6, 8, 19].

Local depolarizations or slow potentials open voltage-gated Na^+ channels, increasing g_{Na}. E_M depolarizes, causing more Na^+ channels to open and increasing the inward Na^+ current in a positive feedback cycle that eventually drives E_M towards E_{Na} (Figs. 2.2 and 2.3b) [20]. The opening of a single voltage-gated Na^+ channel is a probability function; the channel population in a given cell opens within a depolarization range. When g_{Na} increases beyond a certain point (the action potential threshold), the depolarization enters the positive feedback cycle, and more voltage-gated Na^+ channels open. In consequence, E_{Na} exerts a greater influence on membrane potential. However, the increase in g_{Na} is time-limited, and it returns to its resting level within 1–2 ms (Fig. 2.3b). This behavior is explained as follows: when membrane depolarization reaches the threshold for a voltage-gated Na^+ channel, an activation gate opens and Na^+ can enter the cell following its electrochemical gradient (Fig. 2.4a). Shortly after the activation gate opens, a time-dependent inactivation gate closes, ending Na^+ influx (Fig. 2.4b) [21, 22]. Once voltage-gated Na^+ channels are inactivated, the cell membrane must repolarize to reverse the inactivation (Fig. 2.4c).

Depolarization also results in a slow increase in g_K, which reverses exponentially as the membrane repolarizes to its resting potential (Fig. 2.3b). The voltage-gated K^+ channels that change g_K activate about ten times slower than their Na^+ counterparts and are known as *delayed rectifiers*. They also close slowly as the membrane is repolarized. Because the voltage-gated K^+ channels close with some delay after repolarization, the membrane may hyperpolarize following an action potential (afterpotential hyperpolarization) (Fig. 2.3b). The initial description of ionic events during an action potential was made in the giant axon of the squid, which contains voltage-gated Na^+ and K^+ channels almost exclusively [23]. It is a testament to the evolutionary importance of the process that the basic mechanism of the action potential is extensively conserved with relatively minor modifications: excitable cells in other species contain these two channel types, in addition to voltage-gated channels that conduct other ions. The heart is a good example: its cells

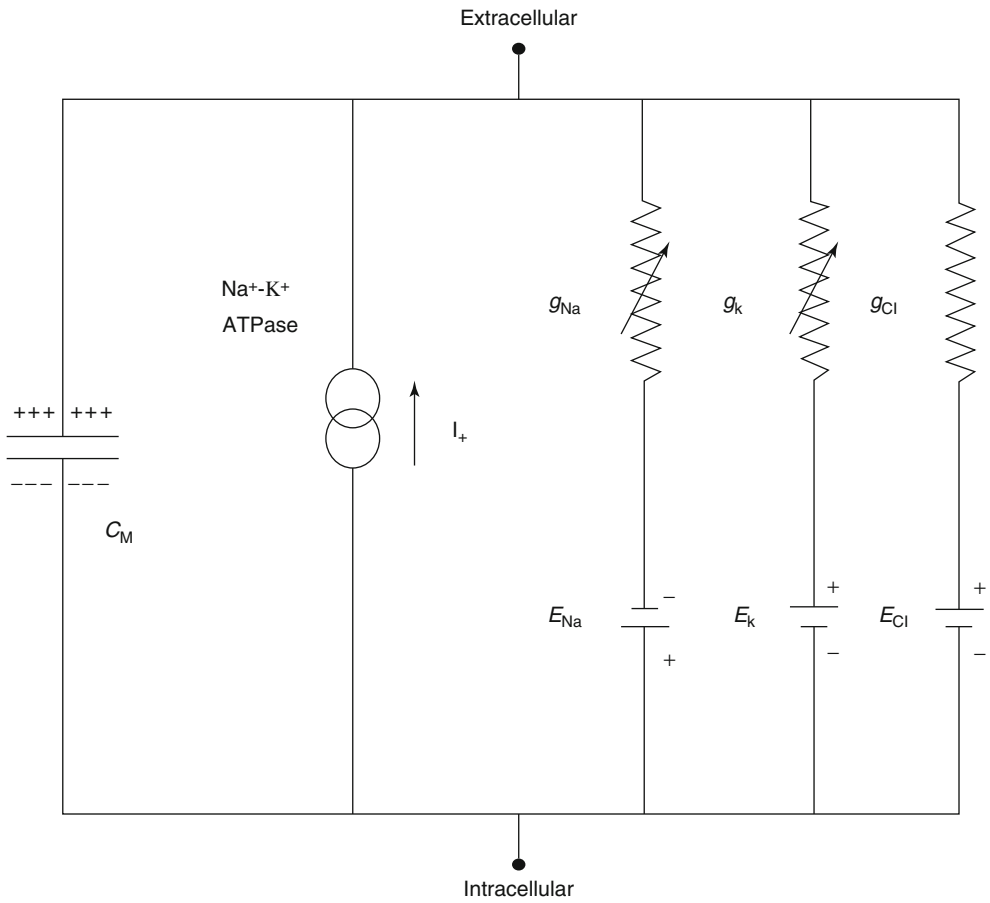

Fig. 2.2 Basic electrical circuit equivalent of the plasma membrane including membrane capacitance (C_M), ionic conductances (g), electrochemical potentials (E), and the current generator Na^+-K^+ ATPase. *Arrows* through g_{Na} and g_K indicate that these conductances can vary, for example, during an action potential

include voltage-gated Ca^{2+} channels that open during depolarization, increasing g_{Ca} which is responsible for the positive potential plateau observed during the action potentials in these cells [24].

Because action potentials are all-or-none responses, once their threshold is reached, the cell is refractory to further stimulation; during the spike of the action potential, voltage-gated Na^+ channels are either open or in their inactivated state (Fig. 2.4b, c). This portion of the action potential is the absolute refractory period: further stimuli will not alter its shape or trigger another action potential. As E_M repolarizes and g_{Na} returns to its resting level, the cell is able to initiate another action potential only if a stronger stimulus is applied. In this phase, the inactivation of voltage-gated Na^+ channels is not completely reversed, and a stronger stimulus is needed to activate enough Na^+ channels and depolarize the membrane. Moreover, g_K remains elevated, resulting in afterpotential hyperpolarization of E_M and increased opposition to depolarization.

Conduction

A notable characteristic of neurons is their enormously elongated cylindric processes known as *axons* and whose main function is the conduction of action potentials. In unmyelinated axons, action potentials are propagated by a wave of depolarization called the *local response*. This means that an action potential occurring in a finite membrane region depolarizes neighboring areas and causes the E_M to reach threshold and generate an action potential. Unless there is a change along the length of the axon in the threshold level or in the membrane resistances and capacitance, the action potential is transmitted at a constant velocity by electrotonic conduction.

The speed of electrotonic conduction is determined by the passive electrical properties of the cell. The axon or muscle fiber behaves as a poorly insulated cable: the amplitude of the E_M change induced by a focal stimulus falls exponentially with distance from its origin. In addition to the transverse resistance and capacitance due to the membrane, the axonal cytoplasm (like any cable) represents an internal resistance to current flow. The distance at which a potential difference declines to 37 % of its original intensity is the *length constant* and is equal to the square root of the ratio of membrane and cytoplasmic resistances. The length constant is typically between 1 and 3 mm, clearly shorter than the length of many axons and muscle fibers. Moreover, the speed of electrotonic conduction is determined by the resistance (inversely proportional to the cross-sectional

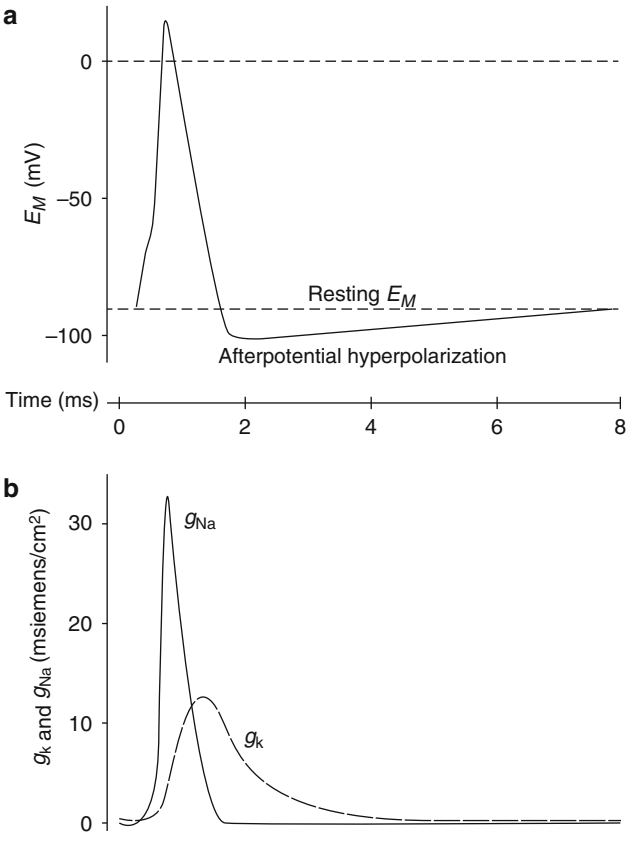

Fig. 2.3 (**a**) Change in membrane potential (E_M) and time course of an action potential. The resting E_M is shown by the dashed line on the bottom. (**b**) Voltage- and time-dependent changes in Na^+ and K^+ conductances during an action potential

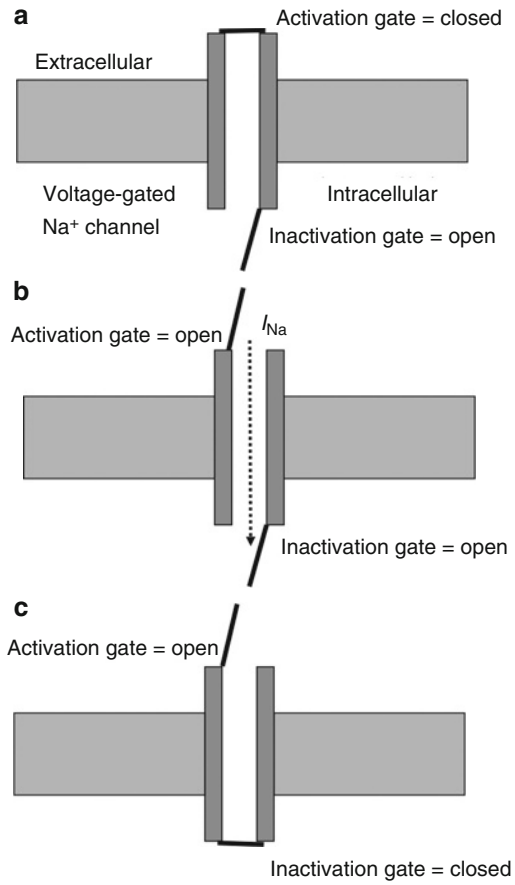

Fig. 2.4 (**a**) Position of "activation" and "inactivation" gates of a voltage-gated Na^+ channel at the resting membrane potential. (**b**) In response to a stimulus, the activation gate opens and allows Na^+ to enter the cell (I_{Na}), depolarizing the membrane; the time-dependent inactivation gate remains open. (**c**) Following a short delay, the inactivation gate closes and stops Na^+ influx; the activation gate remains open until the membrane potential repolarizes below its threshold

area of the axon or muscle cell): larger cells have faster conduction velocities.

Axons and muscle fibers regenerate action potentials by local currents, avoiding the loss of amplitude intrinsic to pure electrotonic conduction. Because conduction velocity is proportional to the cell's radius, some organisms, such as the squid and lobster, have developed giant axons (up to 1 mm in diameter) to rapidly conduct action potentials important for escape maneuvers. That is certainly not a strategy available to all organisms.

An alternative mechanism to optimize the conduction of action potentials in thin axons involves surrounding the axons with a thick layer of insulation, myelin. The axons of motor and large sensory neurons are surrounded by Schwann cells, a specialized type of glia that spirals around the axon in concentric layers that eventually condense to form myelin lamellae (Fig. 2.5). The composition of myelin is similar to that of cellular membranes, with ~70 % lipid (mostly cholesterol and phospholipids) and 30 % protein. Schwann cells are aligned regularly around axons, each covering an axon segment of approximately 0.4–1.0 mm. The small length of axon exposed to the extracellular space between each myelinated segment is called a *node of Ranvier*. The spiral of myelin around the axon increases membrane resistance and decreases its conductance. Therefore, during an action potential, the transmembrane current flow at the nodes of Ranvier is much greater than at the myelinated internodal regions: the nodal regions can generate action potentials, and the depolarization wave spreads through the internodal regions by electrotonic conduction to the next node, where another action potential is triggered. This combination of localized action potentials with electrotonic conduction allows axons to remain relatively small and minimizes the metabolic cost of the action potentials. First, the conduction velocity of unmyelinated axons is proportional to the square root of their diameter: an unmyelinated fiber would have to be 4 mm thick to conduct an action potential with the same velocity as the fastest myelinated axon (~120 m/s). Second, myelinated axons generate action potentials in the nodal regions only; therefore, the amount of transmembrane charge movement

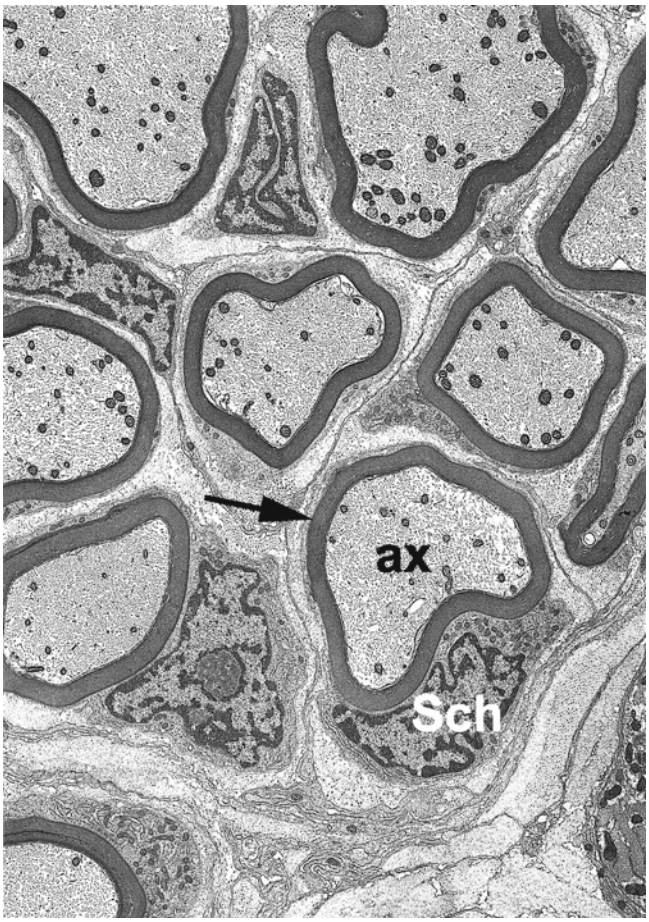

Fig. 2.5 This electron photomicrograph shows a cross section of peripheral nerve. Axons (*ax*) are surrounded by myelin sheaths (*arrow*). Myelin in peripheral nervous system is formed from the plasma membrane of Schwann cells (*Sch*), in contrast to the central nervous system where myelination is by oligodendrocytes

per action potential is less than in an unmyelinated axon, resulting in less energy consumed by ion-motive transporters to restore ionic gradients. Finally, the large internodal regions function as reservoirs for the diffusion of ions in and out of the nodes. This increases the effective nodal volume and minimizes the changes in ionic concentration ratios due to the action potential currents, which would render the axon unexcitable in a relatively short time.

Neuromuscular Junction

Skeletal muscle fibers contract under direct neural control. The activation signals coded by the action potentials are transmitted from the motor neuron's axon to the muscle fiber at a specialized site of close apposition, the neuromuscular junction. This is a type of chemical synapse that uses acetylcholine (ACh) as the transmitter that binds to specific receptor in the postjunctional (postsynaptic) membrane, inducing local depolarizations that spread outside of the neuromuscular junction and trigger all-or-none action potentials.

Organization

The neuromuscular junction is the site where the motor neuron makes contact with the membrane (sarcolemma) of a skeletal muscle fiber. The axon terminal and the sarcolemma present specialized features necessary for the transmission of the action potential from the motor neuron to the muscle fiber. Specific cytoskeletal proteins participate in the formation, consolidation, and maintenance of ACh receptors at the neuromuscular junction [25–27]. The development of the neuromuscular junction is regulated by interactions between the nerve terminal and the muscle fiber [26]. Two of its hallmarks are specialized Ca^{2+}-triggered ACh exocytotic machinery in the presynaptic terminal and the clustering of ACh receptors on the postsynaptic sarcolemma, resulting from the selective activation of ACh receptor genes at this site.

As the motor neuron reaches a group of muscle fibers, its axon loses its myelin sheath and forms very fine Schwann cell-covered branches that end in multiple varicosities. These synaptic boutons, or terminals, are filled with synaptic vesicles, 50-nm-diameter structures that contain ACh. Each synaptic vesicle has roughly the same ACh content (~5,000 mol), called a quantum. In addition, the synaptic terminals contain mitochondria and active zones, dense patches on the presynaptic membrane where vesicles fuse to release ACh into the small space between the pre- and postsynaptic membranes (synaptic cleft). These components show definite polarization within the synaptic terminal, with the synaptic vesicles in the portion facing the muscle fiber, clustering around the active zones, the site for their eventual release, and most of the mitochondria beneath the Schwann cell (Fig. 2.6).

Each terminal innervates a single muscle fiber, over a cup-shaped depression where the sarcolemma forms multiple junctional folds or invaginations. This area is called the *end plate*, and it is usually in the middle third of the muscle fiber. With few exceptions, muscle fibers have only one end-plate region, innervated by a single axon. The narrow synaptic cleft (~60 nm) is occupied by the basement membrane or lamina, an amorphous collection of collagen, glycoproteins, and enzymes, including acetylcholinesterase, which breaks down released ACh to choline and acetate. Both the presynaptic terminal and the muscle fiber secrete the basement membrane proteins. Each active zone in the synaptic terminal is opposite to a postsynaptic junctional fold (Fig. 2.6). The ACh receptors are clustered at the top of the folds, with a density of 10,000–15,000 per μm^2, 1,000-fold greater density than in the rest of the sarcolemma, and higher than for any other known channel [27–29]. Conversely, the regions extending deep into the folds are rich in voltage-gated Na^+

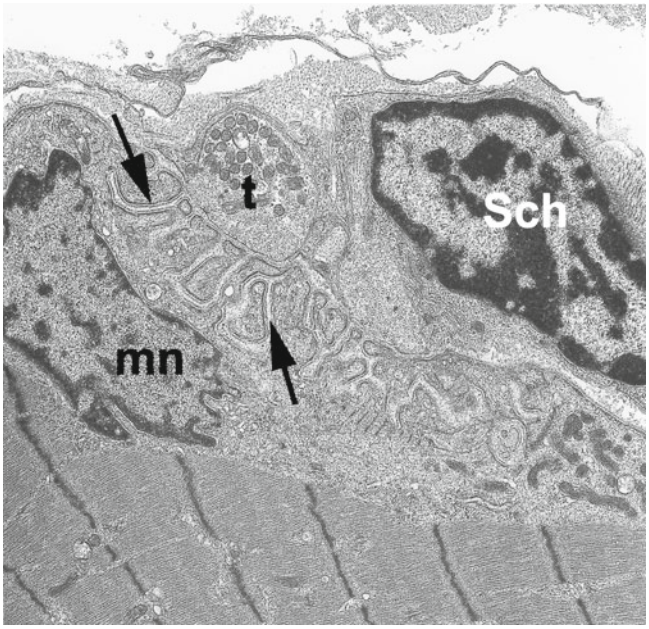

Fig. 2.6 This electron photomicrograph illustrates key elements of a neuromuscular junction. A motor axon nerve terminal (*t*), containing high concentration of mitochondria and synaptic vesicles, is overlain by Schwann cells (*Sch*). A narrow synaptic cleft separates the nerve terminal from the sarcolemma. The sarcolemma is highly involuted with postsynaptic folds (*arrows*) that concentrate acetylcholine receptors and ion channels. Nuclei (*mn*) and mitochondria are often concentrated in the muscle fiber cytoplasm immediately adjacent to the neuromuscular junction

channels, a distribution that improves transmission efficiency by decreasing action potential threshold [30, 31]. This differential distribution of integral proteins may be explained by cytoskeletal elements: rapsyn, utrophin, and α-dystrobrevin-1 co-localize with ACh receptors at the crests of the folds, whereas ankyrin, dystrophin, and α-dystrobrevin-2 are present at the bottom [30, 32].

The nicotinic ACh receptor mediating neuromuscular transmission is a funnel-like intrinsic sarcolemmal pentamer (~275,000 kD) composed of four different subunits (α2βδε) of molecular weights ranging from 40 to 65 kD [6, 33]. Each subunit has four putative sarcolemma-spanning helical domains and participates in the formation of the ion pore. The α-subunits have the binding site for ACh and α-bungarotoxin, a snake venom that is a potent specific inhibitor of the ACh receptor. The ε-subunit replaces the γ-subunit, which is present during development.

Neuromuscular Transmission

The neuromuscular junction allows the efficient transmission of the motor impulse to the muscle fiber. Although direct electrical coupling would be faster, the size of the motor axon is too small to conduct the amount of current necessary to depolarize the much bigger muscle fiber. ACh gives a necessary amplification step. The delay in the transmission of information that is characteristic of neuromuscular junctions and other chemical synapses has not proven to be an evolutionary disadvantage for vertebrate motor systems.

Neuromuscular transmission may be divided into three discrete processes: (1) synaptic terminal depolarization and ACh release, (2) ACh binding and ion channel opening, and (3) end-plate depolarization and action potential generation. The action potential travels down the motor axon, reaching the synaptic terminals. There, voltage-gated Ca^{2+} channels (mostly P-type channels in human neuromuscular junctions) open in response to the depolarization, allow Ca^{2+} to enter the presynaptic terminal, and increase cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$) [34]. The increase in ($[Ca^{2+}]_i$) activates the Ca^{2+}-binding protein synaptotagmin, considered the principal sensor controlling ACh exocytosis [34, 35].

The mechanism for ACh release shares many features with other cellular secretory processes; it has evolved as a specialized form of vesicle trafficking capable of rapid Ca^{2+}-initiated exocytotic cycles. The current model for this process is the SNARE hypothesis: SNARE refers to the synaptic proteins involved [34]. According to this model, Ca^{2+} binding to synaptotagmin allows *synaptobrevin*, the synaptic vesicle v-SNARE (vesicle SNAP receptor), to interact with *syntaxin*, the neuronal t-SNAREs (target membrane SNAP receptors), and SNAP-25 to form a stable 7S complex. Synaptobrevin, SNAP-25, and syntaxin are cleaved by the proteolytic action of botulinum toxins, which block neuromuscular transmission [34, 35]. The 7S complex positions or docks synaptic vesicles at the fusion sites in the active zone and serves as a receptor for the cytosolic α/β/γ-SNAPs (soluble NSF attachment proteins). In turn, SNAP binding recruits the multimeric ATPase, NSF (N-ethylmaleimide-sensitive fusion protein). ATP hydrolysis by NSF disrupts the 7S complex and primes the vesicle for fusion and ACh release. Fusion of the vesicles with the presynaptic membrane proceeds via an unknown mechanism that probably requires synaptotagmin-mediated conformational changes in syntaxin that lead to the release of ACh into the synaptic cleft.

Upon release, ACh diffuses across the synaptic cleft and binds to ACh receptors in the postsynaptic junctional folds. For a single ACh receptor to open, two ACh molecules must bind to its α-subunits. The ACh receptor remains open for approximately 1 ms after ACh binding; then it closes, and ACh dissociates. The ACh concentration in the synaptic cleft falls rapidly by simple diffusion and the action of acetylcholinesterase; therefore, the ACh receptors are not likely to be activated a second time by rebinding of transmitter. Acetylcholinesterase is quite abundant in the mammalian neuromuscular junctions: ~2,500 mol/μm^2 of postsynaptic membrane, enough to quickly hydrolyze the ACh released into the synaptic cleft. Free choline is then taken up into the synaptic terminal by a high-affinity Na^+-choline cotransport system [28].

The release of multiple synaptic vesicles (100–300 per action potential) activates the ACh receptors at the crest of the postjunctional folds. The channel of the ACh receptor behaves as a cation channel with little selectivity: mono- and divalent cations that fit through a 0.65×0.65 nm pore are permeant [36]. Na^+ ions flow inward, and K^+ ions flow outward, following their electrochemical gradients and causing a local depolarization in the end-plate region, termed the *end-plate potential* (EPP). In contrast to an action potential, the ratio of the Na^+ and K^+ conductances does not change with time during an EPP, and the increase in ionic conductances is not initiated by a depolarization. Therefore, the EPP is a local, graded slow potential and not an all-or-none response. It does not regenerate, and its amplitude decreases as it moves away from its point of origin. EPP amplitude is 50–70 mV, unusual for chemical synapses (typically 1–2 mV) and large enough to spread electrotonically into the synaptic folds, where it triggers the opening of voltage-gated Na^+ channels and the development of an action potential that travels the length of the muscle fiber.

There is a short interval (0.3–1.0 ms) between the depolarization of the synaptic terminal and the appearance of an EPP. This delay is a general property of chemical synapses and seems to be due mostly to the exocytotic release of ACh: ACh diffusion across the synaptic cleft and binding to its receptors are not important determinants of the transmission delay [37, 38].

Skeletal Muscle

The function of skeletal muscles is to respond to neural control and efficiently transduce chemical energy (ATP) to force and movement. The structural features typical of skeletal muscle are the result of adaptation to the requirements of contractile activity and provide the checkpoints for its control. Thus, three major areas of specialization are identified: (1) the sarcolemma, including the end plate; (2) the sarcoplasmic reticulum, which regulates Ca^{2+} levels in the cytosol; and (3) the sarcomere, the basic contractile unit.

Skeletal Muscle Structure

Skeletal muscle fibers are elongated cells with multiple nuclei, usually located peripherally around the edge of the fiber. The endomysium, a thin layer of connective tissue, is attached to the sarcolemma. Another layer of connective tissue, the perimysium, surrounds bundles of muscle fibers (*fascicles*), and the whole muscle is encased within the epimysium, an outer layer of thicker connective tissue. These connective tissue layers are continuous with the muscle insertions into tendons and bones.

Skeletal muscle fibers are 10–100 μm in diameter and may be as long as the muscle in which they are located (centimeters). The most abundant cellular components are the filaments that form the sarcomeres, grouped together in myofibrils, tightly packed 1-μm-thick bundles that run the length of the fiber (Fig. 2.7.) The myofibrils are surrounded by the sarcoplasmic reticulum (SR), mitochondria, glycogen and fat droplets, and sarcolemmal invaginations called *transverse tubules* or *t-tubules*. Cardiac and skeletal muscles have a striated appearance on microscopic examination, a result of the repeated contractile units, the sarcomeres, arranged serially in the myofibrils.

Sarcolemma

The cell membrane that surrounds each muscle fiber, the sarcolemma, has multiple functional domains characterized by the clustering of specialized proteins. The individual muscle fibers are linked to the surrounding connective tissue by a trans-sarcolemmal protein network that connects the fiber's interior to the extracellular matrix. The *costameres*, riblike links containing vinculin, α- and β-spectrin, ankyrin, and talin, connect the cytoskeleton and the sarcolemma at the level of the Z line of peripheral sarcomeres. Another protein complex links the subsarcolemmal cytoskeleton, mainly F-actin filaments, to the extracellular matrix: dystrophin binds F-actin, the integral membrane protein β-dystroglycan, and cytosolic syntrophins. β-Dystroglycan also binds to the sarcoglycans (α, β, δ, γ, and possibly ε) and the extracellular protein α-dystroglycan. Finally, the heterotrimeric laminin-2 (α2β1γ1 or merosin) is the extracellular ligand of α-dystroglycan [39].

The sarcolemma has three main areas of specialization: neuromuscular junctions (Fig. 2.6), myotendinous junction, and the t-tubules (inset in Fig. 2.7.) The sarcolemma shows deep invaginations at the myotendinous junction, and sarcomeric actin filaments form close associations with the sarcolemma via α-actinin, vinculin, and talin. Desmin and dystrophin may also participate in the strengthening of the sarcolemma at the myotendinous junctions. These elements assure the continuity between the force-generating muscle fibers and the force-transmitting connective tissue that forms the tendons.

The t-tubular system is a network of narrow sarcolemmal invaginations along the length of the muscle fiber. Based purely on visible surface area, the capacitance of the sarcolemma is about 6 μFarad/cm^2, much higher than for other excitable cells. When the extra membrane area of the t-tubules is factored in the calculation, sarcolemmal capacitance is 1 μFarad/cm^2, which is typical of excitable cells. In mammalian skeletal muscle, there are two t-tubules per sarcomere, located in the planes defined by the tips of the myosin filaments (A-I band junction.) The function of the t-tubules is to propagate the depolarization wave deep into the muscle fiber and to trigger Ca^{2+} release from the SR. This latter process is called *excitation-contraction coupling* (E-C coupling) and is accomplished by the presence of

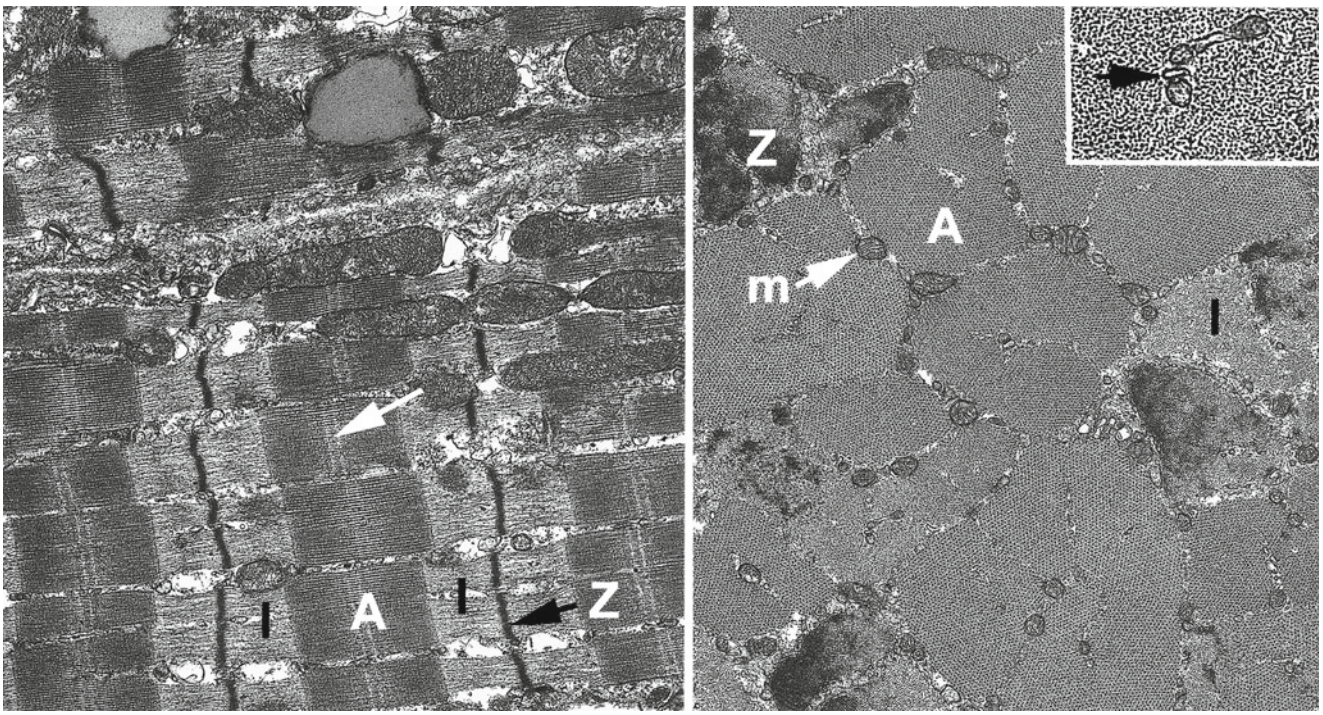

Fig. 2.7 These electron photomicrographs illustrate the basic organization of the muscle fiber contractile unit, the sarcomere, with longitudinal section at the left and cross section at the right. Z bands (*Z*) demarcate each end of individual sarcomeres. The thin filaments in the light-colored I bands (*I*) interdigitate at the Z bands and overlap with the thick filaments in the A band (*A*). The A band is usually bisected by the M line (*arrow*). The separate portions of the sarcomere also can be recognized in the muscle cross section to the right. Units of contractile proteins, known as myofibrils, are surrounded by sarcoplasmic reticulum and mitochondria (*m*). The *inset* at the *upper right* shows a triad. Note the close proximity between the t-tubule (*arrow*, in the *middle*) and the two elements of the sarcoplasmic reticulum

voltage-gated Ca^{2+} channels, the dihydropyridine receptors (DHPr). The DHPr has five subunits (α1α2, βγ, and δ). The α1-subunit (212 kD) is the central component of the complex. It has four transmembrane domains, each with six α-helices, and can function as a voltage-gated ion channel. The fourth α-helix in each domain contains positively charged amino acids every third or fourth position. This could be the structural correlate of a charge movement that is observed after sarcolemmal depolarization [40]. The other DHPr subunits modulate gating, inactivation, and current amplitude.

Sarcoplasmic Reticulum

The SR is a highly developed network of interconnected membranous vesicles, analogous to the endoplasmic reticulum. Each sarcomere is surrounded by a portion of this network. The SR forms sacs, called *terminal cisternae*, on either side of each t-tubule. These closely associated structures are called *triads* (see inset Fig. 2.7), or T-SR junctions, and play a central role in E-C coupling. The gap between the t-tubule and the terminal cisternae is 10–20 nm. It is occupied by the *junctional feet*, periodically arranged structures that seem to physically connect the two membranes and are distributed in orderly tetragonal arrays. Between two triads, the nonjunctional SR continues as narrow tubes parallel to the long axis of the sarcomere, the longitudinal SR, which then fuse to form a single structure perforated from side to side by small round opening, or fenestrae (fenestrated SR).

The junctional feet have been identified as the cytosolic portion of the Ca^{2+} release channels present in the terminal cisternae; they may also include aldolase, triadin, glyceraldehyde phosphate dehydrogenase, and immunophilin-binding proteins. The SR Ca^{2+} release channels can be activated pharmacologically with the plant alkaloid ryanodine, hence the term *ryanodine receptors* (RyR). There are three RyR genes in mammals, producing three isoforms; two of them, RyR1 and RyR3, are present in skeletal muscle [8, 10, 41]. RyR are homotetramers (>550 kD subunits) with a central canal leading to four radial cytoplasmic openings. Each tetramer has a large cytoplasmic domain (foot) that inserts into the cisternal membrane and occludes the central canal [10, 41]. There are multiple regulatory sites, mostly around the putative ion channel on the C-terminal third of the protein, including sites for phosphorylation, Ca^{2+}- and ATP-dependent activation, Mg^{2+}-dependent inhibition, calmodulin, and immunophilin binding [10, 41].

The most abundant integral SR protein is a Ca^{2+}-ATPase, a single polypeptide chain of 140 kD, corresponding to the

α-subunit of other P-type transport ATPases, such as membrane Ca^{2+}, Na^{+}-K^{+}, and H^{+}-K^{+} ATPases. The SR Ca^{2+}-ATPase belongs to the family of intracellular Ca^{2+} pumps present in sarcoplasmic and endoplasmic reticula known as *SERCA* (sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPases). Three isoforms have been identified in skeletal muscle (adult fast, neonatal fast, slow/cardiac), derived from the alternative splicing of two genes (SERCA 1 and 2) [42]. The proposed structure of SR Ca^{2+}-ATPase contains ten α-helical transmembrane and two cytoplasmic domains. One of the cytoplasmic domains contains phosphorylation and ATP binding sites [43]. The purpose of the SR Ca^{2+}-ATPase is to move Ca^{2+} ions from the cytoplasm into the lumen of the SR, ending muscle contraction. Because resting $[Ca^{2+}]_i$ in skeletal muscle fibers is on the order of 100 nM and the SR $[Ca^{2+}]$ is in the millimolar range, the SR Ca^{2+}-ATPase works against a 10^4-fold concentration gradient [42, 43]. More than 70 % of the total SR membrane protein is Ca^{2+}-ATPase, a density of 30,000 mol/μm^2 distributed uniformly along the SR [44, 45]. This high transport capacity is necessary to restore $[Ca^{2+}]_i$ to its resting level and terminate a contraction rapidly (<50 ms).

The lumen of the junctional SR contains calsequestrin, an acidic low-affinity and high-capacity Ca^{2+}-binding protein (40 mol Ca^{2+}/mol calsequestrin) that combines with the Ca^{2+}-ATPase to increase Ca^{2+} storage [41]. Less abundant SR Ca^{2+}-binding proteins (calreticulin, sarcalumenin, and histidine-rich Ca^{2+}-binding protein) may also participate in Ca^{2+} storage between SR release and uptake cycles [46].

Sarcomeres

Microscopically, thin dense transverse lines appear every 2–3 μm along the length of myofibrils. These are the Z lines, a planar network that delimits the sarcomeres (Fig. 2.7). A dark, electrodense region in the middle of each sarcomere, the A band, contains the 1.6-μm-long *thick filament*s. The A band is between two lighter (less electrodense) regions: the lighter regions of two adjacent half-sarcomeres form the I band. The I band contains two sets of 1-μm-long *thin filaments*, connected in series at the Z line. A lighter central region of variable width in the A band is the H zone, between the ends of the two sets of thin filaments. The H zone is typically bisected by a darker line, the M line, produced by links between the thick filaments in the middle of the sarcomere (Fig. 2.7). The thick filaments contain myosin and associated proteins, including C protein and H protein; M protein and myomesin localize at the level of the M line. In addition, the M line contains the skeletal muscle isoform of creatine kinase, the enzyme that catalyzes the transfer of phosphate from creatine phosphate to ADP, producing ATP [47].

The myosins in skeletal muscle thick filaments are conventional class II myosins, hexameric proteins consisting of two heavy chains (MHCs, 200 kD each) and two pairs of nonidentical light chains (MLCs, 17–23 kD), referred to as *essential* (or *alkali*) and *regulatory* light chains. The MHCs have two globular amino-terminal head domains that contain the motor function (ATPase) and a long α-helical coiled-coil carboxy tail with filament-forming properties. At least six MHC isoforms are present in human muscles: the genes coding for 5 of them (embryonic, perinatal, 2A, 2X/D, and extraocular) form a cluster in chromosome 17; the gene for slow/β is clustered next to α (cardiac-specific) in chromosome 14 [48, 49]. A few other MHC isoforms have very restricted expression and unknown functional significance [49, 50]. The MHC isoforms are highly conserved (78–98 % amino acid identity), particularly in the tail region. Two surface loops in the globular head, near the ATP- and actin-binding sites, show the most divergence and likely determine differences in motor activity.

Five major skeletal muscle MLCs (4 genes) are members of the superfamily of EF-hand Ca^{2+}-binding proteins [48]. Two isoforms of regulatory MLCs have been definitely identified: these proteins have phosphorylation sites that may modulate force production.

The main components of the thin filaments are actin, tropomyosin, the troponin complex, and tropomodulin. Skeletal muscles contain only one actin isoform (α-skeletal), a globular protein (G-form) that polymerizes to form a double helix filament that is fairly inextensible (F-actin). The amino terminal of each actin monomer has a myosin-binding site that participates in the activation of myosin ATPase.

The tropomyosins are dimeric proteins with α-helical coiled-coil subunits, α and β (34 and 36 kD, respectively). Three skeletal muscle tropomyosin genes have been identified in humans, coding for one β- and two α-isoforms (fast and slow) [48]. The tropomyosin subunits assemble in head-to-tail fashion to form filaments that associate with the F-actin double helix. Each tropomyosin binds to seven actin monomers on each of the actin filaments, end-to-end in the grooves of F-actin.

The troponin complex consists of three polypeptide chains: troponin C (TnC), an 18 kD protein with regulatory Ca^{2+}-binding sites; troponin I (TnI), a 21 kD protein that inhibits the actin-dependent activation of myosin ATPase; and troponin T (TnT), a 31 kD protein that attaches the whole complex to tropomyosin. The carboxy and amino terminals of TnC form two globular domains linked by a central helix. Each globular domain contains two divalent metal ion-binding sites formed by the helix-loop-helix EF-hand motif. The binding sites in the amino terminal are low-affinity Ca^{2+}-specific sites that regulate contraction. The binding sites in the carboxy terminal bind both Ca^{2+} and Mg^{2+} with high affinity and are probably occupied at all times. There are two TnC isoforms in skeletal muscle (fast and slow) derived from different genes [48].

In contrast, multiple TnI isoforms are produced by the alternative splicing of three TnI genes (fast, slow, and cardiac): four fast, two slow, and four cardiac isoforms [48]. TnC interacts with TnI and TnT; the strength of interaction between TnC and TnI depends on whether Ca^{2+} is bound: when it is, TnC interacts more strongly with TnI. This is the regulatory mechanism of the troponin complex. Tropomodulin (43 kD) is a protein that caps the free ends of the actin filaments and is required to maintain constant thin filament length [51].

The Z line is composed mainly of α-actinin and CapZ (β-actinin.) α-Actinin is an actin-binding homodimer that associates with the end of the thin filaments at the Z line. Its two elongated subunits (100 kD each) have antiparallel orientation, actin-binding amino terminals, and a basic structure similar to spectrin and dystrophin. CapZ, or capping protein, is a heterodimer (α-subunit, 32 kD; β-subunit, 33 kD) that binds to the Z line ends of the thin filaments.

Three giant proteins, titin, nebulin and obscurin, are thought to play important roles in the assembly and stabilization of skeletal muscle sarcomeres. Titin (connectin) is a large modular protein, the largest described to date (>3,000 kD), extending up to 1 μm from the Z line to the M line, where it binds mainly to M protein and myomesin. Titin has an elastic segment at the I band level, but it is inextensible in the A band. It serves a growing number of functions: thick filament positioning, fiber elasticity, mechanosensing [48, 52, 53]. Nebulin (500–800 kD) is a large protein associated with thin filaments. It extends the full length of the thin filament, and its carboxy terminal interacts with α-actinin in the Z line. It associates on either end with actin filament capping proteins: CapZ at the edge of the Z line and tropomodulin on the I band end. Despite its localization, nebulin does not seem to participate in the determination of thin filament length. Instead, it seems to act as a stabilizer of formed thin filaments [52]. Obscurin is the most recently identified member of this trio. Its largest variant, obscurin-A (700–900 kD), is the product of a single gene; a couple of smaller isoforms arise from different transcription initiation sites on the same gene. The location of obscurin remains a bit of a puzzle: the most recent evidence show it is found at the Z line and M line on the periphery of myofibrils [52].

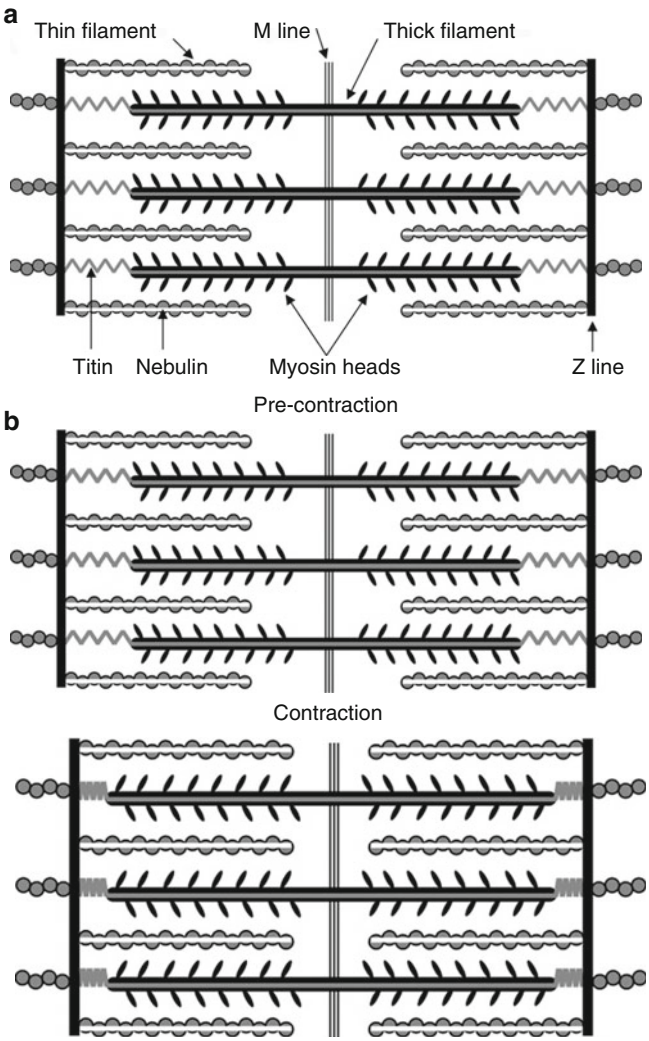

Fig. 2.8 (**a**) Schematic representation of a sarcomere. Thin filaments attach to the Z lines and provide support for the sliding of the thick filaments. Titin is a springlike protein that maintains the thick filaments in register within the sarcomere. (**b**) Sliding-filament hypothesis of contraction. The first drawing shows a sarcomere in the "resting" position. The *bottom* drawing shows sarcomere shortening resulting from the myosin power stroke (note the change in the position of the myosin heads in the thick filaments). The length of the thick and thin filaments remains unchanged

Sliding-Filament Theory

The sarcomere is the functional unit of skeletal muscle. The thick filaments contain myosin, the molecular motor that produces movement and force, and the inextensible thin filaments anchored on the Z line provide the rigid scaffold that transmits force and the regulatory proteins that initiate and terminate contraction. The globular heads of myosin attach to actin to form crossbridges, which attach and detach cyclically, sliding the thin and thick filaments by each other, thereby producing movement and force. This sliding-filament mechanism of muscle contraction is based on detailed knowledge of the structure and biochemical properties of the participating molecular elements. However, the description of bridge-like structures between the thin and thick filaments by high-resolution electron microscopy gave rise to the functional concept of the crossbridges.

During a contraction, the thick and thin filaments slide by one another, shortening sarcomere width, but the length of each filament remains constant (Fig. 2.8b). The change in sarcomere width is due to the cyclic formation and breakage of crossbridges between the thick and thin filaments. The crossbridges

pull the thin filaments towards the center of the sarcomere in a sequence of events that couple ATP hydrolysis to mechanical activity. Although each sarcomere can shorten 1 μm at the most, the serial arrangement of sarcomeres in myofibrils increases the magnitude and speed of the movement.

Myosin fulfills three basic functions: (1) it aggregates forming the thick filaments, (2) its ATPase activity transduces the energy of ATP to movement, and (3) it binds to F-actin to produce movement and force. The intrinsic ATPase activity of myosin is determined by the MHC isoform of the molecule. The ATPase rate is slower in MHC 1 (0.22 s^{-1}), followed by MHC 2X and 2A (~0.8 s^{-1}) and MHC 2B (1.15 s^{-1}) [54]. Myosin ATPase is a measure of the rate of crossbridge cycling and correlates with the speed of muscle shortening: muscles with fast myosin isoforms shorten faster than muscles with slower myosins [55, 56].

The role of F-actin in the contractile process is twofold. First, it accelerates the kinetics of the myosin-ATP interaction, making myosin a more effective ATPase. Second, it provides the cytoskeletal backbone against which the power strokes of the crossbridges exert force.

The interaction of the myosin heads with actin (crossbridges) forms actomyosin, a reaction that constitutes the basis for sarcomere shortening and is reversed by ATP. Actomyosin has a higher ATPase activity than pure myosin and represents an intermediate step in the activation of myosin as a mechanical transducer. Initially, ATP is bound to the globular head of myosin; ATP hydrolysis leads to weak actin binding and the formation of actin•myosin•ADP•Pi, seen structurally as a crossbridge. Upon ATP hydrolysis, the head of myosin rotates away from the rod domain to the position prior to the power stroke, a configuration denoted as myosin*. The release of Pi from the actomyosin complex leads to the formation of a force-producing state, actin•myosin*•ADP. Force is produced when the myosin head returns to its initial position (power stroke), ADP is released, and actin and myosin bond strongly. Finally, ATP must bind to detach myosin from actin, form myosin•ATP, and start the cycle again. This simple reaction scheme assumes that the hydrolysis of one ATP molecule results in one power stroke, an issue that has not been settled definitively. In addition, the orientation of the myosin head changes in one direction only; therefore, the swinging crossbridges generate movement towards the center of the thick filament (Fig. 2.8b). The length of each crossbridge step during ATP hydrolysis is estimated at 10–20 nm, based on the size of the myosin head, but remains unproven.

Regulation of Contraction

Generally, the translation of electrical activity into other cellular actions is accomplished by changes in $[Ca^{2+}]_i$ via voltage-gated Ca^{2+} channels. Resting $[Ca^{2+}]_i$ is maintained at low levels (<100 nM) by the combined action of cellular Ca^{2+}-ATPases and Na^{+}-Ca^{2+} exchange transport systems on the membrane, and Ca^{2+}-ATPases on intracellular compartments, including the SR in skeletal muscle fibers.

The architecture of muscle fibers hints to how Ca^{2+} regulates the contractile process: the SR, an enormous Ca^{2+} reservoir, is placed between the sarcolemma and the myofibrils (Fig. 2.7, right). Action potentials are conducted down the sarcolemmal t-tubules, activating DHPrs. Unlike cardiac and most smooth muscle, Ca^{2+} influx through DHPr is not necessary to initiate E-C coupling in skeletal muscle fibers; moreover, Ca^{2+} flux through the skeletal muscle isoforms of the DHPr channel is too slow to significantly alter $[Ca^{2+}]_i$ [57]. Sarcolemmal depolarization induces the movement of electrical charges within the DHP that cause a structural shift in the neighboring RyR (on the terminal cisternae), opening the Ca^{2+} channel and releasing Ca^{2+} from the SR to the cytosol. This process is called "electromechanical coupling" [57]. In mammals, DHPr tetrads face alternating RyR along triad junctions; therefore, electromechanical coupling may not directly cause the opening of all available SR RyR. A current E-C coupling model proposes that the kinetics of SR Ca^{2+} release in response to electromechanical coupling are sufficiently fast to mediate Ca^{2+}-induced Ca^{2+} release from RyR not coupled to DHPr.

SR Ca^{2+} release in response to sarcolemmal depolarization increases cytosolic $[Ca^{2+}]$ rapidly. Free Ca^{2+} ions bind to troponin-C on the thin filaments, producing a change in the shape of the troponin complex, shifting tropomyosin into the grooves of the thin filaments, and exposing myosin-binding sites on the actin monomers. In this "steric blocking" hypothesis, the movement of a single tropomyosin molecule unblocks seven actin monomers, allowing actomyosin formation and ATPase activity [58]. The crossbridges cycle between attachment and detachment states as long as cytosolic $[Ca^{2+}]$ remains elevated and there is sufficient ATP to sustain the reaction.

Once sarcolemmal depolarization ends, SR Ca^{2+} release stops, and the process of Ca^{2+} uptake predominates. The fast and efficient restoration of cytosolic $[Ca^{2+}]$ is mostly due to high-capacity SR Ca^{2+}-ATPase activity. As cytosolic $[Ca^{2+}]$ falls towards its resting level, Ca^{2+}-binding sites in troponin-C become unoccupied, restoring tropomyosin to its blocking position and preventing the interaction between actin and myosin.

Motor Systems

Muscle Fiber Diversity

Three factors determine the functional characteristics of a particular muscle fiber: (1) the composition of the contractile filaments, (2) the capacity and speed of the Ca^{2+}-dependent regulatory system, and (3) the efficiency of the metabolic

Table 2.2 Skeletal muscle fiber types

	Slow type 1	Fast fatigue resistant type 2A	Fast fatigable type 2B
Diameter	+	++	+++
Capillary supply	+++	+++	+
Mitochondrial content	+++	+++	+
SR volume	+	+++	+++
Myofibrillar ATPase	+	+++	++++
Myofibrillar Ca^{2+} sensitivity	+++	+	+
SR Ca^{2+} uptake	Slow	Fast	Fast
Myoglobin content	+++	+++	+
NADH dehydrogenase	+++	+++	+
Succinate dehydrogenase	+++	+++	+
Glycerophosphate dehydrogenase	+	+++	+++
Lactate dehydrogenase	+	+++	+++
Twitch kinetics	Slow	Fast	Fast
Speed of shortening	Slow	Fast	Fast
Fatigue resistant	Yes	Yes	No

pathways that supply the energy currency needed for the production of force and movement. As previously described, there are different isoforms for all the proteins involved in contraction and whose kinetics determine the timing of events and energy requirements. Particular isoform combinations in sarcomeres, their regulatory systems, and their metabolic pathways define skeletal muscle fiber types. Based on their mechanical properties, which, in turn, depend on the speed of the actomyosin reaction and the Ca^{2+}-dependent activation and relaxation regulatory systems, muscle fibers may be "fast" or "slow" [49]. Another physiological characteristic, the resistance to fatigue, is more or less directly related to fiber metabolism and classifies fibers as fatigable or fatigue resistant. Using these principles, a basic classification scheme of muscle fiber types is presented in Table 2.2. For example, fatigue resistance correlates with higher mitochondrial content, smaller fiber diameter to minimized diffusion distances, and a more abundant capillary supply to provide substrates and eliminate end products (Fig. 2.9). A caveat, while this classification assigns particular morphological, biochemical, and functional features to the different fiber types, these should be seen as a continuum.

Motor Units

The integral unit for motor activity, the motor unit, is composed of a motor neuron and the muscle fibers it innervates [59]. The original description of the motor unit assumed that (1) all the muscle fibers in the motor unit respond equally to the motor neuron and (2) each muscle fiber is innervated by to a single motor neuron and there is no polyneural innervation.

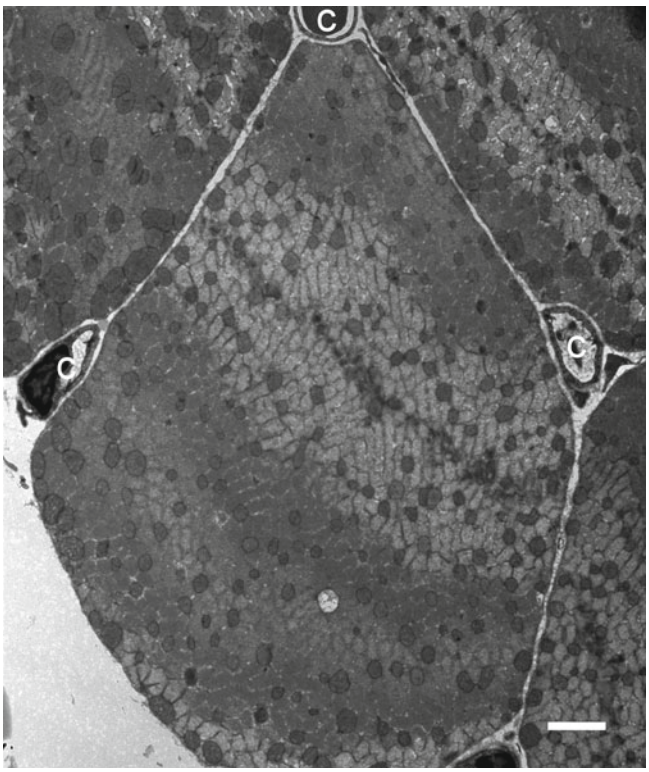

Fig. 2.9 This electron photomicrograph illustrates components of oxidative energy metabolism in skeletal muscle. The muscle illustrated is extraocular muscle, a highly oxidative, fatigue-resistant muscle. The muscle has a high mitochondrial content and an extensive capillary network. Capillaries are marked with "c". Scale bar = 2 μm.

Both assumptions are essentially correct, but not universally true. First, neuromuscular transmission reliably activates muscle fibers but may fail under certain conditions such as fatigue. Second, polyneural innervation is rare in adult muscles, but it is widespread during development. Persistent polyneural innervation may also occur after muscle damage or reinnervation of denervated muscle. Nevertheless, the motor neuron and the muscle fibers that constitute a motor unit can be considered as a functionally reliable and anatomically exclusive entity in normal adult skeletal muscles.

The characteristics of the different motor unit types reflect the functional properties and requirements of the muscle fibers and motor axons that integrate them. The number of muscle fibers innervated by a single motor axon is the innervation ratio: a low ratio indicates a greater ability for finely grading muscle force, and it is typically found in small, fine-movement muscles such as the extraocular and hand muscles. Functionally, motor units can be slow, fast fatigue resistant, and fast fatigable. The activation of motor units follows the "size principle": the smallest α-motor neurons tend to be activated first [60]. As more force is required, progressively larger motor neurons are recruited. This ascending size order of recruitment indicates that neuronal and axonal size correlates with the functional properties of the motor

units: the smallest axons form motor units that are slow and fatigue resistant, while the largest axons form fast and fatigable motor units. Thus, slow motor units are activated more frequently and for longer periods of time than the fast fatigable units [61].

Organization of Muscles

Movement and force are the consequences of skeletal muscle activation. The range and variety of movements and the forces exerted by muscles depend on the architecture of the skeleton and muscles attached to it. Most skeletal muscles fall into one of two basic anatomical organizations: "pennate" and "staggered array." In pennate (feather-like) muscles, fibers extend from origin to insertion in parallel arrays, at an angle (angle of pennation) to the axis of the force vector of the whole muscle. Muscle length is usually longer than the length of the individual fibers, and the force along the axis of the muscle is proportional to the cosine of the angle of pennation (1 for 0°, 0 for 90° pennation). Pennation increases the fiber cross-sectional area per unit volume, allowing muscles to generate relatively high forces, but limiting the range for force generation [62].

In other muscles, fascicles of relatively short muscle fibers are staggered along the length of the muscle, in parallel with the force vector. The individual muscle fibers originate and end on intramuscular connective tissue. The increased number of sarcomeres in series gives staggered array muscles a broader physiological range for force generation, although the total force output is less than in pennate muscles [63].

A small subset of muscles with circular geometry, such as trapezius, temporalis, deltoid, and diaphragm, have fibers that act on loads in different directions; the actions of different parts of a single muscle can be antagonistic or can vary over more than one degree of freedom [64].

Approach to Neuromuscular Diseases: Neuromuscular Investigations

Serum Muscle Enzymes in Neuromuscular Disease

3

Rahila Ansari and Bashar Katirji

Introduction

Enzymes are protein catalysts found in all tissues and involved in most biochemical reactions. Even prior to the discovery of their precise catalytic functions, many enzymes were measured for diagnostic purposes [1, 2]. Based on their properties, some enzymes are also used as therapeutic agents.

Enzymes, which are intracellular, are released systemically through normal physiologic function or when there is increased membrane permeability due to cell injury or necrosis. The concentration of enzymes may also increase in the serum due to a block in metabolism, obstruction to the routes of elimination or excretion, or from increased rates of intracellular production. In general, levels tend to correlate with the extent and severity of disease. Enzymes are typically measured in serum rather than plasma and, in rare situations, in whole blood. Since enzymes are intracellular proteins, hemolysis may result in false elevations.

Certain enzymes are present in many organs, while others are more tissue specific. Isoenzymes are enzymes that catalyze the same biochemical reaction but differ in their sequence of amino acids. A given enzyme may have many isoforms, with each isoform being restricted to a specific tissue. Hence, assays for isoenzymes are often more tissue specific than assays for the parent enzyme. Enzyme-linked immunosorbent assay (ELISA), using monoclonal antibodies that specifically bind to an enzyme isoform, is a rapid method for clinically measuring isoenzymes.

Creatine Kinase (CK)

Basic Principles

Creatine kinase (CK), also known as creatine phosphokinase and creatine phosphoryltransferase, reversibly catalyzes the conversion of creatine phosphate and ADP into creatine and ATP.

$$\text{Creatine phosphate} + \text{ADP} \xleftrightarrow{\text{Creatine kinase}} \text{Creatine} + \text{ATP}$$

Creatine phosphate is important for energy storage in muscle [3]. It is essential in providing a rapidly available store of ATP for excitation/contraction coupling of actin and myosin in muscle. The highest concentration of CK is in skeletal and cardiac muscle; however, it is also present in the brain, and minimal amounts exist in the intestine and lungs [3, 4].

CK is the single most useful routine blood test for the evaluation of weakness in neuromuscular disease, as it correlates with the functional status of muscle. In myopathies, serum CK is elevated when there is active muscle fiber necrosis, as in inflammatory myopathies, Duchenne muscular dystrophy, or rhabdomyolysis. However, it is also increased, to a lesser degree, in neurogenic processes such as in amyotrophic lateral sclerosis. CK elevation in neuromuscular disease is closely related to the available muscle mass that can leak the enzyme. Any interpretation should take into consideration normal values in relation to gender, sex, and race as well as the available muscle mass and underlying physiologic status of the patient and toxic/metabolic abnormalities.

Table 3.1 Serum CK and its isoenzymes

Isoenzyme	BB	MB	MM
Synonym (abbreviation)	CK1	CK2	CK3
Composition of skeletal muscle	–	1–3 %	97–99 %
Composition of cardiac muscle	–	15–20 %	75–80 %
Composition of brain	≈100 %	–	–
Contribution to total serum CK	–	–	≈100 %

Apart from its common use in the diagnosis and management of neuromuscular disease, particularly myopathies, elevated serum CK is a highly valuable marker in acute myocardial infarction. Low serum CK values are associated with hyperthyroidism, connective tissue disorders, corticosteroid therapy, and alcoholism [5, 6]. Low levels are also noted during pregnancy, in subjects with sedentary lifestyle, with prolonged bed rest, and in the elderly [4, 7].

Clinical Biochemistry

CK occurs as a dimer composed of any combination of the two globular monomers: muscle (M) and brain (B) [7–9]. Each monomer has a molecular weight of 43 kDa and is encoded by a distinct gene. Human cytoplasm contains three typical dimer isoenzymes: BB, MB, and MM. They are also referred to as CK1, CK2, and CK3, respectively. Additionally, two other atypical, large molecular weight isoforms may also be found in serum: macro-CK types 1 and 2. Macro-CK type 1 is an octomeric protein that results from the polymerization of isoform BB (typically) with immunoglobulin G (IgG) [10]. This polymerization is thought to be secondary to antigen-antibody binding [11]. Macro-CK type 2 is an oligomeric protein composed of a third CK monomer found in mitochondria [11]. Macro-CK type 1 is clinically relevant as it is associated with autoimmune processes, specifically myositis [11] and autoimmune cardiovascular disease [12]. In contrast, macro-CK type 2 is increased primarily in malignancies [11–13]. The clinical benefit of measuring macro-CK is for disease prognostication. Measuring the mitochondrial CK monomer is also of clinical significance, as it is elevated in mitochondrial myopathies and found in the pathological inclusions seen on muscle biopsies [14].

In the clinical setting, the most commonly measured isoforms are: MM, MB, and BB. The CK in skeletal muscle is almost exclusively MM (97–99 %), with the remaining (1–3 %) composed of the MB fraction (Table 3.1). Myocardial CK is mostly MM (75–80 %) but with a more substantial amount of MB (15–20 %). Brain CK is comprised exclusively of the BB fraction. In normal serum, total CK is provided mainly by skeletal muscles and is almost exclusively the MM fraction. This is likely due to the small mass of myocardium and brain, as compared to skeletal muscle, and the relatively short half-life of MB and BB. An exception is that during the first 6 weeks of fetal life, only BB is synthesized. However, by the 12th week, MM predominates in skeletal and cardiac muscles [3].

As previously mentioned, serum CK is primarily composed of the MM and MB isoenzymes. BB is mostly localized to neurons and astrocytes in brain tissue. Following acute brain damage, we expect to see a rise in the BB isoenzyme, which can be measured in the cerebrospinal fluid (CSF). However, isolated cerebral injuries will not result in elevated total serum CK, unless there is associated myocardial or skeletal muscle damage [15]. Processes that may lead to increased BB levels in the CSF are parenchymal or meningeal disease, intracranial hemorrhage, traumatic brain injury, brain tumors, stroke, seizure, hypoxic/ischemic insult, infections, and electroconvulsive therapy. In general, the higher the BB level in CSF, the greater the extent of brain damage, and the worse the prognosis [16, 17]. In contrast, MB or MM isoenzymes, when detected in the CSF, are almost always due to blood contamination. An intact blood brain barrier isolates the MB and MM isoforms to the systemic circulation, while keeping the BB isoform within the central nervous system.

For our purposes, the clinical value of CK isoenzymes is primarily related to the MM, and then the MB fractions. The MM isoform is bound to the M-line, which is a myofibrillar structure that connects thick myosin fibers to one another, within a sarcomere. The M-line is a site with high energy requirements; hence, it follows that MM serves the important purpose of enzymatically regenerating ATP as required during muscle contraction [12].

Normal Serum Creatine Kinase Values

Serum CK concentration is highly variable between individuals and dependent on gender, race, age, muscle mass, and physical activity [18–25]. Among these variables, serum CK value is most strongly related to gender and race [18–20, 24]. Lean muscle mass is also an independent factor correlating with serum CK levels [23]. However, the influences of gender and race are independent of muscle bulk, height, weight, or physical exertion. In general, men have higher serum CK than women, and people of African decent have higher values than other racial groups [20]. Serum CK does not statistically differ between Asians, Caucasian, and Latinos [20, 26]. Based on race and gender, the general population could be divided into three general groups: (1) high CK group, composed of African men; (2) intermediate CK group, made up of African women and non-African men; and (3) low CK group composed of non-African women [18]. Typically, CK values in the high group are double those of the intermediate group, and the values in the low group are half those of the intermediate group. For most of the laboratories in the United States, the reference CK values are biased toward the intermediate group.

Table 3.2 Physiologic causes for sustained asymptomatic CK elevation

Gender – men
Race – African decent
Age – neonates and children
Increased amount of lean muscle mass
Regular, prolonged, or weight-bearing exercises

Normal serum CK levels also vary with age. CK is markedly elevated (three to ten times normal) in the neonatal period, specifically in the setting of a vaginal delivery [27, 28]. This increase is thought to be secondary to birth trauma. The elevated CK from birth normalizes in approximately 4 days [27]. Prepubescent children have slightly higher CK values than adults. In women, CK levels falls to nearly half the normal level during pregnancy and increase significantly during the postmenopausal period [29]. It is hypothesized that during pregnancy, the release of estrogens and proinflammatory cytokines serves to stabilize the muscle membrane and hence decrease the serum CK [30]. In adulthood, serum CK increases slightly with age [24] but then declines in the geriatric population. However, serum CK is lower in sedentary people, which may in part explain the low values found in elderly patients. The physiologic factors contributing to hyperCKemia are listed in Table 3.2.

HyperCKemia After Physical Exercise

Strenuous exercise may result in elevated serum muscle enzymes, most specifically CK. Direct mechanical damage to the contractile elements, particularly the sarcolemma and Z-disks, is the most widely accepted cause of elevated CK in athletes [31, 32]. When exercise exceeds the metabolic range of normal muscle, myocyte membrane permeability increases and enzymes leak into the surrounding interstitial fluid [12]. If the exercise intensity increases and sarcomeres reach their breakpoint, then additional CK is released into the surrounding milieu [31, 33]. The CK is then taken up by the lymphatic system and returned to circulation [34]. Rhabdomyolysis and myoglobinuria may occur after extraordinary physical stress and can lead to acute renal failure and death.

Although most of the serum CK released after exercise is of the MM fraction, the MB fraction may also be found in the serum after strenuous and prolonged physical activity. Levels of MB similar to acute myocardial infarction, reaching 8–18 % of the total serum CK, are not uncommon after intense periods of exercise, such as marathon running [31, 35–38]. The source of skeletal MB is postulated to be from undifferentiated, regenerating muscle fibers which, like many fetal myoblasts, express higher concentration of MB than mature muscle cells [9, 31, 36].

Multiple factors determine the extent of post-exercise hyperCKemia. Most notably, CK levels are highest after prolonged exercise, such as marathons or triathlons [35–39], and weight-bearing exercises with eccentric muscle contractions, such as bench stepping or running downhill [12, 40]. Another important factor is the training level of the subject [12, 31]. Serum CK elevation after exercise is variable between individuals and even within the same individual. Among these factors, the duration of physical activity is the most significant. For example, post-exercise serum CK values in marathon runners and triathletes reach levels as high as 50-fold above normal [35–38]. In contrast, a short-duration running, such as sprinting 400 m, results in a much lower rise in CK. Non-weight-bearing exercises such as swimming or cycling have little or no effect on serum CK. With training, CK levels tend to decrease in athletes. This is thought to be due to an adaptive response either in enzyme clearance from blood [41] or through adaptive muscle changes leading to decreased enzyme leakage [42]. Due to a greater amount of lean muscle mass, baseline CK levels remain higher in athletes (approximately 1.5 times normal) [43] as compared to nonathletes [44, 45]. However, the rise in post-exercise CK is associated with the level of training. Hence, experiments looking at athletes and their sedentary, yet healthy, age-matched controls show that with the same degree of physical exertion, the CK level will rise less in athletes [46, 47].

Timing of CK collection following exercise is important. Serum CK usually begins to rise a few hours after the completion of exertion and peaks at 1–4 days [4, 31, 39, 48–50]. With eccentric or intense exercises, the peak CK levels are at 4 days, and with continued training, the values normalize after 4–10 days [42]. Duration more so than fitness level corresponds to when the peak CK is reached [51]. CK normalization time is associated with the length of the rest period following exercise [52]. However, it is important to note that there is no correlation between impairment of muscle function and CK [53]. Therefore, CK levels cannot be used to monitor or quantify post-exertional muscle recovery. The likelihood of skeletal muscle injury increases with exercising in the cold or using androgenic steroids [54, 55].

Frequent or intense training, particularly with weight-bearing exercises, may result in persistent elevation of CK, mimicking neuromuscular disease [56]. Nonetheless, athletes with very high post-exercise CK, or resting CK may have an underlying myopathy, such as McArdle's disease, Becker's muscular dystrophy, caveolin-3 deficiency, or an alpha-dystroglycanopathy [57–60]. Hence, these individuals should be evaluated for a chronic hyperCKemia at rest and with exertion, to look for a subclinical myopathy.

Distinguishing Acute Myocardial Infarction from Muscle Disease

In the hospital setting, the most common reason to check a CK level is for the evaluation of acute myocardial infarction

(MI). Although the nuances of diagnosing an MI are beyond the scope of this chapter, it is important to discuss how to distinguish hyperCKemia from a cardiac versus a skeletal muscle etiology.

As previously stated, the heart is rich in CK, specifically with the MB isoform accounting for about 15–20 % of total myocardial CK (see Table 3.1). Following the onset of an MI, the total serum CK begins to rise at 4–8 h, peaks within 12–24 h, and declines to normal values within 2–3 days (Fig. 3.1). Elevated serum MB isoenzyme is highly sensitive (98–99 %) and specific (95–97 %) for the diagnosis of an MI [62–64]. Since a small amount of the MB isoenzyme is present in skeletal muscles (1–3 %), the percentage elevation of MB (i.e., MB/total CK × 100) is more important than the absolute MB level in the diagnosis of an MI. In the first 2–3 days after an MI, the MB portion usually exceeds 5 % of the total CK activity, is often 10–15 %, but never reaches a value greater than 40 %. Thus, using the ratio of the MB isoform to total serum CK is essential in preventing false-positive results. This, in turn, minimizes further unnecessary, and at times invasive, cardiac evaluations.

Of note, ratios of MB to total CK greater than 5 % have been documented in rhabdomyolysis, crush injury, malignant hyperthermia, Duchenne muscular dystrophy, dermatomyositis, polymyositis, healthy marathon runners, and professional athletes [35–38, 65–68]. The origin of MB elevation in these patients is usually skeletal, and without a cardiac component [69]. In addition to the history and physical examination, criteria to distinguish that the rise in MB is of skeletal origin rather than cardiac include the following:

1. A peak MB ratio less than 5 % is not consistent with an acute MI.
2. Marked elevation of the total serum CK to more than 20 times above normal is not compatible with an acute MI.
3. An atypical time course of MB elevation, such as prolonged elevation, should raise suspicion for a noncardiac source.

In addition to the MB isoform, additional cardiac enzymes are useful in distinguishing between a cardiac and skeletal etiology. Troponins I and T, which regulate the calcium-mediated contractile process of striated muscle, are present in cardiac and skeletal muscles. However, they have different amino acid sequences and are encoded by different genes [62, 64, 70, 71]. Cardiac isoforms of troponins, particularly troponin I, are highly specific and not present skeletal muscle. As the serum concentration of troponin I in normal subjects is near zero, its sensitivity is higher than MB, enabling the detection of minor degrees of myocardial necrosis. Following an acute MI, the initial rise of cardiac troponin I in serum is similar to MB, but its return to baseline is much more gradual, over 7–10 days (Fig. 3.1). Thus, in addition to being highly sensitive and specific, troponin I is useful for the subacute diagnosis of an MI. Hence, in conjunction with MB and CK ratios, it is a valuable tool to distinguish between neuromuscular diseases and cardiac diseases.

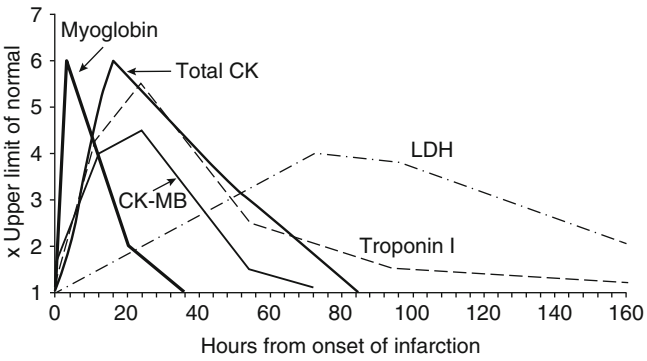

Fig. 3.1 Time course of serum marker elevations following an AMI (Reprinted with permission from Antman [61])

Creatine Kinase in Neuromuscular Diseases

Serum CK is the single most useful, reliable, and studied biochemical blood test in neuromuscular disorders. HyperCKemia is most commonly associated with primary muscle diseases but may also be seen in neurogenic disorders.

Creatine Kinase Elevation in Myopathies

As CK is a sarcolemmal enzyme, destruction of the sarcomere or damage leading to increased membrane permeability will allow for enzyme leakage. Sustained serum CK elevation is most often due to myopathies [66, 68, 72–74]. The degree of hyperCKemia is usually dependent on the following factors:

1. *Severity of disease*: Diseases with marked muscle destruction are responsible for the highest serum CK concentrations (Table 3.3). Duchenne muscular dystrophy and rhabdomyolysis are documented to have CK concentrations well over 100 times greater than normal.
2. *Course of disease*: Rapidly progressive myopathies such as Duchenne muscular dystrophy or polymyositis are associated with higher CK levels than slowly progressive disorders such as facioscapulohumeral muscular dystrophy or inclusion body myositis.
3. *Absolute muscle mass*: Since CK serum concentration is dependent on muscle mass, advanced muscle diseases are often associated with a declining CK. For example, CK values in Duchenne muscular dystrophy are highest early during the disease course when children are asymptomatic, or during their ambulatory phase. Serum CK gradually declines toward normal values during advanced phases of the disease as muscle is replaced with fibrous tissue.
4. *Myofiber necrosis*: Sarcomere necrosis and membrane leakage are the main causes of serum CK elevation. Thus, myopathies not associated with muscle destruction or

Table 3.3 Myopathies commonly associated with marked elevation of serum CK (sometimes more than 50–100-fold above normal)

Dystrophinopathies (Duchenne and Becker muscular dystrophies)
Rhabdomyolysis and myoglobinuria
Malignant hyperthermia[a]
Neuroleptic malignant syndrome
Polymyositis
Miyoshi distal myopathy

[a]During attack

Table 3.4 Myopathies commonly associated with normal serum CK

Steroid myopathy
Hyperthyroid myopathy
Mitochondrial myopathies
Channelopathies[a]

[a]Excluding malignant hyperthermia

those which maintain an intact sarcolemma, such as mitochondrial myopathies or steroid myopathy, often have a normal CK (Table 3.4). Thus, a normal serum CK level does not necessarily exclude a myopathy.

The skeletal MM isoform is the predominant isoenzyme in myopathies. However, as in the case of severe post-exercise hyperCKemia, other isoenzymes can also be markedly increased with muscle diseases. A high ratio of MB, imitating an acute myocardial infarct, has been reported with Duchenne muscular dystrophy, dermatomyositis, polymyositis, rhabdomyolysis and malignant hyperthermia, as well as following traumatic crush injury [31, 35–38, 65, 69]. As previously stated, this is explained by the CK activity of regenerating muscle fibers, which express higher MB more than mature myocytes [9, 31, 36]. Although cardiac disease is associated with many primary myopathies, an elevated MB isoform does not automatically point to a cardiac etiology. Hence, checking a troponin I, in addition to further neuromuscular testing may be beneficial for such patient presentations.

Creatine Kinase Elevation in Neurogenic Disorders

Occasionally, CK is mildly elevated in neurogenic disorders, such as amyotrophic lateral sclerosis, spinal muscular atrophies, acute poliomyelitis, post poliomyelitis syndrome, and Guillain-Barré syndrome [75–79]. As a muscle fiber loses its innervation due to primary nerve or anterior horn cell damage, it atrophies and is unable to function. Hence, as the surrounding muscle fibers experience increased force requirements, they may also suffer mild damage leading to CK leakage. Since neurogenic diseases do not result in significant myocyte destruction, the CK levels are typically less than five times above normal [80].

Creatine Kinase Elevation in Secondary Muscle Disorders

Many systemic diseases may result in secondary muscle damage, which in turn can lead to increased CK levels. It is always important to evaluate for systemic causes before making a neuromuscular disease diagnosis. Table 3.5 lists systemic and traumatic causes for hyperCKemia. Hypothyroidism is the most common cause of secondary myopathy and is often associated with elevated CK [81, 82]. Viral infections, electrolyte imbalances, celiac disease, seizures, dystonia, malignancy, acute psychosis, violent behavior, and trauma are other causes of CK elevation [83–92]. The degree of muscle involvement and CK elevation is variable for the above etiologies. Aside from supportive management, treatment of the underlying condition is important. However, unexplainable residual elevations in CK may be related to a subclinical neuromuscular disorder and should be investigated.

Table 3.5 Systemic diseases and trauma leading to secondary CK elevation

Hypothyroidism
Viral infections
Influenza
Coxsackie
Echovirus
Adenovirus
Herpes
Connective tissue diseases
Electrolyte imbalance
May be secondary to acute kidney disease or heart disease
Celiac disease
Malignancy
Iron-sulfur cluster diseases
Muscle trauma/ischemia
Generalized epileptic seizures
Malignant hyperthermia
Neuroleptic malignant syndrome
Serotonin syndrome
Severe dystonia
High fever with rigors
Muscle bacterial infections
Compartment syndrome
Crush injury
Needle electromyography
Repeated intramuscular injections
Surgery
Acute psychosis
Violent behavior

Additionally, mild transient CK elevations are common after iatrogenic muscle trauma, including intramuscular injections and needle electromyography (EMG), or surgery. Needle EMG, especially with concentric needles, may result in a mild rise of serum CK which returns to baseline after about 2–3 days [93]. Thus, serum CK measurements should be avoided up to 3 days after mild muscle trauma to prevent false-positive results. In contrast to the mild asymptomatic transient serum CK increase, a significant rise is usually symptomatic and associated with crush injury, compartment syndrome, or rhabdomyolysis.

Elevated Creatine Kinase Due to Drug Toxicity or Nutritional Deficiency

Reversible serum CK elevation is usually due to medication side effect or toxicity, nutritional deficiency, or the treatable systemic diseases listed above. Medication-induced hyperCKemia may be clinically asymptomatic or associated with myalgia, subjective weakness or fatigue, or objective weakness. One of the most common classes of offenders, especially in the setting of prescribing frequency and likelihood of myopathy, is statins (3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors). These cholesterol-lowering agents may cause symptomatic or asymptomatic hyperCKemia. Although the exact mechanism of injury is unknown, it is known that statin blocks the synthesis of cholesterol and of isoprenoids. Cholesterol is important for the structural integrity of muscle membranes. Isoprenoids are required for mitochondrial function and cytoskeletal stability. Either or both of these mechanisms may result in myotoxicity [94].

In addition to statins, there are many other classes of medications that induce hyperCKemia including: fibrates, antiretrovirals, angiotensin II receptor antagonists, immunosuppressants, chloroquines, antipsychotics, antidepressants, and antiemetics. Table 3.6 summarizes a more complete list of the known drugs and vitamins associated with myopathy.

Typically, sustained pathological elevation of CK occurs and persists only as long as the offending agent remains in the system. Depending on the patient, the same etiological factor may cause mild to marked elevations of CK. Severe myonecrosis is particularly common when multiple offending factors (such as two drugs) are present. Early detection, management, and withdrawal of the offending factor(s) often results in normalization of serum CK. However, there are instances in which the hyperCKemia persists, despite discontinuation of the medication. In these cases, it is important to search for an underlying neuromuscular disease that may have been unveiled by the addition of a stressor, such as a statin medication [95].

Patients with reversible serum CK elevation may be asymptomatic but often complain of myalgia, muscle tenderness, subjective weakness, or fatigue with exertion. Objective weakness due to overt myopathy is not uncommon, but often reversible. Failure in early recognition may result in frank rhabdomyolysis, malignant hyperthermia, or neuroleptic malignant syndrome; conditions which carry high morbidity and mortality.

Idiopathic HyperCKemia

Although serum CK elevation is often a sign of a neuromuscular disease, it may be encountered in non-pathological conditions. An elevated CK in a healthy individual is sometimes discovered incidentally, especially in institutions

Table 3.7 Suggested criteria for the diagnosis of idiopathic hyperCKemia

Inclusion criteria
Persistent, asymptomatic or minimally symptomatic, elevation of serum CK of skeletal muscle origin
Normal neurological examination
Normal EMG study
Normal muscle biopsy – histopathology, immunohistochemistry, and electron microscopy
Normal genetic testing
Exclusion criteria
Family history of neuromuscular disease
Clinical and/or laboratory evidence of other medical diseases, ex. thyroid disease
Intake of medications or vitamin deficiency, associated with elevated serum CK
History of trauma
History of strenuous or persistent exercise

where CK is included in the routine blood chemistry profiles. It is not uncommon for these patients to undergo extensive cardiac work-up before they are referred to a neurologist. Idiopathic hyperCKemia is a term coined in 1980 by Rowland et al. [96, 97]. They defined it as a persistent elevation of serum CK-MM isoform, with a normal neurological examination, EMG, and muscle biopsy.

Subjects with idiopathic hyperCKemia are of all ages but have a male predominance. Serum CK elevation is modest, usually between three and ten-fold above normal. Although none of these patients have objective weakness, some individuals report myalgia, stiffness, or cramps. Long-term follow-up of asymptomatic patients with idiopathic hyperCKemia reveals that about a third go on to develop clinical and/or pathological evidence of a neuromuscular disorder [98–103]. As discoveries of new genes in inherited neuromuscular diseases continue, more patients with idiopathic hyperCKemia will be diagnosed with a neuromuscular disease or carrier state of such a disease. Reported diagnoses have included distal myopathy, inclusion body myositis, polymyositis, myoadenylate deaminase deficiency, McArdle's disease, central core disease, and the carrier state of Duchenne muscular dystrophy.

A specific protocol should be followed before a diagnosis of idiopathic hyperCKemia can be made (Table 3.7). First, when a patient presents with an increased CK level, the family history should be investigated thoroughly. In addition, the physiologic and secondary causes of elevated CK need to be considered (see Tables 3.2, 3.5, and 3.6). If there is a history of recent myotoxic medication use, trauma, strenuous exercise, or other medical diseases, then the underlying etiology or offending agent needs to be appropriately addressed. The CK should then be repeated after 15 days. If it continues to be abnormal, then the patient should be referred to a neuromuscular subspecialist for consultation, a thorough neuromuscular examination, and an EMG study. If there is no electrodiagnostic evidence for a specific myogenic or neurogenic etiology, then a muscle biopsy can be obtained. The biopsy processing should include histology, immunohistochemistry, and electron microscopy. Also, blood and/or tissue samples may be analyzed for genetic DNA analysis for carrier states of different muscle diseases [104–106]. As long as this initial evaluation is exhaustive and the patient remains asymptomatic with a normal neurological exam, then a diagnosis of idiopathic hyperCKemia is permissible [100, 101, 107–110]. Importantly though, if the patient develops symptoms or weakness on clinical exam, then reevaluation is required. The above protocol will diagnose the majority of etiologies for hyperCKemia. However, additional tests are available and may be useful depending on the circumstance. Most notably, it may be beneficial to obtain a contracture test on all patients with diagnosed idiopathic hyperCKemia, prior to giving general anesthesia for a procedure [102, 103]. Although the likelihood of diagnosing malignant hyperthermia, which is often associated with central core myopathy, is very low, the consequences for missing this diagnosis are great.

Other Muscle Enzymes

Similar to creatine kinase, other serum enzymes of muscular origin are released when muscle is destroyed. Most of these other enzymes (aldolase, lactate dehydrogenase, pyruvate kinase, and muscle-specific enolase) are essential components required for glycolysis. Hence, they are typically found in tissues with high metabolic requirements, such as: muscle, liver, and/or kidney. Hence, unlike CK, these enzymes are less specific for muscle. With less specificity, there is an increased likelihood that serum elevations are secondary to nonmuscular diseases or medication use. Nevertheless, based on the clinical context, the following muscle enzymes can be useful in diagnosing myopathies and/or identifying specific pathophysiological etiologies.

Aldolase

In glycolysis, aldolase catalyzes the reversible conversion of fructose 1,6-bisphosphate into glyceraldehydes 3-phosphate and dihydroxyacetone phosphate. As such, it is found in tissues with a high metabolic demand. In addition to muscle, aldolase is also found in the liver, kidney, intestines, and brain. There are three major isoforms of aldolase. Type A is the most prevalent and is nearly isolated to muscle. Type B is found in the liver and kidneys, and type C (plus trace amounts of type A) are found in the brain and other nervous system tissues [111]. Within skeletal muscle, aldolase A is

typically bound to actin. Therefore, a myopathic process results in the release of aldolase into the serum. It is important to note that most clinical laboratory testing is not specific for the aldolase A isoform. Hence, aldolase levels may be increased with liver disease and/or hepatotoxic drugs.

Importantly, studies have shown that increased aldolase levels, in the setting of muscle discomfort and weakness, are associated with myopathology secondary to perimysial disorders (such as dermatomyositis, fasciitis, and perimyositis) [112, 113]. This increase in aldolase can be in isolation and seen with a normal CK, especially in patients with muscle pain or mild weakness.

Lactate Dehydrogenase

Lactate dehydrogenase (LDH) catalyzes the reversible oxidation of lactate to pyruvate, with concomitant reduction of NAD (nicotinamide adenine dinucleotide) to NADH. There are five, tetrameric, immunoglobulin-bound, LDH isoenzymes (LHD-1 through LDH-5), which are normally expressed in tissues. Each of the four subunits can either be an M polypeptide or an H polypeptide. LDH-1 is composed of 4 H units, LDH-2 has 1 M and 3 H units, LDH-3 has 2 M and 2 H units, LDH-4 has 3 M and 1 H units, and LDH-5 has 4 M units. The more M monomers an isoform has, the more likely it is for that enzyme to favor an anaerobic conversion of pyruvate to lactate. Conversely, more H monomers favor an aerobic oxidation of pyruvate [12]. Additionally there is an LDH-6, composed of 4 M units, but not immunoglobulin-bound. LDH-6 is not normally produced and is associated with a poor prognosis in patients with hepatic circulatory disease, which is beyond the scope of this chapter [114].

LDH is not tissue specific and can be increased in lung cancer, other malignant cancers, fibrotic lung disease, chronic granulocyte leukemia, non-Hodgkin's lymphoma, ischemic hepatitis, cardiac infarction, and intravascular hemolysis. However, isoenzyme determination may increase its tissue specificity. Generally, heart and red blood cells, with predominant aerobic metabolism, are highest in LDH-1 and LDH-2. In comparison, skeletal muscle and liver, with predominant anaerobic metabolism, are highest in LDH-4 and LDH-5. In the brain, LDH isoenzyme composition is evenly distributed from LDH-1 to LDH-4. For all clinical purposes, elevated LDH-1 and LDH-2 is related to hemolysis, or an acute myocardial infarction. Similarly, elevations of LDH-5 typically reflect liver or skeletal muscle disease. In acute rhabdomyolysis, LDH-5 rises significantly and remains elevated for up to 10 days [115].

A subtype analysis looking at the ratio of the M to the H polypeptides is more useful in distinguishing between progressive myopathology and nonprogressive neuromuscular diseases. The M monomer is generally more associated with muscle, while the H can be thought of as being associated with the heart. In progressive myopathies, as the muscle deteriorates and is replaced by adipose and fibrous tissue, the M polypeptide gradually disappears [116]. Hence, the M/H ratio is markedly lower when there is a severe myopathic process [117]. Similarly, in carriers with an abnormal dystrophin gene, a shift is seen from the LDH-4 and LDH-5 isoenzymes into the LDH-1 and LDH-2 isoforms [118].

Pyruvate Kinase

Through transfer of a phosphate group, pyruvate kinase (PK) catalyzes the reaction of phosphoenolpyruvate and ADP into pyruvate and ATP. This is the final step of aerobic glycolysis. In humans, there are four distinct isoforms: PKM1, PKM2, PKL, and PKR [119]. The PKL and PKR isoenzymes are expressed in liver and red blood cells, respectively. PKM1 is expressed in skeletal muscle, heart, and brain; whereas PKM2 is expressed in lung, pancreas, retina, adipose, and fetal tissue. Additionally, PKM2 is also expressed in cells with high rates of proliferation: embryonic cells and neoplasms [120]. PKM1 is a cytosolic protein. In contrast, PKM2 is a nuclear protein, which is also associated with apoptosis. The PKM gene encodes for both the PKM1 and PKM2 isoenzymes [121].

When PK activity is measured in the hospital setting, it is not specific for a distinct isoform. Using isoenzyme specific assays can increase the sensitivity and specificity of making a neuromuscular diagnosis. However, clinically significant conclusions may still be drawn from nonspecific PK measurements. In myopathies, such as Duchenne muscular dystrophy and limb-girdle muscular dystrophy, PK is often markedly elevated (up to 28 times above normal) [122, 123]. Although this is typically associated with increases in CK and aldolase, this is not an invariable finding. As the muscular dystrophy progresses and muscle is replaced with fibrosis and fatty infiltration, PK, along with other muscle enzymes, decreases. The combination of measuring CK and PK is also beneficial in identifying carriers of myopathic diseases [124]. In one study, all individuals out of 17 known carriers, had either an elevated CK or PK. Ten of the carriers had elevations in both enzymes [122].

Secondary to the nonspecificity of PK measurements, it is important to distinguish between muscle and non-muscle etiologies. In the setting of an acute MI, PK levels rise to peak within 2 days and then return to the baseline [123]. In contrast, PK levels remain elevated in muscle diseases and only decrease during the end stages of the myopathy. In liver diseases, elevations in aminotransferases and LDH are

much higher than changes seen in PK [123]. Hence, by understanding the patterns of change in muscle enzymes, it is easier to identify a neuromuscular disease.

Muscle-Specific Enolase

Enolase is a class of enzymes that catalyze the conversion of 2-phosphoglycerate to phosphoenolpyruvate during glycolysis. Although it is present in all tissues, its concentration is associated with the degree of metabolic activity within the tissue. Enolase is a dimer composed of two out of the three distinct subunits (α, β, and γ). There are five specific isoforms: αα, αβ, αγ, ββ, and γγ. Three of these isoenzymes are commonly found in adult human tissues: (1) non-neuronal enolase (NNE or enolase 1-αα isoform found in the liver, brain, kidney, spleen, and adipose tissue); (2) neuron-specific enolase (NSE or enolase 2-γγ isoform); and (3) muscle-specific enolase (MSE or enolase 3-ββ isoform) [125].

MSE is an unbound muscle enzyme, with a much lower concentration than CK in skeletal muscle. Although its clinical significance in neuromuscular disorders is theoretical, elevations in MSE have been documented in muscular dystrophies and spinal muscular atrophies [126, 127].

Carbonic Anhydrase III

Carbonic anhydrases (CA) reversibly catalyze the interconversion of carbon dioxide and water into bicarbonate and protons. The primary function of these enzymes is to maintain the acid–base balance in blood and tissues. There are five distinct families of CA (α, β, γ, δ, and ε) found throughout the animal and plant kingdom. The α-CA family is specific to humans. There are well over a dozen isoforms within the α-CA family. The enzyme of particular interest in muscle diseases is CA-III, as it is present in high concentrations in skeletal muscle and to a lower degree in cardiac and smooth muscle [128].

CA-III has much higher concentration in type I muscle fibers and is localized primarily to the actin within the I-band of muscle [129, 130]. Studies have shown that elevation in CA-III is comparable to the rise seen in CK with muscle damage [126, 128, 131–133]. CA-III may even be a more sensitivity marker for ruling out a myopathy than CK [133]. Carriers of Duchenne muscular dystrophy have been identified to have elevated CA-III levels [128]. However, CA-III is also elevated in neurogenic diseases (such as amyotrophic lateral sclerosis) [133]. Hence, it is important to evaluate for neurogenic causes of muscle damage before using CA-III to make a definitive diagnosis of a primary muscle disease.

Aminotransferases

Typically, a body's energy requirements are met by metabolizing carbohydrates or adipose tissue. However, there are instances when muscle protein needs to be catabolized into amino acids, which can be used to make different proteins, or be shunted into the glycolytic pathway. Aminotransferases (or transaminases) are the enzymes that catalyze the interconversion between amino acids and α-keto acids via transfer of amino groups. There are numerous transaminases. The most clinically significant and commonly measured aminotransferases are: alanine aminotransferase (ALT), aspartate aminotransferase (AST), and gamma-glutamyl transferase (GGT) [3, 4].

ALT is predominantly a liver enzyme but is also present in the kidneys. The most common clinical use for ALT is to evaluate for hepatocellular diseases. It is normal or slightly elevated in acute myocardial infarction and rarely elevated in necrotizing myopathies. AST is less tissue specific due to its predominance in mitochondria. Its greatest concentration is in the heart, liver, skeletal muscle, kidney, brain, pancreas, spleen, and lung. Hence, elevated serum AST is sensitive but not specific for muscle diseases [134]. As with the aforementioned muscle enzymes, elevations of transaminases should be interpreted within the context of the clinical setting and as an adjunct to other enzymes. However, in the appropriate context, these enzymes can provide a valuable tool in diagnosing muscle diseases.

One of the benefits of AST and ALT is that they are frequently measured. Multiple studies have shown that persistent elevations can point to muscle pathology [135–137]. Unfortunately, due to the emphasis on evaluating for a hepatocellular etiology, the diagnosis of a muscle disease can take months to years, and often after invasive gastrointestinal testing is completed. Therefore, it is recommended that prior to obtaining invasive testing, such as a liver biopsy, other muscle enzymes, such as CK, be checked [138]. Furthermore, it is useful to analyze changes in the AST/ALT ratio. In liver disease, the ratio is less than 1. In contrast, with myopathology, the AST/ALT ratio is greater than 1. With acute muscle damage, the sudden rise in AST can often yield a ratio greater than 3 [139]. However, this ratio approaches 1 within a few days, due to a steady and more rapid decline of AST as compared to ALT. Additionally, to help establish a pattern of enzyme elevation, it is also worthwhile to check a GGT level. GGT is not elevated in muscle diseases, and is highly specific for hepatocellular disease. In one study specifically evaluating the GGT level in 28 patients with Duchenne muscular dystrophy, no patient was ever found to have an abnormal level [140]. Hence, this is a useful marker in differentiating between liver and muscle pathology, especially when analyzed in conjunction with other muscle enzymes.

Autoantibody Testing in Peripheral Neuropathy

4

Alan Pestronk

Neuromuscular disorders result from a wide variety of pathological processes. In clinical practice immune-mediated neuromuscular disorders are an important focus of diagnostic efforts as treatment often leads to improvements in function and quality of life in patients. Categorization of immune-mediated neuromuscular disorders provides information about prognosis and possible responses to different therapeutic agents.

Immune-mediated polyneuropathies have historically been categorized by defining clinical patterns of involvement and tissue or subcellular targets of disease. Clinical patterns of polyneuropathy that are diagnostically useful include involvement of different functional classes of cells or axons, the anatomical patterns of symptoms and signs, and the time course of disease [1–3]. Tissue targets of the pathologic processes in immune-mediated polyneuropathies include myelin, axons, cell bodies, vessels, and connective tissue. Electrodiagnostic testing is useful for defining the anatomic patterns and tissue targets of immune disorders [4, 5].

Serum autoantibodies are an increasingly important biomarker for many immune neurologic and neuromuscular disorders. Autoantibodies to specific antigens are commonly used in the formulation of neuromuscular diagnoses. Autoantibodies can also provide useful clues to the pathogenesis of some neuromuscular disorders [6]. General consideration of the autoantibody types, classes, locations, and kinds of target antigens provide useful diagnostic classifications of immune neuromuscular disorders, identify likely accompanying systemic abnormalities, and suggest likely responses to different treatments. Table 4.1 is organized according to a general classification of neuromuscular disorder-associated autoantibodies.

Autoantibody Classification

IgG in Serum Directed Against Cell Membrane Antigens: IgG Autoantibody Type 1 (IgG-AAb1)

IgG-AAb1 are polyclonal and located in the serum and occasionally the CSF. IgG-AAb1 antigenic targets are cell surface molecules, including receptors or ion channels. Specific neuromuscular disease antigenic targets in cell surface membranes include acetylcholine receptors in muscle [7–9] and nerve [10], calcium channels in presynaptic membranes [11], and molecules in complex with voltage-gated potassium channels [12]. Many IgG-AAb1 are likely to be pathogenic, acting by cross-linking antigenic targets and increasing their degradation rate, binding complement and damaging membranes, or, less often, altering channel or receptor function. Associated neuromuscular syndromes are usually chronic. They often improve with immunomodulating therapy, rapidly with intravenous immunoglobulin or plasma exchange, and over a longer term with corticosteroids or T-cell immunosuppressants. After treatment, persistent reductions in antibody levels often correlate with clinical improvement. The presence of IgG-AAb1 usually increases the likelihood of finding an associated neoplasm. The type of neoplasm depends on the specific antigenic target and its associated neuromuscular syndrome. Several different IgG-AAb1 antibodies may occur simultaneously in individual patients.

Serum IgG Versus Ganglionic (α3) Acetylcholine Receptors (AChR)

α3-AChRs are nicotinic AChR located on neurons in autonomic ganglia [10]. Anti-α3-AChR antibodies are detected and quantitated with radioimmunoprecipitation methodology that relies on serum IgG autoantibody binding to a complex of α3-AChR (solubilized from a human neuroblastoma) with iodine 125-labeled epibatidine (from the Ecuadorian frog, Epipedobates tricolor). Radioimmunoprecipitation

Table 4.1 Classification of types of neuromuscular autoantibodies

Antibody					Antigen		Disease		
	Class	Location	Type	Pathogenic properties	Features	Antigen examples	Neuromuscular disease examples	Associations, systemic	Common treatments
IgG-AAb1	IgG	Serum	Polyclonal	Often	Cell surface membrane protein	Receptors ion channels	Myasthenia gravis Autonomic PN LEMS Isaac's	Neoplasms Thymoma Adeno Ca Small cell lung	Corticosteroids T-cell suppressants IVIg Plasma exchange
IgG-AAb2	IgG	Serum	Polyclonal	Possible	Carbohydrate	Glycolipids GM1; GQ1b	AMAN Miller Fisher	Infection Prodromal	? Disease often monophasic
IgG-AAb3	IgG	Serum	Polyclonal	Few	Intracellular protein	tRNA synthetases SRP ANCA	Immune myopathies Vasculitis, small vessel	Organ system disease, neoplasm, or none	Corticosteroids T-cell suppressants Rituximab
IgG-AAb4	IgG	Serum + CSF	Polyclonal	No	Intracellular protein	Hu nuclear antigens CRMP5	Sensory or autonomic neuronopathy	Neoplasms Small cell lung Gynecologic	Screen for and treat associated neoplasm
IgG_4-AAb	IgG_4	Serum ± CSF	Polyclonal	Possible	Cell surface or extracellular protein	MuSK Lgi1	MG-MuSK Encephalopathy + neuropathy		Corticosteroids Rituximab
IgM-AAb	IgM	Serum	Monoclonal, or polyclonal	Possible	Carbohydrate	Glycolipids or glycoproteins GM1, MAG, TS-HDS	Motor MAG	Neoplasms M-protein	Rituximab Cyclophosphamide Intravenous Ig (conduction block)
M-protein	IgM, IgG, or IgA	Serum	Monoclonal	Some	Not identified	Not identified	Polyneuropathy	POEMS Waldenström's Cryoglobulins	

Table Legend: *PN* polyneuropathy, *LEMS* Lambert–Eaton myasthenic syndrome, *AMAN* acute motor axonal neuropathy, *Adeno Ca* adenocarcinoma, *Ig* immunoglobulin, *GM1* GM1 ganglioside, *MAG* myelin-associated glycoprotein, *TS-HDS* trisulfated heparin disaccharide, *SRP* signal recognition particle, *ANCA* antineutrophil cytoplasmic antibody, *CRMP5* collapsin response mediator protein 5, *POEMS* polyneuropathy, organomegaly, endocrine (edema), M-protein, skin, *M-protein* monoclonal protein

methodology is useful for identifying and quantitating antibody binding to conformation-sensitive epitopes on antigens, such as membrane proteins, that cannot be entirely purified.

Anti-α3-AChR antibodies occur in about 50 % of patients with acute-onset pure dysautonomia syndromes [13, 14]. Both parasympathetic and sympathetic nervous systems are typically involved. Occasional patients have selective cholinergic or adrenergic involvement. Initial clinical features are most commonly associated with abnormal orthostatic blood pressure or pulse changes, or gastrointestinal motility disorders. Other features include sudomotor disorders (especially postganglionic anhidrosis), dry eyes and mouth, disorders in pupillary responses to light, and urinary bladder dysfunction. The disease course is often monophasic with partial recovery. There are anecdotal reports of improvement of antibody-related dysautonomia syndromes after treatment with various modes of immunomodulation, including intravenous immunoglobulin, plasma exchange, corticosteroids, rituximab, and mycophenolate. High levels of anti-α3-AChR typically occur with a wide spectrum of autonomic signs and have specificity (83 %) for autonomic disorders. Lower levels occur in a variety of limited autonomic syndromes, but are not specific for autonomic disorders. The most common neoplasms associated with anti-α3-AChR antibodies (30 % overall) are adenocarcinoma and lymphoma. The presence of paraneoplastic dysautonomic syndromes has been associated with a poor prognosis [15]. Evidence that anti-α3-AChR antibodies may be pathogenic includes their ability to inhibit α3-AChR function and synaptic transmission in autonomic ganglia in vitro [16].

IgG Versus P/Q Voltage-Gated Calcium Channels (VGCC)

P/Q voltage-gated calcium channels ($Ca_v2.1$) are found on neuronal membranes, especially presynaptic terminals [17]. Antibody binding to P/Q voltage-gated calcium channels is quantitated with radioimmunoprecipitation methodology that relies on serum IgG autoantibody binding to a complex of $Ca_v2.1$ (solubilized from human cerebral cortical membranes) with iodine 125-labeled ω-conotoxin peptides (MVIIC or GVIA from piscivorous snails) [18].

Serum IgG binding to P/Q voltage-gated calcium channels is found with Lambert–Eaton syndrome and its associated moderately severe, syndromic autonomic neuropathy [11, 18]. Dry mouth, erectile dysfunction in men, and constipation are the most common features of the autonomic neuropathy. Blood pressure, micturition and sweating disorders, and dry eyes also occur. Weakness and fatigability are manifestations of dysfunction of motor axon presynaptic terminals at neuromuscular junctions. IgG anti-P/Q VGCC antibodies are commonly associated with small cell lung neoplasms. Some patients with small cell lung neoplasms and anti-P/Q VGCC antibodies (1–4 %) are asymptomatic or have a subacute cerebellar syndrome. Other possibly associated neoplasms are prostate, thymus, and lymphoid. Patients with additional serum IgG binding to SOX1 (initially defined by immunohistochemical binding of IgG to Bergmann glia in cerebellum) may be at the greatest risk for small cell cancer [19]. Neuromuscular syndromes associated with anti-P/Q VGCC antibodies may show good responses to immunomodulating therapies. Evidence that anti-P/Q VGCC antibodies are pathogenic includes presynaptic nerve terminal dysfunction induced by passive transfer of human autoantibodies to mice.

IgG Versus Voltage-Gated Potassium Channel (VGKC) Protein Complexes

Serum IgG autoantibodies, which were originally thought to bind to VGKC, were identified in several complicated central and peripheral nervous system syndromes. Most of these antibodies are now thought to bind to molecules that are complexed with VGKC and not the potassium channel molecule itself [12, 20–22]. Antigenic targets include contactin-associated protein-2 (Caspr2), leucine-rich, glioma-inactivated 1 protein (Lgi1) and contactin-2. Antibodies to the VGKC complex were initially identified and quantitated with radioimmunoprecipitation methodology that relies on serum IgG autoantibody binding to VGKC-associated proteins (solubilized from brain) complexed to iodine 125-labeled α-dendrotoxin (from mamba snakes (Dendroaspis)). Antibodies specifically to Caspr2 or Lgi1 molecules are detected qualitatively using immunocytochemistry to detect IgG binding to human embryonic kidney 293 (HEK293) cells transfected to express those antigens. Comparison of antibody binding to HEK293 cells with and without antigen expression provides specificity to the assays. *Caspr2 protein* is associated with potassium channels at juxtaparanodes of myelinated peripheral nerve axons and is involved in neuron–glia interactions. Serum IgG vs. Caspr2 is polyclonal, predominantly IgG_1, and binds to CNS neuropil, but not neurons.

Autonomic, motor, and painful sensory, peripheral neuropathic disorders are associated with serum IgG binding to Caspr2 and possibly Lgi1 (see IgG_4 antibodies below). IgG anti-Caspr2 autoantibodies are associated with peripheral nerve hyperexcitability in the form of neuromyotonia. Neuromyotonia may occur in isolation, or with other components of Morvan syndrome such as dysautonomia and encephalopathy with marked insomnia [20]. Ninety percent of patients are male. Other frequent associated systemic features can be weight loss, thymoma, and myasthenia gravis. Immunomodulating treatment of Caspr2 antibody-related syndromes can produce improvement. However, there is a high mortality in the setting of Caspr2 antibody syndromes with associated neoplasms.

IgG in Serum Directed Against Carbohydrate Moieties on Glycolipids: IgG Autoantibody Type 2 (IgG-AAb2)

IgG-AAb2 are polyclonal and located in the serum, but not usually the CSF. IgG-AAb2 bind to cell surface glycolipids, often gangliosides. Gangliosides occur in neuron membranes, anchored in the external leaflet of the lipid bilayer by a ceramide moiety. Their sialylated oligosaccharide moieties are exposed extracellularly. In the peripheral nervous system gangliosides are present in both axons and myelin. There are no significant quantitative biochemical differences of the major gangliosides in human ventral and dorsal roots [23]. Gangliosides GM1, GD1a, and GD1b are enriched at, or near, the nodes of Ranvier, a critical region for generation and propagation of action potentials, and contribute to stability of paranodal junctions and ion channel clusters. Many IgG-AAb2 were originally characterized by showing selective serum IgG binding to specific glycolipids among those separated on thin layer chromatography plates. Clinical testing to detect IgG-AAb2 now generally uses enzyme-linked immunosorbent assays (ELISA) that can quantitate antibody binding to purified glycolipids that are attached to wells in ELISA plates. Nonspecific IgG binding is ruled out by comparing binding to the test antigen and another similar glycolipid.

Clinical neuromuscular syndromes associated with IgG-AAb2 are usually acute-onset immune polyneuropathies (AIP) with a monophasic course [23]. Serum antibodies may also be only transiently present during the first few weeks of disease. This temporal pattern contrasts with IgM anti-glycolipid antibodies (see below) which are most often associated with chronic, persistent neuropathies. Antecedent infections in patients with IgG-AAb2 are commonly reported [24]. Some AIP prodrome-associated bacteria contain glycolipid epitopes similar to those on nervous tissue and may induce a cross-reactive immune reaction with peripheral nerve antigens that underlies the disease syndrome. AIP can be subdivided into clinical categories that include motor–sensory demyelinating (classically described Guillain–Barré; AIDP), motor axonal, sensory axonal, and Miller Fisher-like syndromes. For some of these subgroups, and in some regions of the world, IgG-AAb2 are common, while in others, like AIDP in most of the United States, IgG-AAb2 are infrequently detected [24, 25]. There is no increased frequency of neoplasms with IgG-AAb2. Evidence of clinical utility of immunomodulating therapy for these acute immune neuropathy syndromes, such as more rapid improvement or shorter disease course, is sparse. Some IgG-AAb2 may be pathogenic, binding to and causing dysfunction or damage to axons and sodium channel clusters at the nodes of Ranvier, juxtaparanodes, or presynaptic nerve terminals [26–28].

IgG Versus GM1 Ganglioside

Serum IgG binding to GM1 ganglioside is most strongly related to acute motor axonal neuropathies (AMAN) which have weakness, but little sensory loss, that evolve over a period of weeks [29, 30]. The incidence of AMAN is highest in China, Japan, and Bangladesh. Compared to AIDP, AMAN patients have more rapid progression and less frequent facial weakness, respiratory failure, sensory loss, and autonomic instability. AMAN patients can have retained or brisk tendon reflexes. Acute motor and sensory axonal neuropathy (AMSAN) may be a more severe form of AMAN [31]. Conduction block can occur early in the course of AMAN, but definite demyelinating features such as prominent or persistent conduction velocity slowing are unusual [32, 33]. While GM1 ganglioside is the most frequently described target of IgG autoantibodies in AMAN, IgG binding to GD1a, GalNAc-GD1a [34–36], and GM1b gangliosides also occurs. Up to 90 % of AMAN patients have IgG binding to at least one of these gangliosides. Several IgG autoantibody specificities can occur in the same serum. IgG anti-GM1b antibodies are associated with rapidly progressive distal weakness, few cranial or sensory deficits, and slow recovery [37]. IgG anti-GD1a antibodies are associated with prolonged artificial ventilation and poor recovery [38]. Reports of selective IgG binding to GD1a ganglioside are subject to some doubt as it is difficult to purify GD1a from GalNAc-GD1a. Patients can have IgG or IgM binding to complexes containing two or more glycolipids, but not to single gangliosides alone [39–43]. The presence of anti-glycolipid antibodies in AMAN syndromes can be related to infection by *Campylobacter jejuni* which contains glycolipids having structural similarity to the carbohydrate moieties on gangliosides [44]. GM1 ganglioside is present on both motor and sensory neural structures [45, 46]. The anatomical distribution of GM1 ganglioside cannot explain the association of anti-GM1 antibodies with predominantly motor syndromes. Anti-GM1 antibodies may have pathogenic effects. Immunization of rabbits with GM1 ganglioside can cause a subclinical neuropathy with conduction block and axonal degeneration [47]. Anti-GM1 antibody containing serums can produce conduction block, loss of sodium channel clusters from membranes, and spinal motor neuron damage [48–52].

IgG Versus GQ1b or GT1a Gangliosides

GQ1b is highly expressed in the paranodal myelin of the human oculomotor, trochlear, and abducens nerves and is present at neuromuscular junctions [53, 54]. Serum IgG vs. GQ1b ganglioside is associated with features of Miller Fisher syndromes including ophthalmoplegia and ataxia [55, 56]. An epidemiological association between *C. jejuni* and *Haemophilus influenzae* infections has been established in Miller Fisher syndromes [57, 58]. Serum IgG vs. GQ1b also

occurs with more severe syndromes such as Bickerstaff brainstem encephalitis with disordered consciousness along with ataxia and ophthalmoplegia and acute immune neuropathies with ophthalmoplegia and generalized weakness [59]. An acute onset of oropharyngeal, neck and shoulder weakness, and areflexia is associated with IgG vs. GT1a ganglioside in serums that also bind to GQ1b [60, 61]. Milder isolated ataxia, ophthalmoplegia, or oropharyngeal syndromes have also been described with IgG binding to GQ1b [62]. IgG vs. GQ1b may play a role in disease pathogenesis [26–28].

IgG Versus GD1b Ganglioside

GD1b ganglioside is present in primary sensory neurons, muscle spindles, and paranodal myelin of motor and sensory axons [63, 64]. Serum IgG binding to GD1b ganglioside is associated with an acute-onset, large fiber sensory axonopathy syndrome that may involve ganglion cells in more severe cases. Clinical features can include sensory ataxia, impaired vibratory and joint position sensations, and lost deep tendon reflexes with normal strength. Nerve conduction studies show absent or reduced sensory nerve action potentials with spared motor potentials. Antecedent infections are common. The disease course is typically monophasic with recovery within 2 months. Antibodies that bind selectively to GD1b ganglioside can cause a sensory neuropathy [65–67]. Antibodies to GD1b may be cytotoxic to sensory ganglion cells. Rabbits immunized with GD1b ganglioside develop a syndrome of ataxia and areflexia with structural damage to sensory neurons and large sensory axons in peripheral nerves.

IgG Versus Other Glycolipid or Carbohydrate Antigens

Polyclonal IgG or IgM antibody binding to galactocerebroside occurs in some patients with classical motor–sensory demyelinating Guillain–Barré syndrome (1–12 %) [68, 69]. Patients with anti-galactocerebroside reactivity can have serologic evidence of previous infection with *Mycoplasma pneumonia* [68]. Immunization with galactocerebroside can lead to a demyelinating neuropathy [70]. Anti-galactocerebroside antibodies can produce demyelination in vitro [71]. Polyclonal IgG or IgM antibodies to heparan sulfate occur in some patients with acute immune, demyelinating motor–sensory neuropathies [72].

IgG in Serum Directed Against Intracellular Proteins: IgG Autoantibody Type 3 (IgG-AAb3)

IgG-AAb3 are polyclonal IgG and located in the serum, but not usually the CSF. They bind to intracellular proteins. Although IgG-AAb3 often have strong disease specificity, it is often difficult to show pathogenic effects. Associated clinical neuromuscular syndromes include immune myopathies (myositis-specific antibodies) [73] and neuropathies with a subacute or progressive onset and a chronic course (antineutrophil cytoplasmic antibodies (ANCA)). Many IgG-AAb3-associated neuromuscular syndromes are treatable with immunomodulating agents.

ANCA

Detection of ANCA plays an important role in the diagnosis and classification of systemic immune vasculitides [74, 75]. Two types of ANCA assays are used. Indirect immunofluorescence (IIF) assays that detect patterns of serum IgG binding to cultured cells are more sensitive. Quantitative ELISA measurement of antibody binding to purified antigens is more specific for ANCA-related vasculitis [76].

ANCA are most often IgG. Immunofluorescence studies show antibody binding to azurophilic granules of peripheral blood neutrophils in two distinct patterns with different clinical associations. Diffuse cytoplasmic binding (c-ANCA) usually (90 %) targets proteinase 3 (Pr-3). c-ANCA are typically associated with Wegener's granulomatosis, especially with renal involvement [77]. Antiproteinase 3 ANCA are associated with HLA-DP and the genes encoding α(1)-antitrypsin (SERPINA1) and proteinase 3 [78]. Perinuclear binding (p-ANCA) commonly (70 %) targets myeloperoxidase (MPO). p-ANCA are frequent in several systemic inflammatory vasculopathy syndromes which frequently target small- to moderate-sized vessels. Clinical syndromes, which often include neuropathies, include microscopic polyangiitis (MPA) and Churg–Strauss syndromes [77]. There may be more frequent fibrinoid necrosis in vessel walls and less tissue eosinophilia in Churg–Strauss neuropathies with p-ANCA [79]. Anti-myeloperoxidase ANCA are genetically associated with HLA-DQ [78]. ANCA are unusual in some other inflammatory vasculopathies, including polyarteritis nodosa (PAN) and nonsystemic vasculitic neuropathies [80]. p-ANCA can be induced by drugs (propylthiouracil, minocycline, hydralazine) in the absence of a vasculitis. Rheumatoid arthritis or systemic lupus may have ANCA, but the target antigen is often neither Pr-3 nor MPO. Neuropathies in ANCA-related syndromes usually have both motor and sensory features. They are often a component of multisystem disorders that include general systemic (arthralgia, arthritis, myalgia, fever, and weight loss), cutaneous, mucous membrane, and ENT involvement. There is no strong association of ANCA-positive neuropathies with life-threatening organ involvement (chest, renal, cardiovascular, or abdominal) [81]. Nerve or muscle biopsy confirmation of the inflammatory vasculopathy, with epineurial perivascular mononuclear cellularity, is useful before treatment of the neuropathy. Immunomodulating treatment, including high-dose corticosteroids, cyclophosphamide (pulse, intravenous), methotrexate, and rituximab, is typically followed by improvement or resolution of both the neuropathy and

systemic features. ANCA can provide prognostic information. Continued or recurrent ANCA positivity after treatment increases the likelihood of a relapse [82]. Although IgM and IgA ANCA have been described, for routine diagnostic purposes only IgG antibodies are measured. ANCA can stimulate degranulation of neutrophils, but their pathogenicity in producing tissue and vascular damage is debated. T cells, rather than humoral pathology, may be the main effector mechanism [74].

IgG in Serum and the CSF Directed Against Intracellular Proteins: IgG Autoantibody Type 4 (IgG-AAb4)

IgG-AAb4 are polyclonal IgG and located in both serum and the CSF. IgG-AAb4 bind to intracellular protein antigens. Associated clinical syndromes usually have a subacute onset over weeks to months with little subsequent progression. Associated neoplasms are common. Many of these antibodies are more strongly associated with a neoplasm than a specific neurologic syndrome. Response of the associated neurologic or neuromuscular disorders to immunomodulating treatment is typically poor. There is generally little evidence showing pathogenic effects of IgG-AAb4.

Hu

Hu antigens are a family of nuclear proteins, three of which, Hel-N1, HuC, and HuD, have specificity for normal neurons [83]. A fourth protein, HuR, is ubiquitous. Hu proteins can also occur in cells of some neoplasms like small cell lung carcinoma, but, other than HuR, are not generally present in normal systemic tissues. Several different qualitative methods are used clinically to detect IgG antibodies that bind to Hu proteins. Immunohistochemistry to visualize patterns of IgG binding to neuronal nuclei (in animal or human CNS tissue) is used alone, or along with confirmatory methods [83]. When immunohistochemistry is used alone, tested serum is often first pre-adsorbed with a preparation containing systemic nuclear antigens to remove other types of antinuclear antibodies. These immunohistochemical results are also known as antineuronal nuclear antibodies (ANNA-I). IgG binding to Hu antigens in CNS tissue or preparations of recombinant Hu protein (often HuD) are also detected using Western blot methods. The most specific evaluation for Hu antibodies probably includes testing with both immunohistochemistry and Western blot [84]. Anti-Hu autoantibodies from patients generally bind to all four Hu protein family members.

High-titer IgG antibody binding to Hu proteins is associated with several central and peripheral neurologic paraneoplastic syndromes which may occur individually, or in combination [85, 86]. Associated clinical syndromes have a subacute onset between ages 20 and 80. Clinical syndromes with anti-Hu antibodies include encephalitis (limbic or brainstem), cerebellar ataxia, subacute sensory neuronopathy, and autonomic neuropathy. The subacute sensory neuronopathy presents with numbness and pain, often involving the upper extremities, progressing over 1–8 weeks. Sensory loss is asymmetric, involves large and small fiber modalities, and may occur on the face, trunk, and proximal as well as distal regions of the upper and lower extremities. Patients are often disabled by the severe sensory ataxia and pseudoathetosis resulting from the sensory loss. Pain is experienced by some patients. Strength is usually normal but mild distal weakness is described. Tendon reflexes are diffusely absent. Anti-Hu antibodies are unusual in patients with distal, symmetric sensory neuropathies. About 25 % of patients with anti-Hu antibodies have features of dysautonomia, with gastrointestinal dysmotility as the most common. Orthostatic hypotension or urinary dysfunction can also occur. A history of smoking is obtained in most patients. Nerve conduction studies show diminished or absent sensory responses with normal motor studies. Subacute sensory neuronopathy with anti-Hu antibodies is associated with central nervous system signs, ranging from mild nystagmus to severe encephalopathy, in 75 %. The CSF commonly shows a mild pleocytosis and elevated protein. Anti-Hu antibodies are very strongly (>95 %) associated with neoplasms, especially small cell lung cancer (SCLC). Extrathoracic neoplasms occur in 15 %. Anti-Hu testing is typically performed on serum, although the antibodies are usually also present in the CSF. The highest titers of anti-Hu antibodies are associated with autonomic gastrointestinal dysmotility syndromes or subacute sensory neuronopathy [83]. Median survival is 1 year. Three-year survival is 20 %. Low levels of IgG binding to Hu can occur with neoplasms without associated neurologic signs. Death can be related to either the paraneoplastic syndrome or tumor progression. Worse prognosis is associated with age greater than 60 years, involvement of multiple regions of the nervous system, and lack of treatment. There is no correlation of Hu antibody titer with disease progression or outcome [87]. The finding of anti-Hu antibodies mandates screening for cancer. When a neoplasm is not found at initial evaluation, periodic follow-up evaluations, every 1 or 2 years, are required. Treatment consists of therapy for the associated neoplasm. There is almost no improvement in the SSN itself. Physical therapy may allow patients to partially compensate for the sensory loss over time. There is little experimental support for a role of Hu antibodies in neural tissue damage.

CRMP5

Collapsin response mediator protein 5 (CRMP5; CV2; DPYSL5) is involved in neuronal and glial development, migration, and neurite extension [88]. In adults, CRMP5 is normally expressed in non-myelinating Schwann cells and a

subpopulation of oligodendrocytes and is upregulated during axonal regeneration. Two methods are used clinically to detect IgG antibodies that react with CRMP5. Immunoreactivity of anti-CRMP5 IgG to the cerebellum includes binding to synaptic regions in the granular and molecular layers with sparing of molecular and Purkinje layer neuron cell bodies [89]. Western blot confirmation uses recombinant CRMP5 protein or brain proteins as antigens [90, 91].

Peripheral neuropathy is the most frequent neurologic manifestation with IgG binding to CRMP5 [91, 92], occurring in a majority of patients. The polyneuropathy has a progressive onset over months. The signs are sensory and distal predominant, more severe in the legs. Distal leg or toe weakness occurs in some patients. Electrodiagnostic testing shows axon loss. Demyelinating features occur in some patients. Nerve pathology shows axon loss and regeneration. Some patients have thin myelin sheaths or macrophage-mediated demyelination. Accompanying clinical features most commonly include cerebellar ataxia, uveo-retinal features, limbic encephalitis, and Lambert–Eaton myasthenic syndrome (LEMS). CRMP5 antibodies are associated with neoplasms, especially small cell lung but occasionally thymoma. The neurologic syndrome typically precedes diagnosis of the neoplasm. Treatment consists of therapy for the associated neoplasm. There are reports of improvement of the neuropathy after treatment. Long-term mortality caused by the neoplasm or paraneoplastic syndromes is about 30 %.

IgG_4 Autoantibodies (IgG_4-AAb) Directed Against Surface Membrane or Extracellular Proteins

IgG_4 antibodies account for less than 5 % of total IgG in normals [93, 94]. They do not effectively activate the classical complement pathway. IgG_4 can undergo a distinctive process of "half-antibody exchange" in vivo, resulting in recombined antibodies with two different binding specificities. IgG_4-AAb are polyclonal and located in the serum and in some cases also the CSF. IgG_4-AAb often bind to surface membrane or extracellular proteins. Disease-related antigens include desmogleins in types of pemphigus, collagen VII in epidermolysis bullosa acquisita, M-type phospholipase A2 receptor in membranous glomerulonephritis, and MuSK in a subtype of acquired myasthenia gravis. IgG_4-related disease is a multiorgan disorder with tumefactive lesions, extensive fibrosis, and lymphoplasmacytic infiltrates that are rich in IgG_4-positive plasma cells and T cells and, commonly, elevated serum IgG_4 levels. Most IgG_4-related disorders have low frequencies of associated neoplasms, but an association with lymphoma is reported. Corticosteroid treatment can produce benefit. Short-term treatment with rituximab may be effective in corticosteroid-resistant IgG_4-related disorders [95–97]. Some IgG_4 autoantibodies may be pathogenic [98, 99].

Lgi1

Lgi1 is a secreted neuronal protein that interacts with presynaptic ADAM23 and postsynaptic ADAM22, regulates some VGKC, and enhances AMPA receptor-mediated synaptic transmission. Lgi1 antibodies are polyclonal, can be detected in serum and the CSF, and bind to CNS neurons. Predominant features in Lgi1 autoantibody-associated clinical syndromes are limbic encephalitis with delusions and mood changes, generalized or focal seizures, and memory loss [12, 21]. MRI shows increased T2 signal in medial temporal lobes. Pain with sensory neuropathies may occur [20]. Hyponatremia occurs in 60 %. Although associated neoplasms have been reported, they are present in relatively few patients (10 %) and there is no consistent tissue type. The disease course may be monophasic after immunomodulating treatments. At least partial improvement occurs, over a period of months, in 75 % of patients.

Serum IgM Autoantibodies (IgM-AAb) Directed Against Carbohydrate Moieties

IgM-AAb are typically located in serum, can be monoclonal or polyclonal, and bind to extracellular carbohydrate moieties on glycoproteins or glycolipids [100–102]. Testing for IgM-AAb generally utilizes ELISA methodology for quantitative or semiquantitative measurement of binding to purified antigens. Clinical neuromuscular disorders with IgM-AAb are commonly polyneuropathies with a chronic, slowly progressive course. Some syndromes predominantly involve motor axons, causing weakness. Others produce disability due to sensory involvement or gait disorders. Patients with IgM antibodies directed against carbohydrates have an increased frequency of serum IgM monoclonal proteins (M-proteins), usually benign but occasionally due to lymphomas, Waldenström's macroglobulinemia, or other bone marrow dyscrasias. Treatment of IgM antibody-associated neuropathies can be difficult. There are few controlled trials. Corticosteroids and T-cell immunomodulating agents rarely produce benefit. Patient subgroups with motor conduction block on electrodiagnostic testing are more likely to improve with IVIg treatment although there is no change in IgM-AAb titers [103]. Intravenous cyclophosphamide, rituximab, or fludarabine may be useful in neuropathies that produce disability [104, 105]. The benefit of these drugs in IgM-AAb-associated disorders is more likely with reduction in antibody titers of 50–60 % or more. Reduction in IgM antibody titers may be more rapid in patients with Waldenström's macroglobulinemia than in those with monoclonal gammopathies of unknown significance (MGUS) or no detected M-proteins. Improvement in IgM-AAb syndromes is less likely with short-term treatments which produce less reduction in antibody titers [106]. Some IgM-AAb may be pathogenic.

Motor Neuropathies (IgM Versus GM1 Ganglioside or NS6S Disaccharide)

Serum IgM binding to GM1 ganglioside or NS6S is associated with motor neuropathy syndromes. The sensitivity and specificity of ELISA testing for IgM binding to GM1 ganglioside or NS6S heparin disaccharide depend to an important extent on methodology of antibody testing [100, 107, 108]. Covalent linkage of these antigens to ELISA plates increases the sensitivity and specificity of antibody testing. Embedding GM1 ganglioside in lipid complexes that may mimic its membrane environment can allow detection of IgM binding to GM1 that is not found in pure GM1 [39–41]. In some serums IgM binding GM1 or NS6S is the result of polyspecific IgM that binds to multiple antigens and has no strong clinical correlations. Disease specificity of IgM binding to GM1 ganglioside or NS6S for motor neuropathies is greatly increased by subtracting polyspecific IgM antibody levels which are measured by determining serum binding to other antigens such as GD1a ganglioside or histone H3 [109].

Immune motor neuropathies associated with IgM autoantibodies are characterized by asymmetric, slowly progressive weakness that typically begins distally in the arms [110–112]. With disease progression proximal muscles can be involved [108]. Onset ranges from 20 to 70 years of age with male predominance. Cramps, fasciculations, or myokymia occur in over 50 % of patients, but sensory symptoms are rare. Laboratory testing is useful in distinguishing immune motor neuropathies from untreatable motor neuron diseases. Motor conduction block, a focal reduction (>50 %) in CMAP amplitudes in distal nerves at locations other than sites of compression [113], can be found in about 60 % of patients with immune motor neuropathies. The identification of motor conduction block in motor neuropathies supports a diagnosis of multifocal motor neuropathy (MMN) [110]. Some patients with a typical motor neuropathy phenotype have no conduction block. IgM binding to GM1 ganglioside or NS6S disaccharide are independent serum markers of immune motor neuropathies [108], occurring with similar frequencies of 40–50 % in immune motor neuropathies. At least one antibody is present in 60–70 %. GM1 antibodies are more specific for immune motor neuropathies than NS6S antibodies [114]. About 90 % of patients with high-titer serum IgM binding to GM1 have motor neuropathies. IgM binding to NS6S is uncommon in amyotrophic lateral sclerosis but can occur in patients with sensory neuropathies who have IgM binding to MAG or TS-HDS. The combination of electrodiagnostic and antibody testing has about 90 % sensitivity for immune motor neuropathies. Responses of immune motor neuropathies to immunomodulating treatment are typical of IgM-AAb syndromes. Intravenous immunoglobulin is useful in patients with multifocal motor neuropathy with conduction block [110, 115, 116]. Benefits can decline over time [117, 118] and are less likely in motor neuropathies without conduction block. IVIg treatment does not generally produce a change in anti-GM1 antibody titers [103]. Treatment with cyclophosphamide or rituximab may produce functional benefit and a reduction in IgM-AAb titers [104]. Corticosteroids and T-cell immunosuppressive treatments are rarely associated with improvement. Corticosteroids can produce exacerbations in weakness [119–121].

IgM Versus Myelin-Associated Glycoprotein (MAG)

MAG is a cell surface glycoprotein that is present in Schwann cells and uncompacted myelin in the peripheral nervous system [122]. IgM binding to semi-purified MAG protein is often initially measured by ELISA assay. Validation of serum binding to MAG using Western blot methods is important for disease specificity [123]. Serums with IgM binding to MAG by ELISA that are low titer, or negative by Western blot, are not specific for the characteristic-associated demyelinating polyneuropathy syndrome [109, 124–126].

High-titer serum IgM binding to MAG is often found in patients with an IgM monoclonal protein and a demyelinating polyneuropathy [105, 127, 128]. The polyneuropathy is typically slowly progressive, symmetric, and predominantly distal. The legs are involved more severely than the arms. Sensory loss, involving all modalities, occurs earlier than any weakness. A gait disorder, manifest on examination as difficulty with tandem gait, is often an early manifestation and develops with a severity and dysfunction out of proportion to the degree of sensory loss. Weakness, most severe in the distal legs or toes, eventually develops in 80 % of patients with anti-MAG antibody-associated polyneuropathies. Tendon reflexes are usually absent at the ankles and hypoactive or absent elsewhere. Tremor, predominantly in the hands, can be a severe late manifestation [129]. The neuropathy is slowly progressive. Moderate disability due to the gait disorder or tremor develops over a period of years [130, 131]. Electrodiagnostic testing shows a polyneuropathy with demyelinating features and some axon loss. The earliest and most consistent demyelinating change is prolonged distal motor latencies [132–134]. Slowing of nerve conduction velocities occurs in 50 % of patients, becoming more common with disease progression. Focal conduction block is unusual in anti-MAG antibody-related demyelinating polyneuropathies, in contrast to CIDP and multifocal motor neuropathy. Characteristic pathologic abnormalities in peripheral nerve myelin in anti-MAG polyneuropathies include wide spacing of myelin lamellae, especially near the nodes of Ranvier, and swelling of terminal myelin loops and tomaculae [135]. Axon loss develops with disease progression and may be associated with IgM penetration into nerve fascicles [136]. Nerve biopsy is not used to diagnose anti-MAG polyneuropathies. Anti-MAG polyneuropathies are difficult to treat [105]. There is no response to prednisone, azathioprine, or IVIg. Rituximab or cyclophosphamide may produce benefit [137–139]. Most

patients who improve after treatment have titers of anti-MAG antibodies reduced by at least 50 %. Improvement usually begins 3–6 months after starting rituximab or cyclophosphamide treatment and can continue for 1–2 years. Relapses after rituximab treatment are more common in patients with initial high titers of IgM binding to MAG, less reduction in antibody titers, and shorter-term treatments with rituximab [140, 141]. Fludarabine, a drug with significant possible toxicity, may also be useful [142, 143].

IgM anti-MAG antibodies may cause the demyelination and axonal loss [135, 136]. The target antigens in nerve may be MAG, or glycolipids that contain similar carbohydrate epitopes [144]. Anti-MAG antibodies bind to compact peripheral nervous system myelin and associated Schwann cell cytoplasm. Deposits of IgM and complement can be found on myelin sheaths in biopsies from patients. Direct injection into cat sciatic nerve of serum from patients with anti-MAG antibodies has produced widening of myelin lamellae and demyelination in experimental animals [145–147]. Passive transfer of human anti-MAG IgM into chicks produces pathology that is similar to the human disorder [148].

IgM Versus GD1b Ganglioside

ELISA testing showing IgM binding selectively to GD1b ganglioside, without binding to GM1, indicates antibody recognition of gangliosides containing disialosyl groups [149]. Selective IgM anti-GD1b antibodies cross-react with Pr2 antigens on red blood cells and may cause cold agglutination [150]. Serum IgM binding to GD1b ganglioside with concurrent binding to GM1 occurs in some patients with entirely different syndromes, immune motor neuropathies.

Selective serum IgM binding to GD1b occurs in chronic sensory ataxic neuropathy syndromes with panmodal, distal sensory loss, sensory gait ataxia, normal or relatively preserved strength, and, in some patients, cranial nerve features, including ophthalmoplegia and dysphonia (50 %) [151, 152]. Electrodiagnostic testing consistently shows axonal loss. Demyelinating features, such as prolonged distal latencies or slowed conduction velocities, may also be present. Serum IgM M-proteins are common. There are reports of partial improvement after IVIg [153] or rituximab [154] therapy. Corticosteroid treatment is not effective. Similar ataxic sensory neuropathy syndromes without cranial nerve features have been reported with IgM binding to GM2 and GalNAc-GD1a gangliosides without binding to GM1 ganglioside [155, 156]. Nerve conduction testing can show demyelination with conduction block and slowed velocities.

Antibodies against GD1b ganglioside bind to dorsal root ganglion neurons, paranodal myelin, myelinated axons, and motor nerve terminals [157]. An affinity-purified anti-disialosyl antibody impaired nerve excitability and reduced quantal release of neurotransmitter from nerve terminals [158]. Rabbits immunized with GD1b ganglioside develop ataxia and areflexia with structural damage to sensory neurons. Passive transfer of IgG anti-GD1b antibodies can cause degeneration of rabbit sensory neurons and induce nodal disruption predominantly in sensory nerves [27, 159].

IgM Versus TS-HDS

Trisulfated heparin disaccharide (TS-HDS) is the most abundant disaccharide component of heparin oligosaccharides. The distribution of TS-HDS in the nervous system is not well defined. Detection of serum IgM-AAb binding to TS-HDS depends strongly on specific methods of covalent binding of TS-HDS antigen to ELISA plates [109]. Serums with IgM binding to MAG frequently also have IgM vs. TS-HDS, often in higher titers than to MAG.

Selective serum IgM binding to TS-HDS is the most common neuropathy-related autoantibody. Patients with IgM vs. TS-HDS commonly have slowly progressive, distal, predominantly sensory, painful axonal polyneuropathies. Sensory loss more commonly involves small fiber modalities. Sensory symptoms and pain often occur in regions that are not length dependent. Distal weakness occurs in some patients (20 %) and is more common in the presence of IgM M-proteins. IgM binding to TS-HDS is often monoclonal, frequently κ class. Detection of serum IgM binding to TS-HDS raises the likelihood of finding an IgM M-protein in patients with neuropathies by tenfold. Biopsies of muscle and nerve show endomysial and endoneurial capillary pathology with thickened basal lamina and C5b-9 complement deposition. Serum IgM binding to TS-HDS suggests a possible immune etiology underlying some otherwise idiopathic sensory polyneuropathies. No treatment studies have been reported. Serum IgM from some patients with TS-HDS antibodies binds to endomysial capillaries in normal muscle, suggesting that the antibodies could play a role in producing capillary pathology. Possible causes of a neuropathy associated with capillary pathology include ischemia due to reduced blood flow or leakage of pathologic factors through capillary walls that have reduced integrity of their blood–nerve barrier.

IgM Versus Sulfatide

Sulfatide is a major anionic glycolipid in CNS myelin [160]. Many neural proteins have binding domains for sulfogalactolipids, like sulfatide. Sulfatide, like MAG, is associated with myelin-related inhibition of axonal outgrowth [161]. Sulfatide is an antigenic target of antibodies generated by immunizing mice with CNS myelin. IgM antibody binding to purified sulfatide is quantitated by ELISA [128].

High titers of IgM anti-sulfatide antibodies have specificity for predominantly sensory axonal neuropathy syndromes [101, 133, 162–165]. Distal, symmetric, panmodal, slowly progressive sensory loss in the legs and arms is typical. Pain and paresthesias are more common symptoms with polyclonal anti-sulfatide antibodies. Distal weakness is more

frequent with monoclonal anti-sulfatide antibodies. Some patients with IgM anti-sulfatide antibodies have an ataxic gait disorder or tremor similar to that seen in anti-MAG neuropathies. IgM M-proteins probably have an increased frequency. Electrodiagnostic testing shows an axonal sensorimotor polyneuropathy with occasional demyelinating features. Reports of treatment responses are sparse. Moderate or low titers of anti-sulfatide antibodies have been reported in patients with infections, including human immunodeficiency virus [166, 167] and trypanosomiasis [168]. Patients with the GALOP syndrome (gait disorder, autoantibody, late-age onset, and polyneuropathy) have IgM binding to sulfatide in a lipid membrane (cholesterol, galactocerebroside) environment. The clinical GALOP syndrome combines gait ataxia and a sensorimotor polyneuropathy with late-age onset (mean 70 years of age) [125]. Electrophysiologic studies are heterogeneous, but some patients have features suggesting demyelination, similar to those found in patients with anti-MAG neuropathies. Immunomodulating treatment with IVIg or cyclophosphamide may result in functional improvement in patients with GALOP syndromes. Nerve biopsies in patients with IgM binding to sulfatide show that IgM and components of complement bind to myelin and could play a role in myelin wide spacing [169]. Serum IgM anti-sulfatide antibodies can bind to dorsal root ganglia [170]. Monoclonal IgM anti-sulfatide antibodies bind to peripheral nerve myelin, while polyclonal antibodies can bind to peripheral nerve axons [171]. Experimental demyelinating neuropathies develop after immunization with sulfatide [172] or passive transfer of patient serum from a patient with an IgM monoclonal anti-sulfatide antibody [173].

Other IgM Target Antigens

Sulfated Glucuronyl Paragloboside (SGPG)

SGPG and other sulfoglucuronosyl glycosphingolipids are present in axons and myelin in human peripheral nerve [174]. IgM binding to the glycolipid SGPG occurs in some patients with IgM anti-MAG antibodies. Anti-MAG antibodies that cross-react with SGPG more often bind to axons, while anti-MAG antibodies without SGPG cross-reactivity usually bind to areas of noncompact myelin [175]. Anti-SGPG antibodies are not strongly associated with a specific clinical syndrome and may occur in demyelinating neuropathies, motor syndromes, and other disorders [123, 127, 176, 177]. There is no clear clinical indication to test for anti-SGPG antibodies. Immunization with SGPG can cause an ataxia syndrome with inflammation in dorsal root ganglia [178].

Tubulin

IgM monoclonal antibodies that bind selectively to a specific epitope on β-tubulin, amino acids 301–314, occur in a few patients with chronic demyelinating neuropathies with similarities to CIDP [179–181]. Weakness is often slowly progressive and may be asymmetric. There has been a poor response to prednisone in the few patients described with this CIDP variant. IgM or IgG antibodies that bind to β-tubulin are also seen in some patients with classic Guillain–Barré syndrome.

Neurofilaments

An IgM M-protein with high-titer binding to the high molecular weight subunit (200 kDa) of neurofilaments has been reported in a patient with a chronic sensory axonal neuropathy [182]. Lower-titer serum IgM binding to neurofilaments has no specific clinical associations and has been described in many different disorders [183].

GM2 and GalNAc-GD1a Gangliosides

Monoclonal IgM antibodies with binding to both GM2 and GalNAc-GD1a gangliosides are associated with a chronic progressive demyelinating neuropathy [155, 156]. Clinical features include panmodal distal sensory loss, minimal weakness, and an ataxic gait. IgM binding to GalNAc-GD1a may also occur with chronic demyelinating motor neuropathies [184] and variant acute immune neuropathy syndromes with weakness, facial paresis, prodromal cytomegalovirus infections, and a good prognosis [34].

M-Proteins or Other Antibodies Without Binding to a Specific Antigen

Monoclonal gammopathies are characterized by the proliferation of a clone of plasma cells that produces a homogeneous monoclonal antibody [185, 186]. No antigenic target is generally identified for IgA and IgG monoclonal proteins (M-proteins). Some IgM M-proteins have no identified antigenic target. Neuropathy syndromes associated with IgG or IgA are different from those with IgM [187]. Some distinctive neuropathy syndromes are associated with serum M-proteins without defined antigenic targets. These include POEMS syndrome [188, 189], Waldenström's macroglobulinemia [133, 190], amyloidosis [191, 192] and similar disorders [193], cryoglobulinemia [194], and scleromyxedema [195]. There may be an increased frequency of IgG or IgA M-proteins without identified antigenic targets associated with some neuropathy syndromes, including CIDP [196].

POEMS (Crow–Fukase) Syndromes

POEMS is a multisystem clinical syndrome that is associated with serum IgG or IgA M-proteins [188, 189]. POEMS is an acronym for polyneuropathy, organomegaly, endocrinopathy (and edema), M-protein, and skin changes. Not all features are required to make the diagnosis. Dominant

features are most often neuropathy, endocrine disorders, and fluid volume overload. The mean onset of POEMS syndrome is in the fifth decade. The polyneuropathy begins with distal panmodal sensory signs and symptoms, including paresthesias and pain. With time, often over several years, weakness can become a major cause of disability. Examination reveals diffuse, symmetric weakness that is more severe distally. Areflexia is common. Systemic manifestations vary. Organomegaly can involve the liver, lymph nodes, or spleen. Edema or anasarca is a common accompaniment of POEMS. Endocrinopathies are diverse, including diabetes or thyroid, adrenal, or gonadal failure (with gynecomastia or testicular atrophy). Skin disorders can include pigmentation, hypertrichosis, angiomas, and sclerodermatous changes. Some patients have only a subset of these disorders (incomplete POEMS syndromes). On nerve conduction studies in POEMS syndrome, demyelination accompanied by axonal loss is the rule [197, 198]. Slowed motor and sensory conduction velocities, along the length of nerves, are the most prominent demyelinating feature. Motor distal latencies are less prolonged compared to other demyelinating neuropathies, and conduction block is rare. Axon loss is reflected by low-amplitude compound muscle and sensory nerve action potentials. Nerve biopsies show uncompacted myelin lamellae and axon loss. A defining feature of POEMS syndrome is the presence of an IgG or IgA M-protein. M-proteins usually have a λ light chain (95 %) with restricted immunoglobulin light chain variable gene usage (IGLV1). Immunofixation is the most sensitive test in searching for a serum M-protein in POEMS as the amount of the M-protein is characteristically small. A Castleman's disease variant of POEMS has no clonal plasma cell proliferative disorder. Non-antibody biomarkers of POEMS diagnosis and disease activity include high serum levels of VEGF [199] and interleukin-12 [200]. In POEMS syndrome, X-ray screening for bone lesions is necessary as irradiation of a focal plasmacytoma can produce disease improvement. Treatment of diffuse disease involves risk stratification according to the clinical severity and can require chemotherapy or stem cell transplantation.

Waldenström's Macroglobulinemia

Waldenström's macroglobulinemia is an IgM-associated lymphoplasmacytic lymphoma. IgM monoclonal proteins, most commonly with κ light chains, are a hallmark of Waldenström's macroglobulinemia. In Waldenström's macroglobulinemia there is anemia (hemoglobin level less than 12.6 g/dl), higher levels of serum IgM monoclonal proteins, and lower frequency of demyelinating neuropathy and serum IgM binding to MAG compared to IgM monoclonal gammopathy of unknown significance (MGUS) [133, 190]. Rituximab may produce a more rapid fall in levels of total IgM and IgM-AAb in Waldenström's macroglobulinemia compared to MGUS patients. In Waldenström's macroglobulinemia patients, the presence of serum IgM binding to MAG is associated with more frequent distal weakness in the legs and demyelinating features (especially prolonged distal latencies) and more severe sensory axon loss, and the presence of serum IgM binding to sulfatide is associated with more severe axonal loss [133]. Other types of neuropathy in Waldenström's macroglobulinemia, or with IgM M-proteins, include mononeuritis multiplex or asymmetric, sensory–motor neuropathies associated with immunoglobulins, such as light chains or amyloid, deposited in nerve [126, 193, 201]. Hyperviscosity syndromes, associated with the high total levels of serum IgM and cryoglobulins, may be responsible for other manifestations such as bleeding, focal central nervous system signs, and organomegaly [202]. High levels of serum IgM (greater than 1,830 mg/dl) help to identify Waldenström's macroglobulinemia and its association with malignancy. In the presence of an IgM M-protein, high, or rising, levels of total IgM, or suppressed levels of IgG or IgA, indicate the necessity for increased vigilance in screening for Waldenström's macroglobulinemia, myeloma, or other hematopoietic neoplasms.

Cryoglobulinemia

Cryoglobulins are serum immunoglobulins that abnormally precipitate with cooling [203] and may redissolve with rewarming. Cryoglobulins composed of one type of immunoglobulin (type 1) are associated with lymphoproliferative disorders such as Waldenström's macroglobulinemia and are frequently asymptomatic [204]. Mixed cryoglobulins (types 2 and 3) are immune complexes composed of polyclonal IgG and mono- or polyclonal IgM, respectively. The IgM component of mixed cryoglobulins typically has rheumatoid factor activity and forms immune complexes by binding to the IgG Fc fragment. Mixed cryoglobulins are most often related to hepatitis C (up to 90 %) and other infections. Connective tissue diseases, especially Sjögren's syndrome (up to 15 %) and lupus, also predispose to mixed cryoglobulinemia. Some patients have "essential" syndromes with no other associated disease [205, 206]. The associated clinical syndrome of cryoglobulinemia is a triad of purpura, asthenia and arthralgias, and peripheral neuropathy. Serum features include low C4 complement levels and rheumatoid factor. Essential mixed cryoglobulinemia may be more severe than secondary syndromes with more frequent renal and peripheral nerve involvement. Polyneuropathy syndromes in mixed cryoglobulinemia include a predominantly sensory, often small fiber, axonal disorder and, with more active cryoglobulinemia, a more severe sensory–motor syndrome [194]. Nerve conduction studies show patchy axon loss. Nerve pathology in the sensory–motor neuropathies includes epineurial inflammatory vasculopathy involving small- and intermediate-sized vessels [207]. Axon loss can be multifocal. Treatments for mixed

cryoglobulinemias include corticosteroids and rituximab [208] and management of associated infections (interferon-α plus ribavirin in hepatitis C) or malignancy.

5 Autoantibody Testing of Autoimmune Neuromuscular Junction, Hyperexcitability, and Muscle Disorders

Elham Bayat and Henry J. Kaminski

Introduction

Serological evaluation for neuromuscular disorders expands commensurate with understanding of their autoimmune etiology. In myasthenia gravis (MG) and Lambert-Eaton syndrome (LES) and stiff person syndrome (SPS), there is a clear link between an autoantibody and disease pathogenesis, while the association of autoantibodies and inflammatory myopathies is less clear. Despite the uncertainty of the pathogenic role of autoantibodies in certain disorders, their detection may be useful in diagnosis and prognosis. This chapter reviews use of serological evaluation in diagnosis of neuromuscular junction disorders, hyperexcitability syndromes, and inflammatory muscle diseases.

Autoantibodies Associated with Neuromuscular Junction Disorders

There are two autoimmune disorders that compromise neuromuscular transmission, MG and LES [1, 2]. The pathology of MG is localized to the postsynaptic membrane of the neuromuscular junction where nicotinic acetylcholine receptors (AChRs) are reduced in number and function. In the majority of patients, antibodies directed against the AChR are responsible for the disorder, and detection of these antibodies strongly supports the diagnosis. Antibodies to the muscle-specific receptor tyrosine kinase (MuSK) are present in 20–40 % of AChR antibody-negative patients with generalized MG [3, 4]. MuSK antibodies are usually not observed in pure ocular myasthenia although rare patients have been reported with ocular myasthenia with MuSK antibody [5, 6]. Classification as seronegative MG now applies to patients without AChR or MuSK antibodies using conventional assays at presentation and at follow-up of 12 months. Antistriational muscle antibodies are also detected in patients with MG, usually in late-onset MG and in association with thymoma, but these are not diagnostic of an autoimmune neuromuscular transmission disorder. In LES, antibody-mediated voltage-gated calcium channel dysfunction causes reduced calcium influx to the nerve terminal leading to impaired release of acetylcholine. Serological testing for antibodies to calcium channels is highly sensitive and specific for LES. The sections below describe autoantibodies found in patients with LES and MG and focus on their diagnostic utility.

Acetylcholine Receptor Antibodies

AChR antibodies are detected in about 90 % of patients with generalized MG and in about 50 % of patients with MG involving only the ocular muscles [7]. Three commercially used tests for detection of AChR antibodies are the binding, modulating, and blocking assays. Each differs in methodology as well as sensitivity and specificity for diagnosis of MG.

Binding antibodies are identified by a standard radioimmunoassay. The binding assay should be used for initial screening of patients for suspected MG and is the primary assay used in reporting seropositivity in research studies. However, patients with mild disease and those who are early in their disease course are often seronegative (Fig. 5.1) [8, 9]. As a population, there is a moderate correlation between antibody concentration and disease severity. Titers fall with successful treatment and therefore may be used as a measure of therapeutic response; however, ultimately clinical response is the only true measure of efficacy. However, it must be

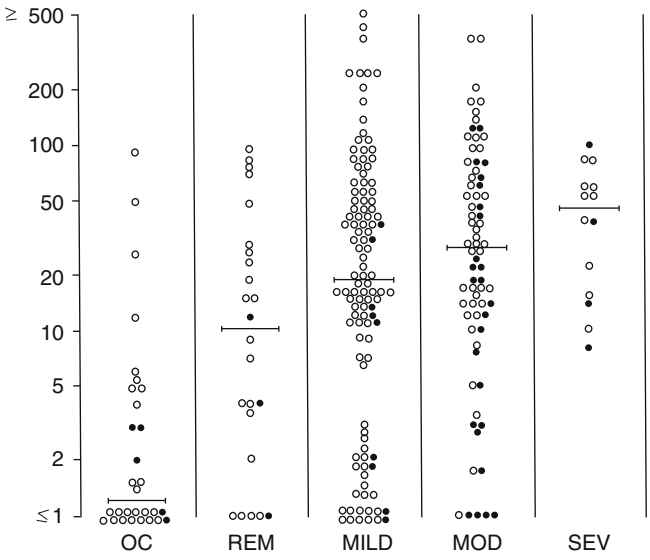

Fig. 5.1 Distribution of AChR binding levels (nM) in 250 patients with myasthenia gravis as a function of the severity of the disease. *OC* ocular myasthenia, *REM* remission, *MOD* moderate, *SEV* severe disease (Reprinted from Limburg et al. [8])

appreciated that an individual antibody level in an individual patient is not predictive of the severity of the disease; a patient with a low level may have severe weakness. AChR antibodies are polyclonal and all are not pathogenic, which offers an explanation for why an individual patient may have high titers but be in remission. Also, about 15 % of patients initially found to be seronegative become positive a year later [10]. Therefore, there is value in retesting to confirm a diagnosis if AChR antibodies are initially negative.

About 10 % of otherwise typical patients with MG do not have detectable AChR antibodies. Antibodies against constituents of the motor endplate that are not detected by the conventional assays probably cause some cases of "seronegative" MG, but antibodies directed at other endplate components, including MuSK, are also likely pathogenic [11, 12].

Binding AChR antibodies are highly specific for MG, but they are rarely detected in patients with other conditions (Table 5.1). False-positive binding antibodies are observed in amyotrophic lateral sclerosis (3–5 %), polymyositis (<1 %), and other neurological conditions at low levels [13]. LES is often misdiagnosed as MG, and it is particularly important to appreciate that about 7 % of patients with LES may have antibodies directed against the AChR [8, 9]. Careful electrodiagnostic and serologic testing for calcium channel antibodies should differentiate the two conditions. AChR antibodies are rarely identified in non-neurologic disorders including systemic lupus, thymoma without MG, primary biliary cirrhosis, and in first degree relatives of patients with MG [14–16].

Serological confirmation of the diagnosis of MG is often more difficult in patients with only ocular manifestations. At most, 70 % of patients with ocular myasthenia have AChR binding antibodies. There are several potential factors that influence the susceptibility of the ocular muscles to MG and the low seropositivity of these patients [17, 18]. One appears to relate to the source of antigen for the binding assay. Because the AChR is derived from partially denervated muscle, or cultured muscle cells, there is a high concentration of the fetal isoform of the AChR. One report indicates that if adult AChR produced by genetically engineered cells is used for the radioimmunoassay, then seropositivity rates are higher, in particular, the seropositivity rate for ocular myasthenia is increased about twofold [19]. However, this test is not widely commercially available.

AChR-modulating antibodies are detected using cultured, human cells, which express primarily the fetal AChR. These antibodies when applied to the cell cultures increase degradation of AChR by cross-linking receptors. The reduction of receptors is detected by a decrease in binding of radioactive bungarotoxin. The modulating assay has a similar sensitivity but is technically more difficult than the binding assay. This assay should be performed in patients who test negative for binding antibodies (Table 5.1). The sensitivity of this assay is similar to the binding assay, but performing the combination of binding and modulating assays raises the sensitivity of detection by approximately 5 %. False-positive results are problematic, and technical errors should be considered especially in the setting of a normal binding and blocking results [8, 9, 16].

AChR-blocking antibodies prevent the binding of bungarotoxin. The assay involves preincubating the antigen source with sera and then incubating with ^{125}I-labeled bungarotoxin. A decreased level of binding indicates the presence of blocking antibodies. Less than 1 % of patients have blocking antibodies without detectable binding antibodies, and therefore, blocking antibodies should not be ordered as a screening test in the authors' opinion [8, 9, 16]. The assay is positive in roughly 50 % of patients with generalized myasthenia. They are rarely positive in other conditions and, therefore, may be of some utility in differentiating patients with a possible false-positive binding assay.

MuSK antibodies occur in up to 50 % of patients with MG who are negative for AChR antibodies [4]. MuSK is a neuromuscular junction protein that plays an important role in the clustering of AChR on the postsynaptic surface. The antibodies are predominantly of the IgG4 subclass which suggests they do not activate complement as a pathogenic mechanism in contrast to AChR antibody-associated MG. The patients tend toward having a predominance of bulbar manifestations, and the response to cholinesterase inhibitors is variable. Patients with MuSK antibodies appear to respond less well to immunosuppressive treatments, while plasma exchange appears preferentially effective. The presence of MuSK antibodies is not associated with thymoma [20]. MuSK antibody detection aids in diagnosis and may assist in therapeutic

Table 5.1 Acetylcholine receptor antibody tests

	Sensitivity (%)			
Antibody test	OcMG	Mild	Mod-Sev	False positive
AChR binding	71 %	88	93	LES, graft-versus-host disease, immune-mediated liver disorders, healthy relatives of MG patients, thymoma, and rarely lung cancer and motor neuron disease
AChR blocking	30	52	66	LES, curare-like muscle relaxants
AChR modulating	72	89	91	Sample damage (bacterial contamination, heating, hemolysis) if modulating antibody +, but others negative suspect false elevation

Adapted from Howard et al. [9]
AChR acetylcholine receptor, *OcMG* ocular myasthenia, *Mod-Sev* moderate to severe *LES* Lambert-Eaton syndrome

choices. The clinical picture of MuSK antibody-associated neuromuscular disorders and in patients with atypical myopathic presentations their evaluation should be considered.

Striational Antibodies

Striational antibodies were the first autoantibodies discovered in patients with MG. Nearly half of patients with MG presenting after the age of 50 years have striational antibodies; however, normal individuals above the age of 60 have high rates of striational antibody detection limiting their diagnostic value [21]. These antibodies are heterogeneous and reactive against thymic myoid cells as well as the contractile elements of skeletal muscle including titin, ryanodine receptor, actin, myosin, potassium channels, and other muscle proteins [22]. Titin and ryanodine receptor antibodies have been found in association with the presence of thymoma [23, 24]. Striational antibodies are present in about a quarter of patients with MG and up to 90 % of patients with MG and concurrent thymoma [25, 26]. Patients with striational antibodies and no radiographic evidence of thymoma, if they do not undergo a therapeutic thymectomy, should have serial imaging performed. A progressive rise in antistriational antibody titers may be the first indication of thymic tumor recurrence, but their clinical usefulness in monitoring recurrence compared to chest imaging is not known. Rarely, striational antibodies may be present in the absence of AChR antibodies [27].

Titin antibodies are detected in 90 % of MG patients with thymoma and are almost never detected in early-onset MG with thymic hyperplasia [23]. Titin antibodies are associated with more severe MG in late-onset patients, but there is no convincing evidence that titin antibodies are pathogenic [28]. In older patients the specificity of titin antibodies for thymoma is much lower, and they are found in about half of late-onset patients with thymic atrophy.

Ryanodine receptor (RyR) antibodies are detected in about half of MG patients with thymoma, rarely in late-onset MG patients without thymoma, and never in early-onset MG patients without thymoma [29, 30]. They are often found in patients with an invasive or malignant thymoma [31]. Thymoma patients with RyR antibodies, especially those with high concentrations, have more severe clinical manifestations of MG than RyR antibody-negative thymoma patients. RyR antibodies could prove to be helpful in identifying thymoma patients at risk for developing MG with poor prognosis. However, at present, tests for RyR and titin antibodies are not available commercially in the United States.

Ten to fifteen percent of patients with LES have antistriational antibodies, regardless of whether a lung cancer is present. Also, individuals with lung cancer, autoimmune liver disease, undergoing penicillamine treatment, and thymoma without MG may have striational antibodies [27]. Striational antibodies are detected in about 90 % of thymoma patients but also in 20–30 % of non-thymoma patients leading to the problems of false positives, either suggesting a thymoma in a myasthenic or myasthenia in a nonmyasthenic.

The diagnostic utility of striational antibodies for thymoma detection is dependent on patient age [21]. Under age 20 years, striational antibody studies are not useful since the probability of a thymoma is so low in this age group that results of antibody testing do not significantly alter the clinical suspicion for the tumor. In patients older than 60 with a relatively high frequency of thymoma and increased rates of false-positive values, the positive predictive value of the test is poor, and so the test does not offer additional diagnostic value. In patients between 20 and 60 years, a positive test increases the likelihood of a thymoma being present. Unfortunately, striational antibody testing is not sensitive or specific enough to guide whether chest imaging should be performed, and therefore, all patients with MG should undergo imaging in search of a thymoma.

Calcium Channel Antibodies

The development of diagnostic assays for calcium channel autoantibodies was largely dependent on identification of toxins from cone snails that bind specifically to calcium channel subtypes [32]. The ω-conotoxin MVIIC binds P/Q-type channels expressed at motor nerve terminals, while ω-conotoxin GVIA binds N-type channels of central and autonomic synapses. Calcium antibodies in LES patients are

measured by a radioimmunoassay using immunoprecipitation of ^{125}I-conotoxin-labeled solubilized, calcium channel extracts [33]. Calcium channel antibodies to either channel isoform are detected in 95–99 % of LES patients. Small cell lung cancers express calcium channels of various types and presumably induce an immune response with production of autoantibodies that cross-react with normal neuronal calcium channels. P/Q-type calcium channel antibody testing is a highly reliable method of confirming the diagnosis of LES. Calcium channel antibodies are detected in almost 100 % of LES patients with cancer and in 90 % of nonparaneoplastic LES patients. Although antibody concentrations do not correlate well with clinical severity across groups of patients [34], in a single individual, calcium channel antibody titers do decrease with clinical improvement [35].

Calcium channel antibodies are detected in some patients with paraneoplastic cerebellar degeneration and other paraneoplastic syndromes without LES, in small cell lung cancer and ovarian carcinoma patients without LES, and in some MG patients. Fewer than 2 % of normal control patients possess calcium channel antibodies. False-positive tests are rare and occur in clinical situations that are easily differentiated from LES on clinical or electrodiagnostic grounds. Immunosuppressive treatment of LES patients often leads to a suppression of calcium channel antibody levels and negative results of serologic testing. This observation needs to be considered in patients with possible LES who have been treated with corticosteroids or other immunosuppressives for presumed MG or polymyositis.

Neuronal AChR Antibodies

Neuronal AChR antibodies have also been detected in subacute autonomic neuropathy and neuromyotonia with autonomic dysfunction [36]. The AChR in autonomic ganglia mediates fast synaptic transmission. Antibodies against ganglionic AChR are measured by a radioimmunoassay with immunoprecipitation of ^{125}I-epibatidin-labeled AChR from peripheral neuroblastoma membranes [37]. Autonomic dysfunction is a feature of LES that may be related to the presence of antibodies to neuronal nicotinic AChR in autonomic ganglia. Antibodies specific for the neuronal ganglionic AChR have also been found in Isaacs syndrome [38].

Other Autoantibodies in Neuromuscular Transmission Disorders

Autoantibodies are observed at higher frequencies among patients with MG. Thyroid peroxidase, thyroglobulin, gastric parietal cell, and glutamic acid decarboxylase (GAD65) autoantibodies are found at a frequency two to three times above that of neurological controls [39]. The same is true for patients with LES [40]. Detection of these antibodies in a patient with a strong clinical suspicion of an autoimmune neuromuscular transmission disorder, but without detectable antibodies against the AChR or calcium channels, provides indirect evidence for the diagnosis of MG or LES.

Autoantibodies Associated with Hyperexcitability Disorders

Three neuromuscular disorders associated with increased muscle activity appear to be caused by autoantibodies, rippling muscle disease, neuromyotonia, and stiff person syndrome. Rippling muscle syndrome has inherited and immune etiologies, including association with MG and thymoma [41, 42]. Patients experience slow, undulating muscle movements sometimes with muscle ache and stiffness. Some consider cramp-fasciculation syndrome and acquired rippling muscle syndrome as autoimmune disorders that are part of a pathophysiological continuum with neuromyotonia [38].

Neuromyotonia (Isaacs syndrome, continuous muscle fiber activity) is an autoimmune disorder with hyperexcitability of peripheral motor nerves causing muscle stiffness and cramps on attempted muscle contraction, slow relaxation after voluntary movement, and often visible myokymia. Needle electromyography in patients with visible myokymia shows characteristic bursts of high-frequency motor unit action potential discharges. Neuromyotonia may occur as a paraneoplastic disorder related to lung cancer or thymoma [30] and may occur in association with MG without thymoma. In a variant of neuromyotonia called as Morvan's syndrome, besides muscle manifestations, patients have CNS dysfunction, including confusion, memory loss, insomnia, hallucinations, or seizures. In all these disorders the cause appears to be antibodies against voltage-gated potassium channels. The differential affinity of antibodies to subunits of the potassium channel may explain the different tissue involvement (Isaac, Moravan and VGKC-Ab limbic encephalitis) [43].

Potassium Channel Antibodies

VGKC are widespread in the peripheral, autonomic, and central nervous systems and play a key role in controlling neuronal excitability [44]. Autoimmune neuromyotonia appears to be caused by antibody-mediated dysfunction of voltage-gated potassium channels of peripheral nerves [45, 46]. Antibodies to VGKC have been described in half of patients with acquired neuromyotonia and are found in rare patients with myasthenia gravis but without neuromyotonia [30]. The VGKC antibodies in neuromyotonia are probably directed against potassium channels concentrated in the paranodal and

terminal regions of myelinated axons and may decrease channel density, either through increased degradation or by decreased expression of VGKC [47]. Their effect prevents potassium efflux and chronically lowers resting membrane potential, resulting in decreased repolarization and neuronal hyperexcitability. Passive transfer of neuromyotonia can be achieved by injection of purified VGKC antibodies from neuromyotonia patients into mice.

VGKC antibodies may be identified by a radioimmunoassay using immunoprecipitation of ^{125}I-dendrotoxin-labeled extracts of human frontal cortex. However, the sensitivity of the assay is low with antibodies detected in not more than half of patients. Immunohistochemistry using *Xenopus* oocytes, which express various different types of human potassium channels, detects antibodies in nearly all neuromyotonia patients [46], but the assay is not commercially available.

Stiff Person Syndrome

Stiff person syndrome is a rare disorder of the central nervous system with muscle manifestations characterized by continuous muscle contraction with spasm, progressive axial muscle spasm and rigidity [48], abnormal postures, and progressive disability. EMG studies demonstrate continuous motor activity in the paraspinal muscles in patients with SPS which is typically decreased by intravenous diazepam, sleep, and local or general anesthesia. Autoantibodies to the GABA-synthesizing enzyme glutamic acid decarboxylase (GAD), present in about 60–85 % of patients, have indicated an autoimmune pathogenesis. Among patients with SPS, there is evidence of marked intrathecal GAD antibody synthesis [49–51].

GABA-Synthesizing Enzyme Glutamic Acid Decarboxylase (GAD)

GAD is an enzyme selectively concentrated in neurons secreting GABA and in pancreatic beta cells. In one study by Solimena et al. 20 of 33 (60 %) patients with stiff person syndrome had anti-GAD, making it the principal autoantigen in this syndrome [52, 53]. Although these antibodies associate with type I diabetes, their detection in the CSF is specific for neurologic disease. Although elevated GAD antibody titers is a specific marker for SPS, they are observed occasionally in patients with other neurologic manifestations without SPS, such as myoclonus, epilepsy, cerebellar ataxia, eye movement disorders, and neuromyotonia [49].

Amphiphysin Antibodies

Amphiphysin antibodies (amphiphysin Ab) are associated with paraneoplastic variant of SPS [54, 55]. Small cell lung and breast cancers are the most common [55]. Amphiphysin antibody-associated SPS is strongly associated with several clinical observations: cervical region stiffness, female sex, older age groups, electrophysiological abnormalities, and benzodiazepine responsiveness. The condition may respond to steroids and can dramatically improve with cancer treatment [49, 54]. The pathogenic role is suggested by passive transfer studies demonstrating that administration of purified IgG from an amphiphysin antibody-positive patient results in muscle stiffness and spasms [56, 57]. However, amphiphysin antibodies are not specific to SPS, as they are identified in several neurologic disorders, usually paraneoplastic cerebellar degeneration, sensory neuropathy, and limbic encephalitis, often coexisting with other onconeural antibodies [57, 58].

Autoantibodies Associated with Disorders of Muscle

Three distinct inflammatory myopathies (IM) are recognized: dermatomyositis (DM), polymyositis (PM), and inclusion body myositis (IBM). Although autoantibody testing is useful in diagnosis and prognosis of certain IM, the pathogenic role of these antibodies is uncertain. The autoantibodies may be an epiphenomenon of the immune destruction of muscle [59]. Autoantibodies to nuclear and cytoplasmic antigens are found in up to 80 % of patients with IM. Half of autoantibodies are of recognized specificity, i.e., myositis-specific antibodies, while others occur in association with systemic immune disorders. The myositis-specific autoantibodies (MSA) are unique to patients with myositis and are helpful in predicting manifestation of myositis, response to therapy, and prognosis. Most of MSA are associated with decreased risk of malignancy (except anti-155/140) [60]. To date, 60–80 % of patients with autoimmune myopathy are found to have at least one myositis-specific antibody (MSA) [60, 61], each of which is associated with a distinct clinical phenotype (Table 5.2).

Myositis-Specific Antibodies

Antisynthetase Autoantibodies

Aminoacyl-transfer RNA (tRNA) synthetases catalyze the binding of amino acids to their corresponding tRNA. Autoantibodies to six synthetases (histidyl, threonyl, alanyl, asparaginyl, isoleucyl, and glycyl-tRNA synthetase) are identified in patients with PM and less frequently in DM [64]. Each patient has only one of these autoantibodies. Despite individuals having antibodies to different types of the synthetases, patients share common clinical features, so-called antisynthetase syndrome, including PM, polyarthropathy, pulmonary fibrosis, scaling and cracking of the lateral

Table 5.2 Myositis-associated antibodies

Antibodies	Frequency (%)	Nature of target antigens	Clinical features	Corticosteroid responsiveness	Prognosis
Myositis-specific autoantibodies					
			Antisynthetase syndrome		
Anti-Jo-1	20–30	Histidyl-tRNA synthetase (50KD)	3/4 of patients have interstitial lung disease	Moderate	Fair
Anti-PL-7	<5	Threonyl-tRNA-synthetase (80 kD)		Moderate	Fair
Anti-PL-12	<5	Alanyl-tRNA-synthetase (110 kD)	Correlate more with pulmonary fibrosis	Moderate	Fair
Anti-OJ	<5	Isoleucyl-tRNA-synthetase		Moderate	Fair
Anti-EJ	<5	Glycyl-tRNA-synthetase (75 kD)		Moderate	Fair
Anti-KS		Asparaginyl-tRNA-synthetase	Correlate more withpulmonary fibrosis	Moderate	Fair
Anti-SRP	<5	Signal recognition particle (SRP)	Severe, refractory PM myocarditis	Poor	Poor
Anti-Mi-2	<8	Helicase family protein	Acute DM	Good	Good
Anti-KJ	<1	Translation factor? (30–34 kD)	PM with pulmonary fibrosis		
Anti-Fer	<1	Elongation factor 1 alpha (48 kD)	Nodular myositis		
Myositis-overlap syndrome-associated autoantibodies					
Anti-Ku	20–30	70 kD/80 kD DNA-PK regulatory subunit	PM-scleroderma (Japanese)	Good	Good
Anti-PM-Scl	<10	Nucleolar protein complex	PM-scleroderma (Caucasians)	Good	Good
Anti-U2RNP	<5	U2 small nuclear RNP	PM-sclerodrerma	Good	Good
Anti-DN-PKcs	<5	460 kD DNA-PK catalytic subunit	PM, PM-SSc	Good	Good
Other muscle-related antibodies					
Anti-U1 RNP	10	U1 small nuclear RNP (pre-mRNA splicing factor)	MCTD, PM overlap, SLE	Good	Variable
Anti-SSA/Ro	<20	Y1-Y5 scRNP (60 kD/52 kD and Y1-Y5 RNA)	PM/DM with Sjögren's syndrome	Good	Variable
Anti-56kD	87	56-kD unidentified nuclear RNP	Seen in all Ims; predict muscle involvement in SLE		
Anti-calpastatin	24	Inhibitor of calpain (72 kD)	Predominantly found in rheumatoid arthritis		

Data from Miller [62] and Targoff [63]
tRNA transfer RNA, *SRP* signal recognition particle, *PM* polymyositis, *DM* dermatomyositis, *PK* protein kinase, *RNP* ribonucleoprotein, *SSc* systemic sclerosis, *MCTD* mixed connective tissue disease, *SLE* systemic lupus erythematosus, *mRNA* messenger RNA, *IM* inflammatory myopathy

fingers (mechanic's hand), and (less frequently) Raynaud's phenomenon. Their presence predicts moderate response to immunotherapy and persistent disease [65].

Among the autoantibodies to tRNA synthetases, anti-histidyl-tRNA or anti-Jo1 is the most common, found in 25–30 % of patients with myositis [61, 66]. Anti-Jo-1 continues to be a particular focus because of its relative frequency as the most common "myositis-specific" autoantibody (MSA) and its strong association with the clinical manifestations of the antisynthetase syndrome [67]. About three quarters of PM and DM patients with anti-Jo-1 antibodies have interstitial lung disease. The anti-Jo-1 patients have a relatively good prognosis compared with other ILD patients [67]. These patients usually are considered to have lower cancer risk. The antibodies are associated with the HLA-DR3 or HLA-DRw6 haplotype. The other anti-tRNA synthetases are much less common. The prevalence of each of these antibodies in patients with DM or PM is approximately 1–5 % [61, 66]. Anti-alanyl-tRNA and anti-asparaginyl synthetase antibodies correlate more closely with pulmonary fibrosis with myositis compared to the four other tRNA synthetases [66]. Presence of anti-Jo-1 antibodies essentially excludes the diagnosis of inclusion body myositis, although these patients may have low titers of nonspecific autoantibodies and other associated immune disorders [66, 68–70].

Anti-signal Recognition Particle Antibodies

Antibodies against SRP occur in 3–5 % of PM patients [71, 72]. The SRPs are cytoplasmic proteins that facilitate translocation of newly translated proteins and direct them to the endoplasmic reticulum. Patients with these antibodies usually have an acute onset of a severe myositis with cardiac involvement and respond poorly to corticosteroids. Because of the poor response to treatment and early myocarditis, the prognosis is poor. Necrotizing myopathy is not uncommon and supported with findings in muscle biopsy consistent with necrotic fibers [72, 73].

Anti-Mi-2

Antibodies against Mi-2 react with a 220-kD nuclear antigen which is of unknown function. Unlike antisynthetases, anti-Mi-2 is mainly found in DM patients with a prevalence of 20 % [61, 74, 75]. Anti-Mi-2-positive patients present with prominent dermatologic findings and an acute myositis. In contrast to the anti-SRP-positive patients, they respond well to steroids and have a relatively good prognosis. Despite a similar clinical presentation, DM seropositive Mi-2 patients have a lower risk of malignancy compared with DM anti-Mi-2 seronegative [61, 75].

Anti-p155/140 and Anti-MJ (Anti-NXP-2)

Anti-p155/140 is present in up to 20 % of DM patients [76–78]. DM patients who are anti-p155/140 seropositive have a significantly higher risk of cancer (71 %) compared with DM seronegative patients (11 %) [61, 77, 78].

Anti-MJ has been found primarily in patients with juvenile DM and is associated with calcinosis (54 %) and joint contracture [61, 72]. The function of the antigenic targets of these antibodies is not known.

Myositis-Overlap Antibodies

PM and DM which occur in association with other well-defined connective tissue diseases are defined as overlap syndromes (OS). Several antibodies serve as serologic markers for the OS, and some investigators suggest that the myositis occurring with OS responds better to treatment [79]; however, this opinion is not universally shared [80]. The major OS and associated muscle-related antibodies are described below.

Polymyositis-Scleroderma Overlap Syndrome

Myositis occurs in up to 17 % of patients with scleroderma and may develop in patients with progressive systemic sclerosis or CREST syndrome (calcinosis cutis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia). Up to a quarter of such patients have antibodies to PM-Scl, a nuclear antigen that may be important in ribosomal assembly [80]. Anti-PM-Scl antibodies are identified in about 8 % of DM and PM patients and in 3 % of patients with systemic sclerosis without muscle disease. Therefore, identification of these antibodies is not necessarily diagnostic of muscle disease. Anti-PM-Scl antibodies are found in 75–100 % of patients with HLA-DR3. Patients with scleroderma who are seropositive for anti-Pm-Scl usually have a young age of onset (average 33 years), a high rate of lung involvement, and a trend toward a higher rate of kidney involvement (25 %) [61]. The response to steroid therapy and the long-term outcome appears better in patients with this syndrome with a more favorable response of immunosuppression [81]. Recognition of the anti-PM-Scl antibody-associated overlap syndrome may be of practical importance, because patients may not require aggressive therapy.

Mixed Connective Tissue Disease (MCTD)

MCTD has features of several connective tissue diseases, i.e., systemic lupus erythematosus (SLE), scleroderma, and rheumatoid arthritis, but does not fulfill clinical criteria to diagnose a specific disorder. DM occurs more frequently than PM in the context of MCTD. The anti-U1RNP antibody, directed at a ribonucleoprotein [77], is most commonly associated with MCTD, and 16–79 % of patients with this antibody will have myositis [81]. However, the antibody is not specific for myositis or MCTD and is found in patients with SLE. The clinical features resemble those of patients with

anti-tRNA synthetase syndrome. Prognosis depends largely on the degree of major organ involvement.

Lupus Myositis and Other Overlap Syndromes

PM occurs in 4–16 % of patients with SLE and differs little in presentation from patients without lupus. No meaningful differences exist in extent of creatine kinase elevation at presentation or during the course of the disease, duration of symptoms, degree of weakness, or response to therapy [82]. Anti-56-kD nuclear RNP antibody is a relatively specific marker for primary myositis, occurring rarely in patients with SLE without myositis and thus may help predict muscle involvement in patients with SLE. The antibody is found among patients with all types of myositis and some patients with pure connective tissue disorders [83]. Patients with Sjögren's syndrome and rheumatoid arthritis less commonly develop a myositis. Muscle disorders in these patients more often are related to corticosteroid treatment or disuse [65].

Forearm Exercise Testing

6

Eugene Dulaney and Bashar Katirji

Introduction

In 1951, Brian McArdle described a patient with muscle cramps on exertion and failure to generate lactate when exercising under ischemic conditions [1]. He postulated that the patient's muscle disease resulted from "a gross failure of the breakdown of glycogen to lactic acid," which was later shown to be due to muscle phosphorylase deficiency [2, 3]. Subsequently, the ischemic forearm exercise test, first used by McArdle, has become the most widely employed assay of muscle anaerobic metabolism.

Exercise testing in muscle disorders quantitates exercise capacity, reproduces exercise-induced symptoms, and helps define the pathophysiology of exercise limitations. Exercise is a useful tool for evaluating the integrity of the metabolic pathways which power muscular work. Hence, exercise testing is of particular use in detecting disorders of muscle energy metabolism. Forearm exercise test is relatively simple to perform and interpret and has proved to be a robust tool in diagnosing defects in muscle energy metabolism

Exercise testing may be carried under conditions of ischemia or unrestricted blood flow. Reports of complications of the ischemia during forearm exercise testing in patients with glycogenoses have led some researchers to modify the test so that muscle ischemia is not intentionally produced [4–6]. Results of these modified forearm exercise tests have been similar to those of the ischemic forearm exercise testing.

Basic Principles

Forearm exercise testing is performed as a screening test for patients with suspected metabolic myopathies, due to defects in glycogenolysis and glycolysis (Fig. 6.1). It is also a useful test for myoadenylate deaminase deficiency. Ischemia blocks oxidative phosphorylation and ensures dependence on anaerobic energy pathways during exercise. An overview of these pathways is provided below.

During periods of maximal exercise and energy demand (high rate of adenosine triphosphate [ATP] hydrolysis), three anaerobic pathways are available to re-phosphorylate adenosine diphosphate (ADP). These include transfer of phosphate from phosphocreatine to ADP and the transphosphorylation of ADP catalyzed by myokinase to form ATP and adenosine monophosphate (AMP). However, the main source of ATP in anaerobic exercise is metabolism of muscle glycogen stores via glycolysis. During glycolysis, nicotinamide adenine dinucleotide (NAD) serves as a hydrogen acceptor, converting to NADH. The consequent elevation of the NADH-to-NAD ratio shifts the lactate dehydrogenase equilibrium from pyruvate toward lactate, resulting in a disproportionate increase in lactate. Alanine, produced via transamination of pyruvate, also increases during anaerobic glycolysis [7]. The accumulation of ADP shifts the equilibrium of the myokinase reaction toward production of AMP, and the combination of increased ADP and AMP promotes AMP deamination via myoadenylate deaminase, with production of ammonia, inosine monophosphate (IMP), hypoxanthine, and xanthine (Fig. 6.2) [8, 9]. Thus, lactate, ammonia, purine compounds, and alanine are by-products of ischemic exercise.

A regulatory relationship exists between these anaerobic pathways. Inorganic phosphate (Pi) accumulating as a net product of the creatine kinase reaction activates glycogenolysis at the level of glycogen phosphorylase [10]. AMP, IMP, and Pi produced by the myokinase/myoadenylate deaminase reactions also activate glycogenolysis [11]. Similarly, the $[H^+]$ derived from glycolysis promotes phosphocreatine hydrolysis and AMP deamination [12]. A disturbance in any

of these energy pathways can affect the remaining mechanisms for ATP production.

Lactate, pyruvate, ammonia, alanine, hypoxanthine, and related purine metabolites readily diffuse from working muscle. Their levels in venous blood can be used to monitor the metabolic pathways from which they arise. However, only lactate, ammonia, and sometimes pyruvate levels are followed in clinical practice. The venous concentration of a muscle metabolite after exercise depends on the activity of rate-limiting muscle enzymes and intensity of force generated per unit of muscle tissue. Thus, exercise of similar relative intensity is necessary for valid comparison of metabolite levels. In addition, the rate of metabolite efflux from working

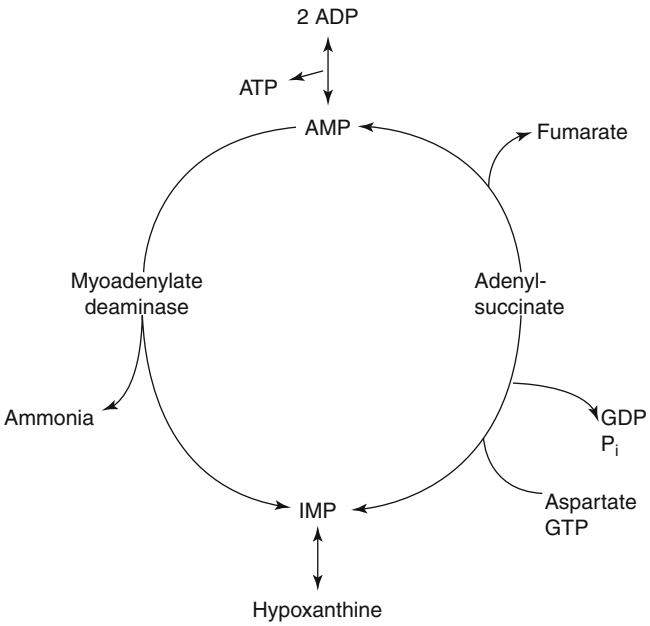

Fig. 6.2 The adenylate kinase, adenylate deaminase, and purine nucleotide cycle

muscle may modify levels of metabolites in blood. For example, a defect of lactate transport would be expected to delay the clearance of lactate from contracting muscle (see below). Finally, muscle blood flow, particularly following exercise, may affect the clearance rates of muscle metabolites. An exaggerated blood flow response to ischemic and aerobic exercise has been identified in myophosphorylase deficiency [6, 13].

Forearm Exercise Procedure

Protocols for performance of the forearm exercise testing are not standardized and differ somewhat between institutions. The procedure described below has been used successfully at University Hospitals Case Medical Center in Cleveland, Ohio, for over two decades.

The staff required for the forearm exercise testing includes a nurse or medical assistant for catheter insertion and blood sampling and a physician to oversee the test. Provisions must be made to rapidly transport the blood samples to a clinical laboratory. Materials needed for performing the forearm exercise testing include a sphygmomanometer, dynamometer, timer, ice bucket, phlebotomy supplies (intravenous catheter, syringes, alcohol swabs, gauze, etc.), and two sets of six blood drawing tubes (gray top [fluoride and oxalate] for lactate and green top [heparin] for ammonia) prelabeled as B (baseline) – 0, 1, 3, 6, and 10 min postexercise. Additional tubes for pyruvate collection may be also prepared, particularly if lactate dehydrogenase deficiency is suspected. Performing the forearm exercise test in the fasting or nonfasting state does not appear to alter the results [14].

Table 6.1 Forearm exercise procedure

1. Draw baseline (resting) samples of ammonia and lactate and place them on ice (make sure that the baseline samples are drawn after hand is rested for five minutes)
2. Ask the patient to hold the dynamometer and apply force to measure the maximal voluntary contraction (MVC). Calculate 80 % of the MVC
3. If done under ischemic conditions, place the sphygmomanometer cuff over the upper arm and inflate it above systolic blood pressure
4. Ask the patient to hold the dynamometer and perform repetitive forearm exercise by squeezing it once per second with a force aiming at 80 % of MVC. This standardized method of exercise is superior to nonstandardized exercise such as opening and closing the fist vigorously for 2 min [16]. If a muscle cramp or contracture occurs, exercise should be terminated and the cuff deflated immediately
5. After 1 min, the exercise is halted and the blood pressure cuff is quickly deflated (if done under ischemic conditions). Collection of blood samples without first deflating the cuff can result in false-positive results [17]
6. Collect venous blood samples immediately after the cuff is deflated (samples labeled 0) and at 1, 3, 6, and 10 min postexercise. Perform small blood draws between these intervals to keep the flow of the blood and preserve the patency of the vein
7. Place the blood samples on ice, and take them to the laboratory to be tested as soon as possible. Plasma lactate concentration may remain stable for several hours when samples are collected in grey top tubes containing sodium fluoride and potassium oxalate [18]. However, plasma ammonia concentration increases by 4 μmol/L per hour at 0 °C and by 25 μmol/L per hour at body temperature [19]. Thus, rapid chilling and processing of the ammonia samples is necessary to avoid spuriously elevated values

Prior to performing the forearm exercise test, the test should be explained in detail to the patient, and informed consent should be obtained. Patients should be aware that discomfort or cramping may occur and that there are rare reported cases of more serious complications after performing this test (see below). The importance of cooperation to achieve adequate exercise should be emphasized. Then, following determination of the patient's systolic and diastolic blood pressure in the dominant arm, a tourniquet is applied and an intravenous catheter inserted into the ipsilateral antecubital vein. Catheter placement in a hand vein or contralateral antecubital vein should not be done since this will result in reduced postexercise lactate values [14]. To prevent a premature rise of baseline lactate and ammonia, the patient should avoid making a forceful fist to help visualize the veins. Also, caution should be taken to prevent clotting of the catheter. This can be achieved by introducing a small amount of saline or heparin, which should be discarded before blood sample collection. Before starting the procedure, ensure that the catheter is in the vein by withdrawing a small amount of blood into a syringe [15]. The method in performing the forearm exercise test is described in Table 6.1.

Indications for the Forearm Exercise Test

The forearm exercise test is a screening test for patients with suspected metabolic myopathies, particularly the glycogenoses, before more expensive or invasive testing is performed. A final diagnosis of these disorders is usually established by appropriate biochemical or genetic testing (see Chap. 63). These disorders may present with a variety of clinical syndromes including exercise-induced muscle cramps, myoglobinuria, exercise intolerance, and weakness. Table 6.2 outlines a list of the clinical symptomatology in which the forearm exercise test is helpful or of low yield. It should be noted that the forearm exercise test is typically normal in patients with chronic fatigue syndrome [20].

Table 6.2 Indications for forearm exercise test

Clinical manifestations in which forearm exercise test is helpful
Exercise-induced myoglobinuria
Exercise-induced muscle pain or cramps
Exercise intolerance
Exertional fatigue
Myopathy with fixed weakness or myotonia
Clinical manifestations in which forearm exercise test is probably not helpful
Muscle cramps at night or unrelated to exercise
Diffuse muscle pain, continuous or at rest
Generalized fatigue

Although the test is usually performed in adults, a modified version has been performed successfully in children [4].

Forearm Exercise Test Findings

Normal Patterns

With effort near 80 % of MVC, the typical response to the forearm exercise test in normal subjects is as follows:

- Venous lactate level increases four- to sixfold over baseline, with the peak occurring at 1–2 min following exercise (i.e., a rise in venous lactate from 1 to 4–6 mmol/L).
- Venous ammonia level rises five- to tenfold, with peak levels usually seen at 2–5 min following exercise.
- Venous ammonia and lactate levels are linearly related. Thus, subjects in whom lactate levels are low due to poor effort show proportionally low ammonia levels [15, 21].

Abnormal Patterns

Abnormal responses to forearm exercise test occur in predicted patterns, as follows:

- No rise in lactate with increase in ammonia suggests a glycolytic or glycogenolytic disorder.

- A normal rise in the lactate level with no rise in the ammonia level suggests myoadenylate deaminase deficiency.
- No rise in lactate level with marked increase in pyruvate level suggests a deficiency of lactate dehydrogenase.
- If lactate and ammonia levels are proportionally low, this is usually due to poor patient effort. However, the rare occurrence of myoadenylate deaminase deficiency along with a glycogenosis ("double trouble") may also produce this finding [22].
- An elevated baseline level of serum lactate may occur if the forearm muscles are contracted while the baseline sample is taken.
- Mitochondrial disorders myopathies may be associated with elevated baseline lactate [14], as may numerous other toxic and metabolic disorders [5, 23].
- An elevated baseline serum ammonia level may be due to medications such as valproic acid, smoking, and undue exertion prior to the test [24]. In the setting of a baseline elevation of ammonia or lactate, the validity of the forearm exercise test is questionable, and caution should be used in interpreting the results.

Findings in Metabolic Myopathies

The clinical manifestations, inheritance, definitive diagnosis, and treatment of these disorders are detailed in Chap. 63. The common findings on forearm exercise test in patients with metabolic myopathies are summarized in Table 6.3 and discussed below.

Myophosphorylase Deficiency

Myophosphorylase deficiency (glycogenosis type V; McArdle's disease) is the prototypical glycogenosis and the most common one. Myophosphorylase catalyzes the first step in glycogen breakdown by removing 1,4 glucosyl residues phosphorylitically, with liberation of glucose-1-phosphate (Fig. 6.1). Absence of myophosphorylase prevents use of muscle glycogen stores for glycolysis and thereby blocks any rise in lactate during forearm exercise test (Fig. 6.3a). In contrast, ammonia levels are typically higher than those recorded in normal subjects, probably due to increased deamination of AMP [25]. Although, the forearm exercise test is capable of identifying the vast majority of patients with myophosphorylase deficiency, it can yield low-normal elevation of lactate in rare patients with milder phenotypes of this disorder [26, 27]. Biochemical assay of myophosphorylase levels in muscle tissue or genetic testing for mutations in the myophosphorylase gene is required for definitive diagnosis.

Table 6.3 Forearm exercise test findings in metabolic myopathies

Disorder	Forearm exercise test findings[a]
Glycogenosis[a]	
Myophosphorylase deficiency (glycogenosis V, McArdle's disease) (see Fig. 6.3a)	No rise in lactate in complete absence of the enzyme Possible normal rise in partial deficiency Possible exaggerated rise in ammonia
Phosphofructokinase deficiency (glycogenosis VII, Tarui's disease)	No or little rise in lactate
Phosphorylase kinase deficiency (glycogenosis VIII)	Normal rise in lactate
Phosphoglycerate kinase deficiency (glycogenosis IX)	No or little rise in lactate
Phosphoglycerate mutase deficiency (glycogenosis X)	Attenuated rise in lactate
Lactate dehydrogenase (glycogenosis XI)	No rise in lactate and marked increase in pyruvate
Acid maltase deficiency (glycogenosis II)	Normal rise in lactate
Debrancher deficiency (glycogenosis III, Cori-Forbes disease)	No or little rise in lactate
Brancher deficiency (glycogenosis IV, Andersen's disease)	Normal rise of lactate
Phosphoglucomutase deficiency (glycogenosis XIV)	Normal rise in lactate
Glycogen synthase deficiency (glycogenosis 0)	No rise in lactate
Beta-enolase deficiency	No rise in lactate
Other metabolic myopathies	
Lactate transporter defect	Normal rise in lactate with prolonged delay in return to baseline
Myoadenylate deaminase deficiency (see Fig. 6.3b)	No rise in ammonia (and hypoxanthine) with normal lactate rise
Carnitine palmitoyltransferase II deficiency (see Fig. 6.3c)	Normal lactate rise with possible exaggerated increase in ammonia

[a]All glycogenoses result in normal rise of ammonia

Phosphofructokinase Deficiency

Phosphofructokinase deficiency (glycogenosis type VII; Tarui's disease) results in failure of a key regulatory step in glycolysis, the conversion of fructose-6-phosphate to fructose-1, 6-diphosphate. Lack of functioning phosphofructokinase impedes glycolysis and typically prevents an elevation in lactate, a finding identical to that of myophosphorylase deficiency [28, 29]. However, an otherwise classic case of phosphofructokinase deficiency with reproducible elevation of serum lactate 2.5 times above baseline during forearm exercise test has been reported [30]. An adult-onset variant of phosphofructokinase deficiency exists, demonstrating

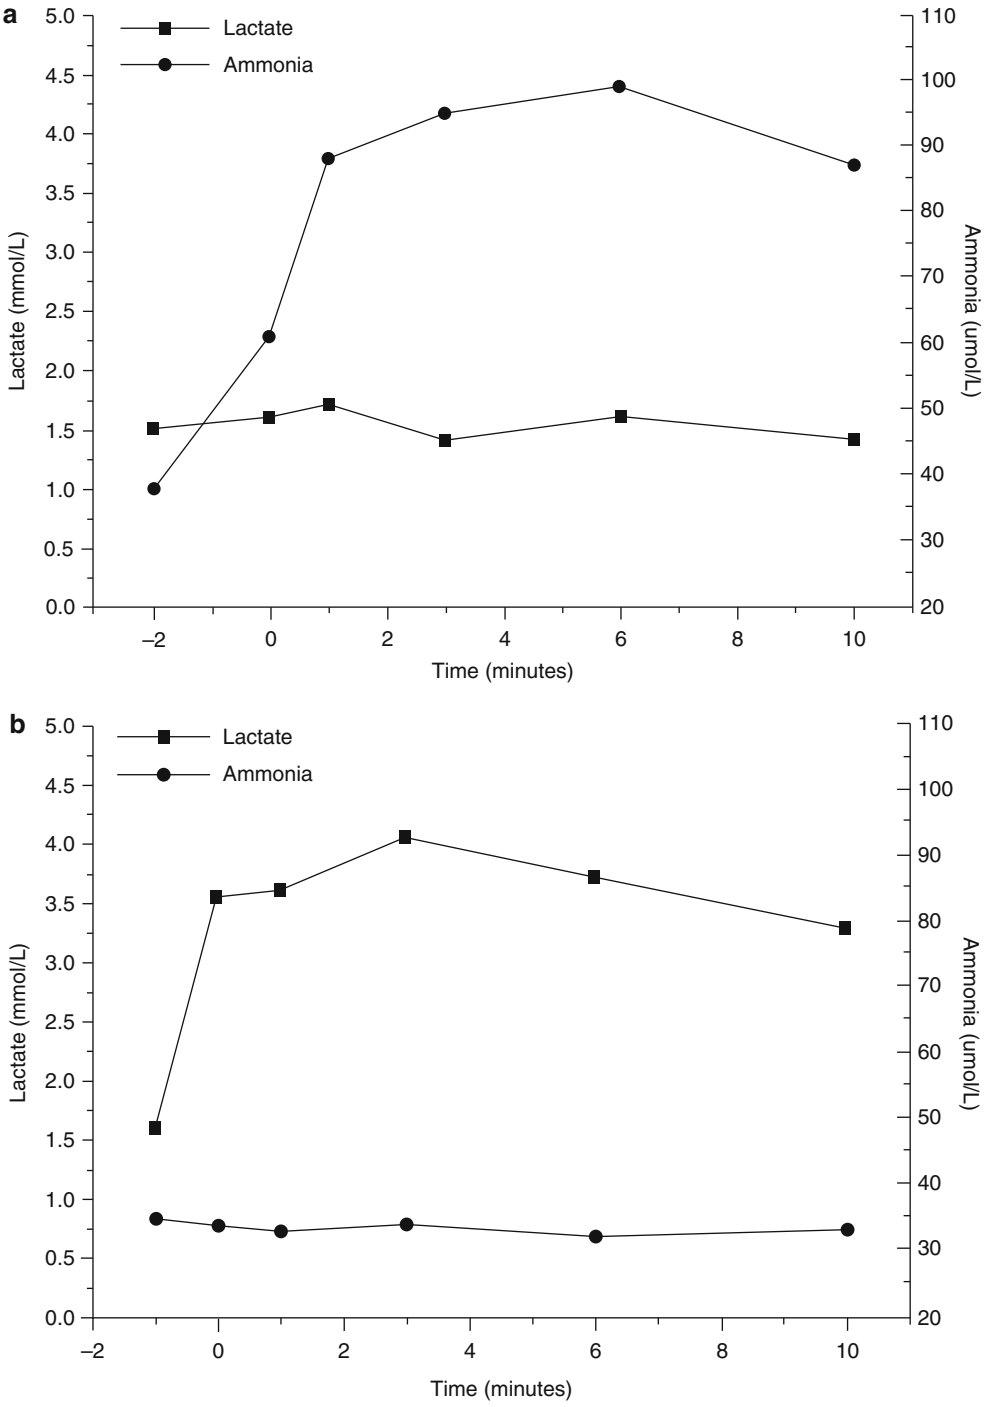

Fig. 6.3 (**a**) The forearm exercise test in a 10-year-old boy with exercise intolerance and cramps. Note the flat lactate curve (no rise) with normal elevation of ammonia. Subsequent investigations confirmed McArdle's disease. (**b**) The forearm exercise test in a 35-year-old woman with myalgia, fatigue, and elevated creatine kinase. Note the flat ammonia and normal lactate curve. Immunostaining and biochemical analysis confirmed myoadenylate deaminase deficiency. (**c**) The forearm exercise test in a 12-year-old girl with repeated episodes of myoglobinuria after strenuous exercise. Note the normal rise in lactate and ammonia after exercise. Subsequent investigations revealed CPT II deficiency

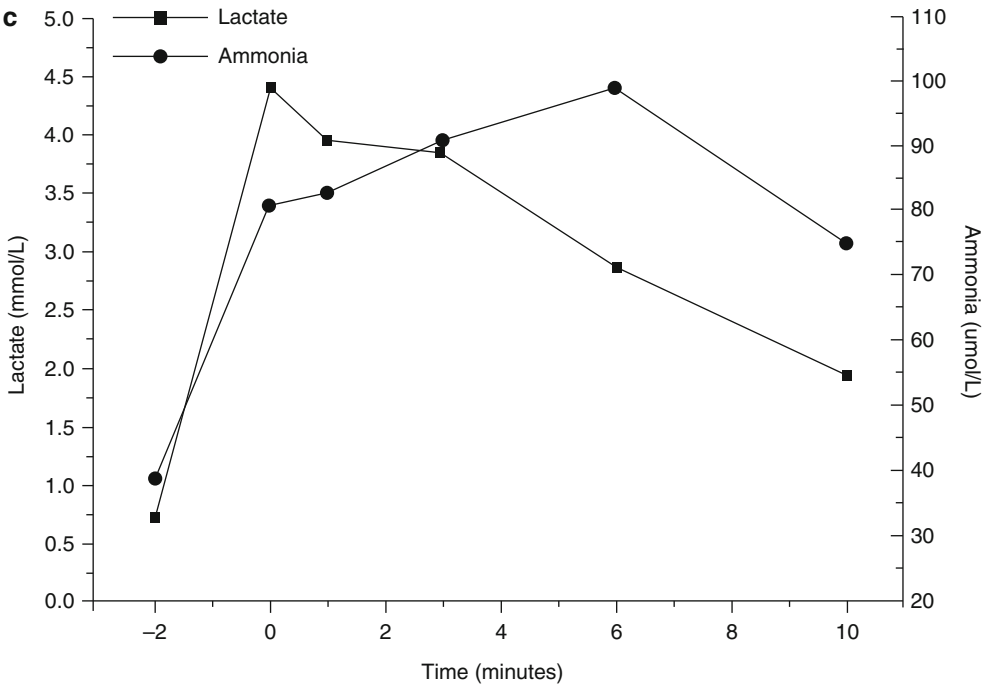
Fig. 6.3 (continued)



progressive proximal muscle weakness. The lactate response to forearm exercise test is typically flat in these patients, though one case showed a 2.6-fold rise in lactate [31–33].

Phosphorylase Kinase Deficiency

Phosphorylase kinase deficiency (glycogenosis type VIII) impairs glycogen breakdown by preventing phosphorylation, and thereby activation, of myophosphorylase. Since the biochemical defect affects the function of myophosphorylase, one might expect little or no rise in lactate during exercise. The forearm exercise test data, however, are typically normal, indicating preserved anaerobic glycogenolysis [34, 35]. This paradox may be explained by recent findings indicating that metabolites such as AMP, IMP, and inorganic phosphate are the major activators of myophosphorylase during anaerobic exercise [36, 37]. In contrast, during aerobic exercise, phosphorylase kinase plays the major role in activating myophosphorylase.

Phosphoglycerate Kinase Deficiency

Phosphoglycerate kinase deficiency (glycogenosis type IX) results in little or no rise in lactate level following exercise [38–42]. Phosphoglycerate kinase catalyzes the transfer of the acylphosphate group of 1,3-diphosphoglycerate to ADP with formation of 3-phosphoglycerate and ATP.

Phosphoglycerate Mutase Deficiency

Phosphoglycerate mutase deficiency (glycogenosis type X) prevents the interconversion of 2-phosphoglycerate and 3-phosphoglycerate. The forearm exercise test usually yields a mild but definite rise in lactate level of 1.3–3 times baseline [43–47]. Although this response is less than the four- to six-fold rise in lactate seen in normal subjects, it is distinct from the essentially flat response seen in patients with myophosphorylase, phosphofructokinase, or phosphoglycerate kinase deficiencies. A single case of phosphoglycerate mutase deficiency with a rise in serum lactate of five times baseline has been reported [48]. A symptomatic heterozygous carrier of a phosphoglycerate mutase gene mutation also had normal forearm exercise test results [49].

Phosphoglucomutase Deficiency

Phosphoglucomutase deficiency (glycogenosis type XIV) prevents conversion of glucose-1-phosphate to glucose-6-phosphate. In a single case report, forearm exercise test showed a normal fivefold increase in lactate coupled with an eightfold rise in ammonia [50].

Glycogen Synthase Deficiency

Glycogen synthase deficiency (glycogenosis type 0) prevents the addition of glucose monomers to the growing glycogen chain. There is profound depletion of glycogen within muscle fibers. Forearm exercise test showed no elevation of lactate in a single patient; ammonia levels were not reported [51].

Beta-Enolase Deficiency

Beta-enolase deficiency prevents the conversion of 2-phosphoglycerate to phosphoenolpyruvate in skeletal muscle. In a single case report, forearm exercise test showed no increase in lactate; ammonia levels were not reported [52].

Lactate Dehydrogenase Deficiency

Lactate dehydrogenase (LDH) deficiency (glycogenosis type XI) blocks the final step in the glycolytic pathway, the conversion of pyruvate to lactate with NADH as a cofactor. Since pyruvate cannot be further metabolized during ischemia, the forearm exercise test fails to show the usual rise in venous lactate level and also shows a marked increase in pyruvate. This is a unique feature of LDH deficiency [53–56].

Acid Maltase Deficiency

Acid maltase deficiency (acid alpha-glucosidase deficiency, glycogenosis type II) causes two major syndromes: a severe, often lethal disease of infancy (Pompe's disease) and a slowly progressive proximal myopathy presenting in juveniles and adults [57]. Respiratory muscle weakness is the initial feature in 30 % of cases. Acid maltase is a lysosomal enzyme with glucosidase activity, capable of digesting glycogen completely to glucose. The forearm exercise test in the adult form of acid maltase deficiency shows a normal rise in venous lactate, indicating that phosphorolytic breakdown of glycogen and glycolysis is able to proceed normally [58].

Debrancher Deficiency

Debrancher deficiency (glycogenosis type III; Cori-Forbes disease) produces little or no rise in lactate level during the forearm exercise test [59, 60]. The debrancher enzyme releases glucose from glycogen.

Brancher Deficiency

Brancher deficiency (glycogenosis type IV; Andersen's disease) effect on forearm exercise test is limited. The brancher enzyme catalyzes the last step in glycogen synthesis by adding short glucosyl chains to linear peripheral chains of nascent glycogen. Its deficiency causes accumulation of abnormal glycogen known as polyglucosan, which can cause myopathy as well as central and peripheral nervous system dysfunction. In three patients with brancher deficiency presenting as myopathy, the forearm exercise test showed a normal rise in lactate level [61–63].

Lactate Transporter Defect

Lactate transporter defect also affects the forearm exercise test. Lactate transporter, a protein found in skeletal muscle and erythrocytes, facilitates movement of lactate across cell membranes. In a single patient with a lactate transporter defect, forearm exercise test produced a normal rise in serum lactate. However, the lactate level failed to decline over the subsequent 6 min postexercise [64]. Of note, other patients have been diagnosed with deficient lactate transport based on an erythrocyte lactate transporter assay. Forearm exercise testing in these patients has not shown prolonged elevation of venous lactate [65].

Myoadenylate Deaminase Deficiency

Myoadenylate deaminase deficiency (MADD) is a disorder of purine metabolism. Myoadenylate deaminase, an enzyme found only in skeletal muscle, catalyzes the deamination of AMP, yielding IMP and an ammonia molecule (Fig. 6.2). The forearm exercise test in MADD patients produces a normal increase of venous lactate but no rise in ammonia, hypoxanthine, or other ATP degradation products (Fig. 6.3b) [66, 67]. When enzymatic testing for myoadenylate deaminase and *AMPD1* genetic mutation analyses are used as gold standards, the sensitivity of the forearm exercise test for MADD is 100 %, but the specificity is 37 % [14]. Submaximal exercise performance due to weakness, pain, or poor effort commonly causes a failure of serum ammonia to rise. False-positive forearm exercise testing results have also been reported in patients heterozygous for the common C34T *AMPD1* mutation [14]. An increase in serum lactate but not ammonia has been reported in a patient with "exertional myalgia syndrome" who had normal MADD activity in a muscle biopsy specimen [68]. Measurement of hypoxanthine and other ATP degradation products (IMP and inosine) reportedly increases the specificity of forearm exercise test for MADD, but is not usually performed in the clinical setting [67, 69, 70]

Carnitine Palmitoyltransferase

Carnitine palmitoyltransferase (CPT) deficiency is a disorder of lipid metabolism. Two genetically distinct enzymes make up the CPT system: CPT I and CPT II. CPT II, located on the inner mitochondrial membrane, mediates transport of long-chain fatty acids into the mitochondrial matrix where beta-oxidation occurs. In patients with CPT II deficiency, the forearm exercise test produces a normal rise in lactate but an exaggerated elevation of ammonia (Fig. 6.3c) [71, 72].

Forearm Exercise Test Complications

There are case reports of rhabdomyolysis and compartment syndrome developing after ischemia in patients with myophosphorylase deficiency. Meinck et al. reported a 57-year-old man with late-onset myophosphorylase deficiency who developed a 20-min-long contracture of the right forearm during forearm exercise test [73]. He subsequently developed myoglobinuria and marked elevation of serum creatine kinase. A whole-body nuclear medicine scan showed uptake of 99Tc methylene diphosphonate restricted to the musculature of the right forearm, and a diagnosis was made of focal rhabdomyolysis. The patient recovered following oral hydration. Lindner et al. described a 22-year-old woman with myophosphorylase deficiency who developed a 10-min-long contracture of the left forearm during forearm exercise test [74]. Six hours after the test, the patient was suffering severe

pain in the forearm and had hypoesthesia in the distribution of the ulnar nerve. A decompressive fasciotomy was performed for acute compartment syndrome of the forearm, after which pain and cutaneous sensation improved dramatically. The authors speculate that acute failure of energy production during forearm exercise test led to both muscle contracture and intracellular edema of muscle fibers, producing an increase in tissue pressure to a level that caused tamponade on blood flow.

Niepel et al. reported a 32-year-old man with brancher deficiency who had forearm compartment syndrome following forearm exercise test [75]. The patient completed 40 s of exercise without contracture, but had prolonged forearm pain and developed sensory loss in the distribution of the median nerve. Despite superficial and deep forearm fasciotomy, he was left with residual median sensory neuropathy.

There are no reports of forearm exercise test complications in subjects with normal carbohydrate metabolism, including those with myoadenylate deaminase deficiency or mitochondrial disorders.

Given the potential for complications, the forearm exercise test must be performed by an experienced physician in a setting where evaluation and treatment for rhabdomyolysis and compartment syndrome are available. Compartment syndrome is an orthopedic emergency in which the degree of recovery is determined by the rapidity of surgical decompression (see Chap. 37). The forearm exercise test should be immediately discontinued if a contracture develops. Any patient with prolonged pain or contracture should be closely observed. Development of sensory symptoms is an indication for surgical consultation.

Modified Forearm Exercise Tests

Concerns about discomfort, rhabdomyolysis, and compartment syndrome produced by the forearm exercise test have prompted modifications of the test. Hogrel et al. utilized isometric exercise for 30 s at 70 % of maximal voluntary contraction, without a sphygmomanometer cuff [5]. Although the authors describe their test as "nonischemic," this level of isometric contraction is probably sufficient to block blood flow [76]. Therefore, the main difference between this test and the standard forearm exercise test is the reduced duration of exercise. Of 7 patients with a glycogenosis (most with myophosphorylase deficiency), 4 could maintain the force target for only 15–25 s. However, no patient experienced prolonged pain or contracture, and all had a flat lactate curve with elevation of ammonia. A control group of 26 healthy volunteers showed a fourfold increase in lactate, but only a threefold increase in ammonia. Nevertheless, these results identified patient with a glycogenosis with 100 % sensitivity. Kazemi-Esfarjani et al. compared 10 patients with a glycogenosis and 9 healthy volunteers using a standard ischemic forearm exercise test and 3 modified, nonischemic, exercise tests [6]. Their ischemic test included repetitive squeezing of a dynamometer at 100 % of maximum voluntary contraction for one minute during blocked blood circulation. All patients, most of whom had myophosphorylase deficiency, experienced pain or cramps during the ischemic exercise test, but tolerated the modified forearm exercise test with minimal symptoms. A protocol identical to their ischemic forearm exercise test but without a cuff blocking circulation was as sensitive and specific as their ischemic test in distinguishing patients with glycogenoses from volunteers.

In summary, patients with myophosphorylase deficiency appear to experience less discomfort during various modifications than during the standard forearm exercise test. It remains to be seen whether serious complications such as rhabdomyolysis and compartment syndrome occur with a modified test. Since only one study has directly compared ischemic to nonischemic exercise tests, physicians contemplating the use of a modified exercise testing should consider performing a comparison using their own forearm exercise test protocol.

Performing forearm exercise test in children represents a significant challenge. Bruno et al. reported a modified forearm exercise test designed to be tolerable and safe for children [4]. Under their protocol, a sphygmomanometer cuff was inflated to, but not above, mean arterial pressure, and nonstandardized forearm exercise was performed for 1 min. Out of 25 patients 10 years of age or older, 23 were able to exercise adequately, and two were identified with a glycogenosis. No patients experienced painful cramps or contractures. Four out of 5 patients below the age of 10 failed to show a rise in either lactate or ammonia, suggesting inadequate effort. The authors concluded that their modified forearm exercise test was well tolerated and reliable in children ten or older.

Clinical Electromyography (Nerve Conduction Studies and Needle Electromyography)

7

Barbara E. Shapiro, Bashar Katirji, and David C. Preston

Introduction

Nerve conduction studies (NCSs) and needle electromyography (EMG), often referred to collectively as electrodiagnostic (EDX) or EMG studies, play a pivotal role in the evaluation of patients with neuromuscular disorders. They are well suited to aid in the diagnosis of disorders of the peripheral nervous system, including those involving sensory nerves and the dorsal root ganglia, as well as those involving the motor unit, which includes the anterior horn cells, motor nerves, neuromuscular junctions, and muscles (Fig. 7.1). These studies may also provide useful diagnostic information in disorders of the central nervous system (e.g., tremor, upper motor neuron weakness).

EDX testing serves as an extension of the clinical neurologic examination. A directed history and a brief neurologic examination prior to the EDX studies guide the electromyographer in selecting the appropriate tests to reach the correct diagnosis. *Each EDX study must be individualized, based on the manifestations and differential diagnosis, and modified as the study progresses and further information is gained*. A meaningful EDX examination relies upon (1) choosing the correct studies, (2) obtaining accurate data, and (3) properly interpreting the data collected. If the interpretation is incorrect, then technically accurate data may be of little value. Each study is then properly interpreted within the clinical context. The same EDX data may have very different meanings in different clinical situations. For example, long-duration motor unit action potentials (MUAPs) with reduced recruitment in the proximal arm may indicate a chronic

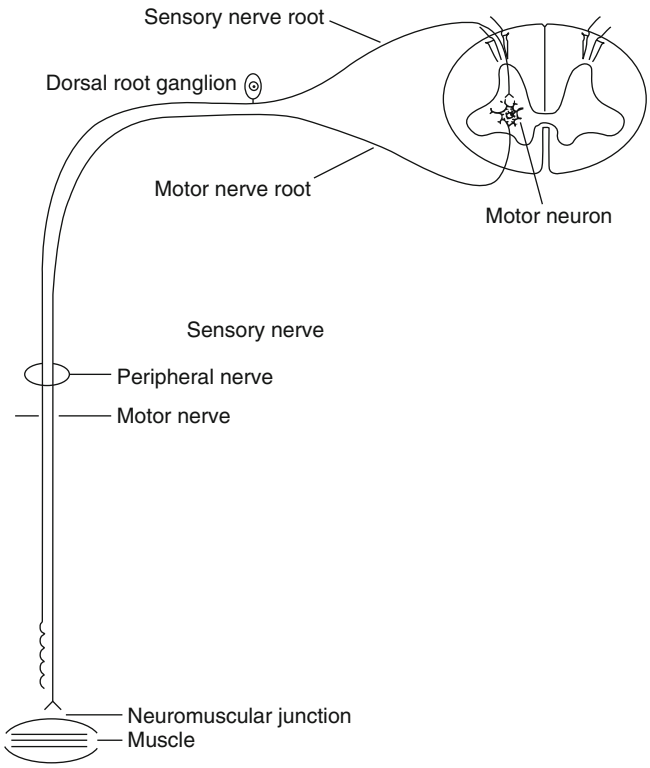

Fig. 7.1 Elements of the peripheral nervous system. Note that the primary motor neuron resides within in the spinal cord, whereas the primary sensory neuron, the dorsal root ganglion, lies outside of the spinal cord. The dorsal root ganglion is a bipolar cell. Its proximal process forms the sensory nerve root; the distal process becomes the peripheral sensory nerve (Reproduced with permission from Preston and Shapiro [1])

radiculopathy, plexopathy, spinal muscular atrophy, or the effects of old poliomyelitis. Likewise, data that are not technically accurate may obscure an accurate diagnosis.

Basic Principles and Indications for Performing the Electrodiagnostic Examination

The primary goals of EDX studies are to localize the lesion, characterize the underlying nerve pathophysiology, quantitate the severity, and assess the temporal course of the disorder (Table 7.1). For example, in neurogenic lesions, the underlying primary pathophysiology, that of axonal loss or demyelination, can usually be determined. Once the pathophysiology is determined, one can then localize the lesion (based on the distribution of abnormalities) and assess its severity and time course. Although EDX findings may be distinctive as to suggest a precise etiology, in most cases the exact cause cannot be determined based on these studies alone.

In order to arrive at a final EDX, one must first recognize the pattern of abnormalities on NCSs (motor, sensory, and late responses), repetitive nerve stimulation (slow and rapid rate), and needle EMG (insertional and spontaneous activity and MUAP morphology, recruitment, and activation). The pattern of EDX findings usually marks the underlying disorder as neuropathic, myopathic, secondary to a neuromuscular junction (NMJ) disorder, or consistent with a disorder of the central nervous system. The final diagnosis can only be determined when the overall pattern of EDX findings is analyzed and interpreted in the context of the clinical history and examination.

The EDX Evaluation Localizes the Lesion or Disorder

EDX studies often help localize the disorder precisely, a task which is not always possible clinically. For example, in a patient with hand weakness and numbness of the fourth and fifth fingers, the EDX examination helps in the differential diagnosis which includes a lesion of the ulnar nerve, the lower trunk of the brachial plexus, or the C8–T1 spinal nerve roots. More important, the study may demonstrate an ulnar neuropathy across the elbow, a condition only caused by few disorders (e.g., cubital tunnel syndrome, compression at the ulnar groove). Similarly, a patient with proximal weakness may have a motor neuron disorder (e.g., spinal muscular atrophy), a neuromuscular junction disorder (e.g., Lambert-Eaton myasthenic syndrome – LEMS), or a muscle disorder (e.g., polymyositis). EDX studies can readily discriminate between these disorders, thereby providing important information to guide the subsequent evaluation and treatment.

The EDX Evaluation Often Characterizes the Underlying Pathophysiology

EDX studies can often determine the primary pathological process. For example, in a patient with peripheral polyneuropathy, findings on NCSs often narrow the differential diagnosis by defining the involved fiber types (motor, sensory, or both) and the underlying pathophysiology (axon loss or segmental demyelination). While sensorimotor polyneuropathies are common and subsume a fairly large differential diagnosis, predominantly motor or sensory polyneuropathies are rare and have a limited number of causes. The determination of whether the pathology is primary demyelination or axonal loss has important implications for both diagnosis and prognosis. While most peripheral polyneuropathies are associated with primary axonal degeneration, the causes of demyelinating polyneuropathies are few, limiting the differential diagnosis. Finally, if the EDX findings are characteristic of an acquired demyelinating polyneuropathy, this group of disorders is often potentially treatable and may have a good prognosis.

The EDX Evaluation Is Useful in Quantitating the Severity of Illness and Assessing Its Prognosis

The EDX examination is useful in assessing the degree of axonal loss versus demyelination in peripheral nerve disorders. This has implications for severity and prognosis. After a demyelinating injury, a nerve can often remyelinate in a short time, usually within weeks. However, if significant axonal loss occurs, the prognosis is considerably more guarded. Axonal regrowth is limited by the rate of slow axonal transport, which is approximately a millimeter a day. For example, a patient with a 50 % axonal loss lesion of the peroneal nerve has a much graver prognosis and a longer rehabilitation time than a patient with a demyelinating lesion causing a 50 % conduction block at the same location.

The EDX Evaluation Is Useful in Assessing the Temporal Course, Stage, and Rate of Progression of the Disorder

This is especially pertinent in disorders of peripheral nerve, where there is an orderly, temporal progression of abnormalities that occurs on NCSs and needle EMG. This allows differentiation between hyperacute (<1 week), acute (< few weeks), subacute (weeks to a few months), and chronic (> few months) lesions. The electromyographer must therefore be aware of the patient's clinical time course in order to accurately interpret any electrophysiologic abnormalities, or lack thereof.

The EDX Studies Must Be Planned According to the Clinical Context

Every EDX evaluation should begin with a brief history and directed physical examination. The duration, type, and distribution of symptoms, along with the neurologic findings, help determine the differential diagnosis. This information is essential in planning the EDX studies. The electromyographer must decide which nerves and muscles to study and whether specialized tests such as repetitive nerve stimulation are indicated. The study is often amended as the testing proceeds. For example, in a patient with intermittent double vision, dysphagia, and proximal weakness, the differential diagnosis may include disorders of the neuromuscular junction, muscle, anterior horn cell, or motor nerve. EDX studies in this patient should include repetitive nerve stimulation and needle EMG of at least two limbs. In contrast, the differential diagnosis of a patient with occasional neck pain and numbness of their fourth and fifth fingers includes an ulnar neuropathy, lower trunk brachial plexus lesion, or cervical radiculopathy. EDX studies may include ulnar sensory and motor NCSs, preferably in both upper extremities, along with needle EMG of muscles in multiple upper limb myotomes including the C8/T1 myotome.

The EDX Evaluation Should Maintain a Proper Balance Between Collecting the Data Necessary to Answer the Clinical Question and Minimizing Patient Discomfort

After explaining the test to the patient in simple terms to reduce anxiety, NCSs are performed followed by the needle EMG. Sufficient nerve conduction studies and needle EMG can usually be performed within one to one and a half hours in order to arrive at an accurate electrophysiologic diagnosis. If specialized tests, such as repetitive nerve stimulation, quantitative motor unit analysis, or single-fiber EMG, must be performed, a longer study may be necessary. In children, agitated or demented patients, or when there is any question whether a patient will tolerate the entire examination, the electromyographer should begin the study with the area of most interest. For instance, in a patient with numbness and tingling of the second and third fingers, the median motor and sensory studies should be done first. Likewise, needle EMG of the median innervated muscles as well as C6–C7, non-median innervated muscles (e.g., the triceps) are of greatest interest in such a patient. By planning ahead and considering which NCSs should be performed first and which muscles should be sampled on needle EMG, an accurate diagnosis may be reached in most patients, even when only a few NCSs are performed or muscles are examined.

EDX studies rely on meticulous attention to technical details, while keeping in mind the larger picture of why the study is being performed. As more data is obtained, the study must be analyzed and the test altered as needed. Analysis of results in real time gives the electromyographer the opportunity to modify one's strategy as the test proceeds.

The EDX Studies May Identify Minor Abnormalities That May Suggest Subclinical Disease or May Be Irrelevant

EDX tests are very sensitive; occasionally, one may detect mild abnormalities that are subclinical or insignificant. Subclinical disease that is below the threshold for clinical identification may be easily detected during the EDX evaluation. Examples include asymptomatic median mononeuropathy at the wrist, myotonic discharges in asymptomatic carriers of a myotonic dystrophy gene mutation, and NCS slowing in asymptomatic relatives of patients with Charcot-Marie-Tooth disease.

Clinically insignificant findings occur partly because of the wide range of normal values, which vary with the nerve and muscle being tested, and the numerous physiological and nonphysiological factors that affect NCSs and needle EMG (see below). Making a diagnosis based on minor EDX abnormalities that do not correlate with the clinical manifestations may be hazardous. Examples include isolated denervation of the extensor digitorum brevis; fasciculation potentials and long-duration, high-amplitude MUAPs in the intrinsic foot muscles; and complex repetitive discharges in the iliacus muscle that may be of no clinical importance [2].

An unexpected abnormal finding on NCSs or needle EMG, which does not fit the clinical examination, should always raise the possibility of a technical problem. Accurate EDX studies depend on properly functioning equipment (i.e., EMG machine, electrodes, and stimulator) and an experienced EDX technologist and electromyographer. One clue to determining that an abnormality is due to technical problems is the lack of clinical-electrophysiologic correlation.

There are times when the clinical diagnosis or EDX findings are not clear and a definite diagnosis cannot be reached. Occasionally, nerve conduction studies or needle EMG is abnormal, yet a precise diagnosis cannot be determined. For example, in a patient with a tardy ulnar palsy due to remote trauma to the elbow, EDX studies may demonstrate an axon-loss ulnar mononeuropathy without localizing features (i.e., conduction block or focal slowing across the elbow). While the referring physician usually wants to know if the lesion is at the elbow, and is sometimes confident that it is, often the only correct impression the electromyographer can give is one of a nonlocalizable ulnar mononeuropathy which is at or proximal to the most proximal abnormal ulnar innervated muscle as determined by needle EMG.

One can usually be certain of a diagnosis only when the clinical findings, NCSs, and needle EMG abnormalities all correlate well. If all three fit together, the diagnosis is secure. However, if the NCSs and needle EMG do not fit together and, more importantly, if they do not correlate with the clinical findings, one should strongly question the significance of the EDX abnormalities. The electromyographer must understand the limitations of EMG, keep technical factors well controlled, and establish a good differential diagnosis before beginning the study. Otherwise, the study may do a disservice to the patient and to the referring physician by potentially leading one astray with minor, irrelevant, or technical abnormalities. However, by keeping these general principles of EMG in mind, EDX studies are usually of great help to the referring clinician and the patient with a neuromuscular disorder.

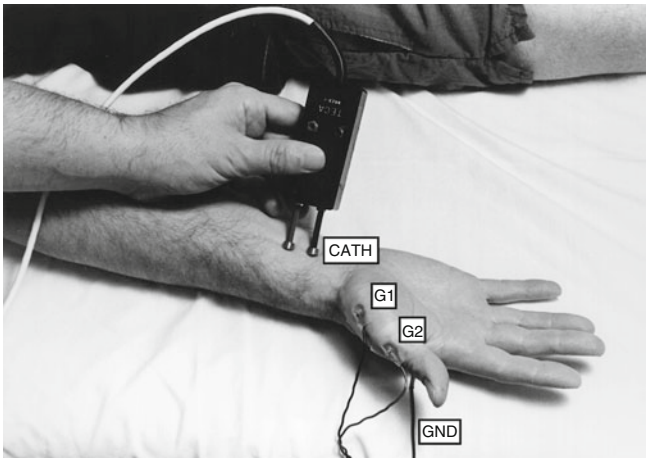

Fig. 7.2 Motor conduction study setup. Median motor study, recording the abductor pollicis brevis muscle, stimulating the median nerve at the wrist. In motor studies, the "belly-tendon" method is used for recording. The active recording electrode (*G1*) is placed on the center of the muscle, with the reference electrode (*G2*) placed distally over the tendon (*CATH* cathode, *GND* ground) (Reproduced with permission from Preston and Shapiro [1])

Methodology

Nerve Conduction Studies (NCS)

Motor Nerve Conduction Studies

Motor NCSs are technically less demanding than sensory and mixed nerve studies. Motor responses are typically in the range of several millivolts (mV), while sensory and mixed nerve responses are in the range of microvolts (μV). Thus, motor responses are less affected by external noise and other technical factors (see section "Factors Affecting Nerve Conduction Studies and Needle Electromyography").

Motor NCSs are usually obtained by percutaneous (surface) stimulation of a mixed peripheral nerve while recording from a muscle innervated by the same nerve. Recording electrodes are placed over the muscle of interest, using the belly-tendon montage (i.e., the active recording electrode (G1) is placed on the center of the muscle belly, which usually correlates with the motor end plate, and the reference electrode (G2) placed distally, over the tendon to the muscle) (Fig. 7.2). The stimulator is then placed over the nerve to the muscle, with the cathode closest to the recording electrode. To perform motor conduction studies, the gain is usually set at 2–5 mV/div. The duration of the electrical pulse is usually set to 200 μs. The current is slowly increased, usually by 5–10 milliampere (mA) increments. This generates nerve action potentials in increasing numbers of underlying fibers, which in turn result in more activated muscle fiber action potentials. When the current is increased to the point that the motor response no longer increases in size, one presumes

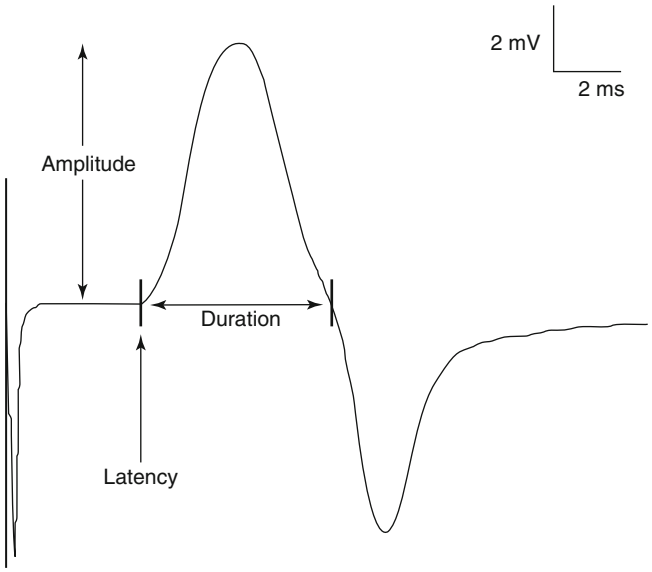

Fig. 7.3 Compound muscle action potential (CMAP). The CMAP represents the summation of all the underlying muscle fiber action potentials. With recording electrodes properly placed, the CMAP is a biphasic potential with an initial negative deflection. Latency is the time from the stimulus to the initial negative deflection from baseline. Amplitude is most commonly measured from baseline to negative peak, but can also be measured peak to peak. Duration is measured from the initial deflection from baseline to the first baseline crossing (i.e., negative-peak duration). In addition, negative CMAP area (i.e., the area *above* the baseline) is calculated by most modern computerized EMG machines. Latency reflects only the fastest conducting motor fibers. All fibers contribute to amplitude and area. Duration is primarily a measure of synchrony (Reproduced with permission from Preston and Shapiro [1])

that all nerve fibers are stimulated. The current is then increased by another 20 % to ensure *supramaximal stimulation*. Most nerves require a current flow in the range of 20–50 mA to achieve supramaximal stimulation. Deeply seated nerves, diseased nerves, and nerves in obese patients may require higher stimulus intensity or duration.

The recorded potential with supramaximal stimulation is known as the *compound muscle action potential* (*CMAP*), sometimes referred to as the motor response or the M (for motor) wave. It results from the sum of all the synchronously activated muscle fiber action potentials generated through all the axons destined to the recorded muscle. The CMAP is an indirect measurement of the number of axons that conduct between the stimulating and recording points.

If the recording electrodes are properly placed with G1 over the motor end plate, the CMAP is a biphasic potential with an initial negativity (i.e., an upward deflection from the baseline). For each stimulation site, the latency, amplitude, duration, and area of the CMAP are measured (Fig. 7.3). A motor conduction velocity can be calculated after two sites, one distal and one proximal, are stimulated.

Amplitude

CMAP amplitude may be measured from baseline to first negative peak or, less commonly, from the first negative peak to the next positive peak. CMAP amplitude (and area) reflects the number and size of muscle fibers that ultimately fire. Low CMAP amplitude following distal nerve stimulation most often results from loss of motor axons or neurons. Less often, it is due to a conduction block (i.e., demyelination located between the distal stimulation site and recorded muscle), a neuromuscular junction (NMJ) disorder, or a myopathy.

Area

CMAP area is also conventionally measured between the baseline and negative peak (negative-phase area). Less often, the total area (negative- and positive-phase areas) may be calculated. Although area cannot be manually determined, this calculation is readily performed by most modern computerized EMG equipment. CMAP area also reflects the number of muscle fibers in the CMAP. Differences in CMAP area between distal and proximal stimulation sites assume special significance in the determination of conduction block from a demyelinating lesion (see section "Electrophysiologic Findings in Neuromuscular Disorders").

Duration

CMAP duration is usually measured from the initial deflection from baseline to the first baseline crossing (i.e., negative-peak duration), but less commonly calculated from the initial to the terminal deflection back to baseline (total duration). The latter may be less accurate because the CMAP returns to baseline very slowly and its terminal point may be imprecisely marked. CMAP duration is primarily a measure of synchrony (i.e., the extent to which each of the individual muscle fibers fire at the same time). Duration characteristically increases in conditions which result in selective slowing of some motor fibers (e.g., in a demyelinating lesion).

Latency

The latency is the time from the stimulus to the initial CMAP deflection from baseline. Latency includes three separate times: (1) nerve conduction time from the stimulus site to the NMJ, (2) the time delay across the NMJ, and (3) the depolarization time across the muscle fibers. Latency measurements are usually in milliseconds (ms). Distal latencies are often the only reported latency because measurements of latencies from proximal stimulation sites are often incorporated in conduction velocity calculations (see section Conduction Velocity).

Conduction Velocity

Motor conduction velocity is a measure of the speed of the fastest conducting motor axons, which is calculated by dividing the distance traveled by the nerve conduction time.

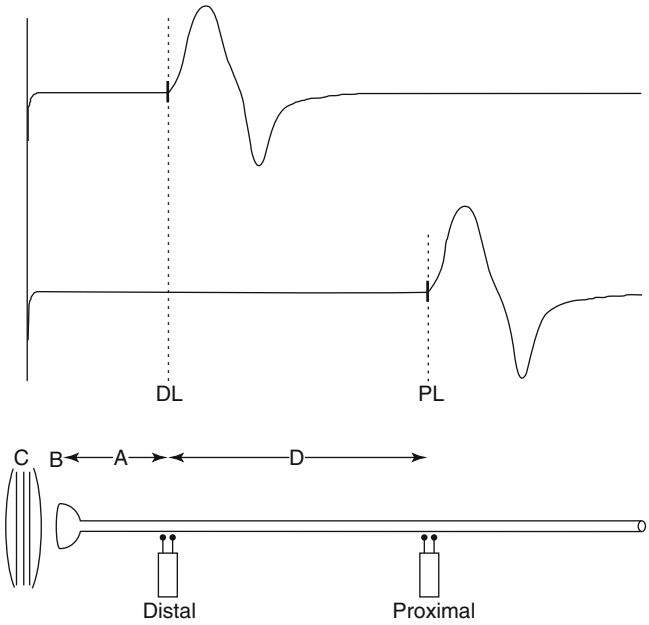

Fig. 7.4 Motor conduction velocity calculation. *Top figure*: Median motor study, recording abductor pollicis brevis, stimulating wrist and elbow (*DL* distal motor latency, *PL* proximal motor latency). The only difference between distal and proximal stimulations is the latency, with the proximal latency being longer than the distal. *Bottom figure*: DL represents three separate times: the nerve conduction time from the distal stimulation site to the NMJ (*A*), the NMJ transmission time (*B*), and the muscle depolarization time (*C*). Accordingly, DL cannot be used alone to calculate a motor conduction velocity. Two stimulations are necessary. The PL includes the distal nerve conduction time (A), the NMJ time (B), and the muscle depolarization time (C), as well as the nerve conduction time between the proximal and distal stimulation sites (*D*). If the distal latency (A + B + C) is subtracted from the proximal latency (A + B + C + D), only the nerve conduction time between the distal and proximal stimulation sites (D) remains. The distance between those two sites can be measured, and a conduction velocity can be calculated (distance/time). Conduction velocity reflects only the fastest fibers (Reproduced with permission from Preston and Shapiro [1])

However, motor conduction velocity cannot be calculated by performing a single stimulation. Motor latencies include nerve conduction time, NMJ transmission, and muscle depolarization time. Thus, to calculate a motor conduction velocity, without including NMJ transmission and muscle depolarization times, two stimulation sites must be used: one distal and one proximal. When the distal latency is subtracted from the proximal latency, then only the nerve conduction time between the proximal and distal stimulation sites remains (Fig. 7.4). The distance between these two sites can then be approximated by measuring the surface distance with a tape measure in millimeters. Thus, conduction velocity (CV) is usually measured in meters per second (m/s) and is calculated as follows:

$$\mathrm{CV}\left(\mathrm{m/s}\right)=\frac{\mathrm{Distance}\left(\mathrm{mm}\right)}{\mathrm{Proximal\ latency}-\mathrm{distal\ latency}\left(\mathrm{ms}\right)}$$

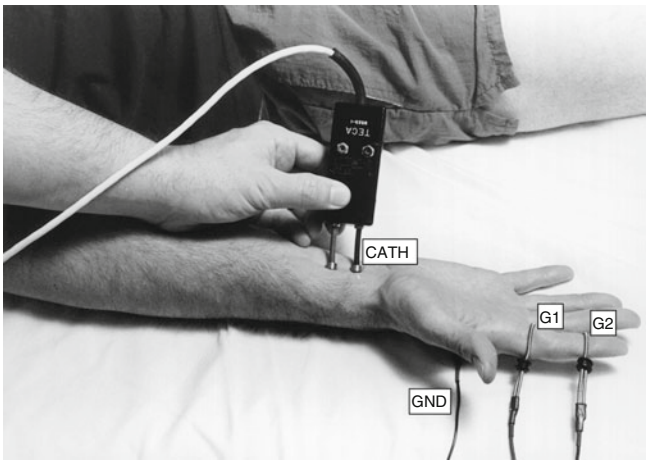

Fig. 7.5 Sensory conduction study setup. Median sensory study, antidromic technique. Ring electrodes are placed over the index finger, 3–4 cm apart. The active recording electrode (*G1*) is placed more proximally, closest to the stimulator. Although the entire median nerve is stimulated at the wrist, only the cutaneous sensory fibers are recorded over the finger (*CATH* cathode, *GND* ground) (Reproduced with permission from Preston and Shapiro [1])

It is important to note that the latencies and conduction velocity reflect only the fastest conducting fibers. Action potentials of these nerve fibers reach the muscle first and determine the onset of the CMAP. The slower conducting motor fibers participate in the CMAP area and amplitude, but are not reflected in the measurements of either the latencies or conduction velocity.

Sensory Nerve Conduction Studies

In contrast to motor NCSs where the CMAP reflects conduction along motor nerve, NMJ and muscle fibers, sensory NCSs are true nerve action potentials and only measure sensory nerve fibers. Because *sensory nerve action potentials* (*SNAPs*) are much smaller than the CMAP (usually in the range of 1–50 μV), technical factors and external noise assume greater importance. At times, signal averaging is utilized, particularly when the SNAP is small or partially contaminated by baseline noise. To perform sensory NCSs, the gain is usually set at 10–20 μV/div. Ring electrodes around the fingers and 5 mm disk electrodes are common recording electrodes (Fig. 7.5). A pair of recording electrodes (G1 and G2) is placed in line over the nerve, at an interelectrode distance of 3–4 cm, with the active electrode (G1) placed closest to the stimulator. Sensory fibers usually have a lower threshold to stimulation than motor fibers with most nerves requiring a current in the range of 5–30 mA to achieve supramaximal stimulation. For sensory studies, an electrical pulse of either 100 or 200 μs in duration is used. Similar to motor studies, the current is slowly increased, usually by smaller (3–5 mA) increments, until the recorded SNAP is supramaximal.

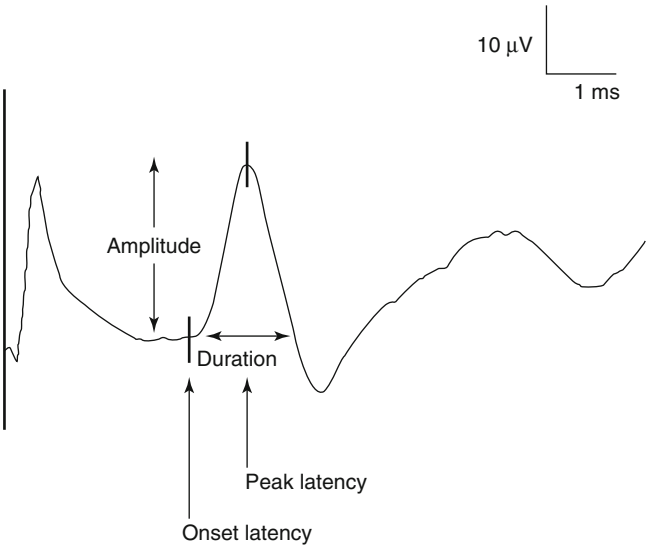

Fig. 7.6 Sensory nerve action potential (SNAP). The SNAP represents the summation of all the underlying sensory fiber action potentials. The SNAP is usually biphasic or triphasic in configuration. Onset latency is measured from the stimulus to the initial negative deflection for biphasic SNAPs (as above) or to the initial positive peak for triphasic SNAPs. Onset latency represents nerve conduction time from the stimulus site to the recording electrodes for the largest cutaneous sensory fibers. Peak latency is measured at the midpoint of the first negative peak. Amplitude is most commonly measured from baseline to negative peak, but can also be measured from peak to peak. Duration is measured from the initial deflection from baseline to the first baseline crossing (i.e., negative-peak duration). Only one stimulation site is required to calculate a sensory conduction velocity, as sensory onset latency represents only nerve conduction time (Reproduced with permission from Preston and Shapiro [1])

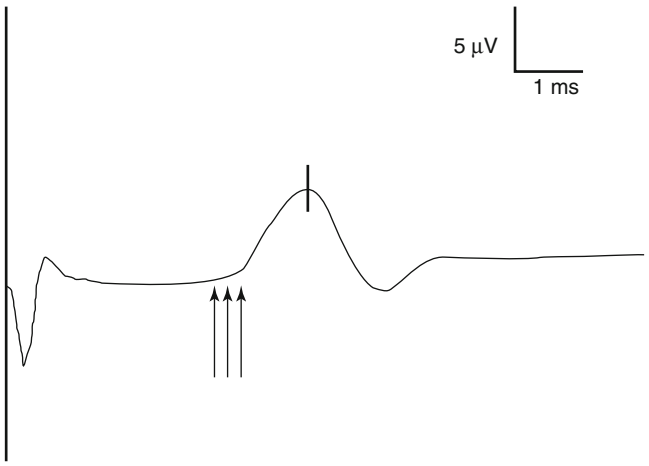

Fig. 7.7 SNAP onset and peak latencies. Onset and peak latency measurements each have their own advantages and disadvantages. Onset latency represents the fastest conducting fibers and can be used to calculate a conduction velocity. However, for many potentials, especially small ones, it is difficult to precisely place the latency marker on the initial deflection from baseline (*arrows*: possible onset latencies). Marking the peak latency is straightforward, with nearly no inter-examiner variation. However, the population of fibers represented by peak latency is unknown; it cannot be used to calculate a conduction velocity (Reproduced with permission from Preston and Shapiro [1])

The SNAP is a compound potential that represents the summation of all the individual sensory fiber action potentials. SNAPs are usually biphasic or triphasic potentials. For each stimulation site, the onset latency, peak latency, duration, and amplitude are measured (Fig. 7.6). In contrast to motor studies, a sensory conduction velocity may be calculated with just one stimulation site, because there is no transmission along NMJ or muscle fibers. In general, the SNAPs are more sensitive than the CMAPs to focal and generalized neuropathies and may occasionally provide evidence of subclinical neuropathy.

Amplitude

SNAP amplitude is often measured from baseline to negative peak, but can also be measured from the first negative peak to the next positive peak. The SNAP amplitude reflects the number of sensory axons that depolarize and contribute to the potential. Low SNAP amplitude usually indicates loss of axons due to a disorder of the dorsal root ganglion or peripheral nerve, but may be due to technical factors, including limb edema, skin induration, or incorrect placement of the stimulating or recording electrodes.

Duration

Similar to CMAP duration, SNAP duration is usually measured from the onset of the potential to the first baseline crossing (i.e., negative-peak duration), but may also be measured from the initial to the terminal deflection back to baseline (total duration). The former is preferred as the terminal deflection returns to baseline very slowly and is difficult to mark precisely. Because the SNAP duration is typically much shorter than the CMAP duration (typically 1.5 ms for a SNAP duration vs. 5–6 ms for a CMAP duration), duration is useful in identifying a response as a sensory as opposed to a motor potential.

Onset Latency

The onset latency is the time from the stimulus to the initial negative deflection from baseline for biphasic SNAPs or to the initial positive peak for triphasic SNAPs. Sensory onset latency represents nerve conduction time of the largest cutaneous sensory fibers from the stimulus site to the recording electrodes. The onset latency is not uncommonly imprecise, particularly in small SNAPs or when associated with baseline noise or stimulus artifact (Fig. 7.7). However, it should be always used whenever one calculates conduction velocity of the fastest fibers.

Peak Latency

The peak latency is measured at the midpoint of the first negative peak. Although the population of sensory fibers represented by the peak latency is not known (in contrast to the

onset latency that represents the fastest conducting fibers), measurement of the peak latency is precise with minimal interindividual variation in its determination. Another potential advantage of using peak latency as opposed to onset latency in sensory and mixed nerve studies is that peak latency is not affected by changes in either sweep speed or sensitivity. Because of their accuracy, peak latencies are often used, except when calculating sensory conduction velocities.

Conduction Velocity

Unlike motor CV that requires two stimulation sites to calculate, sensory CV may be calculated with one stimulation site by dividing the distance traveled by the onset latency. Essentially, the distal conduction velocity and onset latency are the same measurements, differing only by a multiplication factor (i.e., the distance). Proximal CV requires a second and more proximal stimulation; it may be calculated by simply dividing the distance traveled by the proximal onset latency or in a manner similar to the motor CV (see above). However, proximal stimulations result in smaller-amplitude SNAPs, and are often more difficult to perform than distal sensory studies even in normal individuals, due to the normal processes of phase cancellation and temporal dispersion (see below). Similar to motor CV, sensory CV represents the speed of the fastest, myelinated cutaneous sensory fibers.

Mixed Nerve Conduction Studies

Mixed NCSs are similar to sensory studies. Both are compound nerve action potentials, with similar stimulation and recording techniques. However, for mixed NCSs, the potential reflects both motor and sensory fiber action potentials generated along the nerve. An advantage of mixed NCSs over routine sensory and motor NCSs is that these studies incorporate the IA afferent fibers which innervate the muscle spindles. These are the largest and fastest fibers of mixed nerves and are not recorded during routine motor or sensory NCSs. Hence, mixed nerve CVs are usually faster than either routine motor or sensory CVs. Furthermore, as the IA fibers have the largest diameter and, accordingly, the greatest amount of myelin, they are often the fibers earliest affected by demyelinating lesions, such as occurs in entrapment neuropathies.

Although any mixed nerve may be studied, the median, ulnar, and plantar nerves are most often selected during the electrodiagnosis of median mononeuropathy at the wrist, ulnar mononeuropathy at the elbow, and tibial mononeuropathy across the tarsal tunnel, respectively. To perform a mixed nerve conduction study, the settings are similar to those used in sensory conduction studies. The gain is usually set at 10–20 μV/div, as the responses are quite small (i.e., usually in the range of 5–100 μV). A pair of recording electrodes (G1 and G2) is placed in line over the mixed nerve, at an interelectrode distance of 3–4 cm, with the active electrode (G1) closest to the stimulator (Fig. 7.8). The recorded potential, the *Mixed Nerve Action Potential*, is a compound potential which represents the summation of all the individual sensory and motor fiber action potentials. It is usually a biphasic or triphasic potential. Onset latency, peak latency, duration, amplitude, and conduction velocity are measured in a fashion similar to the methods used for sensory conduction studies.

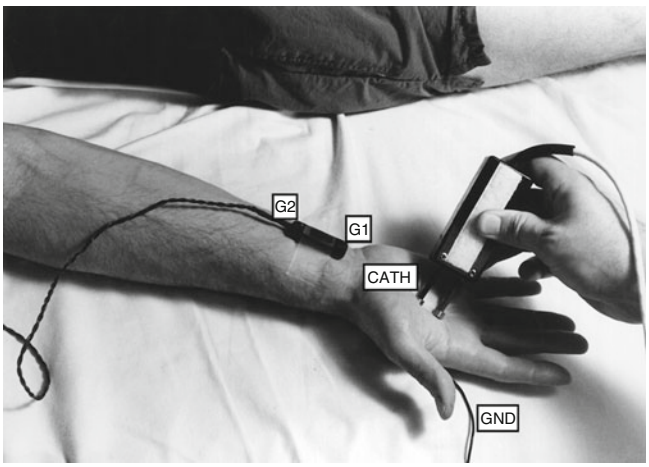

Fig. 7.8 Mixed nerve study setup. Median mixed study, stimulating median nerve in the palm, recording median nerve at the wrist. The active recording electrode (*G1*) faces the cathode (*CATH*) of the stimulator. Mixed studies stimulate and record all motor and sensory fibers, including the muscle afferents, the IA fibers, which are not recorded in either routine sensory or motor conduction studies (*GND* ground) (Reproduced with permission from Preston and Shapiro [1])

Special Considerations in Nerve Conduction Studies

Antidromic Versus Orthodromic Sensory Studies

When a nerve is depolarized, conduction occurs in both directions away from the stimulation site. Consequently, because SNAPs are true nerve action potentials, sensory NCSs may be performed either orthodromically or antidromically. By definition, antidromic sensory NCSs are performed by stimulating toward the sensory receptors and orthodromic studies are performed by stimulating away from the sensory receptors. For instance, when studying median sensory fibers to the index finger, the median nerve may be stimulated at the wrist and the SNAP recorded with ring electrodes over the index finger (antidromic study). Conversely, the same ring electrodes may be used for stimulation of the digital nerves of the index finger and the SNAP recorded over the median nerve at the wrist (orthodromic study).

Sensory latencies and conduction velocities are identical with either method (Fig. 7.9). However, the SNAP amplitude is generally higher in antidromic potentials, because it is directly proportional to the proximity of the recording

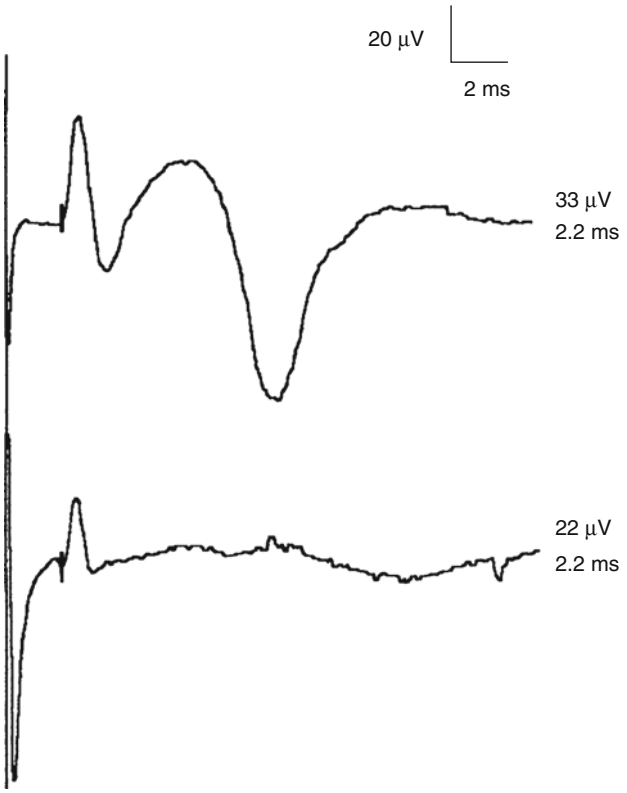

Fig. 7.9 Antidromic and orthodromic sensory studies. Median SNAPs. *Top trace*: antidromic study, stimulating wrist, recording index finger. *Bottom trace*: orthodromic study, stimulating index finger, recording wrist. Latencies and conduction velocities are identical for both. The antidromic method has the advantage of a higher-amplitude SNAP, but is followed by a large volume-conducted motor potential. If the SNAP is absent in an antidromic study, care must be taken not to confuse the volume-conducted motor potential as the sensory potential. Note the difference in duration between the SNAP and CMAP, which helps discriminate between the SNAP and the volume-conducted motor potential that follows (Reproduced with permission from Preston and Shapiro [1])

electrode to the nerve. For most antidromically conducted potentials, the recording electrodes are closer to the nerve than are orthodromic SNAPs. For example, with the antidromically conducted median SNAP, the recording ring electrodes are placed on the finger, very close to the underlying digital nerves from which the potential is recorded. When the montage is reversed for orthodromic recording, the long thick finger flexor tendons and other supporting connective tissues separate the nerve from the recording electrodes placed over the wrist. This results in relative attenuation of the SNAP amplitude. The major advantage of the antidromic technique is the higher SNAP amplitude obtained with antidromic recordings. Furthermore, because the antidromic potential is generally larger than the orthodromic potential, it is less subject to electrical noise or other artifacts. The antidromic technique is especially helpful when recording small SNAPs associated with pathologic conditions.

A disadvantage of the antidromic method is the possible contamination of the waveform by a volume-conducted motor potential which often follows the SNAP (see Fig. 7.9). This results from stimulation of the entire mixed nerve, including the motor fibers. There is usually little trouble differentiating between the two, because the volume-conducted motor potential typically occurs after the SNAP and has a longer duration. However, problems may occur if the two potentials have a similar latency or, more importantly, if the sensory potential is absent or much reduced in amplitude. When the SNAP is absent, one may mistake the first component of the volume-conducted motor potential for the SNAP. Measuring the duration of the potential is useful to distinguish a sensory from a motor potential (SNAP duration is typically 1.5 ms while vs. CMAP duration is usually 5–6 ms).

Preganglionic Lesions

Peripheral sensory fibers are derived from the dorsal root ganglia (DRG) located extradurally outside of the spinal cord within the intervertebral foramina. The primary sensory neurons are unique bipolar cells with central processes forming the sensory (dorsal) nerve rootlets and peripheral projections becoming the peripheral sensory axons. Axon-loss lesions of the dorsal nerve root only affect the central processes, leaving the dorsal root ganglion and the peripheral sensory axons intact. In these situations, the central processes degenerate, effectively disconnecting the ganglion and its peripheral processes from the spinal cord. Except on rare occasions [3], the SNAPs remain normal in lesions proximal to the DRGs, including intraspinal canal lesions affecting the spinal roots and spinal cord (Fig. 7.10). Patients with such preganglionic lesions commonly have sensory manifestations. In fact, the combination of dermatomal sensory loss with normal SNAPs in the distribution of sensory abnormalities should always suggest the possibility of a lesion proximal to the dorsal root ganglia. In postganglionic lesions, such as extraspinal radiculopathies, plexopathies, or peripheral mononeuropathies, SNAPs are usually low in amplitude or absent.

In contrast to the DRGs, the anterior horn cells are located in the ventral gray matter of the spinal cord. Axons projecting from these motor neurons form the motor roots and the motor fibers in the peripheral nerves. Axon-loss lesions of the motor (ventral) roots effectively disconnect the peripheral motor fibers from their primary neurons, resulting in degeneration of motor fibers throughout the peripheral nerve. Consequently, an axon-loss intraspinal nerve root lesion results in abnormalities on needle EMG and, if severe, on motor NCSs.

Physiologic Temporal Dispersion and Phase Cancellation

When proximal and distal motor stimulations are performed, the resultant CMAPs are slightly different in configuration:

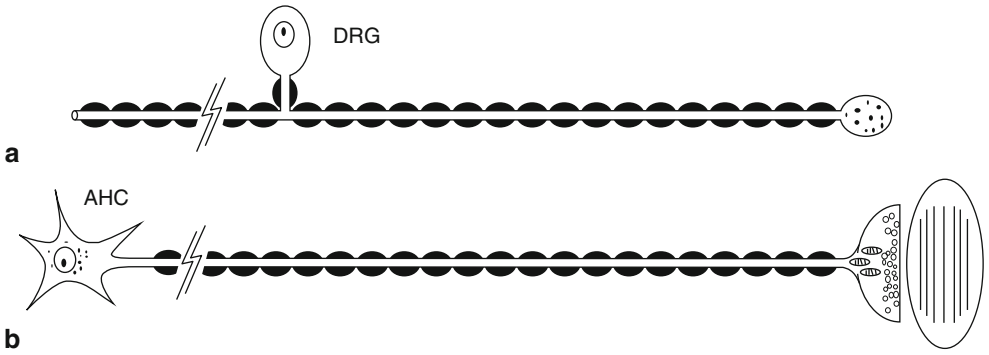

Fig. 7.10 Nerve root lesions and nerve conduction studies. Anatomic differences between sensory and motor nerve fibers result in different patterns of nerve conduction abnormalities in nerve root lesions. The sensory nerve (**a**) is derived from the dorsal root ganglia (*DRG*). The DRG are bipolar cells whose central processes form the sensory roots and distal processes continue as the peripheral sensory nerve fibers. The motor nerve (**b**) is derived from the anterior horn cell (*AHC*), which resides in the ventral gray matter of the spinal cord. Lesions of the nerve roots separate the peripheral motor nerve from its neuron, the AHC, but leave the DRG and its distal processes intact. Thus, nerve root lesions may result in degeneration of the motor fibers distally and, accordingly, abnormalities on motor nerve conduction studies and/or needle EMG. However, the distal sensory nerve remains intact in lesions of the nerve roots, as the lesion is proximal to the DRG. Thus, sensory conduction studies remain normal (Reproduced with permission from Preston and Shapiro [1])

the proximal CMAP amplitude and area may fall and duration increases slightly. These changes are normal findings which result from a combination of temporal dispersion and phase cancellation.

In motor NCSs, the recorded CMAP represents the summation of all individual MUAPs directed to the muscle through the stimulated nerve. The motor axons are not uniform and differ in size, thickness of myelin, and, thus, conduction velocities. The range of conduction velocities between the fastest and slowest individual human motor axons is 12–13 m/s. Because of this variability, the CMAP drops in amplitude and area and increase in duration with proximal stimulation (temporal dispersion), as the slower fibers progressively lag behind the faster fibers (Fig. 7.11). This situation is analogous to a marathon race in which one runner runs a 5 min mile and the other a 6 min mile. At the beginning of the race, both runners are very close to each other (less dispersion), but by the end of the race, they are far apart (greater dispersion). Thus, as the stimulus site moves proximally, slowly conducting fibers are increasingly dispersed in time with respect to the fast-conducting fibers.

If temporal dispersion alone was at work, the amplitude would decrease as the potential duration increases, but the area would be preserved. This would be the case if each motor unit action potential was monophasic in configuration. However, surface-recorded motor unit action potentials are biphasic, with an initial negative phase followed by a positive phase. Their negative duration is 5–6 ms, which is similar to the CMAP negative duration. With such similar durations, most MUAPs are in phase with each other. This results in a slight positive/negative phase overlap and cancellation of the MUAP waveforms, thus reducing both the CMAP amplitude and area while prolonging its duration (see Fig. 7.11).

Temporal dispersion and phase cancellation are more prominent in sensory NCSs, because the disparity of sensory fiber CVs is almost double that of the motor axons (25 m/s) and the recorded single sensory fiber action potentials are often triphasic in configuration. This results in more pronounced temporal dispersion and phase cancellation; the SNAP may drop by 50 % or more and the duration increase by 100 % or more in normal individuals following proximal stimulation (Fig. 7.12) [4]. Temporal dispersion of potentials results from individual sensory fiber action potentials occurring at different times, because faster fibers depolarize before slower ones. A single large myelinated sensory fiber action potential has a negative duration of about 0.5 ms, approximately half the normal duration of the distal SNAP (typical duration = 1.3 ms). This implies that after the first 0.5 ms, the trailing positive phase of the fastest potential overlaps with the leading negative phases of the slower fibers. When overlap occurs between the positive phase of one sensory fiber action potential and the negative phase of another, phase cancellation occurs, resulting in a smaller summated potential. This results in a drop of SNAP area and amplitude.

Needle Electromyography (EMG)

The needle EMG examination is an essential component of the EDX evaluation. It provides an efficient and rapid mean of testing the electrical activity of motor units in a widespread number of muscles. Like NCSs, each needle EMG study must be individualized, based on the clinical findings, EDX data, and the differential diagnosis. The test is often modified as the test proceeds and more data is obtained.

The needle EMG is often uncomfortable for the patient due to needle insertion into skin and muscle. When performed

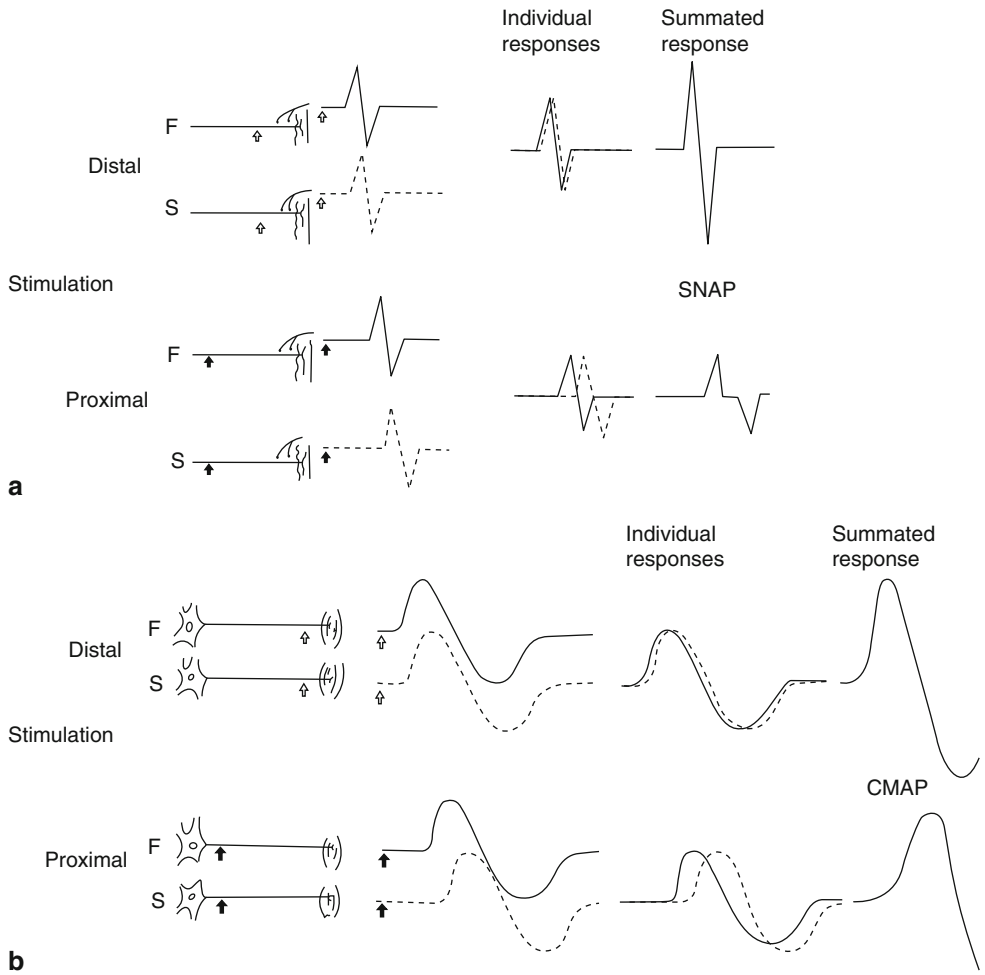

Fig. 7.11 Temporal dispersion and phase cancellation in nerve conduction studies. (**a**) Sensory nerve action potentials (*SNAPs*) and compound muscle action potentials (*CMAPs*) are both compound potentials, representing the summation of individual sensory and muscle fiber action potentials, respectively. In each case there are fibers which conduct faster (*F*) and those which conduct more slowly (*S*). With distal stimulation, fast and slow fiber potentials arrive at the recording site at approximately the same time. However, with proximal stimulation, the slower fibers lag behind the faster fibers. For sensory fibers (*top traces*), the amount of temporal dispersion at proximal stimulation sites results in the negative phase of the slower fibers overlapping with the positive trailing phase of fastest fibers. These superimposed positive and negative phases then cancel each out, resulting in a decrease in area and amplitude, beyond the decrease in amplitude and increase in duration from the effects of temporal dispersion alone. (**b**) The effects of temporal dispersion and phase cancellation are less prominent for motor fibers (*bottom traces*). The duration of individual motor fiber potentials is much longer than that of single sensory fibers. Thus, for the same amount of temporal dispersion, there is much less overlap between negative and positive phases of motor fiber action potentials (From Kimura et al. [4]. With permission of Little, Brown and Company)

skillfully and following explanation and reassurance, most patients tolerate the exam well. On rare occasions, the patient may be extremely apprehensive or needle phobic and the needle EMG cannot be completed. Children, who may tolerate the NCSs, frequently have difficulty with the needle EMG. Although most muscles may be sampled with needle EMG, an extensive needle EMG examination is rarely indicated. For each study, a minimal number of muscles need to be sampled to reach a diagnosis or exclude other clinical suspicions.

Before proceeding with the needle EMG study, it is often useful to consider the possibility that the patient may only tolerate EMG of only one or two muscles. Thus, the choice of muscle to be sampled must be based on the differential diagnosis (determined by the clinical findings and NCS data), the accessibility of the muscle, the ability to activate it, and the degree of pain associated with needle insertion. For example, while both the tibialis anterior (TA) and medial gastrocnemius (MG) are distal leg muscles, sampling the TA is less painful, and the muscle is much easier to activate than the MG. Similarly, during needle EMG of a patient with suspected polyneuropathy or cervical radiculopathy, the first dorsal interosseous (FDI) is often chosen over the abductor pollicis brevis (APB), because the APB is much more painful to sample than the FDI, while both muscles are distal and innervated by the C8 and T1 roots.

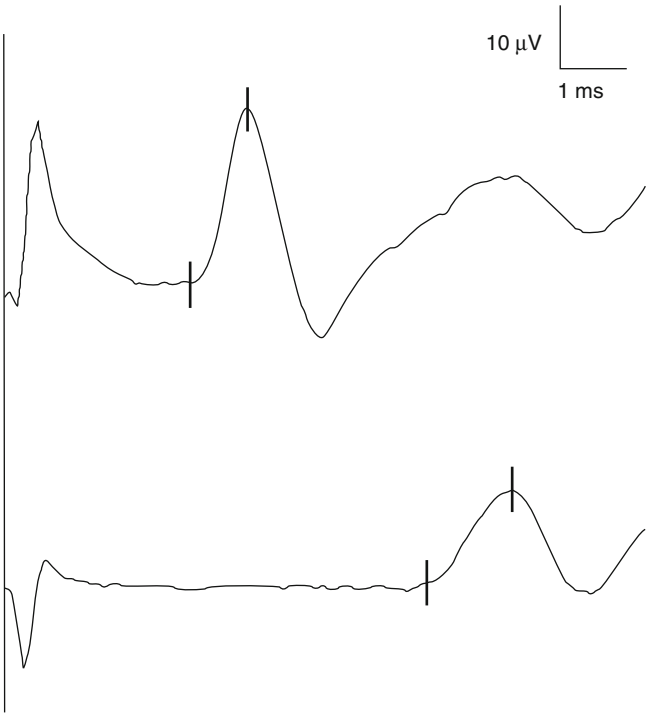

Fig. 7.12 Proximal sensory studies. Normal Median Sensory Study, recording index finger, stimulating wrist (*top*), and elbow (*bottom*). Note: In healthy subjects, proximal stimulation results in SNAPs which are longer in duration and lower in amplitude and area. This occurs as a result of normal temporal dispersion and phase cancellation. If the SNAP is small at the distal stimulation site, it may be difficult or impossible to obtain a potential with proximal stimulation (Reproduced with permission from Preston and Shapiro [1])

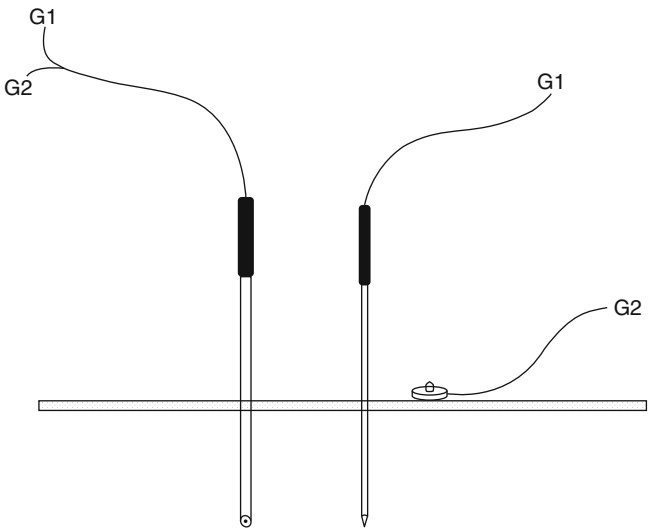

Fig. 7.13 EMG needles. (*Left*) Concentric needle. The concentric needle contains both the active (*G1*) and reference (*G2*) electrodes. The active electrode runs as a small wire through the needle center and is exposed at the tip while the shaft of the needle serves as the reference electrode. (*Right*) Monopolar needle. In the monopolar montage, the needle is Teflon-coated with the exposed tip serving as the as the active electrode (G1); an additional surface disk electrode is needed as the reference electrode (G2) (Reproduced with permission from Preston and Shapiro [1])

Table 7.2 Difference between monopolar and concentric needle electrodes

Concentric	Monopolar
Does not require an independent reference electrode	Requires an independent reference electrode
More painful	Less painful
More expensive	Less expensive
Low baseline noise	High baseline noise
Lower MUAP amplitude	Higher MUAP amplitude
Sharper MUAP rise time	MUAP rise time not as sharp
Shorter MUAP duration	Longer MUAP duration

MUAP motor unit action potential

In children or apprehensive patients, or in a patient who may not tolerate or complete the entire exam, the most important muscles should be sampled first. For instance, if a patient has proximal weakness, in whom the differential diagnosis rests primarily between a myopathy and a proximal neurogenic process (e.g., plexopathy, radiculopathy, and motor neuron disease), a weak proximal muscle should be tested first. If one begins the exam by sampling distal muscles, which are clinically normal, the chance to reach a diagnosis may have been lost if the patient cannot tolerate further examination.

Interpreting the findings on the needle EMG is a challenging part of the EDX examination. Many of the muscle abnormalities are subtle, and the range of normal values is wide and varies with age and the muscle studied. Knowledge of anatomy and physiology and EMG techniques is necessary. Although the basics of the needle EMG study, such as needle placement and recognition of certain types of abnormal spontaneous activity, can usually be learned in a short period of time, recognition of many of the uncommon and subtle needle EMG findings may take years to master.

Recording Technique

In addition to the EMG machine, an EMG needle electrode, needle cable, ground electrode, and gloves are necessary to perform the needle EMG study. The ground electrode is applied to the limb being studied in order to ensure electrical safety and suppress noise. Disposable gloves should be worn to prevent the transmission of blood-borne infections between the patient and the electromyographer. The EMG needle is connected to a cable and then plugged into the EMG machine.

Either a concentric or monopolar EMG needle may be used for recording EMG activity (Fig. 7.13 and Table 7.2). Because the voltage of an electrical potential is measured as the difference between the active and reference recording electrodes, a reference electrode is required. In the concentric

needle, the active electrode is a very small wire in the center of the needle which is exposed at the needle tip, with the needle shaft serving as the reference electrode. In contrast, the monopolar needle is a Teflon-coated electrode exposed at its tip and serves as the active recording electrode. An additional surface disk electrode is required as the reference electrode. The concentric needle has the advantage of not requiring an additional reference electrode, while the monopolar needle has the advantage of being slightly less painful because of a smaller caliber, sharper point, and Teflon coating.

The major disadvantage of the monopolar needle is the need for an additional reference electrode which has to be moved to be near the active electrode with each muscle sampled. Another disadvantage of the monopolar needle is the much greater electrical noise due to electrode impedance mismatch between the intramuscular active electrode and the surface reference disk.

Concentric and monopolar needles are equally satisfactory in recording muscle potentials, with little appreciable differences. MUAP amplitude is slightly smaller and the major spike rise time shorter with a concentric needle, compared to the MUAP obtained with a monopolar needle (see Table 7.2).

Typical Needle Electromyography Examination

Before beginning the needle EMG examination, it is important to explain the procedure to the patient to allay any fears. Good patient rapport both before and during the study is essential. In general, the more cooperative the patient, the more quickly the test proceeds, leading to less discomfort and more reliable data. The following points are useful to clarify to the patient, or if the patient is a child, both the child and family should have the following explained, in a language they can understand:

1. A small needle is used to record electrical potentials from inside the muscle, first while relaxed and then during muscle contraction.
2. Only a short segment of the total length of the needle is inserted (depending on subcutaneous fat).
3. There is no electrical stimulation applied through the needle electrode.
4. The electrical signal from the muscle will be displayed on the screen and heard on the loud speaker. We encourage the patient to watch, listen, and ask any questions.
5. Several muscles are sampled, and their number depends on the clinical symptoms, the questions asked by the referring physician, and the findings as the study proceeds.
6. The patient can take a break at any time.

For each muscle sampled, the electromyographer has to identify the needle insertion point by recognizing the proper anatomical landmarks and the activation maneuver for the muscle. For deeply seated muscles, the electromyographer may ask the patient to contract and relax the selected muscle several times while palpating to locate the muscle contraction. Once the muscle location is identified, the needle is quickly inserted through the skin into the relaxed muscle. Inserting a needle into a contracted muscle is more painful and should always be avoided. To confirm the correct location of the needle, particularly when in doubt or with deeply seated muscles, the patient should be asked to gently contract the muscle. With proper needle location, very sharp and crisp MUAPs (i.e., MUAPs with a short rise time) are displayed. If sharp MUAPs are not seen with minimal muscle contraction, the needle tip location should be adjusted (pulled back slightly or moved slightly deeper) before assessing the findings on the needle EMG. If this fails to produce sharp MUAPs, the needle must be removed, the muscle re-palpated, and the needle reinserted.

Because spontaneous potentials may be low in amplitude, the sensitivity is set at 50 μV/div to evaluate insertional and spontaneous activity. Once insertional and spontaneous activities have been characterized, the needle is left in place, and the analysis turns to the evaluation of MUAPs (see below). Because MUAPs are typically much larger than spontaneous activity waveforms, the sensitivity must be changed to 200 μV/div, while the sweep speed remains at 10 ms/div. To analyze MUAPs, the patient is asked to slightly contract the sampled muscle, preferably in an even manner. MUAPs are very difficult to interpret in patients with uneven muscle contraction, especially those with a tremor. With minimal activation of the muscle, the needle is moved slightly until the MUAPs become "sharp" (i.e., louder and crisper). As the tip of the needle moves closer to the MUAP, there is less intervening tissue to attenuate and filter the potential. Thus, the closer the tip of the needle to the MUAP, the higher the amplitude and the shorter the major spike rise time. It is at this point that the MUAP can be properly evaluated. MUAPs are assessed for duration, amplitude, and number of phases. In addition, the number of MUAPs and their relationship to the firing frequency (recruitment and activation pattern) are also determined (see section "Firing Pattern [Activation, Recruitment, and Interference Pattern]"). As the patient slowly increases force, both the firing frequency and the number of MUAPs normally increase. After the MUAPs are assessed at one location, the needle is moved slightly within the muscle to a different site, and the process is repeated. Ideally, 10–20 different MUAPs should be analyzed.

Once the insertional and spontaneous activity are characterized and the MUAP size, recruitment, and activation patterns are determined for each muscle sampled, one can generally determine if a lesion is present. If a lesion is present, one can use the data to determine its severity and chronicity and, most importantly, whether the primary problem is

Table 7.3 Spontaneous activity

Potential	Source generator/morphology	Sound on loud speaker	Stability	Firing rate	Firing pattern
End-plate noise	Miniature end-plate potential (monophasic negative)	Seashell		20–40 Hz	Irregular (hissing)
End-plate spike	Muscle fiber initiated by terminal axonal twig (brief spike, diphasic, initial negative)	Sputtering fat in a frying pan	–	5–50 Hz	Irregular (sputtering)
Fibrillation potential	Muscle fiber (brief spike, diphasic or triphasic, initial positive)	Rain on a tin roof or ticktock of a clock	Stable	0.5–10 Hz (occ. up to 30 Hz)	Regular
Positive sharp wave	Muscle fiber (diphasic, initial positive, slow negative)	Dull pops, rain on a tin roof, or ticktock of a clock	Stable	0.5–10 Hz (occ. up to 30 Hz)	Regular
Myotonia	Muscle fiber (brief spike, initial positive, or positive wave)	Revving engine	Waxing/waning amplitude	20–150 Hz	Waxing/waning
Complex repetitive discharge	Multiple muscle fibers time-linked together	Machine	Usually stable, may change in discrete jumps	5–100 Hz	Perfectly regular (unless overdriven)
Fasciculation potential	Motor unit (motor neuron/axon)	Corn popping	–	Low (0.1–10 Hz)	Irregular
Myokymia	Motor unit (motor neuron/axon)	Marching soldiers		1–5 Hz (interburst) 5–60 Hz (intraburst)	Bursting
Cramp potential	Motor unit (motor neuron/axon)			High (20–150 Hz)	Interference pattern or several individual motor units
Neuromyotonia	Motor unit (motor neuron/axon)	Pinging	Decrementing amplitude	Very high (150–250 Hz)	Waning

neuropathic or myopathic. The distribution and pattern of abnormalities in different muscles, along with the nerve conduction studies and the clinical data, should allow one to make the final electrophysiologic diagnosis.

Insertional and Spontaneous Activity

Table 7.3 summarizes the main features of the common spontaneous potentials seen during the needle EMG discussed below.

Insertional Activity

The needle EMG examination begins with the assessment of insertional activity. As noted above, the sensitivity is set at 50 μV/div. Once the needle electrode is correctly placed in the muscle, brief and rapid needle movements result in insertional bursts of potentials, known as *normal insertional activity*, which lasts less than 300–500 ms. At least 4–6 brief needle movements are made in each of the four quadrants of the sampled muscle. This can be accomplished without removing the needle from the muscle by first inserting the needle into one quadrant, moving from shallow to deeper along a line, and then pulling back the needle to sample the next quadrant.

Prolonged (increased) insertional activity occurs in neurogenic, myopathic, and myotonic disorders. It may also represent normal variants, which often are familial, have widespread distributions, and consist of short bursts of positive waves (see next section) or irregularly firing potentials (sometimes referred to as "snaps," "crackles," and "pops") [5]. The latter are more prevalent in large muscular subjects and in the calf muscles. Reduced (decreased) insertional activity occurs mainly when there is severe muscle atrophy with replacement of muscle by adipose and connective tissue. It may also be encountered during the paralytic attack of periodic paralysis.

Normal Spontaneous Activity

Normal muscle fibers show no spontaneous activity at rest except in the motor end-plate region, which is usually found near the center of the muscle belly. When the needle is placed in that region, patients frequently perceive a deep burning sensation. Two types of normal spontaneous activity occur in this region, together or independently: end-plate noise and end-plate spikes.

End-Plate Noise

These are low-amplitude, monophasic negative potentials which fire irregularly at 20–40 Hz and have a characteristic "seashell" sound on the loud speaker (Fig. 7.14). They represent miniature end-plate potentials (MEPPs) and result from the normal spontaneous exocytosis of individual quanta of

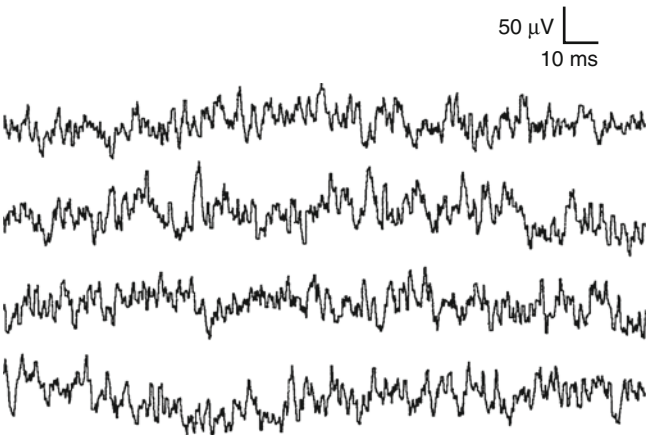

Fig. 7.14 End-plate noise. Small, high-frequency, predominantly monophasic negative potentials which are recognized by their characteristic shape and "seashell" noise on EMG (Reproduced with permission from Preston and Shapiro [1])

acetylcholine traveling across the neuromuscular junction, leading to a non-propagated, subthreshold end-plate potential. They are recognized by their characteristic shape and sound and frequent association with end-plate spikes (see below).

End-Plate Spikes

These are rapid, irregular, and biphasic potentials with an initial negative deflection, reflecting that the needle is at the site where the action potential is generated (Fig. 7.15). They are muscle fiber action potentials which fire irregularly up to a frequency of 50 Hz and are usually seen along with end-plate noise (Fig. 7.16). They are thought to occur as a result of needle mechanical activation of terminal nerve twigs with subsequent activation of a nerve twig action potential leading to a muscle fiber action potential. They have a cracking or buzzing sound on the loud speaker, imitating "sputtering fat in a frying pan." It is of utmost importance to properly identify these potentials, so as not to mistake them for fibrillation potentials. *The key features that differentiate end-plate spikes from fibrillation potentials, which are also brief spikes, are their initial negative deflection and their highly irregular firing rate.*

Abnormal Spontaneous Activity

Muscle is normally electrically silent outside of the end-plate zone. Any persistent spontaneous activity, usually defined as lasting longer than 2–3 s, is abnormal. Spontaneous activity may be ongoing when the needle is placed in the muscle or may be triggered by needle movement, voluntary muscle contraction, muscle percussion, or electrical stimulation.

Fibrillation Potentials

Fibrillation potentials are *spontaneous action potentials of denervated single muscle fibers* (Fig. 7.17). Denervating potentials from single muscle fibers signify active denervation

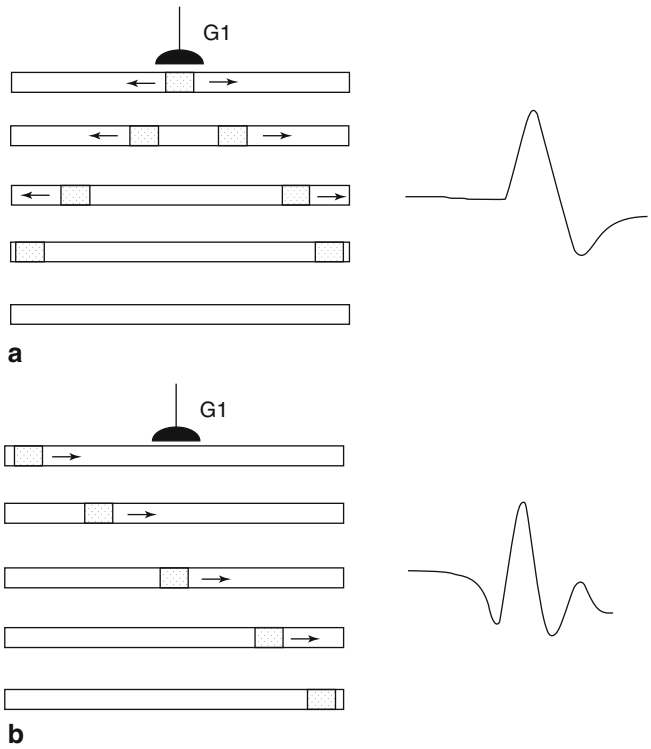

Fig. 7.15 Waveform morphology and site of depolarization. (**a**) (*Top trace*) A traveling depolarizing wave will create a biphasic potential if the waveform begins under the recording needle electrode (initial negative peak) and then moves away from the electrode (positive peak). This is known as an end-plate spike. (**b**) (*Bottom trace*) If the waveform begins at a distance from the needle, there is an initial positive deflection as it moves toward the needle, followed by a negative phase as it moves beneath the needle, and then a final positive deflection as it travels away. This is known as a fibrillation potential. End-plate spikes are differentiated from fibrillations by their absence of an initial positive deflection, as the depolarization begins at the end plate (Reproduced with permission from Preston and Shapiro [1])

Fig. 7.16 End-plate spikes. End-plate spikes result from needle-induced irritation of the terminal nerve twigs near the end plate. Note the initial negative deflection, brief duration, biphasic morphology, and the irregular, sputtering firing pattern which differentiates them from fibrillation potentials (Reproduced with permission from Preston and Shapiro [1])

Fig. 7.17 Fibrillation potential. Spontaneous depolarization of a single muscle fiber. Note the initial positive deflection, brief duration, and triphasic morphology (Reproduced with permission from Preston and Shapiro [1])

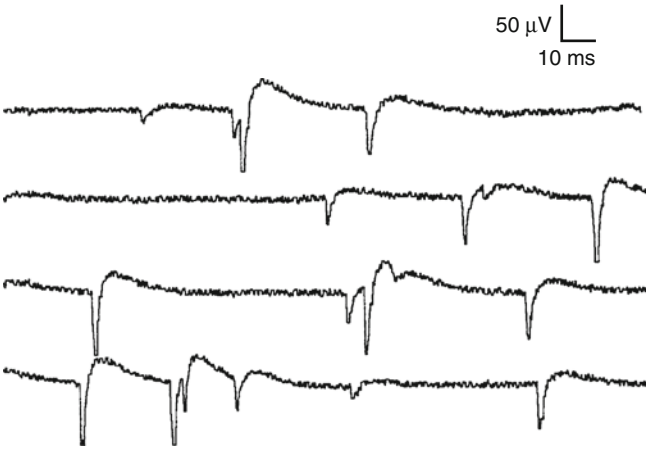

Fig. 7.18 Positive waves (*rastered traces*). Positive waves have the same significance as fibrillation potentials: they are the spontaneous depolarization of a muscle fiber. Note the initial positive deflection and the slow negative phase (Reproduced with permission from Preston and Shapiro [1])

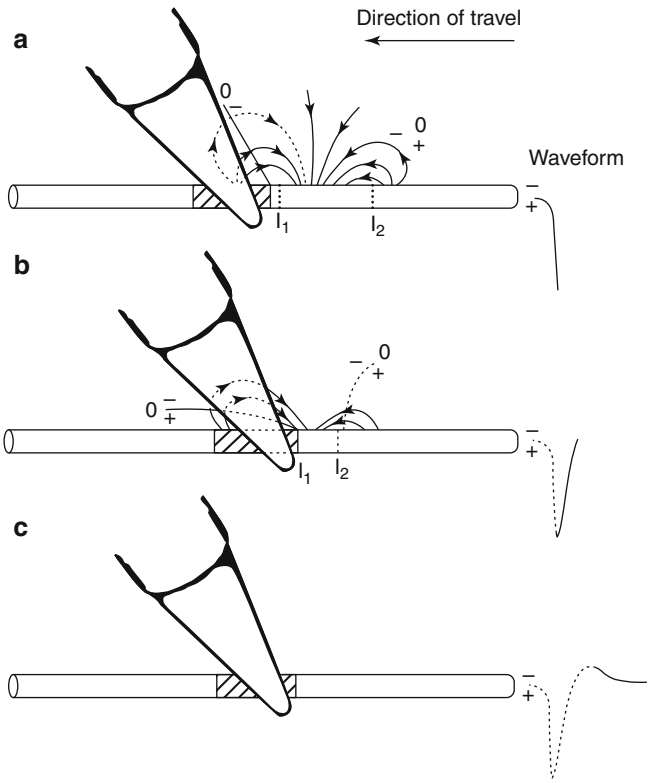

Fig. 7.19 Generation of a positive wave. The cross-hatched area is deformed by the needle electrode which becomes electrically inexcitable. (**a**, **b**) As the traveling depolarization wave approaches, an initial positive wave is generated. (**c**) With failure of conduction beyond the needle, the steep negative phase is aborted and the waveform returns to baseline (Reprinted with permission from Dimitru [8])

and may take one of two forms, either fibrillation potentials (brief spikes) or positive waves.

Fibrillation potentials are brief spikes that have an initial positive deflection and a triphasic morphology, because depolarization starts at a distance from the recording needle's tip (see Fig. 7.15). Their duration is about 1–5 ms, and their amplitude is typically 10–200 µV. In very chronic conditions (>6–12 months), the amplitude may be very low (<10 µV). Their firing pattern is *regular*, with a rate usually 0.5–15 Hz, but occasionally up to 30 Hz. On a loud speaker, fibrillation potentials may sound like "rain on the roof" or "the tick/tock of a clock." Although fibrillation potentials are regular, their firing rate may decrease (or sometimes increase) in a predictable fashion over several seconds before stopping.

Positive Waves

Positive waves have the same significance as brief spike fibrillation potentials (Fig. 7.18). They have a brief initial positive phase followed by a long negative phase. They sound like a dull pop, due to their slow negative phase and long duration. Their amplitude is variable (usually 10–100 µV, occasionally up to 3 mV). Like fibrillation potentials, their firing pattern is regular, with a rate usually 0.5–15 Hz, occasionally up to 30 Hz. This distinguishes them from MUAPs at a distance, which occasionally have positive wave morphology. Positive waves are often accompanied by brief spike fibrillation potentials, but they may be seen alone, sometimes early in denervation.

The explanation for the difference in morphology between a positive wave and a fibrillation potential is not completely agreed upon [6, 7]. One hypothesis is that fibrillation potentials are derived from the extracellular recording of a single muscle fiber depolarization, while positive waves are generated by the intracellular recording of a single muscle fiber depolarization. The more likely explanation for the positive wave is that the needle deforms an irritable muscle fiber, inducing a denervating potential at a distance down the fiber which propagates to the area of the needle but not beyond it (Fig. 7.19). This might explain why positive waves are occasionally seen earlier than fibrillation potentials: the presence of the needle is required to help generate these potentials. Occasionally, fibrillation potentials change to positive waves with EMG needle movement.

Fibrillation potentials are typically associated with neurogenic disorders (i.e., neuropathies, radiculopathies, motor neuron disease). In acute axon-loss lesions, fibrillation potentials appear in affected muscles at about the second week,

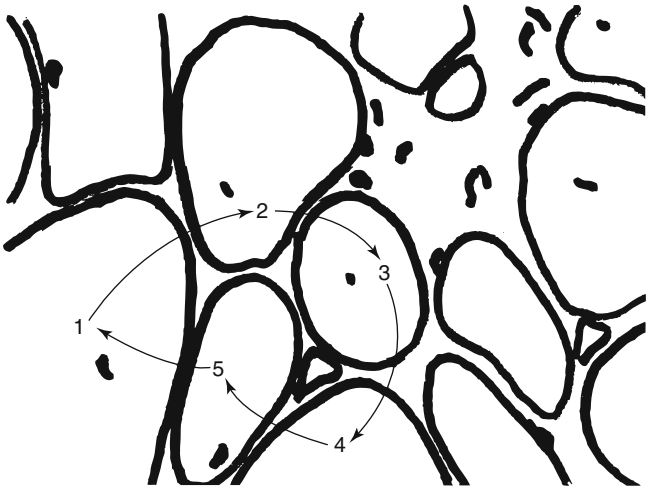

Fig. 7.20 Pathophysiology of a complex repetitive discharge. Ephaptic transmission from one denervated muscle fiber to an adjacent one. If the original pacemaker is reactivated, a circus movement is formed without an intervening synapse (Reproduced with permission from Preston and Shapiro [1])

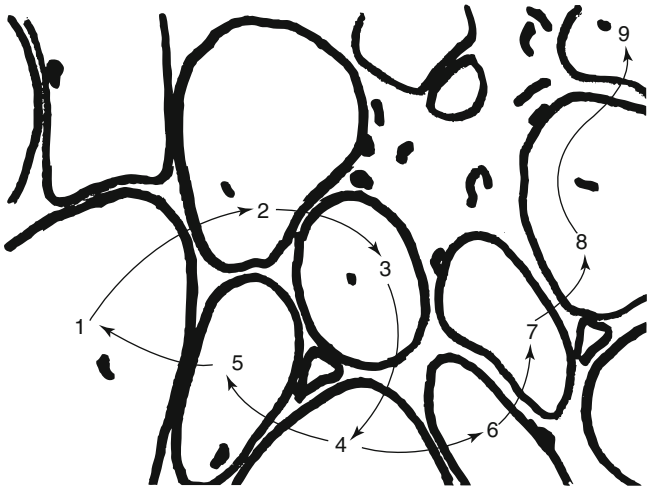

Fig. 7.21 Complex repetitive discharge. CRDs may change abruptly in frequency or number of potentials when extra loops drop in and out (Reproduced with permission from Preston and Shapiro [1])

Fig. 7.22 Typical complex repetitive discharge. Note the multiple spikes (each spike within the complex representing a different single muscle fiber) and the perfectly repetitive nature (Reproduced with permission from Preston and Shapiro [1])

first in proximally situated muscles and then more distally. They do not become widespread in all denervated muscles until about 4–6 weeks after an axonal nerve injury. They will ultimately decrease due to either reinnervation of muscle fibers or fatty degeneration of chronically denervated muscle fibers.

Fibrillation potentials may also be seen in muscle disorders (e.g., inflammatory myopathies and muscular dystrophies) and very rarely in severe diseases of the NMJ (e.g., myasthenia gravis and botulism). There are two possible explanations for the occurrence of fibrillation potentials in myopathies. The first is segmental necrosis of muscle fibers, leading to effective denervation of distal segments, because they become physically separated from the neuromuscular junction. The second explanation is damage to the terminal intramuscular motor axons, presumably by the inflammatory process, which results in denervation of some muscle fibers. In NMJ disorders, fibrillation potentials are rare and are likely due to persistent transmission block at NMJs, resulting in "effective" denervation of some muscle fibers.

The density of fibrillation potentials is a rough estimate of the extent of denervated muscle fibers. Hence, fibrillation potentials are graded from 0 to 4: 0 no fibrillations; +1 persistent single trains of potentials (>2–3 s) in at least two areas; +2 moderate number of potentials in three or more areas; +3 many potentials in all areas; and +4 full interference pattern of potentials.

Complex Repetitive Discharges

Complex repetitive discharges (CRDs) occur from the depolarization of a *single muscle fiber followed by ephaptic spread to adjacent denervated fibers* (Fig. 7.20). If a circus movement is created whereby the original pacemaker muscle fiber is reactivated, a recurrent discharge develops (Fig. 7.20). Occasionally, individual phases or additional ephaptic loops drop in and out, creating an abrupt change in frequency, configuration, and sound (Fig. 7.21). These discharges, referred to previously as bizarre repetitive discharges or bizarre high-frequency discharges, usually occur spontaneously or after needle movement. Less commonly, they are triggered by a stimulated or a voluntary MUAP. CRDs are regular, high-frequency (typically 20–150 Hz), and polyphasic (typically with 3–10 spikes) repetitive discharges with an abrupt onset and cessation (Fig. 7.22). The individual discharges within each CRD are uniform in morphology from one discharge to the next, creating a machine-like sound on loud speaker (Fig. 7.23).

CRDs are pathologic but nonspecific. They occur in chronic neuropathic and myopathic disorders. They may arise in any setting where denervated muscle fibers lie adjacent to each other. In neuropathic disorders, this occurs when there is denervation, reinnervation, and subsequent denervation (i.e., grouped atrophy). This situation may also occur in myopathic disorders associated with denervation/reinnervation (e.g., inflammatory myopathies) or with muscle fiber splitting. CRDs usually persist with neuromuscular junction blockade and have an abnormally low jitter on single-fiber

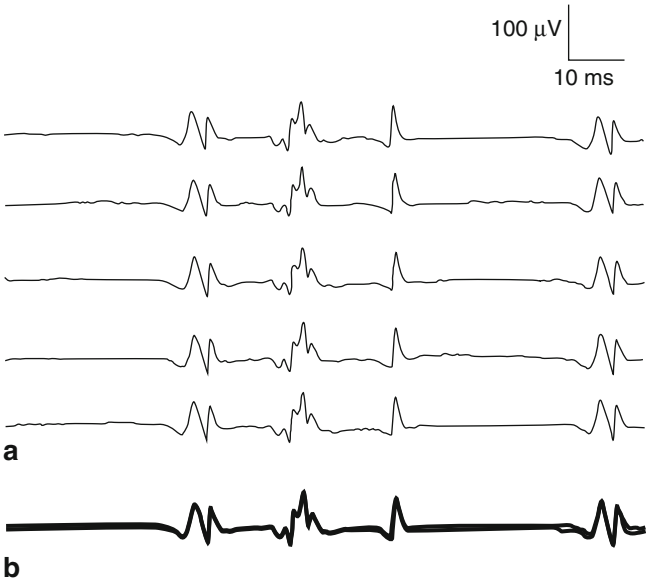

Fig. 7.23 Complex repetitive discharge. (**a**) (*Top traces*) CRD triggered on a delay line; (**b**) (*bottom trace*) Traces superimposed. Note the perfectly repetitive nature of a CRD. When superimposed, there is little or no jitter between successive potentials (Reproduced with permission from Preston and Shapiro [1])

Fig. 7.24 Myotonic discharge (needle induced). *Arrow marks* needle movement triggering the discharge. Myotonic discharges may occur spontaneously or be triggered by needle movement, voluntary contraction, or muscle percussion (Reproduced with permission from Preston and Shapiro [1])

EMG because the discharge spreads ephaptically with no intervening synapse.

Myotonic Discharges

A myotonic discharge is the spontaneous prolonged discharge of a muscle fiber, often induced by mechanical stimulation, which is characterized by waxing and waning of both amplitude and frequency. An individual myotonic potential may have either a positive wave or brief spike morphology. It is the waxing and waning of amplitude and frequency that differentiates a myotonic discharge from denervating potentials (i.e., fibrillation potentials and positive waves) (Fig. 7.24). The firing rate generally ranges between 20 and 150 Hz, which gives them a "revving engine" sound on the loud speaker.

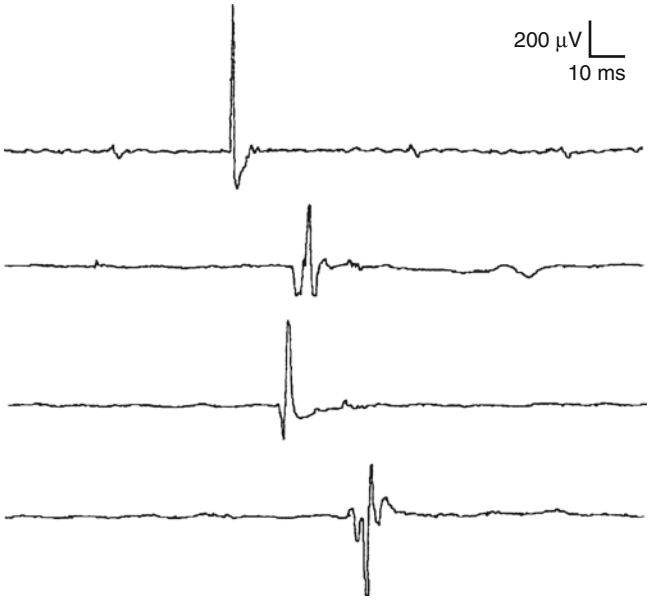

Fig. 7.25 Fasciculations (*rastered traces*). Each potential has the morphology of a motor unit. They are recognized by their morphology and irregular slow firing pattern (Reproduced with permission from Preston and Shapiro [1])

Myotonic discharges may occur with or without clinical myotonia in the myotonic dystrophies, myotonia congenita, paramyotonia congenita, and in some patients with hyperkalemic periodic paralysis. They may also occur in some myopathies (i.e., acid maltase deficiency, polymyositis, and myotubular myopathy). Rarely, they may be encountered in neurogenic disorders, usually as a single brief run where they are never the predominant waveform.

Fasciculation Potentials

A fasciculation potential is the *spontaneous discharge of an individual motor unit* (Fig. 7.25). Unlike a voluntary motor unit, fasciculation potentials generally fire randomly and irregularly, generally between 0.1 and 10 Hz. They usually have variable morphology, depending on the motor unit from which they arise, giving them a "popping corn" sound on the loud speaker. The source generator is the motor neuron or its axon prior to its terminal branches. Despite the notorious association of fasciculation potentials with diseases of the anterior horn cell, the actual site of origin of most fasciculation potentials is likely in the distal segment of the axon [9].

Fasciculation potentials are associated with disease processes affecting the lower motor neuron (e.g., motor neuron disease, amyotrophic lateral sclerosis) as well as radiculopathies, polyneuropathies, and entrapment neuropathies. In addition, they may occur in normal individuals. There is no reliable method of distinguishing "benign" from "malignant" fasciculation potentials except that benign discharges tend to fire faster and affect the same site repetitively (e.g., eye lid twitching).

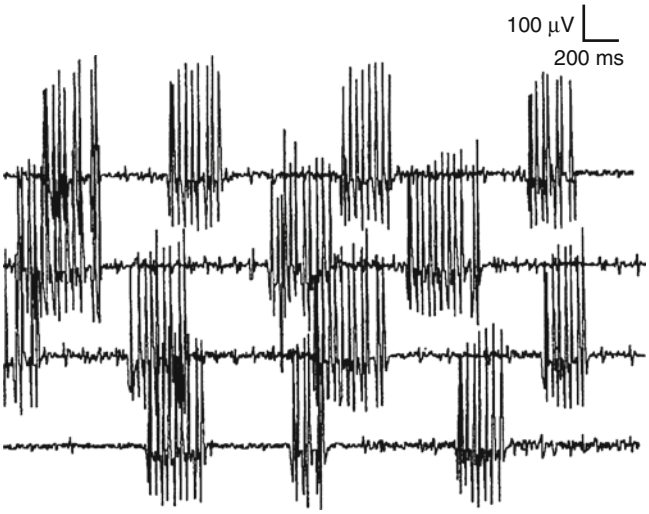

Fig. 7.26 Myokymic discharges (*rastered traces*, long sweep speed). Note that the number of potentials may change from burst to burst (Reproduced with permission from Preston and Shapiro [1])

Table 7.4 Disorders associated with myokymic discharges

Myokymic discharges commonly seen in:
Radiation injury (usually brachial plexopathy)
Guillain-Barré syndrome (facial)
Multiple sclerosis (facial)
Pontine tumors (facial)
Hypocalcemia
Timber rattlesnake envenomation
Myokymic discharges occasionally seen in:
Guillain-Barré syndrome (limbs)
Chronic inflammatory demyelinating polyneuropathy
Nerve entrapments
Radiculopathy

From Preston and Shapiro [1], with permission

Myokymic Discharges

Myokymic discharges are *rhythmic*, *spontaneous*, *grouped repetitive discharges of the same motor unit* (i.e., grouped fasciculations). The firing frequency within the burst is typically 5–60 Hz. The number of potentials within a burst varies widely and may change slightly from burst to burst (Fig. 7.26). The firing frequency between bursts is much slower (typically <2 Hz) and produces a sound like marching soldiers on the loud speaker. Changing the screen sweep to a longer sweep speed often helps to recognize the bursting pattern as that of a myokymic discharge. The origin of myokymic discharges likely involves spontaneous depolarization or ephaptic transmission along demyelinated segments of nerve.

Clinically, myokymia is recognized as continuous, involuntary, fine, wormlike, and quivering movement of muscle. Limb myokymia occurs in a variety of conditions including radiculopathy, entrapment neuropathy, and radiation-induced nerve damage (Table 7.4). In a patient with brachial plexopathy and a history of cancer and radiation, the presence of myokymia strongly supports a diagnosis of radiation plexopathy rather than recurrent neoplastic invasion. Facial myokymia occurs with brainstem lesions associated with multiple sclerosis, pontine gliomas, stroke, and following radiation. In Guillain-Barré syndrome, facial myokymia may occur in 15 % of patients, usually occurring early in the illness and remitting as the patient clinically improves. Generalized myokymia associated with Isaac's syndrome (syndrome of continuous motor unit activity) is often accompanied by neuromyotonic discharges [10] (see below).

Hypocalcemia may lead to spontaneous grouped repetitive discharges. These myokymic discharges, known as *tetany*, tend to occur initially in bursts of 2 or 3 s (doublets, triplets) and are more prevalent in distal muscles. When severe, they may result in involuntary spasms of the hands and feet (carpopedal spasms), with a characteristic hand posture (adduction of the thumb and fingers, extension of the interphalangeal joints, and flexion of the metacarpal-phalangeal joints and wrist). Similarly, myokymia of peripheral nerve origin may be provoked or enhanced by lowering serum ionized calcium with hyperventilation or the use of acid-citrate-dextrose anticoagulant (e.g., during plasma exchange). Administration of calcium can transiently decrease the generation of myokymic discharges.

Cramp Potentials

Cramps are painful, involuntary contractions of muscle which tend to occur when a muscle is in the shortened position and contracting. On EMG, a cramp discharge is either a *full interference pattern of motor unit action potentials with a normal morphology or several motor unit potentials firing repetitively and sometimes irregularly at high frequencies* (*usually 40–60 Hz*) (Fig. 7.27). The discharge often has an abrupt onset and cessation.

Cramps are common in normal individuals and often benign (e.g., nocturnal calf cramps, postexercise), but may be associated with a variety of neuropathic, endocrine, and metabolic conditions (see Chap. 71). Clinically, cramps may resemble muscle contractures that occur in several of the metabolic muscle diseases. However, the latter is characterized by complete electrical silence on needle EMG.

Neuromyotonic Discharges

Neuromyotonic discharges are high-frequency (150–250 Hz) decrementing repetitive discharges of a single motor unit that have a characteristic "pinging" sound on loud speaker (Fig. 7.28). They are rare and are seen either in chronic neuropathic diseases (e.g., patients with a history of poliomyelitis or adult spinal muscular atrophy) or in the syndrome of continuous motor unit activity (Isaac's syndrome) (see Chap. 70).

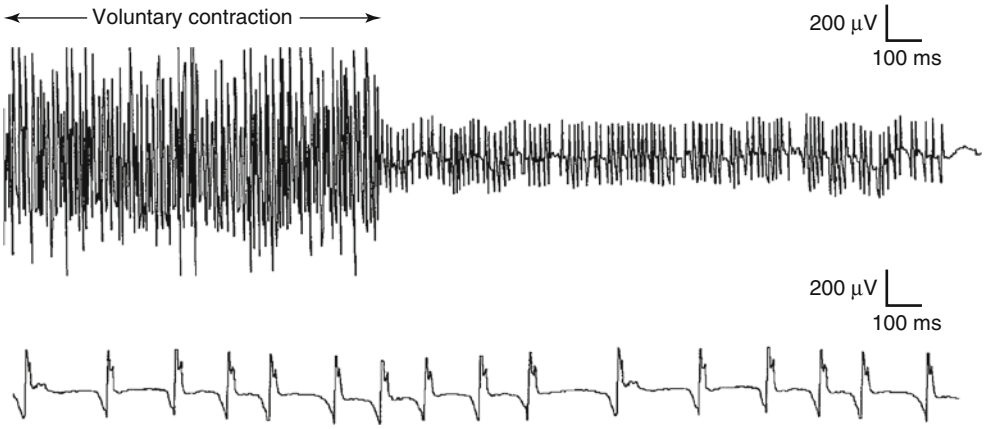

Fig. 7.27 Cramp potential. Note the involuntary repetitive discharge of a motor unit following voluntary contraction (Reproduced with permission from Preston and Shapiro [1])

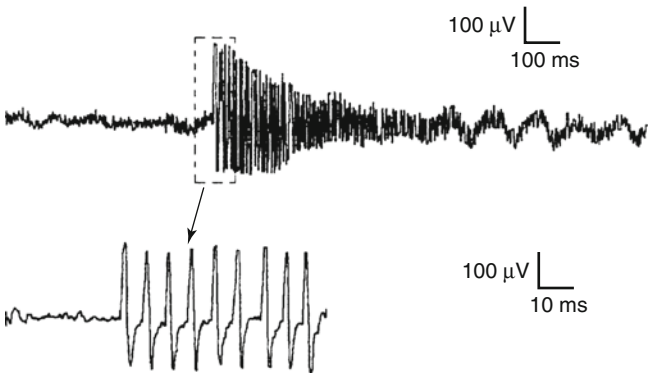

Fig. 7.28 Neuromyotonic discharges. Spontaneous discharge of a single motor unit at very high frequencies (150–250 Hz). Note the decrementing response. *Insert*: change in sweep speed identifies each potential as the same motor unit (Reproduced with permission from Preston and Shapiro [1])

There is strong evidence that neuromyotonic discharges, similar to myokymic discharges, are generated by damaged peripheral motor axons. This activity persists during sleep, as well as during spinal or general anesthesia, and is abolished by curare. Progressively distal nerve blocks diminish the intensity of the spontaneous discharges [11]. Many cases of neuromyotonia or continuous motor unit activity may have an autoimmune etiology, with the target antigen a peripheral nerve potassium channel [12].

Neuromyotonic disorders are associated with involuntary spontaneous discharges of MUAPs that manifest on EMG with neuromyotonic discharges as well as fasciculations, myokymic discharges, or complete interference patterns of MUAPs. The delay in relaxation and improvement with use are clinical features shared by both neuromyotonia and myotonia. However, what distinguishes them is that neuromyotonic discharges are spontaneous discharges generated by peripheral nerve (hence MUAPs), whereas myotonic discharges are the spontaneous discharges of muscle fibers (positive waves or brief spike morphology), hence the term *neuromyotonia*. Note that neuromyotonic discharges are not seen in Stiff man syndrome, a central disorder of spinal interneurons.

Analysis of Voluntary Motor Unit Action Potentials

Similar to the analysis of spontaneous activity, MUAPs must be assessed for morphology (duration, amplitude, phases), stability, and firing characteristics. The pattern of MUAP abnormalities seen on needle EMG often helps determine whether a disorder is primarily neuropathic or myopathic, its time course (acute versus chronic), and its severity. Assessment of MUAPs is often demanding and improves with the experience of the electromyographer over time. The task of evaluating MUAPs is made all the more difficult by the fact that there is wide variation in what is considered a normal MUAP, depending on the muscle being studied and the age of the patient.

Physiology

The motor unit, composed of an individual lower motor neuron and its associated neuromuscular junctions and muscle fibers, mediates all voluntary muscle activity. The number of muscle fibers per motor unit varies greatly, from 5 to 10 in laryngeal muscles to hundreds in the soleus. The territory of a motor unit usually ranges from 5 to 10 mm in adults, with many motor unit territories overlapping with one another, giving muscle a highly mosaic innervation. Hence, two muscle fibers from the same motor unit rarely lie adjacent to each other in healthy muscle. Motor unit territory increases greatly with age, doubling from birth to adulthood, mostly due to the increase in individual muscle fiber size.

When a motor neuron depolarizes, a nerve action potential is generated and propagates down the axon. Under normal circumstances, this results in muscle fiber action potentials of all muscle fibers of the motor unit. These potentials depolarize more or less simultaneously, except for what accounts for differences in the length of the terminal axons and NMJ transmission times. *The motor unit action potential* (*MUAP*) *is the extracellular electrode recording of a small portion of a motor unit* (Fig. 7.29).

The *size principle* governs many of the properties of motor units. The size of the motor neuron is directly related to (1) the size of the axon, (2) the thickness of the myelin sheath,(3) the conduction velocity of the axon, (4) the threshold to

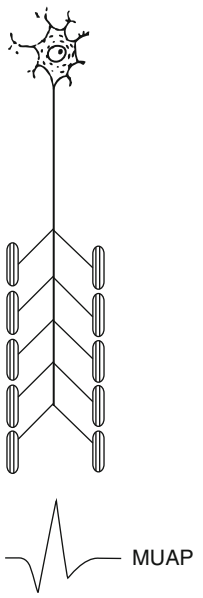

Fig. 7.29 The motor unit. The basic component of the peripheral nervous system is the motor unit, defined as an individual motor neuron, its axon, and associated neuromuscular junctions and muscles fibers. The extracellular needle EMG recording of a motor unit is the motor unit action potential (MUAP) (Reproduced with permission from Preston and Shapiro [1])

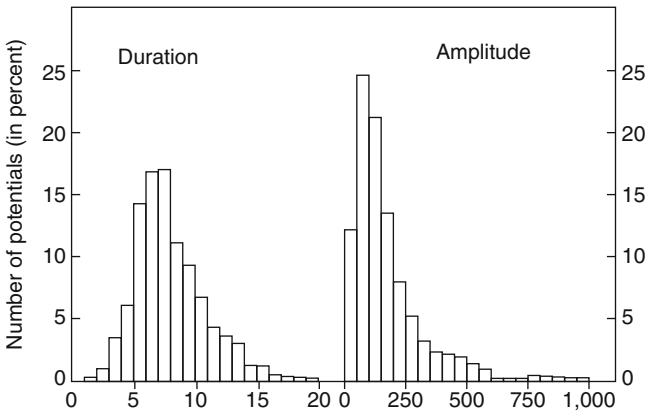

Fig. 7.30 Range of normal MUAP duration and amplitude. Histogram of MUAP duration and amplitude in the biceps brachii of a normal subject. Note: both MUAP duration and amplitude vary markedly in normal muscles with small and large units in the same muscle. MUAP duration or amplitude should not be classified as abnormal based on one or two MUAPs, but requires a mean of many units (Reprinted with permission from Bucthal et al. [13])

depolarization, and (5) the metabolic type of muscle fibers which are innervated. Larger motor neurons have larger axons, thicker myelin sheath, faster conduction velocity, and a higher threshold to depolarization. They innervate type II, fast-twitch muscle fibers. Conversely, smaller motor units have smaller axons, less myelin sheath, slower conduction velocity, and a lower threshold to depolarization. They generally innervate type I, slow-twitch muscle fibers. Thus, with voluntary contraction, the smallest motor units with the lower thresholds fire first. As contraction increases, progressively larger motor units begin to fire. The largest motor units fire only with maximum contraction. Hence, during routine needle EMG, most MUAPs analyzed are the smaller motor units which innervate type I muscle fibers.

During the needle EMG exam, each MUAP recorded represents the extracellular compound action potential of the muscle fibers of a motor unit, weighted heavily toward the fibers nearest to the needle. A MUAP, recorded at the outer surface of muscle membrane, is 1/10 to 1/100 the amplitude of the actual transmembrane potential and decreases rapidly as the distance between the needle and the membrane increases.

The classification of a MUAP as normal, neuropathic, or myopathic is based on the analysis of a MUAP's morphology (duration, polyphasia, and amplitude), stability, and firing pattern.

Motor Unit Action Potential Morphology

There is a wide range of normal MUAP morphology, with both large and small MUAPs present within each muscle (Fig. 7.30). The morphology of a MUAP can be judged on either a qualitative or quantitative basis (see Chap. 9). Over time and with experience, however, the well-trained electromyographer can usually perform qualitative MUAP assessment with the same precision as the quantitative methods. For both procedures, the needle is moved to several locations within the muscle until approximately 20 different MUAPs are examined and analyzed, comparing the findings to the expected normal values for that particular muscle and age group.

MUAP configuration varies depending on the muscle studied, the patient's age, and the location of the needle within the muscle (Table 7.5). This is especially true for MUAP duration. In general, MUAPs in proximal muscles tend to be shorter in duration than those in distal muscles. MUAPs are larger in adults than in children, primarily due to an increase in the size of muscle fibers during development. In addition, MUAPs are larger in older individuals, probably as the result of dropout of motor units from the normal effects of aging, leading to some degree of reinnervation. By comparing mean MUAP morphology in each muscle studied to normal values for that particular muscle and age group, one can judge whether the morphology is normal or abnormal.

The major spike of the MUAP is the largest positive to negative component of the MUAP, usually occurs after the first positive peak, and is the highest-frequency component of the potential (Fig. 7.31). Because tissue acts as a high-frequency filter, as the needle is moved closer to the MUAP, the major spike increases in amplitude, its rise time shortens, and its sound on the loud speaker becomes "sharp." MUAP parameters should only be measured when the needle is very close to the motor unit, with the major spike rise time being less than 500 μs (Fig. 7.32).

Table 7.5 Mean MUAP duration based on age and muscle group

	Arm muscles					Leg muscles

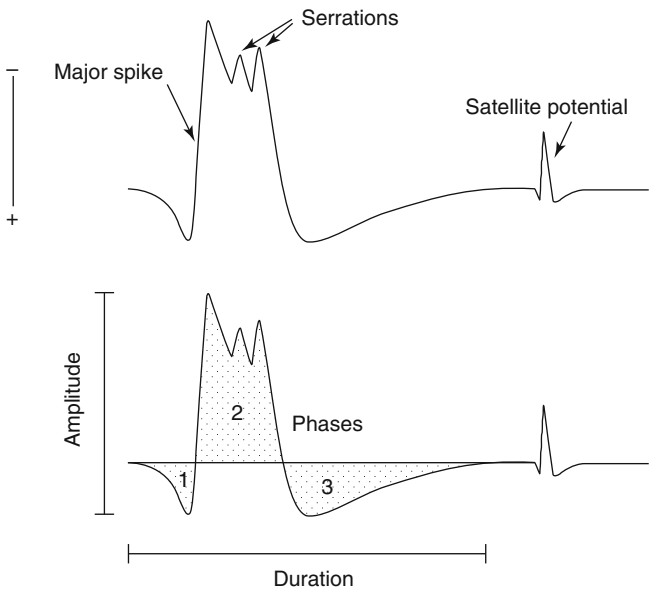

Fig. 7.31 Motor unit action potential measurements. Duration is measured as the time from the initial deflection of the MUAP from baseline to its final return to baseline. It is the parameter that best reflects the number of muscle fibers in the motor unit. Amplitude only reflects muscle fibers very close to the needle and is measured peak to peak. Phases (*shaded areas*) can be determined by counting the number of baseline crossings and adding one. MUAPs are generally triphasic. Serrations (a.k.a. turns) are changes in direction of the potential that do not cross the baseline. The major spike is the largest positive to negative deflection, usually occurring after the first positive peak. Satellite or linked potentials occur following the main potential and usually represent early reinnervated muscle fibers (Reproduced with permission from Preston and Shapiro [1])

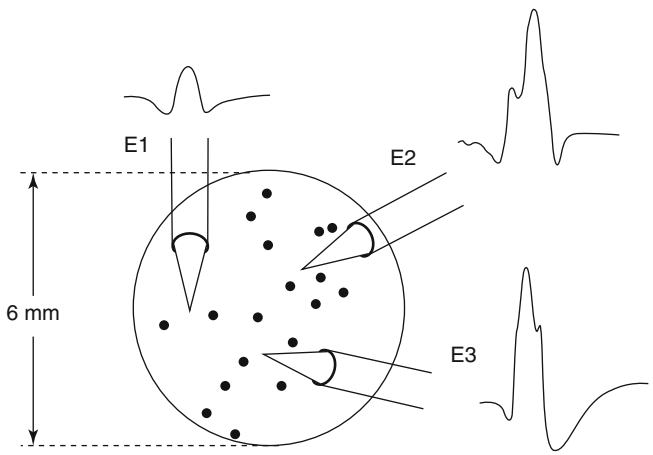

Fig. 7.32 MUAP morphology and needle EMG position. The position of the EMG needle influences the morphology of the recorded MUAP. To properly assess MUAP parameters, the major spike must be as steep as possible, indicating the proximity of the needle to the motor unit. Note that needle electrode position E3 has the shortest major spike rise time and is the preferable position in which to assess the MUAP. Also note that while MUAP amplitude changes markedly with needle position (compare position E1–E3), duration is relatively unaffected (From Dumitru and DeLisa [15]. Muscle Nerve © 1991. Reprinted by permission of John Wiley & Sons, Inc.)

Duration

MUAP duration is the parameter that best reflects the number of muscle fibers within a motor unit. MUAP duration is measured from the initial deflection away from baseline to the final return to baseline. Typical MUAP duration is between 5 and 15 ms. It depends primarily on the number of muscle fibers within the motor unit and the dispersion of muscle fiber depolarizations overtime. This dispersion depends on the longitudinal and transverse scatter of end plates and variations in distances and conduction velocities of distal nerve terminals.

MUAP duration increases with age and with low temperature. MUAP duration correlates well with pitch on the loudspeaker. Long-duration MUAPs (low frequencies) sound dull and thuddy, whereas short-duration MUAPs (higher frequencies) sound crisp and sharp. As the electromyographer gains experience, the sound of a long-duration versus short-duration MUAP becomes unmistakable.

Long-duration MUAPs often show high amplitude and decreased recruitment (see section "Firing Pattern [Activation, Recruitment, and Interference Pattern]"). They are the best indicators of reinnervation. They are usually seen in chronic neurogenic disorders, but may be encountered in chronic myopathies, such as inclusion body myositis, polymyositis, or muscular dystrophy. Long-duration MUAPs are due to increased fiber density in the motor unit, increased number of fibers in the motor unit, or decreased synchrony among its muscle fibers.

Short-duration MUAPs often have low amplitude and early (rapid) recruitment (see section "Firing Pattern [Activation, Recruitment, and Interference Pattern]"). They are caused by loss of muscle fibers from the recorded motor unit, physiologic blockade of end plates, or atrophy of muscle fibers. Short-duration MUAPs are the hallmarks of myopathic disorders, particularly when associated with muscle fiber necrosis. However, they may also be seen in NMJ disorders (e.g., myasthenia gravis and LEMS).

Polyphasia, Serrations, and Satellite Potentials

MUAP configuration may be monophasic, biphasic, triphasic, or polyphasic. Polyphasia depends primarily on the synchrony of muscle fibers firing. The number of phases can easily be calculated by counting the number of baseline crossings of the MUAP and adding one. Normally, MUAPs have two to four phases. However, in normal subjects, 5–10 % of MUAPs may be polyphasic, and this may be up to 25 % in proximal muscles, particularly the deltoid and iliacus muscles. Polyphasic MUAPs have a high-frequency clicking sound on EMG. Increased polyphasia is a nonspecific abnormality, because it may be seen in myopathic and neuropathic disorders.

Serrations (turns or potential reversals) are defined as a change in direction of the potential which does not

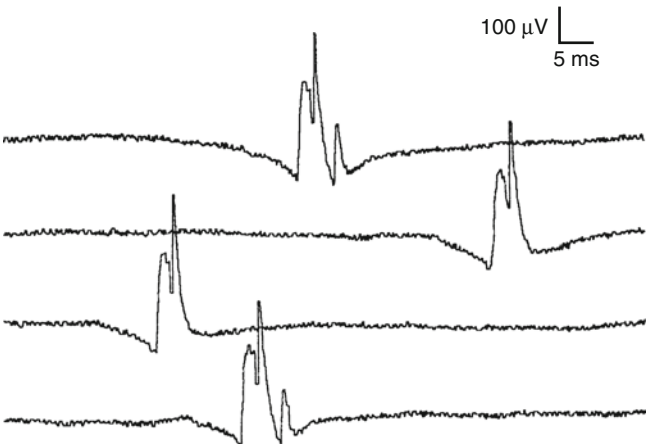

Fig. 7.33 Unstable motor unit action potentials (MUAPs). MUAPs that change in amplitude or number of phases from impulse to impulse are called unstable MUAPs. Unstable MUAPs occur in both primary NMJ disorders and disorders associated with new or immature NMJs as commonly occurs early in reinnervation. Note the blocking of last phase in the second and third MUAPs. This late phase likely represents an early reinnervated muscle fiber attached to the main MUAP (Reproduced with permission from Preston and Shapiro [1])

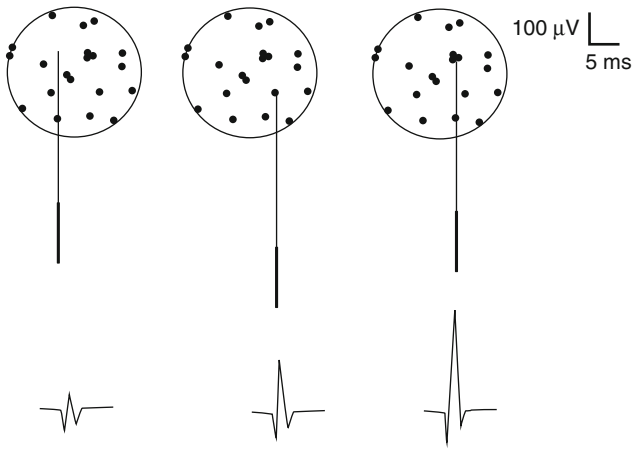

Fig. 7.34 Relationship of MUAP amplitude to needle position. Of all MUAP parameters, amplitude is most dependent on needle position. Only those muscle fibers very close to the needle contribute to amplitude, as opposed to duration where most muscle fibers contribute. Note the change in amplitude as needle is moved to different locations within the same motor unit (Reproduced with permission from Preston and Shapiro [1])

subsequently cross the baseline (see Fig. 7.31). Increased serrations have similar implications as polyphasia, indicating less synchronous firing of muscle fibers within a motor unit. Often, a MUAP turn may be changed into a phase with slight needle movement.

Satellite potentials (a.k.a. linked potentials or parasite potentials) are late spikes of the MUAP, which are distinct, but time locked with the main potential (see Fig. 7.31). Satellite potentials are often seen following early reinnervation of denervated muscle fibers by collateral sprouts from adjacent motor units. The newly formed nerve terminal may be long and is often small, thinly myelinated, and, hence, slowly conducting. Because of slow conduction time, increased distance, or both, reinnervated muscle fibers are seen as satellite potentials that trail the main MUAP. It is useful to record the main MUAP on a trigger line to appreciate a satellite potential and demonstrate that it is time locked to the main potential. Satellite potentials may be unstable (see below), resulting in firing rate variability or intermittent blocking (Fig. 7.33). Over time, the sprout matures, the myelin thickens, and consequently the conduction velocity increases. The satellite potential then fires more closely to the main potential and ultimately fuses with it to become an additional phase or serration within the main complex.

Amplitude

MUAP amplitude is the maximum peak-to-peak amplitude of the potential and varies widely among normal individuals. Most MUAPs have amplitudes greater than 100 µV and less than 2 mV. Unlike duration, only a few muscle fibers of a motor unit contribute to the amplitude. MUAP amplitude only reflects those few fibers nearest to the needle's tip.

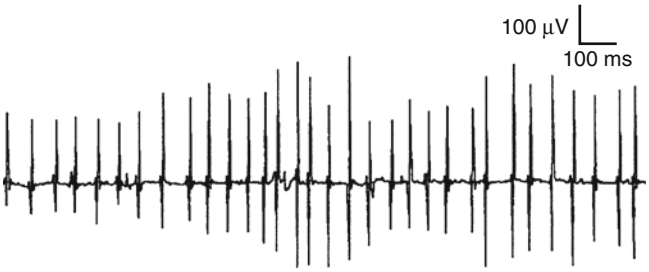

Fig. 7.35 Unstable motor unit action potentials. MUAPs that change in either amplitude or number of phases from impulse to impulse are called unstable MUAPs. Unstable MUAPs occur in both primary NMJ disorders and disorders associated with new or immature NMJs as commonly occurs early in reinnervation. Note the change in amplitude from potential to potential (Reproduced with permission from Preston and Shapiro [1])

Several factors are associated with increased amplitude, including (1) the proximity of the needle to the motor unit (Fig. 7.34), (2) increased density of muscle fibers (increased number of muscle fibers in a motor unit), (3) increased size of muscle fibers (i.e., muscle fiber hypertrophy), and (4) increased synchrony of muscle fibers' firing. On the loudspeaker, the amplitude of the MUAP correlates with volume rather than the pitch.

Stability

Under voluntary control, each firing MUAP is usually stable and has the same amplitude, duration, and morphology. This stability is due to effective transmission across the neuromuscular junction (NMJ), resulting in firing of all muscle fibers of the motor unit. If there is impaired NMJ transmission, unstable (variable) MUAPs may result (Figs. 7.33 and 7.35). Unstable MUAPs occur when individual muscle fibers

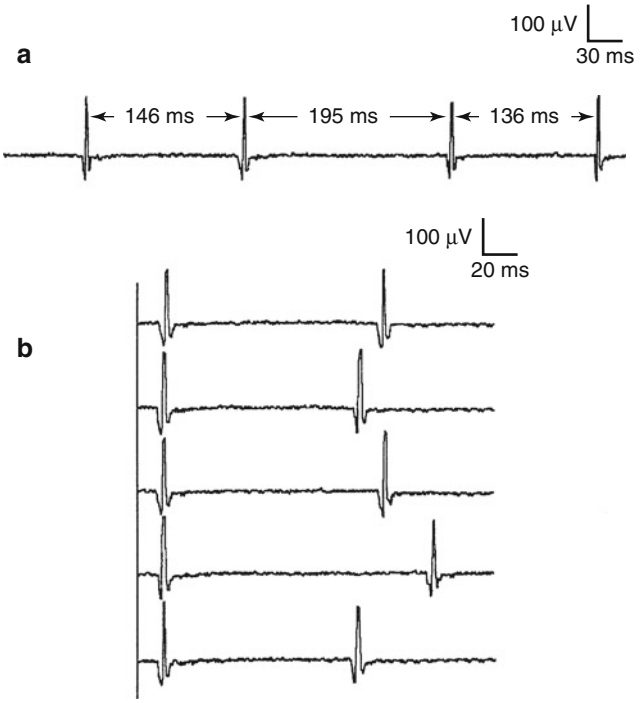

Fig. 7.36 MUAP firing pattern. Normally, MUAPs firing in a semi-rhythmic pattern, with a slight variation in the interval between potentials. (**a**) (*Top trace*) Single voluntary MUAP firing at ë 6 Hz. Note the variation in interpotential intervals; (**b**) (*Bottom trace*) Single voluntary MUAP placed on a delay line and rastered. First potential of each sweep triggers sweep. Note the variation between firing time of the next consecutive MUAP. The pattern is not quite regular (i.e., semi-rhythmic). This firing pattern is only seen with voluntary activated MUAPs (Reproduced with permission from Preston and Shapiro [1])

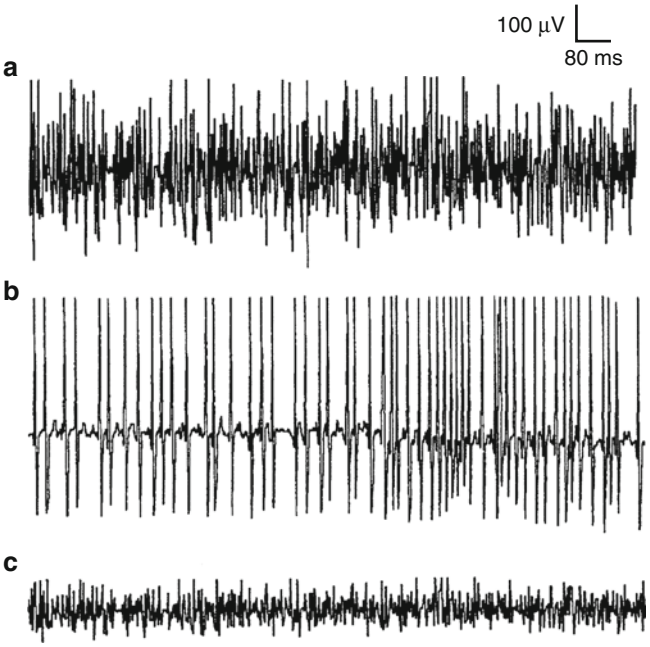

Fig. 7.37 Interference patterns. (**a**) (*Top trace*) Normal; (**b**) (*Middle trace*) Neurogenic; (**c**) (*Bottom trace*) Myopathic. In each trace, the patient is asked to maximally contract. In normals, so many MUAPs fire during maximal contraction that differentiating individual units is difficult. In neurogenic recruitment, a reduced number of MUAPs fire at a high frequency, resulting in an incomplete interference pattern. In myopathic recruitment, while the number of MUAPs is normal, the interference pattern consists of short-duration, small amplitude MUAPs (Reproduced with permission from Preston and Shapiro [1])

are either blocked or come to action potential at varying intervals. An unstable MUAP changes in configuration from impulse to impulse. Either the amplitude or number of phases or serrations changes between potentials. Unstable MUAPs always indicate unstable NMJs and occur in primary disorders of the NMJ (e.g., MG, LEMS), as well as in neuropathic and myopathic disorders associated with denervation and reinnervation. During the early process of reinnervation, newly formed (immature) NMJs often fail to conduct NMJ transmission faithfully. This results in variability in end-plate transmission or intermittent blocking of transmission across some of the muscle fibers within a motor unit.

Firing Pattern (Activation, Recruitment, Interference Pattern)

Under voluntary control, MUAPs normally fire in a *semi-rhythmic pattern*, with slight variation in the time interval between the same MUAP as it fires consecutively (Fig. 7.36). This unique firing pattern distinguishes MUAPs from fibrillation potentials or positive waves, which are fairly regular; CRDs, which are perfectly regular; myotonic discharges, which have a waxing/waning quality; myokymic discharges, which fire in a bursting pattern; and fasciculation potentials, which are very irregular.

At a given time, one may enhance muscle force by either increasing the firing rate of motor units or by adding (recruiting) additional motor units. In normal conditions, one increases force using a combination of these two processes, resulting in an orderly recruitment of motor units. Initially, a single motor unit begins firing semi-rhythmically at 4–5 Hz. As one attempts to increase force, the first motor unit increases its firing rate, and then a second motor unit begins to fire, and so forth. This process continues, with the firing rate increasing and additional motor units being recruited, as force is increased. *Normally*, *the ratio of firing frequency to the number of different MUAPs firing is approximately 5:1*. Hence, by the time the first MUAP firing frequency reaches 10 Hz, a second MUAP should begin to fire; by 15 Hz, a third unit should fire; and so forth. For most muscles, the maximal firing frequency is 30–50 Hz. Important exceptions include quick ballistic contraction, in which the firing frequency may transiently reach 100 Hz, and muscles that are predominantly slow twitch (e.g., soleus), in which the maximal firing frequency is approximately 15 Hz.

During maximal contraction, multiple MUAPs normally overlap and create an *interference pattern* in which no single MUAP can be distinguished (Fig. 7.37). The interference pattern reflects the number of MUAPs firing in relation to their firing rate and depends on two processes: activation and

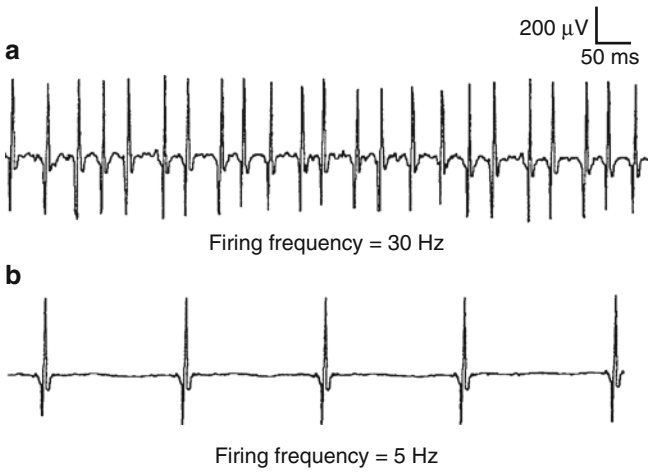

Fig. 7.38 Incomplete interference patterns. In both traces, the patient is asked to maximally contract their muscle with the needle EMG in place. (**a**) The *top trace* demonstrates an incomplete interference pattern due to reduced recruitment. (**b**) The *bottom trace* demonstrates an incomplete interference pattern due to reduced activation (Reproduced with permission from Preston and Shapiro [1])

recruitment. *Activation*, a central process, refers to the ability to increase motor units' firing rates. Hence, poor activation may be seen in central nervous system (CNS) disorders affecting motor unit control or as a manifestation of pain, poor cooperation, or functional disorders. *Recruitment* refers to the ability to add motor units as the firing rate increases. Recruitment is reduced in lower motor neuron disorders and, occasionally, in severe end-stage myopathy.

Recruitment may be assessed during maximum contraction by examining the interference pattern or during moderate levels of contraction by estimating the number of MUAPs firing for the level of activation (firing rate). For example, if only one MUAP is firing at 15–20 Hz (medium level of activation), then recruitment is decreased, regardless of the interference pattern. During maximal contraction, judging the relationship between the number of MUAPs firing and the firing rate can actually be difficult. Maximal contraction is most valuable in excluding mild degrees of decreased recruitment.

An incomplete interference pattern may be due to either poor activation or reduced recruitment. *Decreased recruitment* occurs when there has been loss of MUAPs, usually through axonal loss or conduction block. It may also occur in severe myopathy, wherein MUAPs are effectively lost, due to complete loss of muscle fibers within a MUAP. In Fig. 7.38, tracings from two patients are shown; both were asked to maximally contract the sampled muscle. In the first case (top trace), there is a single MUAP firing rapidly at 30 Hz. Thus, while the firing rate is maximal, only one MUAP is seen firing at 30 Hz. In a normal muscle, one should see 5–6 different MUAPs firing by the time the firing rate reaches 30 Hz (approximately 5:1 ratio). Thus, in this upper trace, the interference pattern is reduced due to decreased recruitment, but activation (firing rate) is normal. Contrast this with the tracing from the second patient (bottom trace), in whom there was a single MUAP firing at 5 Hz. Thus, the firing rate (activation) is clearly submaximal, although the number of MUAPs firing (recruitment) is normal for the firing rate (approximately 5:1 ratio). In this case, the interference pattern is reduced primarily due to decreased activation, but recruitment (number of MUAPs) is appropriate for the level of activation. In this case, the patient's weakness is reflected in the decreased activation of motor units, judged by submaximal sustained firing rate. This pattern of reduced activation may be seen if a patient cannot fully cooperate, perhaps secondary to pain, or if they have a CNS lesion (e.g., stroke, multiple sclerosis).

Poor activation and decreased recruitment may occur simultaneously in disorders affecting both upper and lower motor neurons, such as amyotrophic lateral sclerosis, or in patients with neuropathic disorders and pain (e.g., difficulty flexing or abducting the hip in a patient with painful L5 radiculopathy).

Early (*increased*) *recruitment* refers to the inappropriate firing of many motor units to generate a small amount of force. In diseases in which there is dropout of individual muscle fibers from a motor unit (e.g., myopathies or NMJ diseases with block), the motor unit becomes smaller and subsequently can generate less force. Because each motor unit generates less force, many motor units must fire to generate even a small amount of force. This is known as early recruitment, which refers to the inappropriate firing of many motor units to generate a small amount of force. On the EMG monitor, many MUAPs will appear to fire almost simultaneously with small amounts of force, as assessed by the electromyographer. In addition to early recruitment, mild and severe myopathies may result in normal or reduced recruitment, respectively.

Factors Affecting Nerve Conduction Studies and Needle EMG

Failure to understand the artifacts and technical factors that can influence EDX studies may lead to difficulty obtaining potentials, may prolong a study, and, most importantly, can result in the mistaken impression of pathology where none exists (Table 7.6). Physiologic variables, such as limb temperature, age, and anomalous innervations, as well as nonphysiologic factors, such as electrode impedance and electrical noise, may lead to difficulty obtaining potentials, variability of results among different studies, and misinterpretation of results.

Table 7.6 Important technical factors influencing nerve conduction studies and EMG

Physiologic Factors

Temperature

Temperature is the most important physiologic factor, affecting nearly every parameter measured in NCSs and needle EMG, including conduction velocity, distal latency, and waveform morphology. Cooling produces a delay in activation of sodium channels in axon and muscle membranes, which lead to an increase in the size of the nerve and muscle fiber action potentials.

Cool limb temperature results in slowing of distal latencies and conduction velocities, more so in large than small myelinated fibers. As the large myelinated fibers are those typically recorded during routine NCSs, changes in temperature may have significant effects. Conduction time slows in a fairly linear manner within the normal physiologic range of limb temperature (approximately 21–34 °C). In normal peripheral nerve, motor and sensory conduction velocities slow between 1.5 and 2.5 m/s for every 1 °C drop in temperature, and distal latencies prolong by approximately 0.2 ms/°C.

Cooling also has a significant effect on CMAP and SNAP morphology. Cooling results in higher-amplitude and longer-duration CMAP and SNAP (Fig. 7.39). This effect is more pronounced in sensory fibers. *The combination of increased amplitude with slow distal latency* (*or slowing of conduction velocity*) *is characteristic of a cool limb*.

Lowering the temperature has a similar, though less marked and somewhat controversial, effect on MUAPs. MUAP duration and amplitude increase with cooler temperatures (Fig. 7.40) and, correspondingly, the number of phases may also increase.

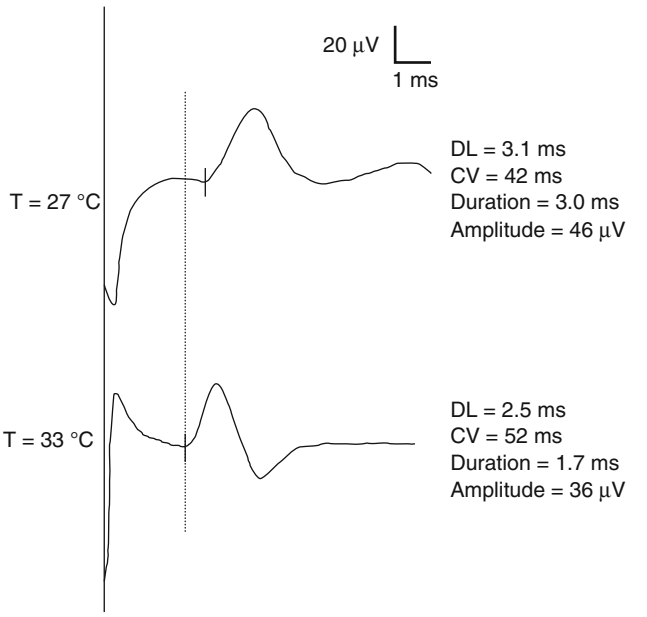

Fig. 7.39 Temperature effect on nerve conduction studies. Median antidromic sensory studies, stimulating wrist, recording second digit. Same patient at different limb temperatures. Note that with cooler limb temperature (*top*), distal latency and conduction velocity slow, while duration and amplitude increase (Reproduced with permission from Preston and Shapiro [1])

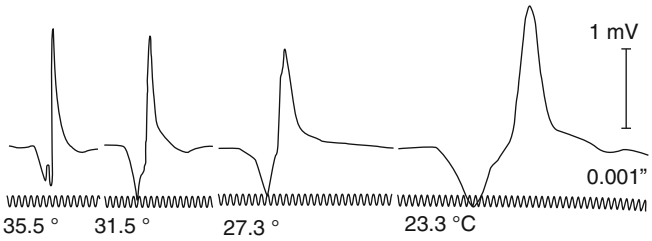

Fig. 7.40 Effect of muscle temperature on motor unit action potential (From Daube [16])

Therefore, limb temperatures should be routinely recorded and monitored in all patients and ideally maintained between 33 and 34 °C. If a limb is cool, immersing the limb in warm water and allowing it to heat up over several minutes is the best warming method. Surface heating with a heating lamp can be used, but often requires a long time to heat the limb adequately and may be hazardous (resulting in burns particularly in patients with impaired sensation). Warming packs or a hydroculator can also be used, particularly in bedridden or intensive care unit patients. Nerve conduction time correction factors can be used for cool temperatures, but are not as preferable as rewarming the limb; correction factors may not necessarily apply in a similar manner to patients with diseased peripheral nerves.

Age

Myelination is incomplete at birth. Peripheral nerves continue to myelinate over the first few years of life, with myelination completed between the ages of three and five. Nerve conduction velocities in newborn infants are approximately 50 % of normal adult values. They quickly increase after birth, reach approximately 75 % of adult normal values by 1 year of age, and are equivalent to adult values by the age of 2–3 years. Distal latencies and conduction velocities remain relatively unchanged throughout adulthood, but have a tendency to slow slightly with advancing age. This effect is slightly more pronounced for sensory than motor fibers, begins as early as the age of 20 years, and becomes more prominent after the age of 40. Overall, motor and sensory conduction velocities decrease by approximately 0.5–4 m/s/decade.

Age also has an effect on CMAP and SNAP amplitudes, both increasing in the first 2–3 years of life and declining slowly after the age of 60 years. This also affects SNAP amplitudes more prominently, so much that normal SNAP amplitude drops up to 50 % by age 70.

Nerve conduction studies reference values should account for age-related changes in SNAP and CMAP amplitudes and in conduction velocities. Commonly, tables of normal control values provide lower limits of normal of nerve conduction parameters, usually for subjects between ages 10 and 60 years. Because normal values for the elderly are not generally available, additional correction factors of 0.5–4 m/s/decade can then be used for older patients. For example, a median motor conduction velocity of 46 m/s (lower limit of normal = 49 m/s) in a 90-year-old patient would be considered normal, within the expected range for advanced age.

Assessment of lower extremity SNAPs in an elderly individual, such as the sural or superficial peroneal sensory response, can be difficult. Because the sural sensory response is often a small potential in healthy subjects above the age of 60 years, it may be challenging to elicit. Thus, very low amplitude or absent lower extremity SNAPs in the elderly must always be interpreted with caution and are not necessarily considered abnormal without other confirmatory data.

Age also affects many parameters of the MUAP on needle EMG. The most prominent change is an increase in MUAP duration. From birth through childhood, the duration increases due to the physiologic increase of muscle fiber and motor unit size. In later life, the aging process is associated with a drop-out of motor units, which results in a small degree of reinnervation, which in turn results in slight prolongation of MUAP duration. Additionally, long-duration and high-amplitude MUAPs may be seen in the intrinsic muscles of the foot, particularly in the elderly patient [2].

Height

Height influences nerve conduction velocity. Taller individuals commonly have slower conduction velocities than shorter persons. The effect of nerve length also explains, in part, the slower conduction velocities in the lower extremities, compared to the upper extremities. For example, on average, the normal sural sensory conduction velocity is 5 m/s slower than the median sensory conduction velocity, and the peroneal and tibial motor velocities are typically 6–9 m/s slower than the median and ulnar motor.

Two separate factors likely account for the effect of height or limb length on conduction velocity. First, nerves taper as they proceed distally. In general, the taller the individual, the longer the limb, and the more tapered the distal nerve. Because conduction velocity is directly proportional to nerve diameter, the more distally tapered nerves in taller individuals conduct more slowly. By the same reasoning, nerves in the leg conduct more slowly than those in the arm, because of the longer limb length and more distal tapering. Second, limbs are cooler distally than proximally, and the legs are generally cooler than the arms. Thus, conduction velocity slowing due to cooling is usually more prominent in the legs than the arms and in tall subjects. Modifications must be made for individuals of extreme height, just as they are for extremes of age. In practice, this adjustment is usually no more than 2–4 m/s below the lower limit of normal. For example, for an individual who is 6′10″ (208 cm) tall, a tibial conduction velocity of 38 m/s (normal >41 m/s) should be considered within the normal range.

Location of Nerve Segment

Nerve conduction velocities vary between the distal and proximal segments of a limb because of changes in nerve diameter and temperature. As outlined above, proximal nerve segments tend to conduct slightly faster than distal segments in a normal individual. This is likely due to: (1) distal nerve segments are tapered and therefore conduct more slowly than proximal segments and (2) distal limb segments are cooler than proximal segments and therefore conduct more slowly as well.

Anomalous Innervations

There are important anatomical anomalous innervations of peripheral nerve that must be recognized routine nerve conduction studies. If these anomalies are not recognized, they may easily be mistaken for technical abnormalities or, in some cases, actual pathology. The most common are the Martin-Gruber anastomosis and the accessory deep peroneal nerve.

Martin-Gruber Anastomosis

The Martin-Gruber anastomosis (MGA) is a crossover of median-to-ulnar fibers. This anastomosis involves only motor fibers with sensory fibers being spared. The crossover usually occurs in the mid-forearm and rarely in the proximal forearm, either directly from the main trunk of the median

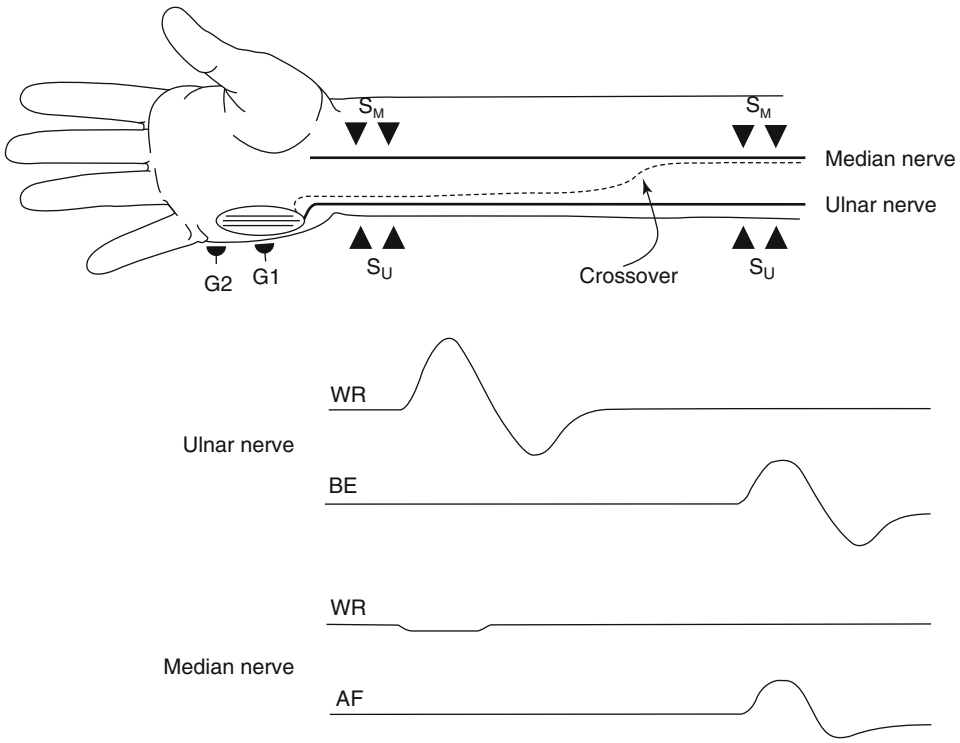

Fig. 7.41 Martin-Gruber anastomosis. Crossover of median-to-ulnar fibers supplying the hypothenar muscles may occur in MGA. During routine ulnar motor studies, recording the abductor digiti minimi and stimulating the ulnar nerve (S_U) at the wrist (*WR*) and below elbow (*BE*), the ulnar CMAP amplitude with below-elbow stimulation is lower than with wrist simulation. If not recognized, a mistaken impression of a conduction block may occur. To demonstrate a MGA in this situation, the median nerve is stimulated (S_M) at the wrist and antecubital fossa, while recording the hypothenar muscles, looking for a CMAP stimulating at the antecubital fossa that is not present stimulating at the wrist (*G1* active electrode, *G2* reference electrode) (Reproduced with permission from Preston and Shapiro [1])

nerve or from one of its branches, most commonly from the anterior interosseous nerve. The median fibers that have crossed over then run with the distal ulnar nerve to innervate either of the following ulnar muscles: (1) the hypothenar muscles (abductor digiti minimi), (2) the first dorsal interosseous muscle, (3) the thenar muscles (adductor pollicis, deep head of flexor pollicis brevis), or (4) a combination of these. This anomaly is quite common and occurs in approximately 15–30 % of patients. When present, it may be unilateral or bilateral.

During routine nerve conduction studies, the MGA may be recognized during several circumstances. First, the anomaly is often recognized during routine ulnar motor studies, recording either the abductor digiti minimi or first dorsal interosseous, stimulating at the wrist and below-elbow sites (Fig. 7.41). If a MGA is present, a characteristic pattern results with a drop in the ulnar CMAP amplitude between the wrist and the below-elbow stimulation sites. With stimulation at the wrist, the CMAP reflects all motor fibers innervating the ulnar muscles, including those that have crossed over from the median nerve. However, stimulation below the elbow activates fewer numbers of fibers, as some fibers innervating the ulnar muscles originate from the median nerve and cross over in the forearm. Other than a MGA, this pattern may also be seen with excessive stimulation of the ulnar nerve at the wrist, resulting in co-stimulation of the median nerve, submaximal stimulation of the ulnar nerve at the below-elbow site, and in true conduction block of the ulnar nerve between the wrist and below-elbow sites. Occasionally, MGA is proximal and the conduction block occurs across the elbow (between below-elbow and above-elbow stimulations), mimicking ulnar neuropathy at the elbow [17].

If a reduced ulnar CMAP is found at the proximal ulnar stimulation site (below elbow or above elbow) compared to the wrist, it is essential to first check that co-stimulation has not occurred at the wrist and that submaximal stimulation has not occurred at the proximal sites. Note that up to a 10–20 % drop in the ulnar CMAP amplitude at the below-elbow sites compared to wrist sites may occur in normal subjects, secondary to physiologic temporal dispersion. The major danger in not recognizing a MGA in this situation is to mistakenly interpret the findings as an unequivocal sign of ulnar nerve demyelination, that is, a conduction block in the forearm or across the elbow [17]. Whenever there is a >10–20 % drop in amplitude between the wrist and proximal sites on routine ulnar motor studies, median nerve stimulation should be performed at the wrist and at the antecubital fossa. If there is no MGA present recording the hypothenar muscles, no CMAP is noted or a small broad response positive deflection is recorded with both the wrist and antecubital fossa stimulation sites, reflecting a volume-conducted potential from median muscles. If a MGA is present recording the hypothenar muscles, median stimulation at the antecubital fossa will evoke a small CMAP over the abductor digiti minimi, while no CMAP or a small and broad positive volume-conducted potential will be present with median nerve stimulation at the wrist. The amplitude of the CMAP, evoked

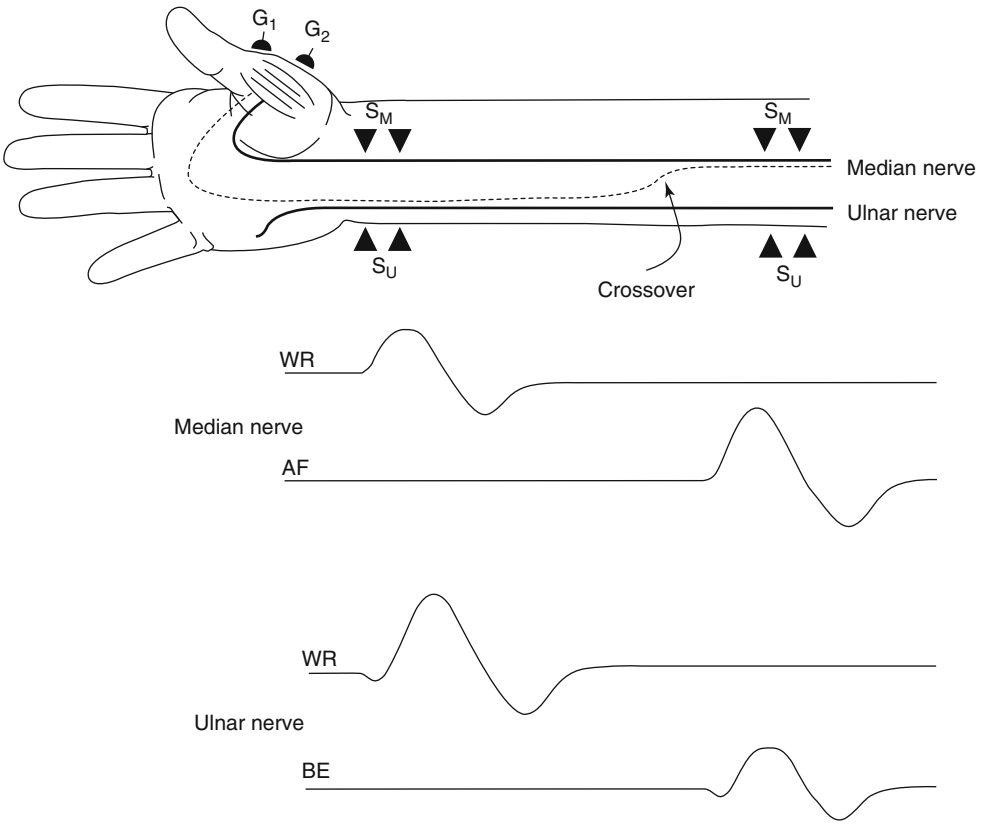

Fig. 7.42 Martin-Gruber anastomosis. Crossover of median-to-ulnar fibers supplying the thenar muscles may occur in MGA. During routine median motor studies, recording the abductor pollicis brevis and stimulating (S_M) at the wrist (*WR*) and the antecubital fossa (*AF*), the median CMAP amplitude stimulating the antecubital fossa is higher than that obtained with wrist simulation. Routine ulnar studies, recording the hypothenar muscles, are normal. To demonstrate a MGA in this situation, the ulnar nerve is stimulated (S_U) at the wrist and below elbow (*BE*), while recording the thenar muscles, looking for a drop in CMAP amplitude between the wrist and below elbow (*G1* active electrode, *G2* reference electrode) (Reproduced with permission from Preston and Shapiro [1])

by stimulating the median nerve at the antecubital fossa (recording the hypothenar muscles), will approximately equal the difference between the CMAP amplitudes evoked with ulnar nerve stimulation at the wrist and below-elbow site (or between below-elbow and above-elbow sites). If there is no MGA present recording the first interosseous muscle, small CMAPs with equal amplitudes are noted with both median nerve stimulations at the wrist and antecubital fossa, reflecting volume-conducted potential from the median thenar muscles into the first interosseous muscle recording site. If a MGA is present recording the first dorsal interosseous muscle, median stimulation at the antecubital fossa and wrist will evoke a CMAP over the first dorsal interosseous muscle, with the CMAP stimulating the antecubital fossa being larger than when stimulating the wrist. The difference in amplitudes of the CMAP, evoked by stimulating the median nerve at the antecubital fossa and wrist (recording the first dorsal interosseous muscle), will approximately equal the difference between the CMAP amplitudes evoked with ulnar nerve stimulation at the wrist and below-elbow sites (or below-elbow to above-elbow sites).

The second instance where a MGA should be suspected is during routine median motor studies, when the median-to-ulnar crossover innervates one of the ulnar innervated thenar muscles (i.e., adductor pollicis or deep head of the flexor pollicis brevis). With this type of MGA, routine ulnar motor studies, recording the abductor digiti minimi, will be normal. However, during routine median motor studies, recording the thenar muscles, a characteristic pattern develops: a higher CMAP amplitude stimulating the median nerve at the antecubital fossa than at the wrist (Fig. 7.42). Causes of this pattern include (1) submaximal stimulation of the median nerve at the wrist, (2) excessive stimulation of the median nerve at the antecubital fossa resulting in co-stimulation of the ulnar nerve, or (3) a MGA with crossing fibers innervating the thenar eminence.

To demonstrate that a MGA is present, the ulnar nerve must then be stimulated at the wrist and below-elbow sites while recording the thenar muscles. Normally, ulnar stimulation at the wrist, recording thenar muscles, evokes a thenar CMAP, usually with an initial positive deflection. This CMAP reflects the normal ulnar innervated muscles in the thenar eminence. If no MGA is present, subsequent stimulation of the ulnar nerve at the below-elbow site will evoke the same size CMAP potential. If a MGA is present, the CMAP amplitude will be substantially lower, stimulating the ulnar nerve at the below-elbow site than at the wrist. The difference in amplitude between these two potentials approximately equals the contribution of the crossing fibers.

When performing routine needle EMG, anatomical localization is based on the pattern of muscles involved and those spared. However, a patient with a MGA may have a different pattern than what is expected. For instance, a proximal lesion of the median nerve at or above the antecubital fossa may

cause abnormalities in median innervated muscles as expected. However, in a patient with a coexistent MGA, EMG abnormalities may also be seen in ulnar innervated hand muscles (especially the FDI and ADM that are commonly sampled during routine EMG). The opposite may occur with lesions of the ulnar nerve at or above the elbow. In this situation, there may be paradoxical sparing of ulnar innervated hand muscles if they receive a substantial portion of their innervation from the median-to-ulnar crossover fibers. This underscores that nerve conduction studies are needed to properly interpret any findings on needle EMG.

Accessory Deep Peroneal Nerve

The accessory deep peroneal nerve (ADPN) in the lateral calf is the most common anomalous innervation in the lower extremity. It is present in 19–28 % of the general population, based on electrophysiological studies, and in up to 67 %, based on anatomical studies, with a likely autosomal dominant mode of inheritance [18, 19]. This anomaly involves the innervation of the extensor digitorum brevis (EDB) muscle. The EDB is the usual muscle recorded during routine peroneal motor conduction studies and is normally innervated exclusively by the deep peroneal nerve. Patients with an ADPN will have an anomalous innervation to the EDB with the medial portion of the EDB supplied by the deep peroneal nerve as usual, but with the lateral portion supplied by an anomalous motor branch originating from the superficial peroneal nerve, the ADPN (Fig. 7.43).

During routine nerve conduction studies, this anomaly is recognized during peroneal motor studies. If the anastomosis is present, the peroneal CMAP amplitude, recording the EDB, is higher stimulating at the below-fibular neck and lateral popliteal sites than with stimulation at the ankle (Fig. 7.44). This pattern can be caused by either (1) submaximal stimulation of the peroneal nerve at the ankle site, (2) excessive stimulation of the peroneal nerve at the below-fibular neck and lateral popliteal sites causing co-stimulation of the tibial motor fibers, or (3) an ADPN.

To demonstrate the presence of an ADPN is quite simple and straightforward. An ADPN, if present, originates from the distal superficial peroneal nerve and travels down the lateral calf, posterior to the lateral malleolus. Following stimulation posterior to the lateral malleolus while recording the EDB, a small CMAP will be evoked if an ADPN is present. Commonly, the amplitude of CMAP, evoked by stimulating the ADPN posterior to the lateral malleolus, will approximately equal the difference between the CMAP amplitudes evoked with ankle and below-fibular neck/lateral popliteal stimulation sites of the peroneal nerve, recording the EDB.

Rarely, the EDB is totally and exclusively innervated by the ADPN [20]. This will result in an absent CMAP stimulating the peroneal nerve at the ankle with a normal CMAP stimulating proximally. The peroneal CMAP evoked behind the lateral malleolus is large and almost equals the below-fibular neck peroneal CMAP. When such a rare anomaly occurs along with a deep peroneal nerve lesion, EDB function is preserved, clinically and with needle EMG confirmation, despite evidence of severe deep peroneal nerve palsy.

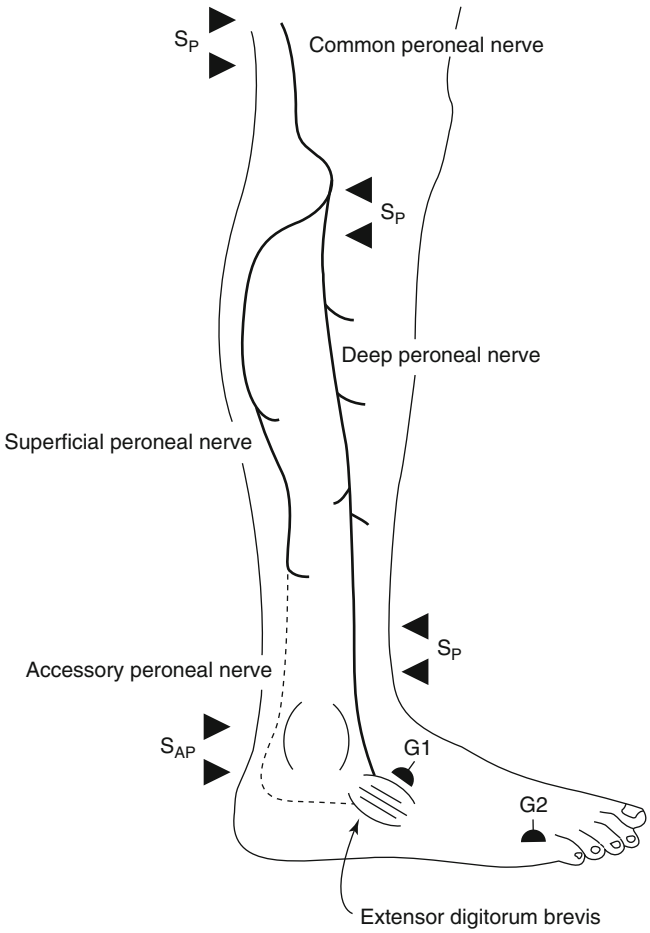

Fig. 7.43 Accessory peroneal nerve. The APN is derived from the distal superficial peroneal nerve and runs posterior to the lateral malleolus to supply the lateral portion of the extensor digitorum brevis muscle. During routine peroneal motor studies, recording the extensor digitorum brevis, the peroneal nerve is stimulated (S_P) at the ankle, below-fibular neck, and at the lateral popliteal fossa. If an APN is present, the CMAP amplitude will be higher stimulating below the fibular neck and lateral popliteal fossa as compared to stimulating at the ankle. To demonstrate an APN, stimulation is performed posterior to the lateral malleolus (S_{AP}), while recording from the extensor digitorum brevis muscle, looking for a CMAP (*G1* active electrode, *G2* reference electrode) (Reproduced with permission from Preston and Shapiro [1])

Riche-Cannieu Anastomosis

The Riche-Cannieu anastomosis is a hand anomaly with communication between the recurrent motor branch of the median nerve and the deep branch of the ulnar nerve. This results in dual motor innervation of some of the intrinsic hand muscles such as the first dorsal interosseous, adductor

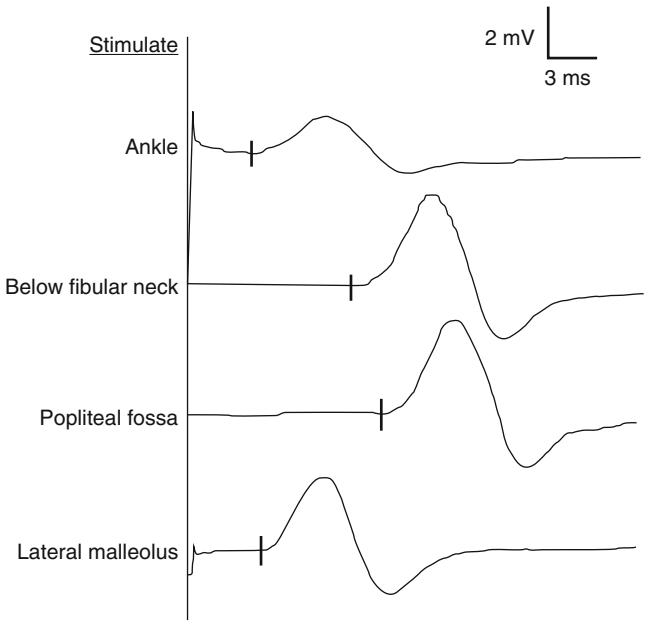

Fig. 7.44 Accessory peroneal nerve (APN). Routine peroneal motor study, recording the extensor digitorum brevis (EDB), stimulating at the ankle (*top trace*), below-fibular neck (*second trace*), and lateral popliteal fossa (*third trace*). The CMAP amplitude is higher stimulating below the fibula neck and popliteal fossa sites compared to stimulation at the ankle site. An APN is confirmed by stimulating posterior to the lateral malleolus and recording the EDB (*bottom trace*) (Reproduced with permission from Preston and Shapiro [1])

pollicis, and abductor pollicis brevis. Anatomical studies and surgical reports suggest that this anastomosis is common. However, this is not frequent apparent clinically or during nerve conduction studies. When prominent, this anastomosis is most evident during routine median motor nerve conduction studies. The median CMAP recording the abductor pollicis brevis is low in amplitude, stimulating wrist and antecubital fossa with normal distal latency, conduction velocity, and needle EMG. Stimulating the ulnar nerve at the wrist will evoke a robust CMAP recording abductor pollicis brevis. Care should be taken not to induce co-stimulation into the median nerve at the wrist. Also, when this anomaly is prominent, a severe or complete median or ulnar nerve lesion may be associated with relative sparing of some median innervated muscles or ulnar innervated muscles in the hand, respectively.

Nonphysiologic Factors

Electrode Impedance and Noise

All signals recorded during the NCSs and needle EMG are the result of differential amplification (Fig. 7.45), in which the difference between the signals at the active (G1) and reference (G2) electrodes is amplified and displayed. Therefore, if the same electrical noise is present at both the active and reference electrodes, it is subtracted out, and only the signal of interest is amplified (i.e., common mode rejection).

The best way to achieve identical electrical noise at each electrode is to ensure that the impedance at each electrode is identical (i.e., prevent electrode impedance mismatch). Impedance is an electrical term combining the effects of resistance to flow for a DC current and capacitance for an AC current. As per Ohm's law, the voltage (E), in this case the voltage from electrical noise, equals the current (I) induced from the electrical noise multiplied by the resistance (R) or impedance (E = IR). If the resistance or impedance is different at each electrode, then the same electrical noise will induce a different voltage at each electrode input. This difference is then amplified and displayed, often obscuring the signal of interest.

The most common cause of electrical noise in the EMG laboratory is 60-Hz interference generated from other electrical devices such as lights and computers. This noise interferes mostly with recording small potentials, such as SNAPs or fibrillation potentials. The best way to eliminate 60-Hz interference is for each electrode to appear identical to the amplifier (Table 7.7). To achieve this, one must use intact electrodes without frayed or broken connections and prepare the skin with either alcohol or acetone to remove dirt and oil. Conducting electrode jelly is then applied to the electrode before it is attached to the skin. The recording electrodes should be held firmly against the skin with tape or a Velcro band. Lastly, the closer the electrodes are to each other, the more likely any associated electrical noise will appear identical to a differential amplifier.

Stimulus Artifact

The stimulus artifact occurs in every NCS and serves a useful purpose by indicating when the shock occurred and from which point latencies are measured. However, the stimulus artifact may obscure the onset of the recorded potential if its trailing edge overlaps with that potential, leading to inaccurate measurements of both amplitude and onset latency (Fig. 7.46). This occurs most commonly when the recording electrode is placed at very short distance from the stimulating point. The following are recommendations for reducing stimulus artifacts:

- Place ground between stimulator and recording electrodes.
- Reduce electrode impedance mismatch between the recording electrodes.
- Use coaxial recording cables.
- Lower the stimulator intensity.
- Rotate the anode of the stimulator while maintaining the cathode.
- Increase the distance between stimulator and recording electrodes.
- Ensure that the stimulator and recording electrode cables do not overlap.

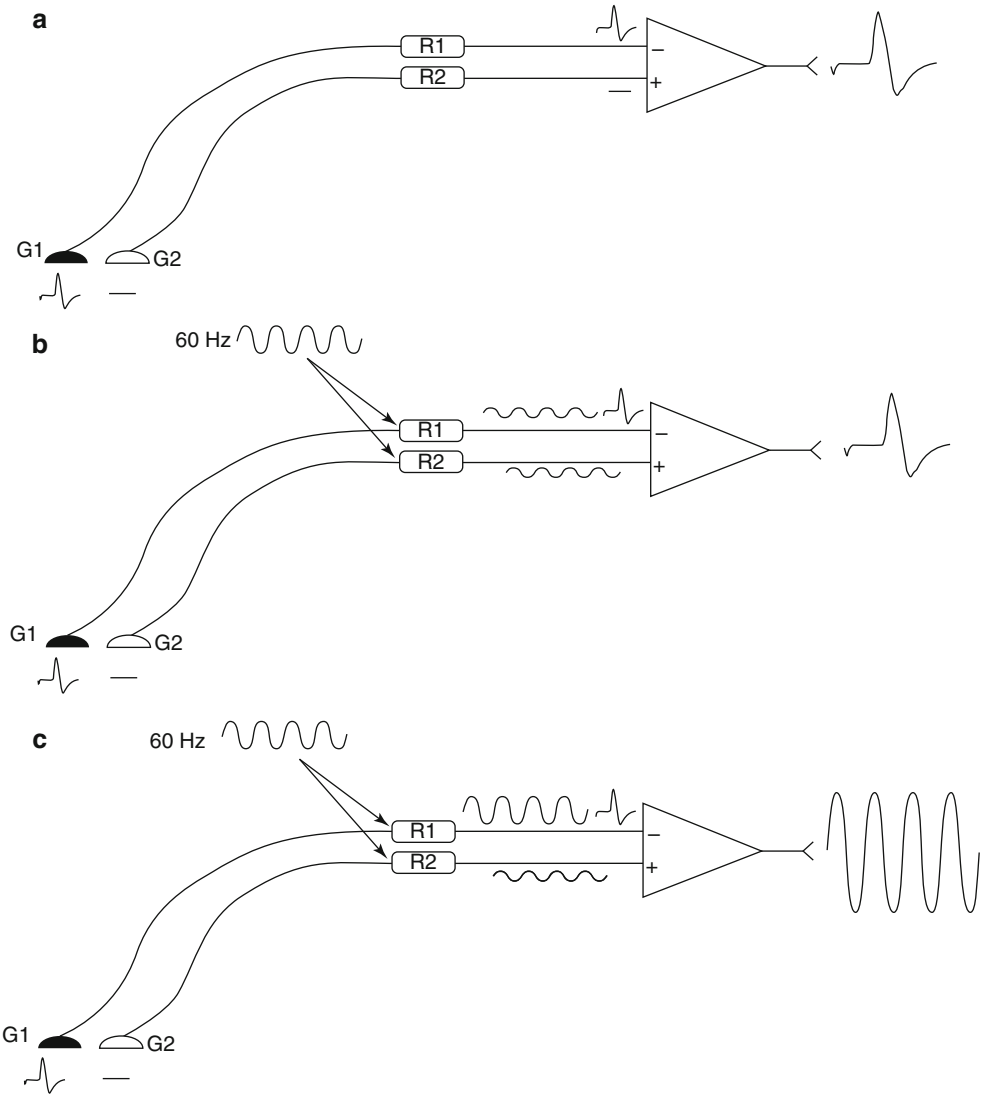

Fig. 7.45 Differentiation amplification and electrode impedance mismatch. All signals recorded in nerve conduction studies and EMG result from differential amplification. The signal present at the reference electrode (*G2*) is subtracted from the signal seen at the active electrode (*G1*) and amplified (**a**). Each recording electrode has its own impedance or resistance, modeled as R1 and R2 above, for the active and reference electrodes, respectively. If R1 and R2 are identical, any 60-Hz interference will induce a similar electrical noise at both inputs (**b**). This noise will then be subtracted out, and only the signal of interest will be amplified. However, if electrode impedances are mismatched (R1 > R2), then the amount of electrical noise will be different at the two inputs (**c**). Some of the electrical noise will then be amplified, often obliterating or obscuring the signal of interest (Reproduced with permission from Preston and Shapiro [1])

Table 7.7 Methods to reduce electrode impedance mismatch and 60-Hz interference

Active and reference recording electrodes should be the same type
Ensure all contacts are intact without any frayed or broken connections
Clean all dirt and oil from the skin with alcohol or acetone
Apply conducting electrode jelly between the skin and electrodes
Secure electrodes firmly to the skin with tape or velcro straps
Place ground between stimulator and recording electrodes
Use coaxial recording cables

Filters

Every recorded potential during NCSs and needle EMG passes through a low- and high-frequency filter before being displayed. Filters help to reproduce the signal of interest and reject low- and high-frequency electrical noise. Low-frequency (high pass) filters exclude signals below a set frequency, while allowing higher-frequency signals to pass through. In contrast, high-frequency (low pass) filters exclude signals above a certain frequency, while allowing lower-frequency signals to pass through. Low-frequency noise (<10 Hz) results in wandering of the baseline (close to DC current), whereas high-frequency noise (>10 kHz) commonly obscures high-frequency potentials (e.g., SNAPs or fibrillation potentials). Hence, the high-frequency filter is set lower for sensory NCSs than for motor NCSs.

The use of filters has some disadvantages. Filtering does not completely exclude all signals above the high-frequency or below the low-frequency settings. Filtering also results in some loss or alteration of the signal of interest. For instance, as the low-frequency filter is reduced, more low-frequency signals pass through, and the duration of the recorded potential increases slightly. Likewise, as the high-frequency filter is lowered, more high-frequency signals are excluded, and the amplitude of the recorded potential usually decreases.

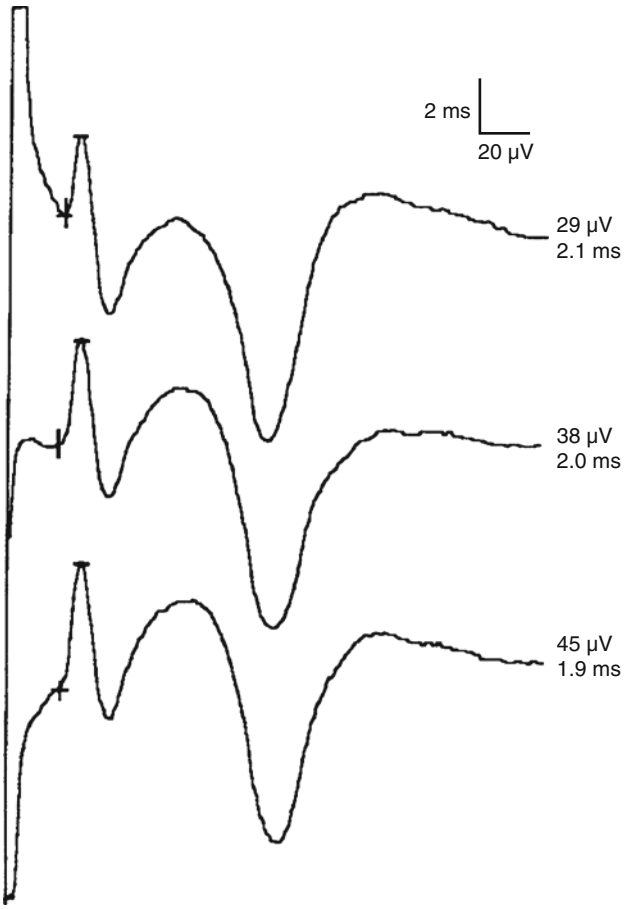

Fig. 7.46 Stimulus artifact and measurement error. Median antidromic sensory study, stimulating wrist, recording second digit. Stimulus artifact can be influenced by rotating the anode while maintaining the cathode in place. Large negative stimulus artifacts (*top*) may result in artifactually low amplitudes and prolonged latencies. Conversely, large positive stimulus artifacts (*bottom*) may result in artifactually large amplitudes and short latencies (Reproduced with permission from Preston and Shapiro [1])

Accordingly, all potentials should be obtained with standardized filter settings and only compared to normal values based on studies using the same filter settings. The recommended low and high filter settings for motor conduction studies are 10 and 10 kHz, respectively. For sensory conduction studies, the low- and high-frequency filter settings are 20 and 2 kHz.

Stimulator Position

When performing NCSs, the proper position of the stimulating cathode is to face the active recording electrode, and distance measurements should always be made between the cathode and the active electrode. If the cathode and anode of the stimulator are inadvertently reversed, there are two possible effects. First, although depolarization occurs under the cathode, hyperpolarization theoretically occurs at the anode. This hyperpolarization may create an anodal block, preventing the depolarization that occurs under the cathode from proceeding past the anode. The resultant SNAP or CMAP may then be reduced or absent. Second, the distal latencies prolong by approximately 0.3–0.4 ms, which represents the approximate time that it takes a normal nerve to traverse 2.5–3.0 cm, the typical distance between the cathode and anode of a stimulator. However, the proximal motor conduction velocities, which are calculated between a distal and proximal site, remain unchanged because the distal latencies are subtracted in velocity calculations. These erroneous findings on NCSs may be misinterpreted as a polyneuropathy or distal entrapment mononeuropathies.

Supramaximal Stimulation

All NCS measurements are based on the assumption that all axons are depolarized using supramaximal stimulation. To achieve such a stimulation, current intensity is slowly increased until a point is reached where the amplitude of the recorded potential no longer increases. At this point, the current is increased an additional 25 % to ensure that the potential does not change further. If it does not, then one can assume that supramaximal stimulation has been achieved.

If a nerve is not supramaximally stimulated at distal and proximal sites, a mistaken impression of axonal loss may result. If supramaximal stimulation is not achieved at a proximal stimulation site, where it had been so with a distal stimulation site, then the findings may be misinterpreted as evidence of conduction block. Conversely, a submaximal stimulation at a distal site with a supramaximal stimulation at a proximal site may erroneously suggest an anomalous innervation.

In addition to their effect on CMAP and SNAP amplitudes, submaximal stimulations at all stimulation sites result in inaccurate conduction velocities. Conduction velocity measurements assume that the same fibers (i.e., the fastest) are stimulated at distal and proximal sites. Without supramaximal stimulation, one may be erroneously measuring different fibers at different sites, resulting in invalid nerve conduction velocity measurements. Finally, latencies with submaximal stimulations are prolonged because the largest fibers have the highest threshold for stimulation and are evoked last.

Co-stimulation of Adjacent Nerves

As the stimulus current is increased to achieve supramaximal stimulation, the current may spread to excite nearby nerves, which may result in a spuriously large amplitude potential, caused by the inadvertent recording of additional nerve or muscle action potentials beyond the potentials of interest. Common sites of co-stimulation are median and ulnar nerves at the wrist, elbow, or axilla and the common peroneal and tibial nerve stimulations at the knee. Co-stimulation of adjacent nerves is unavoidable when stimulating proximal nerves at Erb's point (e.g., axillary or musculocutaneous nerves) or nerve roots (e.g., C8–T1 spinal roots).

Inadvertent co-stimulation of adjacent nerves, distally but not proximally, may be mistaken for conduction block. In contrast, if co-stimulation occurs proximally but not distally, one may erroneously diagnose an anomalous innervation in certain nerves. In addition, a true abnormal low-amplitude potential may become more "normal" if an adjacent nerve is co-stimulated.

To avoid co-stimulation of adjacent nerves, the examiner should watch the morphology of the waveform carefully, and for the resultant muscle twitch with each stimulation. If there is an abrupt change in waveform configuration or in muscle twitch pattern, especially at higher currents, co-stimulation of adjacent nerves may have occurred. For example, stimulation of the median nerve at the wrist results in a characteristic biphasic CMAP and twitch of the thumb and first two lumbricals. If current is increased to a point where the ulnar nerve fibers are inadvertently co-stimulated, the resultant CMAP becomes notched and the twitch abruptly changes to include the interossei and hypothenar muscles, both features of ulnar nerve stimulation.

If the question of co-stimulation is still not clear, one should simultaneously co-record muscles innervated by adjacent nerves, watching for a potential from the unintended muscle. If this occurs, then the stimulus intensity should be lowered until the unintended potential is no longer seen. For instance, when stimulating the median nerve at the wrist, the abductor pollicis brevis and abductor digiti minimi should be simultaneously recorded. With proper median nerve stimulation, no potential should be recorded from the abductor digiti minimi.

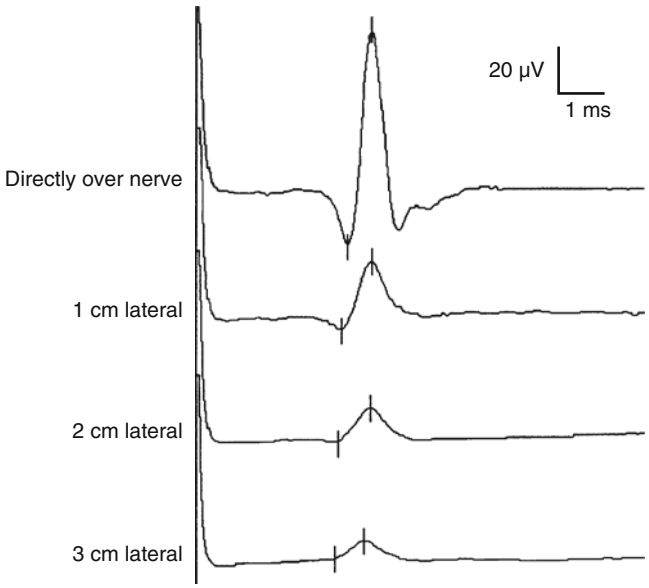

Fig. 7.47 Effect of distance between recording electrodes and nerve. Median mixed nerve study, stimulating wrist and recording antecubital fossa. If the recording electrodes are moved off the nerve, maintaining the same distance, the following changes occur: onset latency shifts to the left, peak latency remains relatively unchanged, and amplitude drops markedly. In nerve conduction studies, side-to-side comparisons between amplitudes are often made, looking for an asymmetry. One can easily appreciate that if the recording electrodes are placed lateral or medial to the nerve on one side and directly over the nerve on the other side, one might be left with the mistaken impression of a significant asymmetry in amplitude. When the location of the underlying nerve is not certain, it is important to try several recording electrode positions to ensure that the maximal amplitude is obtained (From Raynor et al. [21]. *Muscle Nerve* © 1997. Reprinted by permission of John Wiley & Sons, Inc.)

Recording Electrode Placement

Because muscle depolarization occurs first at the motor end-plate zone, the preferred montage for recording motor conduction studies is the belly-tendon method: the active electrode (G1) is placed over the center of the muscle belly, while the reference electrode (G2) is placed over the muscle's distal tendon which is presumably an electrically inert point in most motor studies. If the active recording electrode is not placed over the end plate, the volume-conducted depolarization potential first occurs at a distance from the recording electrode and is seen as an initial positive deflection. When the depolarization subsequently travels under the electrode, the potential then becomes negative. This incorrect placement results in two errors. First, the CMAP may not be maximized, giving the mistaken impression of a reduced amplitude. Second, if an initial positive deflection occurs, the latency is difficult to measure. Whenever an initial positive deflection is seen on a motor conduction study, the active electrode has most likely been placed off the motor end plate and should be moved until the positive deflection is no longer seen.

When performing a sensory or mixed NCS, a lower-amplitude nerve action potential is recorded not only when the nerve lies deep (as in orthodromic studies) but also when the recording electrode is inadvertently placed not directly (lateral or medial) over the nerve trunk. The amplitude of the potential decays dramatically with increasing distance from the nerve (Fig. 7.47) [21]. This occurs most frequently with conduction studies of anatomically variable sensory nerve trunks, including the sural, superficial peroneal, medial, and lateral antebrachial cutaneous nerves [22]. A small repositioning of the recording electrodes slightly medial or lateral to the initial recording position often markedly changes the amplitude of the potential. This assures that the highest-amplitude potential is evoked, especially for making side-to-side comparisons. In addition to its effects on amplitude, placing the recording electrodes lateral or medial to the nerve, the onset latency shortens, while the peak latency remains relatively unchanged. Although not intuitively obvious, these changes are due to the effects of volume conduction through tissue. In summary, recording electrodes placed at a distance from the nerve trunk result in a potential that is lower in amplitude and possibly spuriously fast.

Distance Between Active and Reference Recording Electrodes

Every potential recorded in a NCS is the result of the difference in electrical activity between the active and reference recording electrodes. For motor studies, the reference electrode is placed over the distal tendon, which is presumably electrically inactive, rendering the interelectrode distance not significant. However, for sensory and mixed studies, the active and reference electrodes are typically placed in a straight line over the nerve trunk. Accordingly, the nerve segment under the active electrode depolarizes first, followed by depolarization of the reference electrode. If the active and reference electrodes are too close, they may briefly become electrically active at the same time, resulting in a lower-amplitude potential. Taking into account the normal range of nerve conduction velocities, the preferred interelectrode distance between the active and reference recording electrodes for sensory and mixed nerve recordings is 3–4 cm, which ensures that depolarization will not occur under both electrodes simultaneously.

Distance Measurements

To compute a CV, it is assumed that the surface distance accurately represents the true underlying length of the nerve. In most circumstances, this assumption is correct. However, there are several notable exceptions, the most important being that of the ulnar nerve across the elbow. Surgical and cadaver dissection studies have shown that the ulnar nerve is slack and redundant when the arm is in the extended position. If surface distance measurements of the ulnar nerve are made in this position, the true length of the underlying nerve is underestimated. Thus, ulnar conduction studies performed with the elbow extended often result in artifactual slowing of conduction velocity across the elbow segment. When the elbow assumes a flexed position, the measured surface distance of the nerve across the elbow better reflects the true underlying length of the nerve, and a more valid measurement of nerve conduction velocity can be made [23].

Surface distance measurements of several other nerves are often inaccurate. These include the radial nerve at the spiral groove, the peroneal nerve around the fibular head, and the median and ulnar nerves between the axilla and Erb's point. In these situations, obstetrical calipers are recommended to more accurately approximate the true length of the underlying nerve.

Sweep Speed and Sensitivity

Both the sweep speed and sensitivity can markedly influence the recorded latency of SNAPs and CMAPs. As the sensitivity is increased, the onset latency decreases (Fig. 7.48). Conversely, as the sweep speed is decreased, latency measurements usually increase (Fig. 7.49). For this reason, all latency measurements on nerve conduction studies should be made using the same sensitivity and the same sweep speed.

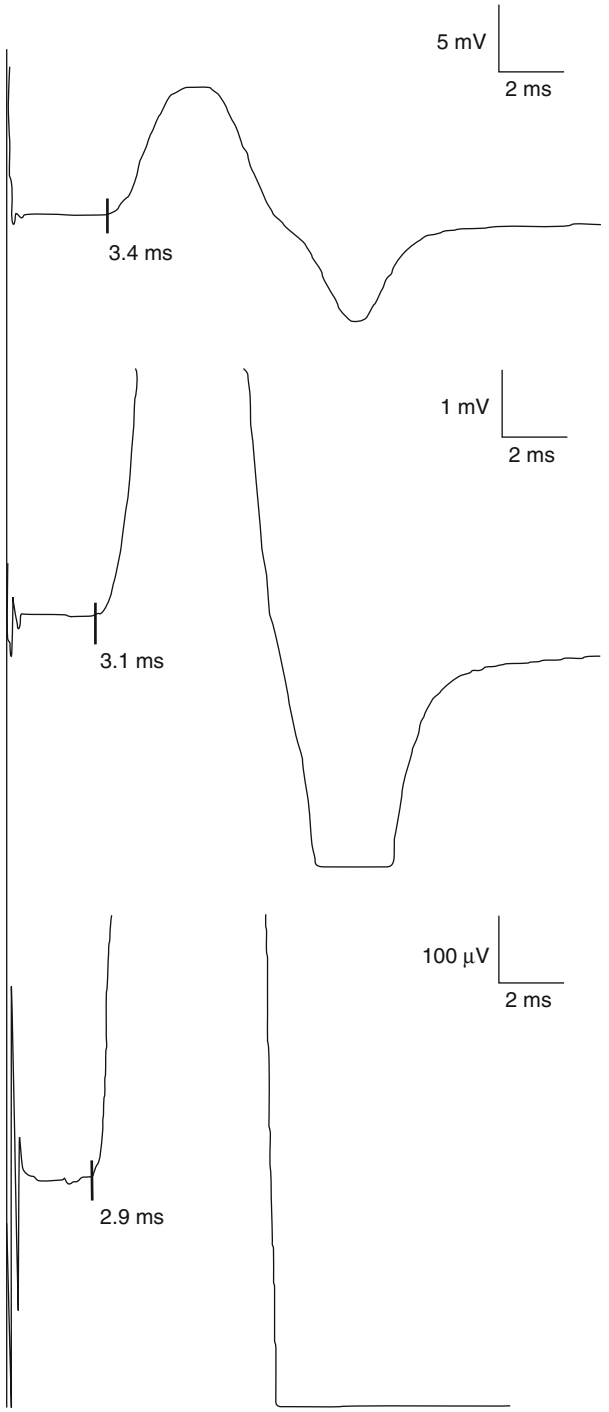

Fig. 7.48 Latency measurement and sensitivity. Median motor study, stimulating wrist, recording the abductor pollicis brevis, using varying sensitivities, with sweep speed held constant. Latency measurements should always be made using the same sensitivity. Note that as sensitivity is increased, latency measurement decreases (Reproduced with permission from Preston and Shapiro [1])

This is especially true within nerves, where potentials obtained with different sweep speeds or sensitivities at distal and proximal stimulation sites along the nerve can easily result in miscalculation of the conduction velocity.

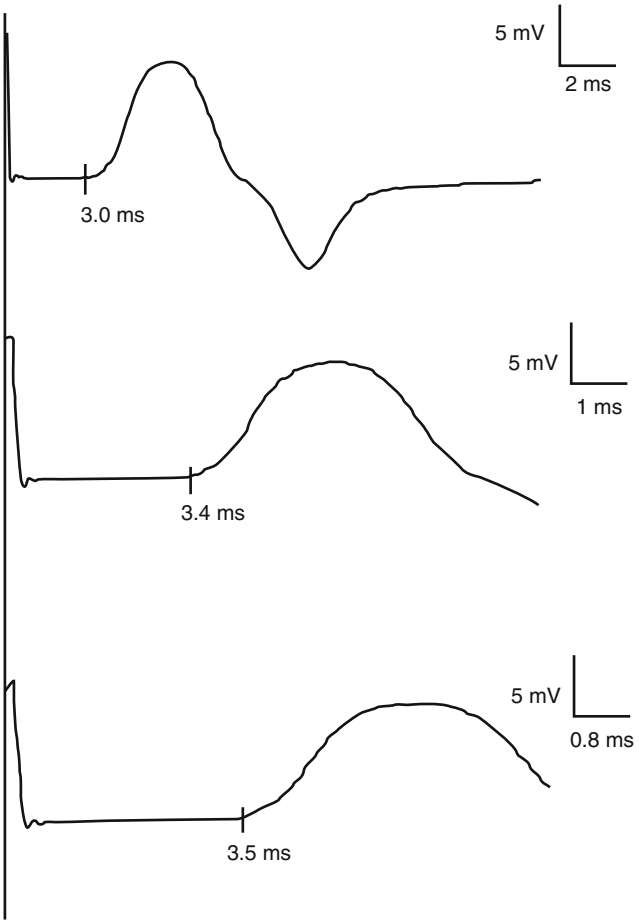

Fig. 7.49 Latency measurement and sweep speed. Median motor study, stimulating wrist, recording the abductor pollicis brevis, using varying sweep speeds, with sensitivity held constant. Latency measurements should always be made using the same sweep speed. Note that as sweep speed decreases, latency measurement usually increases (Reproduced with permission from Preston and Shapiro [1])

Late Responses

NCSs are most often used to assess distal nerve segments, because proximal surface stimulations, such as at Erb's point or the gluteal fold, are technically difficult. Needle, high-voltage, or magnetic stimulations may be used to study proximal nerve segments, although these techniques are also difficult to perform and not widely used. Two late responses, the F wave and H reflex, are commonly used in the EMG laboratory and are useful in assessing proximal nerve segments, but have several limitations (Table 7.8). Although both are usually thought as assessing the proximal nerve segments, they actually conduct through the entire nerve including the distal and proximal segments. However, they are most useful when the routine NCSs, which assess distal nerve segments, are normal. In these situations, when the late responses are abnormal, the findings imply a proximal lesion.

Table 7.8 F response and H-reflex comparison

	F response	H reflex
Afferent	Motor	Sensory (IA muscle spindle)
Efferent	Motor	Motor
Synapse	No	Yes
Nerves studied	All	Tibial-soleus (median-FCR, femoral-quads)
Stimulation	Supramaximal	Submaximal, long duration (1 ms)
Configuration	Usually polyphasic	Triphasic and stable
	Amplitude 1–5 % CMAP	At low stimulation intensity:
	Varies with each simulation	H is present without M
		As stimulation is increased:
		H and M increase
		At high stimulation:
		H decreases and M grows
Measurements	Minimal, maximal latency	Minimal Latency
	Chronodispersion	H/M Ratio (maximal H/maximal M amplitude)
	Persistence	
Major uses	Early Guillain-Barré syndrome	Early polyneuropathy
	C8–T1, L5–S1 radiculopathy	S1 radiculopathy
	Polyneuropathy	Early Guillain-Barré syndrome
	Internal control (entrapment neuropathy)	Tibial, sciatic, L–S1 plexus neuropathy
Normal values	≤32 ms median/ulnar[a]	≤34 ms[a]
	≤56 ms peroneal/tibial[a]	Leg height nomogram
	Compare to F estimate	Height nomogram
	Compare symptomatic to asymptomatic side	≤1.5 ms difference side to sideH/M Ratio ≤50 %
	Chronodispersion <4 ms (median/ulnar)	H-reflex amplitude <50 % difference side to side
	6 ms (peroneal/tibial) Persistence >50 %	
Miscellaneous	In normals, peroneal F waves may be absent or impersistent	Electrical correlate of the ankle jerk
	F responses may be absent in sleeping or sedated patients	Must be present if ankle jerk is present
	F responses may be absent with low-amplitude distal CMAPs	May be present even if ankle jerk is absent
	May be enhanced by Jendrassik maneuver	May be enhanced by Jendrassik maneuver

[a]Assumes median height, normal conduction velocity, and distal latency

F Wave

The F wave is a late motor response which occurs after the CMAP (also referred to in this context as direct motor or M

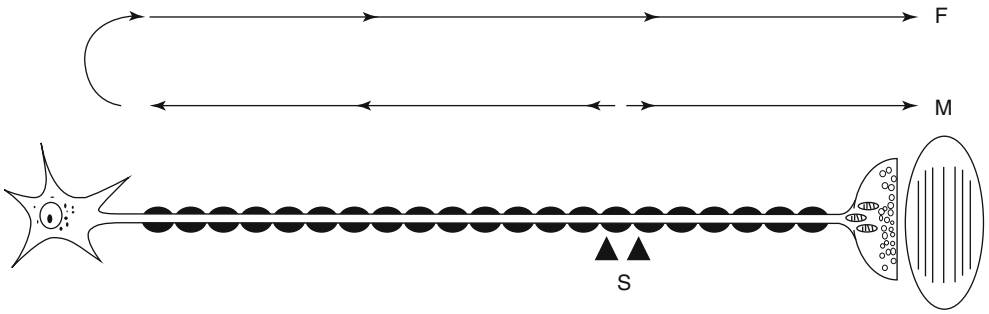

Fig. 7.50 F-response circuitry. When a nerve is stimulated distally (*S*), depolarization occurs both orthodromically and antidromically. The direct muscle response (*M*) occurs from orthodromic travel. The F response (*F*) is derived by antidromic travel to the anterior horn cell, backfiring of some anterior horn cells, and orthodromic travel back down the nerve past the stimulation site to the muscle (Reproduced with permission from Preston and Shapiro [1])

response). The F response derives its name from "foot," as it was first recorded from the intrinsic foot muscles. During a routine motor nerve study, the nerve action potential conducts in two directions, distally (orthodromically) to the NMJ to depolarize the muscle and proximally (antidromically) toward the spinal cord. The F response is triggered by the antidromic nerve action potentials which result in backfiring of a small population (less than 10 %) of anterior horn cells, which results in an orthodromic nerve action potentials toward the muscle (Fig. 7.50). The F response is not a true reflex, because its afferent and efferent loops are purely motor with no intervening synapse. The F response is actually a very small CMAP representing about less than 10 % of the muscle fibers (Fig. 7.51a).

F responses may be obtained easily from any motor nerve, with the exception of the peroneal nerve recording extensor digitorum brevis where F responses may be difficult to elicit even in normal individuals. F responses may also be absent or impersistent in sleeping or sedated subjects. If the stimulator is moved proximally, the latency of the CMAP increases as expected, but the F latency decreases because the action potential travels a shorter distance (Fig. 7.51b). However, with proximal stimulation, the F waves are often superimposed on the terminal CMAP and are more difficult to identify. Hence, they are best identified with distal stimulation.

F-Response Procedure

To obtain an F response, the equipment and recording setup are fundamentally the same as that for a routine distal motor conduction study. However, several technical adjustments need to be made to the EMG machine to record F responses. The gain is increased to 200 μV (as the amplitude of the F response is quite low), and the sweep speed is increased to 5 or 10 ms, depending on the length of the nerve being studied. Supramaximal simulation must be employed, and the stimulator is preferably turned around so the cathode is more proximal, to prevent a potential anodal block (see section "Stimulator Position").

Each F response varies slightly in latency, configuration, and amplitude because a different population of anterior horn cells backfires with each stimulation. As each F response varies in latency and amplitude, it is important to obtain at least ten F responses, preferably on a rastered trace. If F responses are absent or impersistent, one should first ensure that the nerve has been stimulated supramaximally. The Jendrassik (reinforcement) maneuver (e.g., making a fist with the contralateral hand or clenching teeth) before each stimulation can also be useful in helping to prime the anterior horn cells and elicit F waves.

Several measurements may be calculated from the wave including the minimal F-wave latency, maximal F-wave latency, F-wave chronodispersion (maximal minus minimal F-response latency) and F-wave persistence. The *minimal F-wave latency* is the most reliable and useful measurement and represents conduction of the largest and fastest motor fibers. The minimal F-wave latency is dependent on the length of the nerve studied; it is shorter in the arms than in the legs; similarly, taller subjects have longer F-wave latencies than shorter individuals. Because F responses are quite small, there is often some unavoidable error in placing the latency markers. It is best to place the latency marker on the F response at the point that it departs from the baseline, with either a positive or negative deflection. In addition, superimposing the rastered traces is often helpful to determine the minimal latency. Table 7.9 shows normal F-wave minimal latencies, commonly obtained in the upper and lower extremities. *F-wave chronodispersion* is the difference between the minimal (fastest) and maximal (slowest) F response (Fig. 7.52). In the upper extremities, normal chronodispersion is up to 4 ms and in the lower, up to 6 ms. *F-wave persistence* is a measure of the number of F waves obtained for the number of stimulations. Normal F-wave persistence is usually 80–100 % and always above 50 %. Occasionally side-to-side differences in F-wave persistence and chronodispersion help in identifying an abnormality.

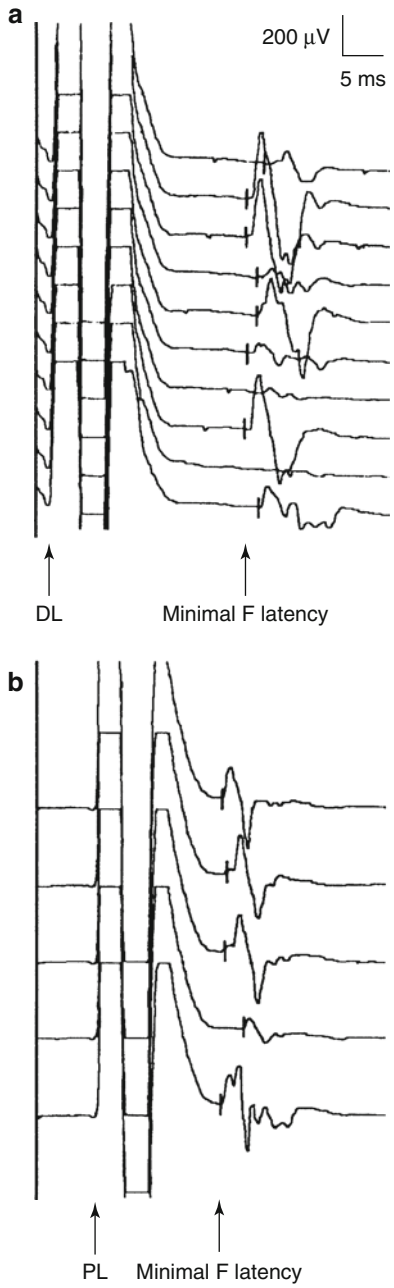

Fig. 7.51 Normal F responses: distal and proximal stimulation. Median F responses recording abductor pollicis brevis, stimulating wrist (**a**) and elbow (**b**). Note that with proximal stimulation, the proximal CMAP latencies increase as expected, but the F-response latencies decrease, due to the F response first traveling antidromically to the spinal cord (*DL* distal CMAP latency, *PL* proximal CMAP latency) (Reproduced with permission from Preston and Shapiro [1])

Table 7.9 Normal minimal values of F-wave latencies in adults, obtained with distal stimulations (wrist or ankle)

Distal	Recording muscle	Upper limit (ms)	Distance (cm)	Side-to-side difference (ms)
Median	Abductor pollicis brevis	<32	<73	<3
Ulnar	Abductor digiti minimi	<32	<73	<3
Peroneal	Extensor digitorum brevis	<57	<127	<4
Tibial	Abductor hallucis	<58	<128	<4

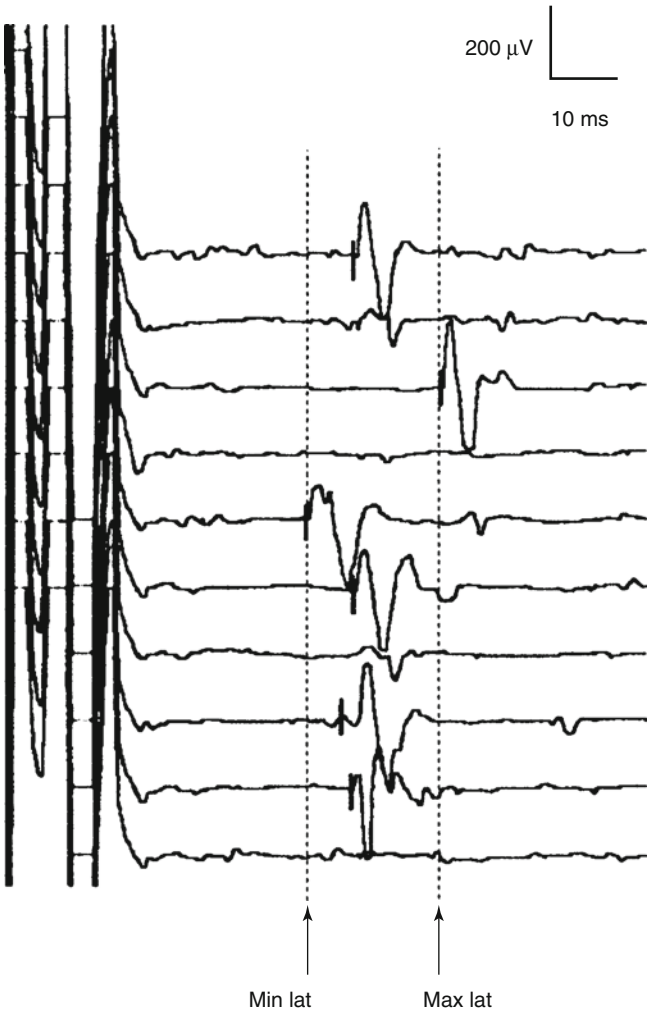

Fig. 7.52 F-response measurements. F responses, 10 rastered traces. Minimal latency is the shortest of the ten responses, representing the largest, fastest conducting fiber. Chronodispersion is the difference between the minimal and maximal latency F response. F-wave persistence is the number of F responses obtained per number of stimulations. In this case, F responses are absent in trace 4 and 10; persistence = 80 % (Reproduced with permission from Preston and Shapiro [1])

Although F responses are usually thought of as assessing the proximal nerve segments, they actually evaluate the entire nerve. A nerve with a prolonged distal motor latency due to a distal entrapment may have a prolonged F latency because the F response must pass through the distal segment of nerve as well. Also, in a generalized polyneuropathy associated with slowing of conduction velocity, the F-wave latency is slowed, reflecting the slowed conduction velocity of the entire nerve. The *F estimate* is a useful calculation to

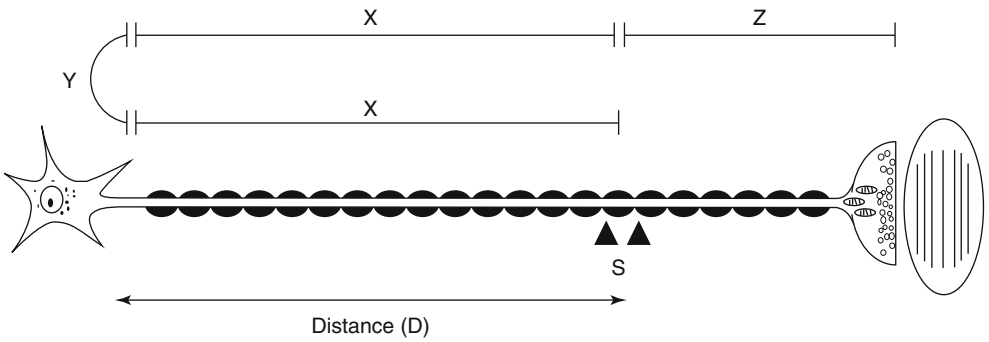

Fig. 7.53 F-estimate calculation. *X* = the time from the stimulation site (*S*) to the spinal cord; *Y* = turnaround time at the anterior horn cell; *Z* = time from the stimulation site to the muscle. Theoretic F estimate = 2*X* + *Y* + *Z*. *X* can be calculated by measuring the distance between the stimulation site and the spinal cord (*D*) which is then divided by the conduction velocity of the nerve. *Z* = distal latency. The turnaround time, *Y*, has been estimated experimentally as 1 ms. Thus, the F estimate = (2*D*/CV) × 10 + 1 ms + DL (a conversion factor of 10 is needed to obtain an answer in ms) (Reproduced with permission from Preston and Shapiro [1])

determine whether a prolonged F-wave latency is due to a lesion of the proximal nerve segment or merely reflects an abnormal distal motor latency or CV or an unusually tall patient. The F estimate determines the theoretic time it should take for the F response to occur, taking into account the distal motor latency, the CV, and the patient's height, as follows (Fig. 7.53). First, the time it takes for the nerve action potential to pass from the stimulation site to the anterior horn cells is estimated by dividing the distance between those sites by the motor nerve CV. The distance between the stimulation site and the spinal cord can be approximated by measuring from the xiphoid process to the stimulation site at the ankle for the peroneal and tibial motor studies and from the C7 spinous process to the stimulation site at the wrist for the median and ulnar studies. A brief turnaround time (approximately 1 ms) at the anterior horn cell is added to that time. Next, the time it takes the nerve action potential to conduct from the anterior horn cell to the stimulation site is again added (this equals the time it takes for the potential to travel up the nerve). Lastly, the distal motor latency is added (i.e., the time it takes the potential to travel from the stimulation site to the muscle).

Hence, the F estimate = (2*D*/CV) × 10 + 1 ms + DL, where *D* = distance from the stimulation site to the spinal cord (cm), CV = conduction velocity (m/s), DL = distal motor latency (ms), and constant 10 is the conversion factor to ms. Characteristically, the actual measured minimal F-wave latency is usually slightly shorter than the F estimate, because the conduction velocity used in the above equation is that of a distal nerve segment (forearm or leg), while the conduction velocity in the proximal nerve segments are slightly faster (due to a combination of larger nerve fiber diameter and warmer temperature). Thus, if the measured minimal F-wave latency is prolonged compared to the F estimate, this implies a delay in the proximal nerve segments, out of proportion to what can be expected for the distal motor latency, motor conduction velocity, and the height of the patient.

Clinical Applications of F Wave

Advantages

The F wave serves a useful purpose in testing the entire nerve circuit and can be used as a good internal control for other nerve conduction abnormalities. For instance, in most polyneuropathies, the F responses are slightly prolonged. In distal entrapment mononeuropathies, such as carpal tunnel syndrome, the F responses are typically prolonged. F responses may have their greatest utility in identifying early polyradiculopathy such as that occurring in Guillain-Barré syndrome. Acute inflammatory demyelinating polyradiculoneuropathy (AIDP), the main subtype of Guillain-Barré syndrome, commonly causes acquired segmental demyelination of the spinal nerve roots. Early in Guillain-Barré syndrome, the routine motor nerve studies may be entirely normal, with prolonged or absent F responses, which implies proximal demyelination. This has been reported in 40–80 % of GBS patients early in the illness and may be the sole EDX abnormality in about ¼ of patients [24, 25].

F responses are generally absent in nerves where the CMAP amplitude is severely reduced due to significant axonal loss. As the F response is 1–5 % of the amplitude of the CMAP, there is a low chance of eliciting an F response from a nerve with such severe axonal loss.

Disadvantages

In theory, the F responses have their greatest utility in the diagnosis of radiculopathy or plexopathy. A prolonged F-wave latency in the context of normal nerve conduction velocity and distal latency may occur in proximal neuropathy, plexopathy, or radiculopathy, but this finding cannot be used to differentiate between these possibilities.

From a practical point of view, their usefulness in the diagnosis of radiculopathies is limited for several reasons:

1. The recorded muscles during motor NCSs are usually innervated by more than one root. Thus, in a single-level radiculopathy, the normal conduction through the

uninvolved root results in normal F-wave minimal latency despite a compressed neighboring root. For example, in L5 radiculopathy, recording a peroneal F wave from the extensor digitorum brevis muscle (innervated by L5 and S1 roots) is frequently normal, because of the normal S1 root. Likewise, with a severe C8 radiculopathy, the median and ulnar F waves are often normal because of the T1 innervation of the abductor pollicis brevis and abductor digiti minimi muscles.

2. Since minimal F-wave latencies are the most reproducible and clinically useful parameter, root compression resulting in motor axon loss can be associated with normal F-wave latencies, because the surviving axons are conducting normally. In order for the F responses to be absent or the minimal latency to be delayed, all or at least most of the nerve fibers must be involved. In these instances, F-wave persistence is usually abnormal and a more useful parameter.
3. If focal slowing occurs at the root segment of the motor axon, the delay in F-wave latency may be obscured, as its latency becomes "diluted" by the relatively long motor axon.
4. Since routine motor NCSs involve recording distal muscles, the F responses can only evaluate the roots and nerve that innervate these muscles. In the upper extremity, median and ulnar motor NCSs are recorded from abductor pollicis brevis and abductor digiti minimi, respectively, both innervated by the C8 and T1 nerve roots. In the lower extremity, peroneal and tibial F waves are obtained recording extensor digitorum brevis and abductor hallucis, supplied by the L5 and S1 nerve roots. Thus, due to this bias, F responses only have utility in assessing possible C8–T1 and L5–S1 radiculopathies. Lesions of the C5, C6, or C7 or L3 or L4 nerve root lesions will not show any F-wave abnormalities.
5. When radiculopathy predominantly affects sensory nerve root fibers (as often occurs with symptoms of pain and radiating paresthesias), the F response, which measures motor fibers only, is normal.

H Reflex

The H (Hoffmann) reflex is a true reflex with a sensory afferent segment, a synapse, and a motor efferent segment. Likewise, there are several other properties that differentiate the H and F responses (see Table 7.8). In newborns, the H reflex may be reproduced from any muscle. However, in adults, the H reflex can only be elicited consistently by stimulating the tibial nerve in the popliteal fossa, recording the gastroc-soleus muscle. An H reflex stimulating the femoral nerve recording the quadriceps muscle, or the median nerve recording the flexor carpi radialis muscle, is described but has significant limitations and so is not clinically useful.

Tibial H-Reflex Procedure

The H reflex involves the IA muscle spindle fibers as sensory afferents and the alpha motor neurons and their axons as efferents (Fig. 7.54). Several adjustments must be made to the EMG equipment to record an H reflex. Similar to changes made for the F response, the gain is increased to 200–500 μV, and the sweep speed is increased to 10 ms/div. Because a submaximal stimulus with a long duration selectively activates the IA fibers, the stimulus duration is increased to 1 ms. The recording montage consists of G1 placed over the soleus, two to three fingerbreadths distal to where it meets the two bellies of the gastrocnemius, and G2, the reference electrode, placed over the Achilles tendon. The tibial nerve is stimulated in the popliteal fossa with the cathode placed proximally at very low stimulus intensities. As the current is slowly increased, a triphasic H reflex first appears at a latency of 25–34 ms. If the H reflex is difficult to elicit, the Jendrassik maneuver can be used to prime the anterior horn cells. As the stimulus intensity is slowly increased, the H reflex continues to increase in amplitude and slightly decrease in latency, and a direct motor (M) potential with a short latency begins to appear. As the stimulus intensity is increased further, the M potential increases in amplitude while the H reflex decreases (Fig. 7.55). At supramaximal stimulation, the H reflex disappears, and the M potential is usually followed by an F wave which replaces the H reflex.

The explanation for these events is as follows: with very low stimulation intensity, the H reflex appears without the M potential, because only the IA afferents are selectively stimulated. As the IA afferents are stimulated, a sensory action potential conducts orthodromically to the spinal cord, crosses the synapse, and creates a motor potential that travels orthodromically down the motor axons to the muscle, generating the H reflex. As the stimulus intensity is increased, both the IA afferents and the motor axons are directly stimulated. At this point, the orthodromic motor fibers generate the M potential, while the antidromic potentials collide with the orthodromically traveling H-reflex potentials, resulting in a decrease in H-reflex amplitude. At supramaximal stimulation, the IA afferents and the motor axons are stimulated at high levels, and there is greater collision, resulting in disappearance of the H reflex which is often replaced by the F response.

Typically, the H reflex with the shortest latency is measured and compared to a set of normal controls for height or leg length (Figs. 7.56 and 7.57). Comparison to the contralateral side is often useful in assessing a unilateral lesion; any difference greater than 1.5 ms is considered significant. In addition, the maximal amplitude of the H response, often measured from peak to peak, is measured and compared to the contralateral side; a difference of more than 50 % in H-reflex amplitude is abnormal. The H response amplitude

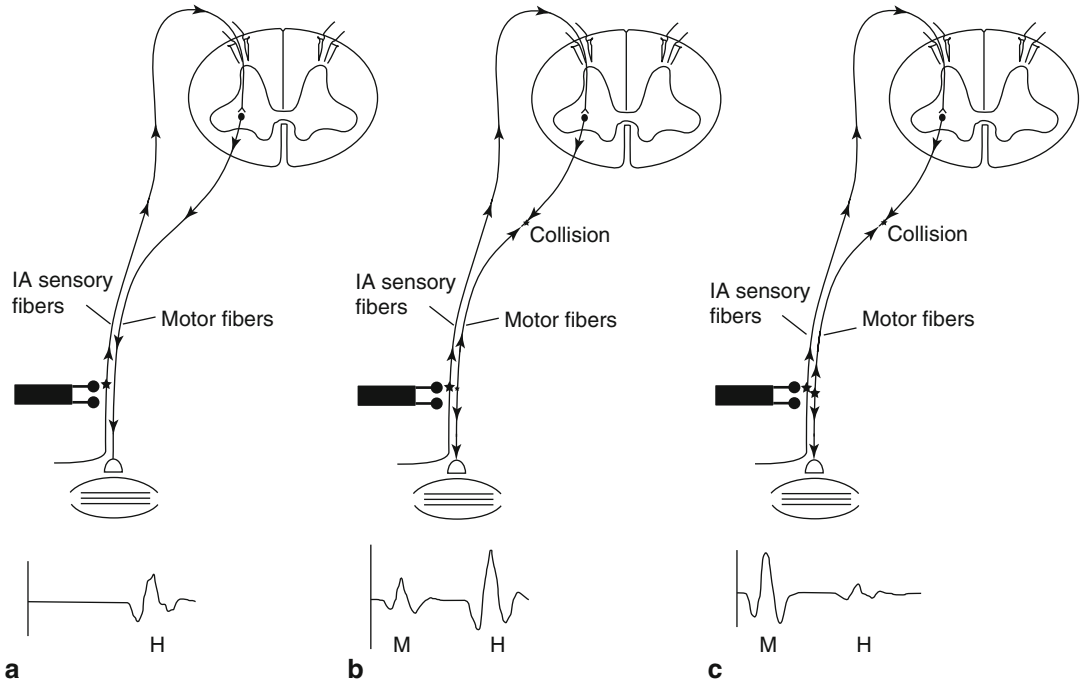

Fig. 7.54 H-reflex circuitry. The afferent loop is formed from IA sensory fibers and the efferent loop from motor axons, with an intervening synapse in the spinal cord. At low stimulation intensity (**a**), the IA sensory fibers are selectively activated, yielding an H reflex without a direct motor (*M*) potential. With increasing stimulation (**b**), more IA sensory fibers are activated, as are some of the motor fibers. The motor fiber stimulation results in a small M potential and some collision proximally of the descending H reflex by the antidromic motor volley. At higher stimulation (**c**), the selective activation of the IA sensory fibers is lost. Both sensory and motor fibers are stimulated at high levels. The motor stimulation results in an increasingly larger M potential. However, the H reflex decreases in size as there is greater collision proximally of the descending H reflex from the antidromic motor volley (Reproduced with permission from Preston and Shapiro [1])

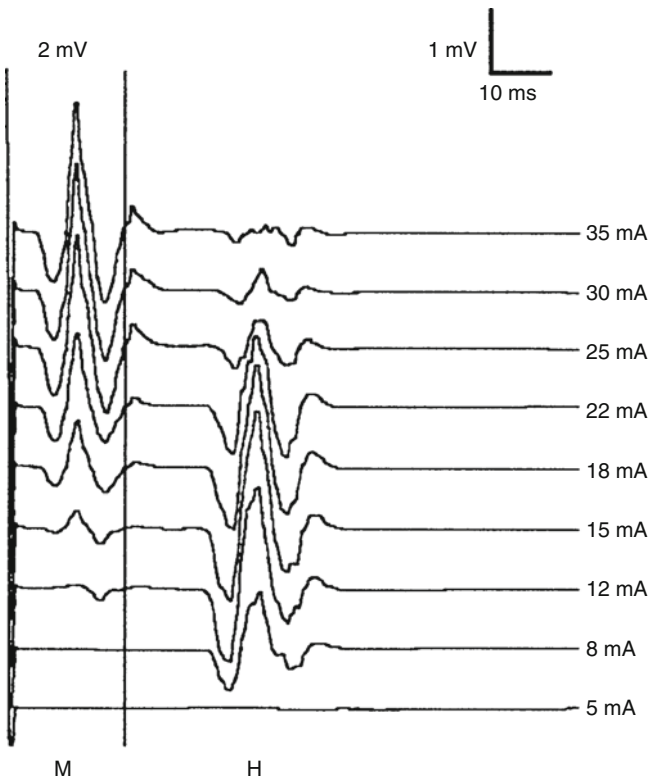

may also be compared to the maximal amplitude of the M potential (measured peak to peak) to calculate an H to M ratio.

Clinical Applications of the Tibial H Reflex

The tibial H reflex is the electrical correlate of the Achilles tendon reflex (ankle jerk), mediated by the S1 arc reflex. The magnitude of ankle jerk correlates well with the amplitude of the tibial H wave, but not with the latency [28]. Any lesion which might decrease the ankle reflex might also reduce the H-reflex amplitude or prolong its latency. Thus, one may see an abnormal H reflex in polyneuropathy, proximal tibial and sciatic neuropathy, and lesions of the S1 nerve root. In addition, the H to M ratio is a crude assessment of anterior horn cell excitability. The H to M ratio often increases in upper motor neuron lesions.

Fig. 7.55 H reflex. Note that as low stimulation intensities, an H reflex is present without a direct motor (*M*) response. With increasing stimulation, the H wave grows and the M response appears. At higher stimulation, the M continues to grow and the H diminishes due to collision between the H-reflex and antidromic motor potentials (Reproduced with permission from Preston and Shapiro [1])

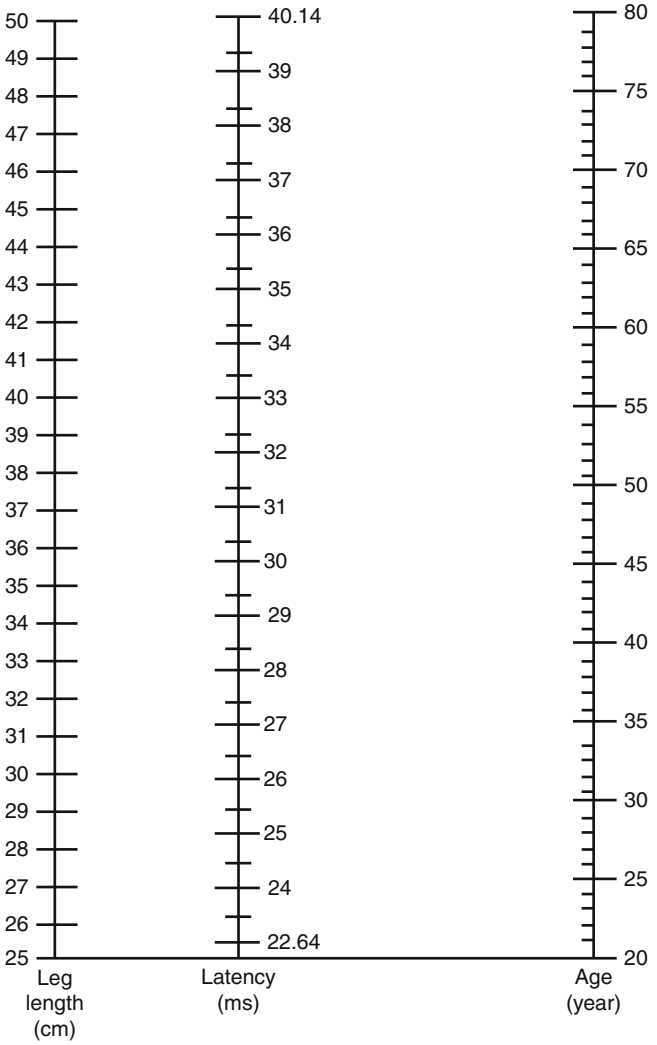

Fig. 7.56 H-latency reference values. Normal H latencies based on leg height and age. Leg height measured between the stimulation site in the popliteal fossa and the medial malleolus (Reprinted with permission from Braddom and Johnson [26])

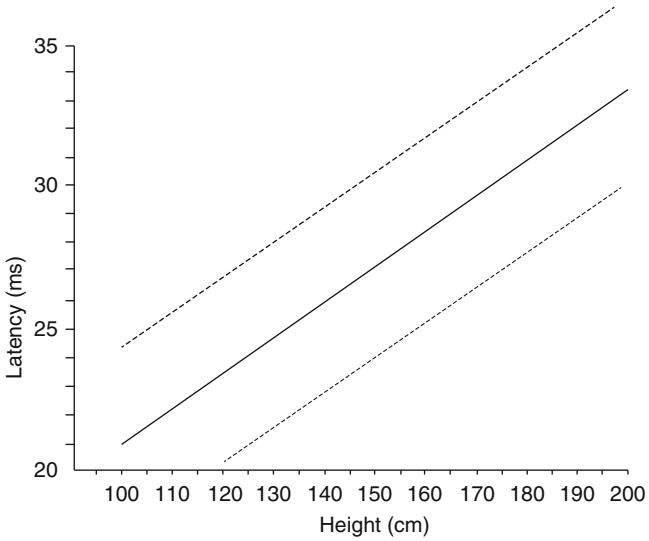

Fig. 7.57 H-latency reference values. Normal H-reflex latencies based on height (From Lachman et al. [27], courtesy of the BMJ Publishing Group)

It is generally accepted that the H-reflex amplitude and latency are potentially helpful in the diagnosis of S1 radiculopathy [29]. However, this has certain limitations:

1. An abnormal H reflex does not localize the lesion to the S1 root, because any pathological process along its long arc can result in an abnormal H reflex.
2. A normal H reflex does not exclude an S1 radiculopathy, because the H reflex is not always abnormal in definite cases of S1 radiculopathy.
3. The H reflex is commonly absent bilaterally in elderly patients or in patients with polyneuropathy.

Axon Reflex

The axon reflex (not a true reflex) is a late potential that is often recognized during the recording of F responses. The axon reflex is a small potential which typically occurs between the F response and the direct motor (M) response (Fig. 7.58a). In contrast to the F response which varies slightly in configuration and latency from stimulation to stimulation, the axon reflex has a fixed latency and configuration following successive stimulations. It is often useful to acquire these potentials on a rastered trace and then superimpose them. This easily shows that axon reflexes, unlike F responses, superimpose perfectly on one another (Fig. 7.58b).

Axon reflexes are typically seen in sprouted nerves, especially when a submaximal stimulus is given. An axon normally divides into its terminal divisions very close to the muscle, which is usually distal to the distal stimulation sites during motor NCSs. In diseased nerves, however, collateral sprouting may occur proximal to the distal stimulation site. As a nerve is stimulated, the proximally traveling (antidromic) action potential may conduct back down the branching nerve fiber to the muscle to generate an axon reflex, which occurs after the M potential but before the F response (Fig. 7.59). With supramaximal stimulation, the antidromic volley usually collides with the orthodromically traveling axon reflex, and the axon reflex is not seen. However, if all the distal nerve fibers have not been supramaximally stimulated, there may be no antidromic volley in the branching fibers to collide with the orthodromically traveling axon reflex, and the potential is free to travel back down the branching fiber to the muscle, creating the axon reflex. Axon reflexes are important to identify because they often suggest reinnervation along the nerve, and they may be confused with the F response. Rarely, the axon reflex follows rather than precedes the F response, if the regenerating collateral fibers are conducting very slowly.

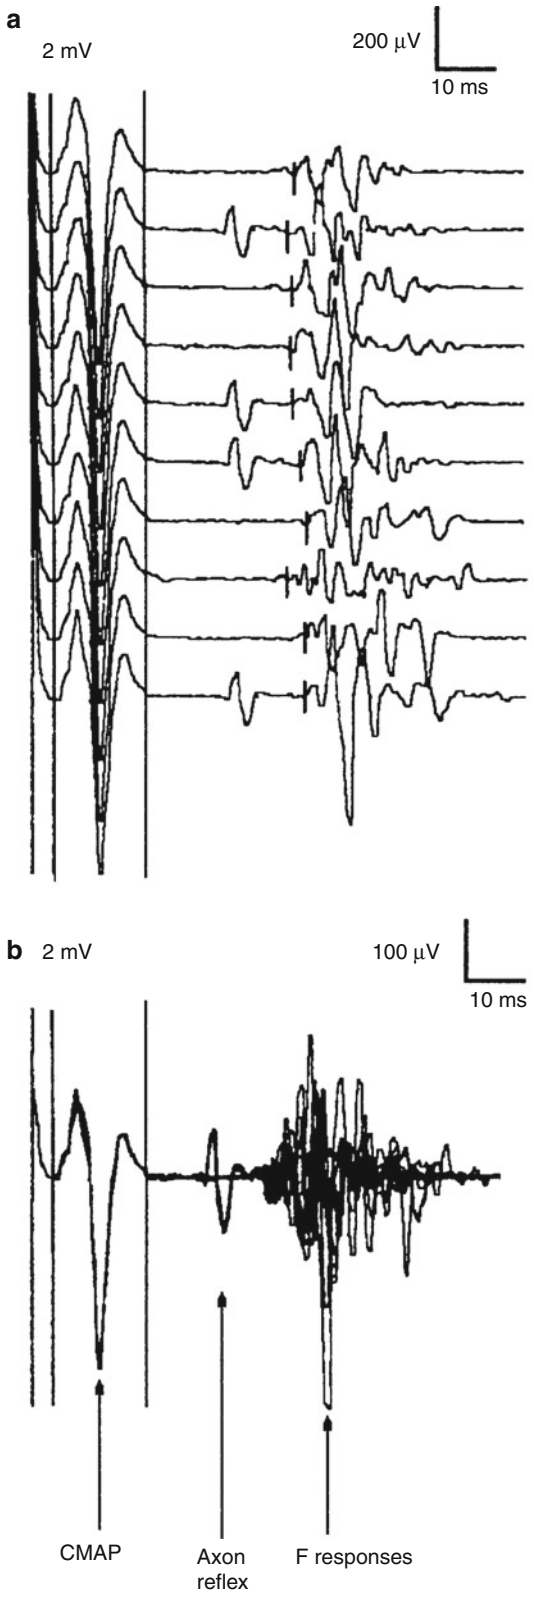

Fig. 7.58 Axon reflex. Tibial F responses, 10 rastered traces. Note that in (**a**) traces 2, 5, 6, 10, there is an additional potential, the axon reflex, that occurs between the CMAP and F response. When superimposed (**b**), the axon reflexes superimpose perfectly, in contrast to the F waves, which differ in configuration and latency in each trace (Reproduced with permission from Preston and Shapiro [1])

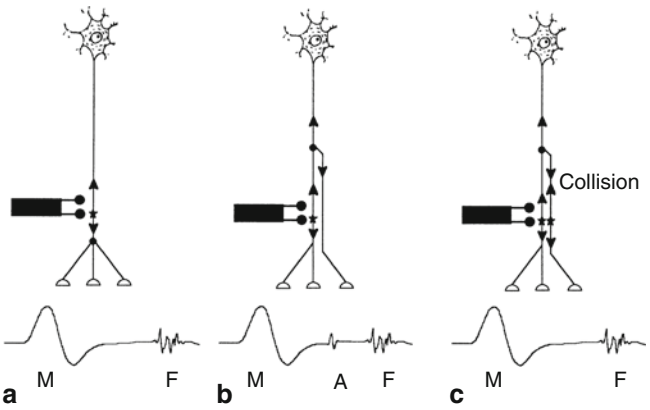

Fig. 7.59 Axon reflex circuit. (**a**) Normally, the axon divides into its terminal divisions close to the muscle. When stimulation occurs distally, orthodromic travel results in a direct motor (*M*) potential, while antidromic travel results in an F response as usual. (**b**) After denervation, collateral sprouts may grow from the more proximal axon to reinnervate denervated muscle fibers. The antidromic pulse may pass a collateral branching point to a nerve fiber and travel orthodromically back down the branching nerve fiber to the muscle to create the axon reflex. This occurs in the situation where all the distal nerve fibers have not been supramaximally stimulated, and there is no antidromic pulse to collide with the action potential traveling down the collateral fibers. Because the length of nerve traveled for the axon reflex is less than that traveled for the F response, the axon reflex usually occurs before the F. It is identified by its identical latency and configuration with each successive stimulation. (**c**) With supramaximal stimulation, the axon reflex is often eliminated, due to collision between the orthodromically traveling axon reflex and the antidromic volley from the reinnervated sprout (Reproduced with permission from Preston and Shapiro [1])

Blink Reflex

The blink reflex assesses the trigeminal (cranial nerve, [CN] V) and facial nerves (CN VII) and their connections in the pons and medulla. The blink reflex is the electrical correlate of the clinically evoked corneal reflex. Similar to the H reflex, the blink reflex represents a true reflex, with a sensory afferent limb, intervening synapses and a motor efferent. The blink reflex is useful in detecting abnormalities anywhere along the reflex arc, including the peripheral and central pathways. Accordingly, neuropathies of the facial or trigeminal nerves, as well as brainstem lesions, may cause abnormal blink reflexes.

Anatomy

The afferent limb of the blink reflex is mediated by sensory fibers of the supraorbital branch of the ophthalmic division of the trigeminal nerve (CN V_1) and the efferent limb by motor fibers of the facial nerve (CN VII). Similar to the corneal reflex, ipsilateral electrical stimulation of the supraorbital branch of the trigeminal nerve elicits a facial nerve (eye blink) response bilaterally. Stimulation of the ipsilateral supraorbital nerve results in an afferent volley along the trigeminal nerve to both the main sensory nucleus of V (midpons) and the nucleus of the spinal tract of CN V (lower pons

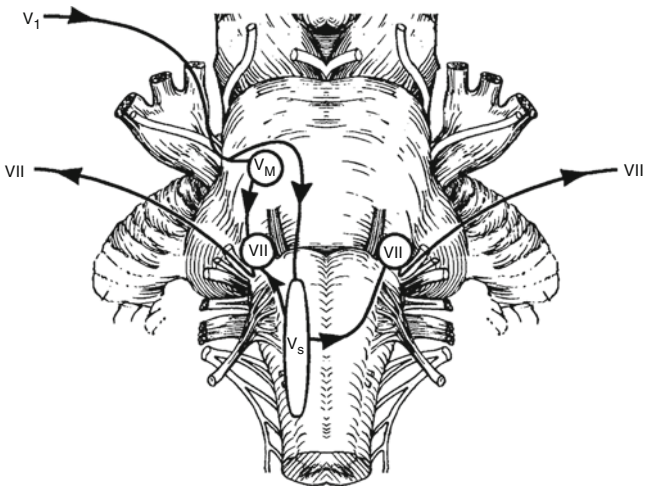

Fig. 7.60 Blink reflex anatomy. The afferent loop of the blink reflex is mediated by the first division of the trigeminal nerve (V_1), which synapses with both the main sensory nucleus of CN V (V_M) in the midpons and the nucleus of the spinal tract of CN V (V_S) in the medulla. The earlier R1 potential is mediated by a di-synaptic connection between the main sensory nucleus and the ipsilateral facial motor nucleus (VII). The later R2 responses are mediated by a multi-synaptic pathway between the nucleus of the spinal tract of CN V and both ipsilateral and contralateral facial nuclei (VII). The efferent pathway for both R1 and R2 is mediated via the facial nerve to the orbicularis oculi muscles (Modified from Chusid [30], with permission)

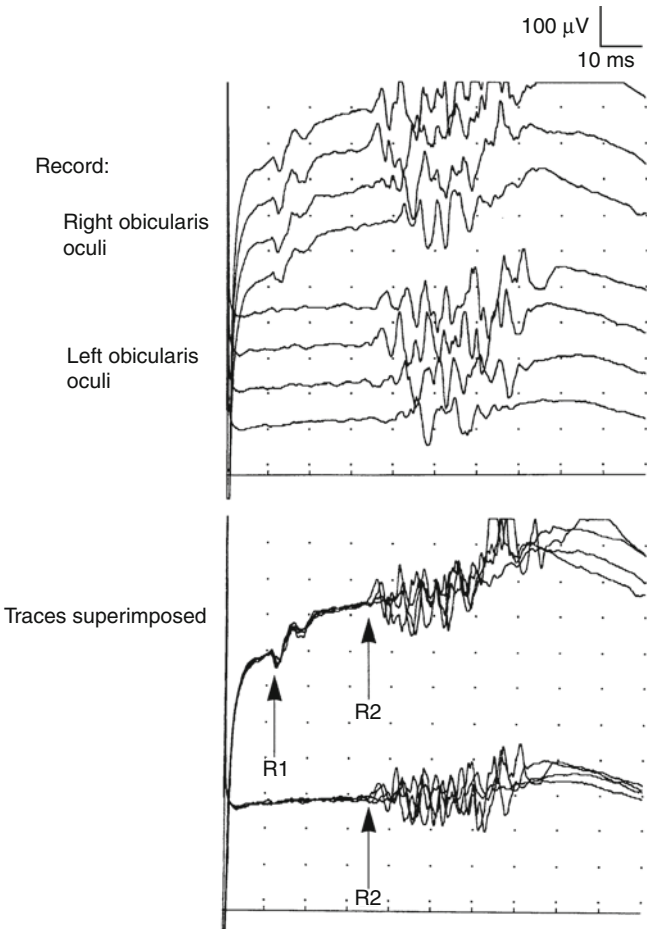

Fig. 7.61 Normal blink reflex. Stimulating right side, recording both orbicularis oculi muscles in a normal subject. On the ipsilateral side, an early R1 potential is present at 11 ms and a late R2 potential at 34 ms. The R1 is usually a bi- or triphasic potential and stable from stimulation to stimulation. The R2 potential is variable and usually polyphasic. On the contralateral side, only a late R2 potential is seen at 35 ms. To help determine the shortest R2 latencies, superimposing several traces is useful (Reproduced with permission from Preston and Shapiro [1])

and medulla) in the brainstem (Fig. 7.60). Through interneurons in the pons and lateral medulla, the nerve impulse next reaches the ipsilateral and contralateral facial nuclei, from which the efferent signal travels along the facial nerve bilaterally.

The blink reflex has two components, an early R1 and a late R2 response (Fig. 7.61). The R1 response is usually present ipsilateral to the side being stimulated, whereas the R2 response is typically present bilaterally. The R1 response is thought to represent the di-synaptic reflex pathway between the main sensory nucleus of V in the midpons and the ipsilateral facial nucleus in the lower pontine tegmentum. The R2 responses are mediated by an oligosynaptic pathway between the nucleus of the spinal tract of V in the ipsilateral pons and medulla, and interneurons forming connections to the ipsilateral and contralateral facial nuclei.

The earlier R1 response is usually stable and reproducible, with a bi- or triphasic morphology. Rarely, the R1 response cannot be reliably elicited on either side. The R2 response, on the other hand, is polyphasic, variable from one stimulation to another, and may habituate with repeated stimulations.

Blink Reflex Procedure

A two-channel recording system is required, and a small pediatric bipolar prong or bar electrode is best suited for stimulations. The sweep speed needs to be set at 5 or 10 ms/div. Initial sensitivity should be set at 100 or 200 µV/div. The filter settings are the same as for a motor conduction study (i.e., 10 Hz and 10 kHz). The patient should be lying supine on the examining table, in a relaxed state, with the eyes either open or gently closed. Surface recording electrodes are placed over the inferior orbicularis oculi muscles bilaterally. To record the CMAP from the orbicularis oculi muscle, the active recording electrode (G1) is best placed just lateral and inferior to the pupil at midposition. The corresponding reference electrodes (G2) are placed just lateral to the lateral canthus bilaterally. Alternatively, recording may be achieved with small concentric needle electrodes placed in the orbicularis oculi bilaterally. The ground electrode is placed either over the midforehead or chin. The supraorbital nerve (branch of the ophthalmic division of the trigeminal nerve) is stimulated ipsilaterally in the superior orbital fissure located in the medial supraorbital ridge and sometimes felt as a slight depression in the bony ridge over the eyebrow. The nerve is

easily stimulated with low currents; hence, an electrical pulse of 100 μs in duration is recommended, and the current is increased in small increments, usually 3–5 mA, until supramaximal stimulation is reached, typically at around 15–25 mA. The patient should be relaxed to eliminate any signal noise, which can obscure or confound one or both components of the blink reflex (especially R2). It is often helpful to use the speaker as an auditory feedback to the patient to help with muscle relaxation, and thereby reduce signal noise.

Once supramaximal stimulation is achieved, four to six responses are obtained on a rastered tracing and superimposed to determine the shortest response latencies. The R1 latency is fairly easy to measure, preferably at the point where the potential departs from the baseline, with either a positive or negative deflection (see Fig. 7.61). Measurement of the R2 latencies is more difficult as the potential varies in latency and morphology from stimulation to stimulation. With several traces superimposed, the shortest R2 latency is generally selected.

In a small number of individuals, stimulation of the infraorbital nerve, another branch of CN V_2, may result in a blink response. The reflex may also be elicited, with some difficulties, with a glabellar tap using a specially devised reflex hammer that automatically triggers the oscilloscope sweep. Mechanical stimulation over the forehead elicits usually an R1 response bilaterally.

Patterns of Abnormalities

For each blink response, the R1 and R2 latencies are compared to normal control values, as well as to the contralateral side. In healthy subjects (Fig. 7.62a), the absolute R1 latency is <13 ms, the ipsilateral R2 latency <41 ms, and the contralateral R2 latency <44 ms. For side-to-side comparisons, the difference between the R1 latencies should be less than 1.2 ms, the difference in ipsilateral R2 latencies should be <5 ms, and the difference in contralateral R2 latencies should be <7 ms. In healthy individuals, electrical stimulation elicits an R1 response on the side ipsilateral to the stimulation, and R2 responses bilaterally. The R1 latency reflects conduction time along the fastest fibers of the afferent sensory fibers of the ipsilateral trigeminal nerve to the main sensory nucleus

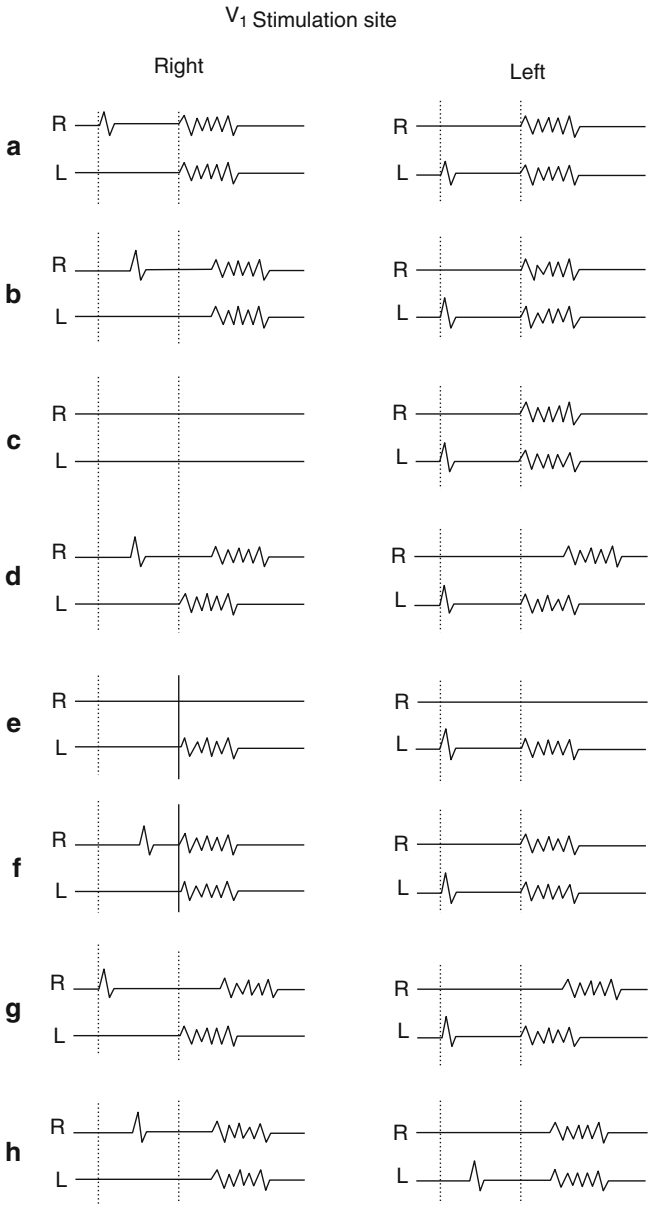

Fig. 7.62 Blink reflex patterns of abnormalities. (**a**) Normal pattern. Recording both orbicularis oculi muscles, stimulating the supraorbital nerve on each side results in an ipsilateral R1 (early) and bilateral R2 (late) potentials. (**b**) Incomplete right trigeminal lesion. Stimulating the affected right side, there is a delay of all potentials, including the ipsilateral R1 and R2 and contralateral R2. Stimulating the unaffected side results in all normal potentials. (**c**) Complete right trigeminal lesion. Stimulating the affected right side, all potentials are absent. Stimulating the unaffected side results in all normal potentials. (**d**) Incomplete right facial lesion. Stimulating the affected side results in delay of the ipsilateral R1 and R2, but a normal contralateral R2. Stimulating the unaffected side results in a normal ipsilateral R1 and R2, but a delayed contralateral R2. In this pattern, all potentials on the affected side are abnormal, regardless of which side is stimulated. (**e**) Complete right facial lesion. Stimulating the affected side results in absent ipsilateral R1 and R2 potentials, but a normal contralateral R2. Stimulating the unaffected side results in a normal ipsilateral R1 and R2, but an absent contralateral R2. (**f**) Right midpontine lesion (main sensory nucleus V and/or lesion of the pontine interneurons to the ipsilateral facial nerve nucleus). Stimulating the affected side results in an absent or delayed R1, but an intact ipsilateral and contralateral R2. Stimulating the unaffected side results in all normal potentials. (**g**) Right medullary lesion (spinal tract and nucleus V and/or lesion of the medullary interneurons to the ipsilateral facial nerve nucleus). Stimulating the affected side results in a normal R1 and contralateral R2, but an absent or delayed ipsilateral R2. Stimulating the unaffected side results in normal ipsilateral R1 and R2 potentials, but a delayed or absent contralateral R2. (**h**) Demyelinating peripheral polyneuropathy. All potentials of the blink response may be markedly delayed or absent, reflecting slowing of either or both motor and sensory pathways (Reproduced with permission from Preston and Shapiro [1])

of V, across di-synaptic pathways in the pons to the facial nerve nucleus, and along the efferent motor fibers of the ipsilateral facial nerve. The R2 latency is a measure of conduction time along the fastest fibers of the afferent pathway of the ipsilateral trigeminal nerve to the nucleus of the spinal tract of V, across multiple synapses in the pons and lateral medulla to both the ipsilateral and contralateral facial nerve nuclei, and along the efferent pathways of the facial nerves bilaterally.

Many different patterns of abnormalities can occur depending on the site or sites of the lesion(s). The major abnormal patterns consist of the following:

- *Unilateral Trigeminal Lesion* (Fig. 7.62b, c): Stimulating the symptomatic side, all potentials (ipsilateral R1 and R2, contralateral R2) are delayed in latencies or absent. However, normal ipsilateral R1 and R2 and contralateral R2 are evoked with stimulation of the asymptomatic side. In this situation, the abnormal potentials correlate with the stimulation side.
- *Unilateral Facial Lesion* (Fig. 7.62d, e): Stimulating the symptomatic side evokes delayed or absent ipsilateral R1 and R2 potentials, but a normal contralateral R2. Stimulating the asymptomatic side results in a normal ipsilateral R1 and R2, but a delayed or absent contralateral R2. In this pattern, the abnormal potentials correlate with the recording side.
- *Unilateral Midpontine Lesion* (*Main Sensory Nucleus of CN V*) *or Lesion of the Pontine Interneurons to the Ipsilateral Facial Nerve Nucleus*, *or Both* (Fig. 7.62f): Stimulating the affected side results in an absent or delayed R1, but an intact ipsilateral and contralateral R2. Stimulating the unaffected side results in all normal potentials, including R1 and ipsilateral and contralateral R2.
- *Unilateral Medullary Lesion* (*Spinal Tract and Nucleus of CN V*) *or Lesion of the Medullary Interneurons to the Ipsilateral Facial Nerve Nucleus*, *or Both* (Fig. 7.62g): Stimulating the affected side results in a normal R1 and contralateral R2, but an absent or delayed ipsilateral R2. Stimulating the unaffected side results in normal ipsilateral R1 and R2 potentials, but a delayed or absent contralateral R2. With a more extensive lesion in the medulla involving medullary interneurons to the contralateral facial nerve, stimulating either supraorbital nerve results in a normal R1, but delayed or absent ipsilateral and contralateral R2 potentials.
- *Peripheral Neuropathy* (Fig. 7.62h): Axonal neuropathies rarely affect the latencies of the blink reflexes, as typical axonal distal dying back neuropathies are unlikely to affect the fibers that mediate the blink reflex, which are proximal. However, in demyelinating neuropathies, all potentials of the blink response may be markedly delayed, reflecting slowing of either or both motor and sensory pathways.

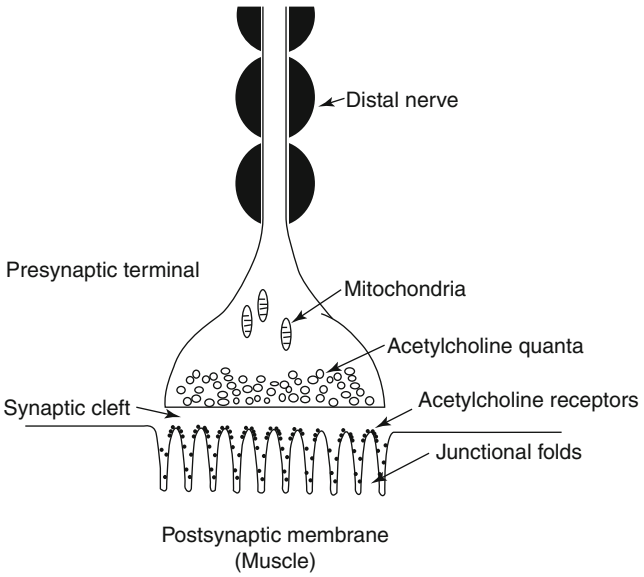

Fig. 7.63 Normal neuromuscular junction anatomy (Reproduced with permission from Preston and Shapiro [1])

Repetitive Nerve Stimulation

Repetitive nerve stimulation (RNS) is a useful EDX test in evaluating patients with suspected neuromuscular junction (NMJ) disorders. RNS is indicated whenever there is a clinical suspicion of an NMJ disorder such as myasthenia gravis (MG), Lambert-Eaton myasthenic syndrome (LEMS), or botulism. Knowledge of normal NMJ physiology and the effects of RNS on the NMJ and its associated muscle fiber in normal subjects and in patients with NMJ disorders is useful in understanding these responses.

Physiology

The NMJ is an electrical-chemical-electrical link between nerve and muscle (Fig. 7.63), with *acetylcholine* (ACH) as the neurotransmitter. ACH molecules are packaged as vesicles in the presynaptic terminal, in discrete units known as *quanta*, with each quantum containing approximately 10,000 molecules of ACH. Each quantum (vesicle) released results in a 1 mV change of postsynaptic membrane potential. This occurs spontaneously during rest and forms the basis of *miniature end-plate potential* (*MEPP*). The quanta are located in three separate stores: (1) *a primary or immediately available store* consisting of approximately 1,000 quanta, located beneath the presynaptic nerve terminal membrane and immediately available for release; (2) *a secondary or mobilization store* that consists of approximately 10,000 quanta that can resupply the primary store after a few seconds; and (3) *a tertiary or reserve store* consisting of more than 100,000 quanta that exists a distance from the NMJ (in the axon and cell body).

When a nerve action potential depolarizes the presynaptic terminal, *voltage-gated calcium channels* (*VGCCs*) open,

allowing an influx of calcium. The infusion of calcium results in the release of ACH from the presynaptic terminal. The greater the calcium concentration inside the presynaptic terminal, the more quanta are released. Normally, calcium diffuses out of the presynaptic terminal for approximately 100–200 ms.

When released, ACH diffuses across the synaptic cleft and binds to acetylcholine receptors (ACHRs) on the postsynaptic muscle membrane. The postsynaptic membrane is composed of numerous junctional folds, effectively increasing the surface area of the membrane, with ACHRs clustered on the crests of the folds. The binding of ACH to ACHRs opens ion channels, resulting in a local depolarization, the end-plate potential (EPP), which is proportional to the amount of ACH that binds to the ACHRs. If the EPP depolarizes the muscle membrane above *threshold*, an all-or-none muscle fiber action potential (MFAP) is generated and propagated through the muscle fiber. Under normal circumstances, the number of quanta (vesicles) released following a single nerve action potential at the presynaptic terminal is about 60. This results in an EPP which always rises above threshold and results in an MFAP. The amplitude of the EPP above the threshold value needed to generate an MFAP is called the *safety factor*, which is estimated to be 7–20 mV.

Following closure of the nicotinic receptor, ACH is released in the synaptic cleft and subsequently hydrolyzed by *acetylcholinesterase* into choline and acetate. Choline is taken back up into the presynaptic terminal and resynthesized to acetylcholine. ACH is finally repackaged into vesicles in order to protect the molecules from hydrolysis (by the presynaptic acetylcholinesterase).

Basic Concepts

RNS in normal subjects and patients with NMJ disorders is better understood after discussing the following facts:

1. The number of quanta released after a nerve action potential depends on the number of quanta in the immediately available store and the probability of release (i.e., $m = pn$, where m = the number of quanta released during each stimulation, p = the probability of release (effectively proportional to the concentration of calcium and typically about 0.2 (or 20 %) in normal conditions), and n = the number of quanta in the immediately available store [typically approximately 1,000 at baseline in normal conditions]).
2. The mobilization store starts to replenish the immediately available store after 1–2 s.
3. The rate at which motor nerves are stimulated dictates whether calcium plays a role in enhancing the release of ACH. Because calcium diffuses out of the presynaptic terminal in 100–200 ms, a slow rate of stimulation (more than every 200 ms) implies that the subsequent stimulus arrives long after calcium has dispersed. Thus, with an interstimulus interval of >200 ms, or a slow RNS rate of <5 Hz, the role of calcium in ACH release is not enhanced. In contrast, with rapid RNS (i.e., an interstimulus interval of <100 ms, or stimulation rate >10 Hz), calcium influx is greatly enhanced, the probability of release of ACH quanta increases, and more quanta are released.
4. The CMAP is the summation of all MFAPs in a muscle, obtained after supramaximal stimulation of the motor nerve. In the EMG lab, all measurements during RNS are made on the CMAP only.

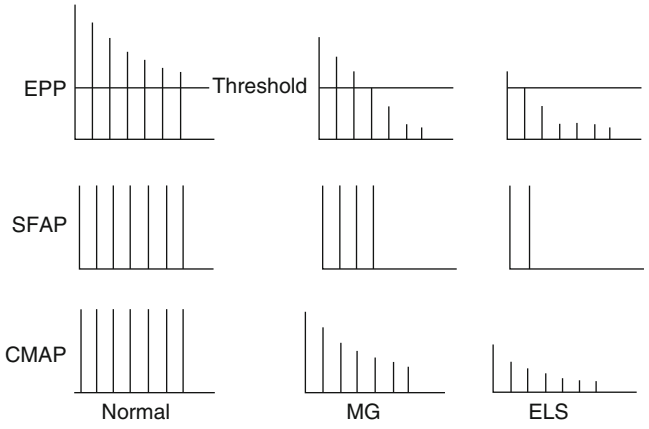

Fig. 7.64 Slow repetitive stimulation effect on end-plate potential (*EPP*), single-fiber action potential (*SFAP*), and compound muscle action potential (*CMAP*) in normal health, myasthenia gravis(*MG*), and Lambert-Eaton myasthenic syndrome (*LEMS*) (Adapted from Oh [31])

Slow Repetitive Stimulation

During slow RNS (<5 Hz, usually 2–3 Hz) in healthy subjects, ACH quanta are progressively depleted from the primary store, and subsequently fewer quanta are released with each successive stimulation. The corresponding EPP falls in amplitude, but because of the normal safety factor, the EPP remains above threshold to ensure generation of an MFAP with each stimulation (Fig. 7.64, left column). After the first few seconds, the secondary (i.e., mobilization) store begins to replace the depleted quanta with a subsequent rise in the EPP.

The effect of slow RNS on the EPP, MFAP, and CMAP is better understood with the following 3-Hz RNS example:

Stimulus	n	m	EPP	MFAP	CMAP
1	1,000	200	40	+	Normal
2	800	160	32	+	No change
3	640	128	26	+	No change
4	512	102	20	+	No change
5	640	128	26	+	No change

In this example, there are initially 1,000 quanta in the immediately available store (n), and with each stimulation, 20 % of the quanta are released. If the EPP is above 15 mV (threshold in this example), an MFAP is generated. Note the

normal depletion of the immediately available store (*n*), the subsequent decline in number of quanta released (*m*), and the corresponding fall in the EPP from the first to fourth stimulation. During the second stimulation, only 160 quanta are released instead of the initial 200, due to the fact that the number of quanta in the immediately available store has dropped to 800 (1,000 minus the 200 released during the first stimulation) and subsequently 20 % of the 800 are released. At the fifth stimulus, however, sufficient time has elapsed for the secondary or mobilization store to begin to resupply the primary store. The number of quanta in the immediately available store increases with a corresponding increase in the number of ACH quanta released and a higher EPP. At all times, the EPP stays above threshold (15 mV), resulting in the consistent generation of an MFAP (Fig. 7.64, left column). In the EMG laboratory, these findings translate to normal baseline CMAPs with no change in amplitude, because action potentials are generated in all muscle fibers.

In *a postsynaptic disorder*, such as MG, where the safety factor is reduced (fewer ACHRs resulting in less binding of ACH), the baseline EPP is reduced but usually still above threshold. Slow RNS will cause depletion of quanta and may drop the EPP below threshold, resulting in the absence of an MFAP (Fig. 7.64, center column). This is better understood with the following 3-Hz RNS example:

Stimulus	*n*	*m*	EPP	MFAP	CMAP
1	1,000	200	18	+	Normal
2	800	160	14	–	Decrement
3	640	128	11	–	Decrement
4	512	102	9	–	Decrement
5	640	128	13	–	Plateau

In this example, the number of quanta in the immediately available store (*n*), the number of quanta released (*m*), and the depletion of quanta with slow RNS are all normal. However, the response to the quanta (i.e., the EPP) is abnormal. Whereas in healthy subjects, the release of 200 quanta generated an EPP of 40 mV, in this case, the same number of quanta generates an EPP of only 18 mV. In MG, this occurs as a result of fewer ACHRs and, accordingly, less binding of ACH. The reduced safety factor, in conjunction with the normal depletion of quanta, results in subsequent EPPs falling below threshold and their corresponding MFAPs not being generated. Thus, the number of individual MFAPs declines and this provides the basis for a decremental CMAP response to slow RNS, as seen in the EMG lab. As the number of individual MFAPs declines, a decrement of the CMAP amplitude and area occurs (Fig. 7.64, center column). This decrement reflects fewer EPPs reaching threshold and fewer individual MFAPs contributing to the CMAP. Often, after the fifth or sixth stimulus, the secondary stores are mobilized and no further loss of MFAP occurs. This results in stabilization or sometimes slight improvement of the CMAP after the fifth or sixth stimulus, giving the characteristic U-shaped decrement.

In *a presynaptic disorder*, such as LEMS, the calcium concentration in the presynaptic terminal is reduced, due to an antibody attack on the VGCCs. Thus, the probability of release (*p*) dramatically falls, with a decrease in the number of quanta released. A slow (3 Hz) RNS may be modeled as follows:

Stimulus	*n*	*m*	EPP	MFAP	CMAP
1	1,000	20	4	–	Low
2	980	19.6	3.9	–	Decrement
3	960	19.2	3.8	–	Decrement
4	940	18.8	3.7	–	Decrement
5	920	18.4	3.6	–	Plateau

In this example, the number of quanta in the immediately available store (*n*) is normal, but the number of ACH quanta released (*m*) is low, due to the reduced probability of release (*p*). Hence, the baseline EPP is low, often not reaching threshold, and many muscle fibers do not fire (Fig. 7.64, right column). With successive stimulations, there is further depletion, though not as marked as in normal or postsynaptic disorders; because so few quanta are released, the subsequent amount of depletion cannot be as great. In this example, as the EPP is below threshold at baseline, an MFAP is never generated (see Fig. 7.64, right column). Thus, the baseline CMAP is low in amplitude, because many muscle fibers do not reach threshold due to inadequate release of quanta after a single stimulus. With slow RNS, there is also further decrement of the CMAP, because subsequent stimuli result in further loss of MFAPs. Note that in some presynaptic disorders, the baseline EPP may be low, but still above threshold, resulting in a reduced safety factor. In this situation, action potentials may be generated initially in large numbers of muscle fibers but then fail to be generated as the EPP falls below threshold with slow RNS. This results in a borderline (rather than low) amplitude baseline CMAP which decrements with slow RNS.

Rapid Repetitive Stimulation

If RNS is rapid enough (>10 Hz, usually 30–50 Hz), so that new calcium influx occurs before the previously infused calcium has diffused back out, then calcium continues to accumulate in the presynaptic terminal, causing an increased probability of quanta release (*p*). This, along with increased mobilization of quanta from the secondary store, usually leads to an increased number of quanta being released and a correspondingly higher EPP. However, in normal subjects, the result is the same as with any other EPP above threshold: an all-or-none MFAP. Thus, in normal subjects, CMAPs generated following rapid RNS do not change significantly in amplitude or area (Fig. 7.65, left column).

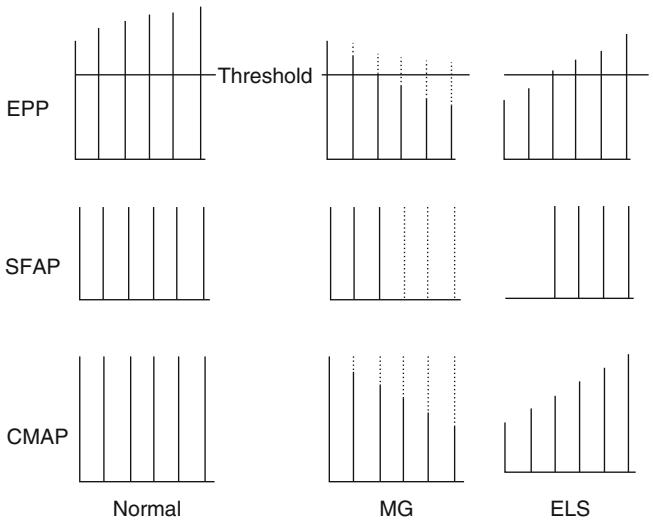

Fig. 7.65 Rapid repetitive stimulation effect on end-plate potential (*EPP*), single-fiber action potential (*SFAP*), and compound muscle action potential (*CMAP*) in normal health, myasthenia gravis, and Lambert-Eaton myasthenic syndrome (*LEMS*) (Adapted from Oh [31])

The physiology of rapid RNS in patients with *postsynaptic disorders* is more complex. In these patients, the EPP will also increase, but because the EPP is usually above threshold at baseline, the result will still be the generation of an MFAP and no subsequent change of CMAP amplitude (Fig. 7.65, center column, *dotted lines*). However, if the EPP has been lowered, such as after slow RNS, the decreased EPP may be repaired or improved with rapid RNS. In severe postsynaptic blockade (e.g., during myasthenic crisis), the increased quantal release cannot compensate for the marked NMJ block resulting in a drop in EPP amplitude and fewer MFAPs being generated, along with an associated CMAP decrement (Fig. 7.65, center column, *solid lines*).

Presynaptic disorders are distinctly different. Because the EPP is abnormally low at baseline, and often below threshold, rapid RNS may increase the EPP above threshold so that an MFAP is generated where one had not been present previously (Fig. 7.65, right column). Hence, the number of individual MFAPs increases. This provides the basis for an incremental CMAP response to rapid RNS seen in the EMG laboratory. As the number of individual muscle fiber action potentials increases, an increment of the CMAP amplitude and area occurs. This increment reflects more EPPs reaching threshold and more individual MFAPs contributing to the CMAP.

Exercise Testing

Maximal voluntary exercise can be used to demonstrate many of the same effects as rapid RNS, because motor units fire at their maximal firing frequency, typically 30–50 Hz. Both result in higher-amplitude EPPs.

In *healthy subjects*, brief intense exercise may lead to a slight increase in CMAP amplitude, known as *pseudofacilitation*. After brief exercise, EPPs are facilitated. However, because they are above threshold at baseline, the same number of MFAPs is generated. Although there is no increase in the actual number of MFAPs that summate to create the CMAP, brief maximal exercise causes the muscle fibers to fire more synchronously. This pseudofacilitation results in an increase in CMAP amplitude, but usually with a decrease in CMAP duration, and little change in the CMAP area. In general, postexercise increments of CMAP amplitude from pseudofacilitation do not exceed 50 % of baseline in normal subjects (see below).

In *postsynaptic disorders*, maximal exercise, just like rapid RNS, results in higher EPPs. Because the EPP is usually above threshold at baseline, the result is the same: the generation of an MFAP. Exercise likewise may repair or improve a low EPP which has developed during slow RNS. If the EPP has dropped below threshold, then subsequent exercise may increase the EPP back to above threshold. In *presynaptic disorders*, exercise, like rapid RNS, can often facilitate low EPPs. If the baseline EPP is below threshold, exercise may increase the EPP above threshold so that an MFAP is generated where one had not been present previously.

The effects of rapid RNS or voluntary exercise described above occur with *brief* periods of exercise or rapid RNS and are best achieved following 10 s of exercise [32]. This process, known as *postexercise* (*or post-tetanic*) *facilitation*, can be demonstrated on the CMAP in patients with NMJ disorders (Fig. 7.66). Following 10 s of maximal voluntary contraction, increased mobilization of quanta and accumulation of calcium occur, resulting in greater numbers of quanta released and a higher EPP. This postexercise facilitation can be demonstrated in two situations. First, in presynaptic disorders such as LEMS associated with reduced release of quanta and subthreshold EPPs at baseline, brief exercise can facilitate EPPs above threshold, giving rise to muscle fiber action potentials that were not present previously. Accordingly, an increment of the CMAP amplitude and area occurs. Second, brief exercise can repair EPPs that have been lowered by slow repetitive simulation. If the EPPs are facilitated above threshold, muscle fiber action potentials will be generated that were not present previously. Accordingly, a decrement of the CMAP amplitude and area that has developed during slow RNS may be lessened or "repaired" (see Fig. 7.66a, b).

The phenomenon of *postexercise* (*or post-tetanic*) *exhaustion* is less well understood. Immediately after a prolonged exercise or rapid repetitive stimulation (usually 1 min), EPPs typically increase initially, as described above, but then subsequently decline over the next several minutes, usually falling below baseline. In normal subjects with a normal safety factor, the EPP never falls below threshold. However, in patients with impaired NMJ transmission, slow repetitive

stimulation performed 2–4 min after a prolonged exercise may result in a greater decline of the EPP, such that the EPP does not reach threshold and its MFAP is not generated.

To demonstrate postexercise exhaustion, the muscle is maximally exercised for 1 min. Slow RNS is then performed immediately after, and at 1, 2, 3, and 4 min later. In healthy subjects with a normal safety factor, the EPP never falls below threshold, and the CMAP amplitude and area remain stable. However, in patients with impaired NMJ transmission, the decrement in CMAP amplitude and area to slow RNS becomes more marked 2–4 min after prolonged exercise (see Fig. 7.66c–e). If this occurs, 10 s of maximal voluntary exercise can then be used to repair the decrement toward normal (see Fig. 7.66f).

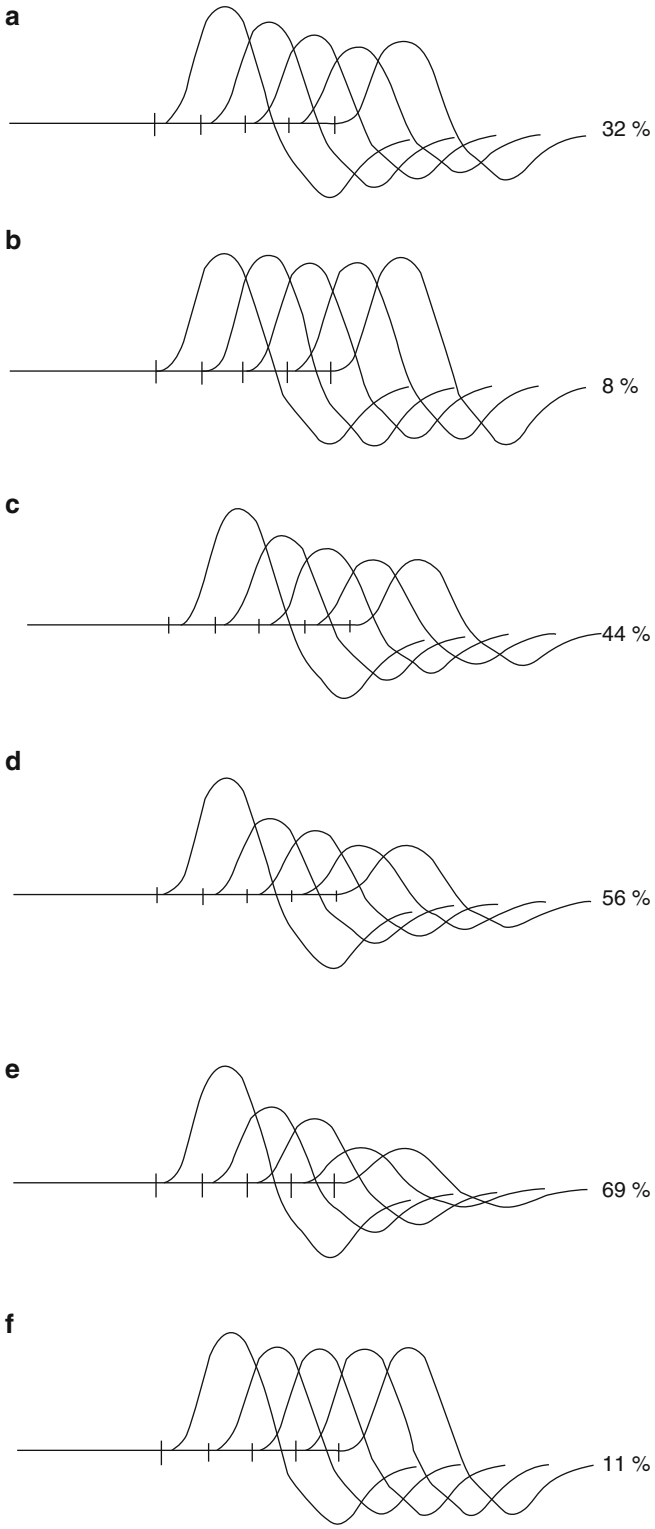

Fig. 7.66 Postexercise facilitation and exhaustion. 3-Hz RNS in a patient with myasthenia gravis. (**a**) Decrement of CMAP amplitude at rest; (**b**) postexercise facilitation: decrement of CMAP immediately following 10 s of maximal voluntary exercise. Decrement has repaired toward normal; (**c**, **d**, **e**) postexercise exhaustion: decrements of CMAP 1, 2, and 3 min after 1 min of maximal voluntary exercise. Decrement becomes progressively more marked over the baseline decrement. (**f**) Postexercise facilitation after a decrement: immediately following another 10 s of maximal voluntary exercise, the decrement, which has worsened as a result of postexercise exhaustion, repairs toward normal (Reproduced with permission from Preston and Shapiro [1])

Technical Factors in Repetitive Nerve Stimulation

Close attention to technical factors is critical when performing RNS. Technical factors, if not appreciated and closely controlled, may result in either factitious decrements or increments and the mistaken impression of an NMJ disorder.

Movement Artifacts

The greatest technical problem with RNS is failure to immobilize the recording electrode over the muscle properly. If the position of the recording electrode moves in relationship to the muscle during stimulation, CMAP configuration may change. The recording electrodes and the stimulator should be secured with tape or a Velcro strap if possible. When stimulating distal nerves such as the median or ulnar nerves, the limb may also be secured to a pad or board. Unfortunately, securing the stimulator and limb to prevent movement is not possible when testing proximal nerves.

Submaximal Stimulation

Submaximal stimulation can create a host of problems, including artifactual CMAP decrements and increments.

Limb Temperature

In NMJ disorders, a CMAP decrement may be diminished if the limb is cold. The reason for this is not completely known, but may be related to decreased functioning of the enzyme acetylcholinesterase when cold, effectively making more ACH available to bind at the ACHRs. Patients with MG note worsening symptoms in warm weather, perhaps because the acetylcholinesterase is more active. RNS should always be performed with the temperature at least 33 °C at the recording site.

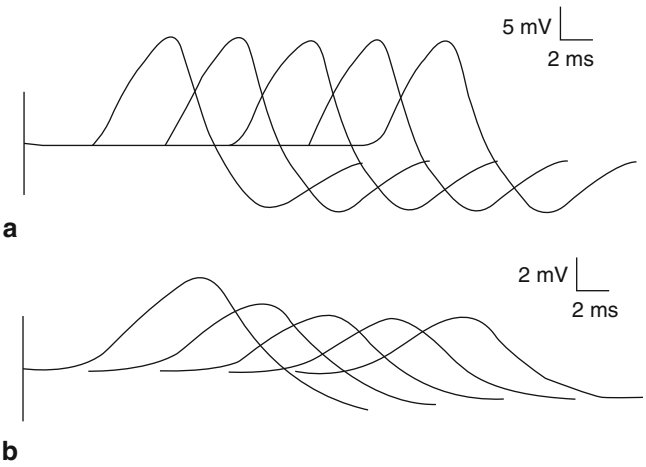

Fig. 7.67 3-Hz RNS of proximal and distal nerves in patient with myasthenia gravis. (**a**) Normal decrement (4 %) in the ulnar nerve. (**b**) Markedly abnormal decrement (42 %) in the spinal accessory nerve. In myasthenia gravis, the yield of an abnormal decrement is greater with proximal nerves. Note also the U-shaped decrement (Reproduced with permission from Preston and Shapiro [1])

Acetylcholinesterase Inhibitors

It is best to advise patients to refrain from taking acetylcholinesterase inhibitors (e.g., pyridostigmine) for 4–6 h, and preferably 12–24 h, before the EDX study if not medically contraindicated. These agents make more ACH available to bind at the ACHRs and may mask a decrement.

Nerve and Muscle Selection

RNS can be performed using any motor nerve. The nerves most commonly used are the ulnar, median, musculocutaneous, axillary, spinal accessory and facial nerves, recording abductor digiti minimi, abductor pollicis brevis, biceps, deltoid, and upper trapezius, respectively. Because weakness in MG patients is predominantly ocular, bulbar, and proximal, the yield of detecting abnormalities increases with the use of more proximal nerves (Fig. 7.67). Unfortunately, there are more technical difficulties stimulating proximal nerves because of pain and movement artifacts. Of the proximal nerves, the spinal accessory nerve recording the upper trapezius is often preferred. The spinal accessory nerve is quite superficial, just posterior to the sternocleidomastoid muscle, and can usually be supramaximally stimulated with a relatively low current. Shoulder movement can be reduced by gentle but firm downward pressure on the shoulder or arm.

The facial nerve can also be used for RNS, recording the nasalis, orbicularis oculi, or other facial muscles (REF check). However, the facial CMAP amplitudes are small at baseline, and one cannot immobilize the muscle and prevent possible electrode movement. Hence, small changes from the baseline CMAP, for example, from electrode movement or failure to perform supramaximal stimulation, are much more likely to confound facial RNS, creating possible false-positive results.

Stimulation Frequency

The optimal frequency for slow RNS is 2 or 3 Hz. The frequency for slow RNS must be kept low enough to prevent calcium accumulation, but high enough to deplete the quanta in the immediately available store before the mobilization store starts to replenish it. For rapid RNS, the optimal frequency is 30–50 Hz. However, brief maximal voluntary exercise can substitute for rapid RNS in cooperative subjects. Exercise testing has the distinct advantage of being painless, whereas rapid RNS is quite painful and often difficult to tolerate. Only in the event of an uncooperative patient (e.g., an infant, a patient in coma) should rapid RNS be used.

Number of Stimulations

A train of 5–10 pulses is preferable for slow RNS. The number of pulses should be kept low to reduce patients' discomfort, but must be counterbalanced by the need to have enough pulses to detect a decrement. When the mobilization store begins to resupply the immediately available store (usually after the fifth or sixth stimulus), the decrement stops or the CMAP begins to improve. This results in a so-called *U-shaped decrement*, which is highly characteristic of NMJ disorders (Fig. 7.67). For rapid RNS, which should only be done in patients who cannot perform brief maximal voluntary exercise, a stimulus train of 5–10 s should be given. This is the length of time often required to see the maximal incremental response from increased mobilization of quanta and calcium accumulation.

Decrement and Increment Calculation

The decrement is usually calculated by comparing the lowest CMAP amplitude (or area) to the baseline CMAP (first CMAP of the RNS train). With slow RNS, the lowest CMAP is usually the third or fourth. By the fifth or sixth stimulation, the decrement plateaus or begins to improve, due to the mobilization store resupplying the immediately available store, (i.e., the U-shaped decrement). The CMAP decrement is expressed in a percentage and calculated as follows:

$$\%\ \text{Decrement} = \frac{\text{Amplitude}\left(\text{Baseline CMAP}\right) - \text{Amplitude}\left(\text{Lowest CMAP}\right)}{\text{Amplitude}\left(\text{Baseline CMAP}\right)} \times 100$$

Normal subjects should have no decrement. Any decrement greater than 10 % is defined as abnormal. The 10 % cutoff allows for inherent technical factors which are often encountered. However, any reproducible decrement is probably abnormal.

CMAP increments are calculated by comparing the highest CMAP amplitude or area with the baseline CMAP and expressed as a percentage as follows:

$$\%\ \text{Increment} = \frac{\text{Amplitude}\left(\text{Highest CMAP}\right) - \text{Amplitude}\left(\text{Baseline CMAP}\right)}{\text{Amplitude}\left(\text{Baseline CMAP}\right)} \times 100$$

With 10 s of maximal voluntary contraction, the calculation is simple and consists of comparing the CMAP obtained after brief exercise with the baseline CMAP. With rapid RNS, the highest CMAP, usually the last one obtained after 5–10 s, is compared with the baseline (first) CMAP. In healthy subjects, pseudofacilitation may cause an increment up to 50 %. The increment in LEMS is often higher than 200 % and is often more pronounced than in patients with botulism which is usually associated with more than 100 % increment. Increments of 50–100 % may also be encountered in cases of botulism with severe presynaptic NMJ blockade.

Decrement in Non-neuromuscular Junction Disorders

Although a decremental response with RNS occurs predominantly in primary disorders of the NMJ, decrements may be seen in severe neurogenic disorders, such as amyotrophic lateral sclerosis. Generally, any condition associated with prominent denervation and reinnervation, and newly formed NMJs (which are immature and unstable), may show a decrement to RNS. In addition, some myopathies, including the myotonic disorders and the metabolic myopathies (e.g., McArdle's disease), may also show a decrement to RNS. This underscores that RNS should not be used in isolation. For every patient, a clinical history and neurologic exam, NCSs and needle EMG need to be performed, so that if a decremental response occurs with RNS, it can be interpreted in the proper context.

Repetitive Nerve Stimulation Protocol

A recommended RNS protocol in the EMG laboratory for patients with suspected NMJ disorders is detailed in Table 7.10.

Electrophysiologic Findings in Neuromuscular Disorders

Focal Neuropathic Lesions

Neuropathic lesions result from loss or dysfunction of peripheral nerve fibers, their primary nerve cells, or both. They represent the bulk of disorders encountered in the EMG laboratory and include mononeuropathies, plexopathies, and radiculopathies and polyneuropathies, as well as disorders primarily affecting the motor neurons or the dorsal root ganglia. Focal peripheral nerve lesions may primarily affect the axon, resulting in axonal loss, or the myelin, resulting in segmental demyelination.

Table 7.10 Protocol for evaluating disorders of the NM

1. Warm the extremity (33 °C)
2. Immobilize the muscle as best as possible
3. Perform routine motor nerve conduction studies first to insure that the nerves are normal
4. Perform RNS at rest. After making sure that the stimulus is supramaximal, perform 3 Hz at rest for 5–10 impulses, repeated 3 times, 1 min apart. Normally, there is <10 % decrement between the first and fifth response
5. If >10 % decrement occurs and is consistently reproducible: (a) Have patient perform maximal voluntary exercise for 10 s (b) Immediately repeat 3 Hz RNS postexercise to demonstrate postexercise facilitation and repair of the decrement
6. If <10 % decrement or no decrement: (a) Have patient perform maximal voluntary exercise for 1 min, and perform 3 Hz RNS immediately, and at 1, 2, 3, and 4 min after exercise to demonstrate postexercise exhaustion (b) If a significant decrement occurs, have patient perform maximal voluntary exercise again for 10 s, and immediately repeat 3 Hz RNS to demonstrate repair of the decrement
7. Perform RNS on one distal and one proximal motor nerve. Always try to study weak muscles. If no decrement is found with a proximal limb muscle, a facial muscle can be tested, keeping in mind technical considerations
8. If the CMAP amplitude is low at baseline, have the patient perform 10 s of maximal voluntary exercise, then stimulate the nerve supramaximally immediately postexercise looking for an abnormal increment (>50–100 % from baseline). If the patient exercises for more than 10 s, or the nerve is not stimulated immediately postexercise, a potential increment may be missed
9. Always perform concentric needle EMG of proximal and distal muscles, especially clinically weak muscles. Any muscle with denervation or myotonia on needle EMG may demonstrate a decrement on RNS, which does not signify a primary disorder of the NMJ

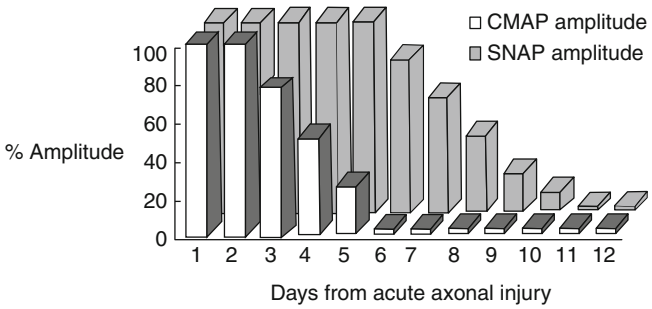

Fig. 7.68 Effect on CMAP and SNAP amplitude after Wallerian degeneration (From Katirji [33], with permission)

Axonal Loss Lesions

After axonal loss lesions (e.g., partial transection of a nerve), the distal segment of the nerve undergoes Wallerian degeneration. With the completion of Wallerian degeneration, the degenerated axons do not contribute to the SNAP and CMAP amplitudes, which decrease or become absent at all stimulation sites. This axon-loss pattern is the most common pattern encountered in the EMG laboratory.

Immediately after an axonal loss lesion, the nerve segment distal to the lesion can conduct action potentials, despite being effectively disconnected from its proximal segment and despite loss of function. With stimulation and recording distal to the site of the lesion, the CMAP and SNAP amplitudes follow two different courses (Fig. 7.68). The CMAP amplitude is normal for 2–3 days and declines rapidly to reach its nadir in 5–6 days. However, the SNAP amplitude is unaffected for 5–6 days and then drops to reach its nadir in 10–11 days [34]. The difference between the decline of the SNAP and CMAP amplitudes following axon-loss nerve lesions is likely related to early transmission failure of the neuromuscular junction which affects only the CMAP amplitude. This is supported by the fact that mixed nerve action potentials follow the time course of SNAPs, both recorded directly from nerve trunks [35].

Therefore, early after a peripheral nerve injury, and as long as some fibers are still conducting distal to the lesion, stimulating the nerve distal and proximal to the lesion results in a conduction block pattern (Fig. 7.69). This "axonal" conduction block (sometimes called *pseudo conduction block*) mimics conduction block encountered with focal segmental demyelination (see section on "Demyelinating Lesions"). In contrast to segmental demyelinating lesions, a repeat NCS after completion of Wallerian degeneration will prove that the lesion is due to axonal loss by revealing a drop in the CMAP amplitude with both distal and proximal stimulation. It should be noted that the identification of "axonal" conduction block in the early days of axonal loss is extremely helpful in localization, particularly in closed nerve injury, where the exact site of trauma is not clear on clinical grounds. This is why it is important to obtain NCSs as early as possible following a suspected acute peripheral nerve lesion. Waiting for the completion of Wallerian degeneration results in low-amplitude CMAPs regardless of stimulation site and does not allow for precise localization of the injury site.

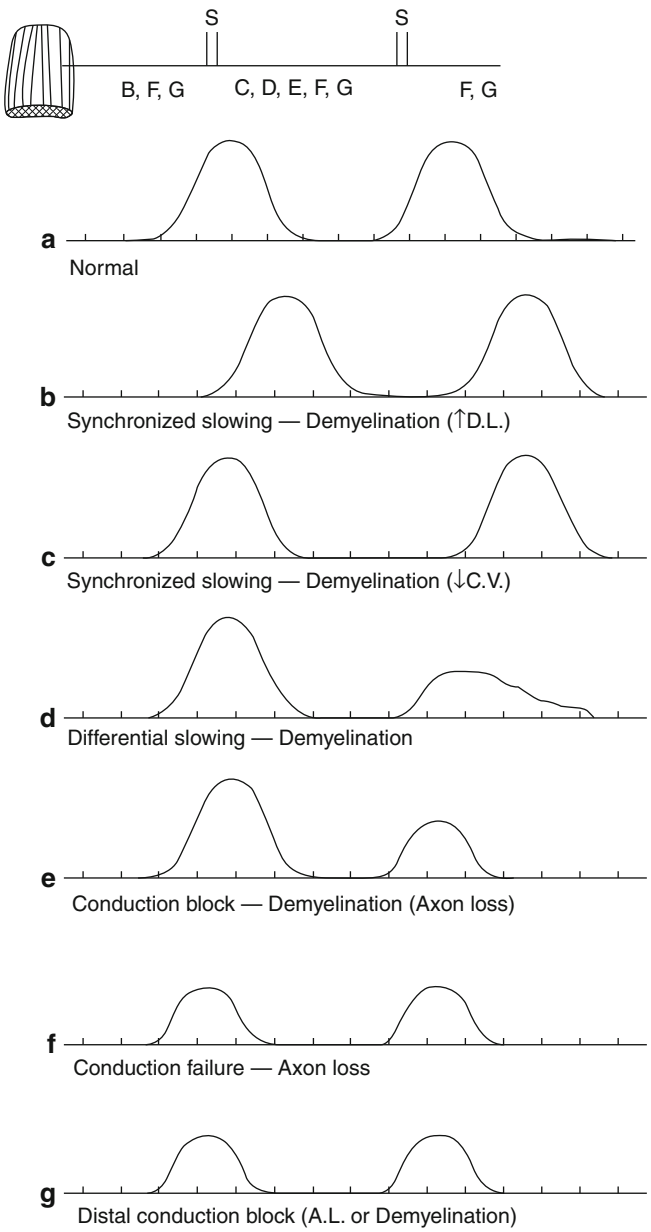

Fig. 7.69 Motor nerve conduction study changes seen with different types of focal pathophysiology located along various nerve segments both proximal and distal to the nerve stimulation sites. The *uppermost drawing* illustrates where lesions are situated to produce the abnormalities seen (*S* stimulation sites, *D.L.* distal latency, *C.V.* conduction velocity, *A.L.* axon loss) (From Wilbourn and Ferrante [36])

In contrast to the significant effect of partial axon-loss lesions on SNAP and CMAP amplitudes, these lesions are often associated with relative preservation of conduction velocities and distal latencies. This is due to the random distribution of conduction velocities of nerve fibers, which

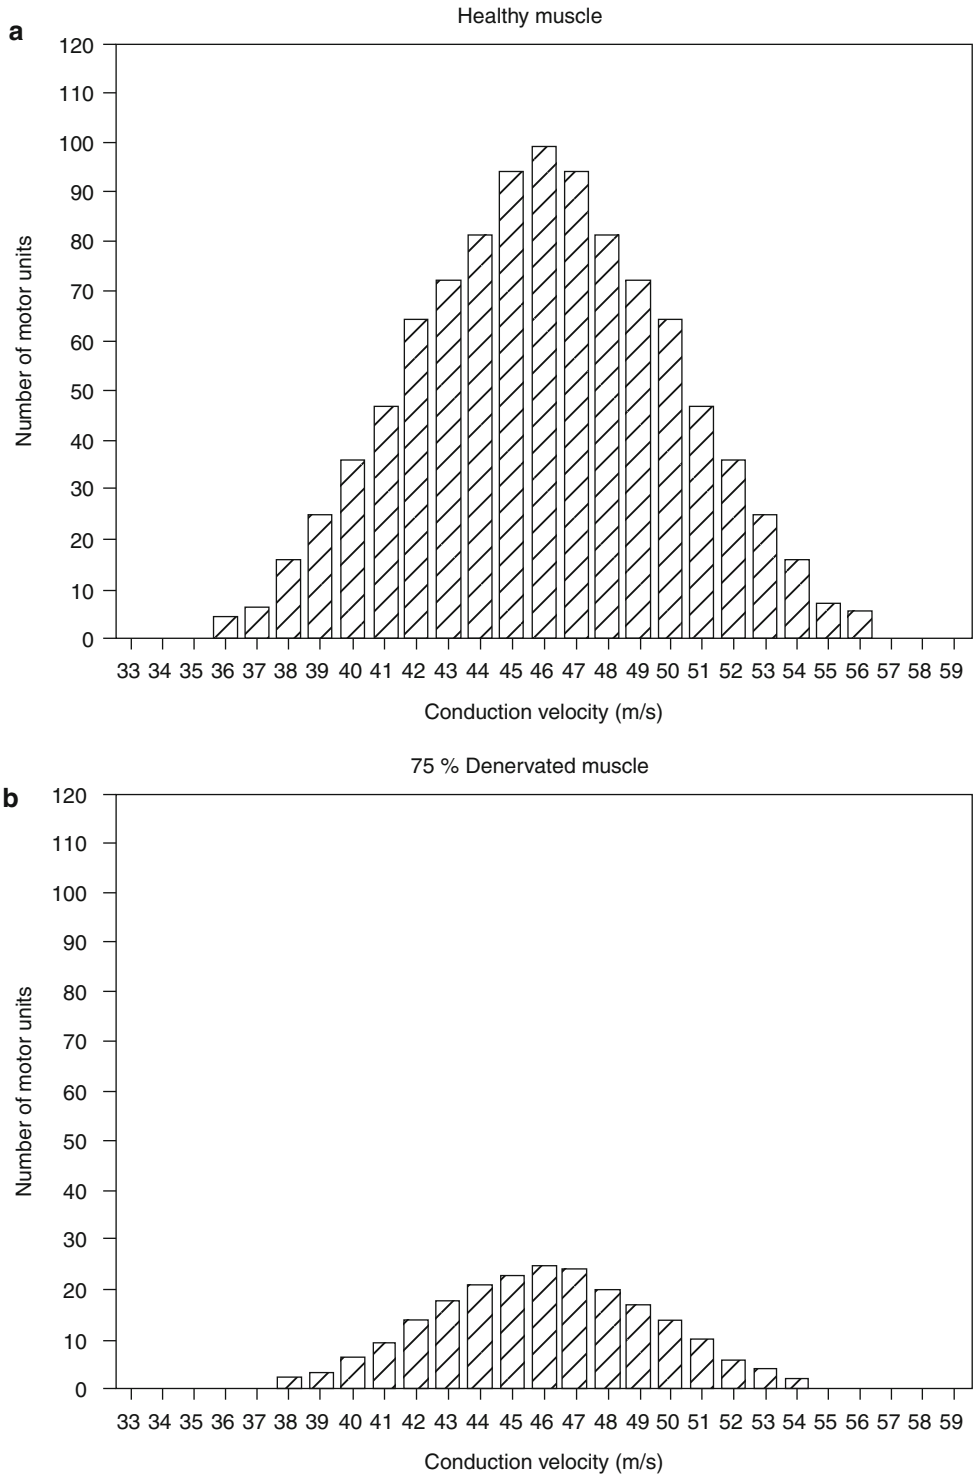

Fig. 7.70 Computer simulation of the effect on the distribution of conduction velocities in (**a**) healthy muscle and (**b**) with 75 % loss of the motor units (From Osselton et al. [37], with permission)

results in survival of some of the fast-conducting fibers (Fig. 7.70). Sometimes, particularly when axonal loss is severe, the largest and fastest conducting axons are lost, resulting in a slight slowing of conduction velocity (CV) and distal latency (DL). This, however, never reaches values in the demyelinating range (i.e., CV <75 % lower limit of normal (LLN); DL >130 % upper limit of normal [ULN]).

On needle EMG, decreased recruitment of MUAPs occurs in weak muscles immediately following the lesion. No abnormal spontaneous activity or change in MUAP morphology is seen acutely; these changes develop over time. Within the next several weeks, fibrillation potentials develop. The time it takes for fibrillation potentials to appear depends on the length of nerve between the muscle and the lesion,

Table 7.11 Time-related changes in axonal loss

	Immediate	Hyperacute <4 days	Acute >1 week <3–6 weeks	Subacute >3–6 weeks <2–3 months	Subacute-chronic >2–3 months < many months/years	Chronic > Several months/years
Clinical	Abnormal	Abnormal	Abnormal	Abnormal	Abnormal	Normal/abnormal
Nerve conductions	Normal	Normal	Abnormal	Abnormal	Abnormal	Normal/abnormal
MUAP recruitment	Decreased	Decreased	Decreased	Decreased	Decreased	Decreased
Spontaneous activity	Normal	Normal	Normal	Abnormal	Abnormal	Normal
MUAP morphology	Normal	Normal	Normal	Normal	Reinnervated	Reinnervated

From Preston and Shapiro [1], with permission

developing first in proximal muscles and proceeding distally. In general, fibrillation potentials appear in denervated proximal muscles in 10–14 days but do not become fully developed in distal muscles until 3–5 weeks.

EDX studies often can determine the severity of the axonal loss. Because of the mosaic distribution of the muscle fibers of individual motor units, loss of few axons may be best diagnosed by detecting fibrillation potentials in denervated muscles. Hence, *the presence of fibrillation potentials is the most sensitive sign of axonal loss*. In contrast, it requires more substantial axonal loss before SNAP or CMAP amplitudes decrease. The SNAP amplitude is more sensitive to axonal loss than the CMAP. Thus, in mild axon-loss lesions, fibrillation potentials on needle EMG may be the only finding. In moderate lesions, the SNAP amplitude may also decline, but the CMAP is often normal. With advancing severity, the SNAP is often absent and the CMAP is low in amplitude. In complete lesions, both are absent.

In the chronic stages, reinnervation follows denervation, which typically takes several months. Reinnervation may occur by collateral sprouting from surviving axons (in partial lesions only) or by proximal-to-distal regeneration of axons from the site of the lesion. "Nascent" MUAPs are the earliest signs of proximal-to-distal axonal regeneration. These MUAPs are very low in amplitude and extremely polyphasic, with normal or increased duration. They are often unstable and associated with decreased MUAP recruitment. As reinnervation proceeds, particularly if collateral sprouting plays a major role, MUAPs become polyphasic and longer in duration and higher in amplitude, reflecting increased numbers of muscle fibers per motor unit. If reinnervation is successful, fibrillation potentials disappear months to years later, leaving only large reinnervated MUAPs with decreased recruitment on needle EMG as a permanent sign of axonal injury. If successful reinnervation occurs, as occurs in partial lesions, CMAP and SNAP amplitudes may improve and even reach normal values after several months or years.

Thus, the time course of focal peripheral nerve lesions with axonal loss (i.e., acute, subacute, chronic) can usually be determined by the combined findings on NCSs and needle EMG (Table 7.11).

Demyelinating Lesions

In pure demyelinating lesions, the pattern of abnormalities is different from axonal loss lesions and depends on the degree of demyelination. Because myelin is essential to maintain the saltatory fashion of nerve conduction, its disruption may result in focal slowing or conduction block.

Focal slowing occurs when the fastest conducting fibers of a nerve segment are demyelinated, usually by widening of the nodes of Ranvier (paranodal demyelination). Focal slowing may affect any segment of a nerve, thus manifesting by slowing of distal latency or conduction velocity (see Fig. 7.69). Prolongation of late responses (F waves and H reflexes) may only imply focal slowing of proximal nerve segments if distal latencies and conduction velocities are normal. If the focal slowing affects different groups of fibers more than others, desynchronized slowing occurs, resulting in excessive temporal dispersion (also referred to as *differential slowing*). Excessive temporal dispersion is defined as greater than a 20 % increase in CMAP duration between distal and proximal stimulations for the median, peroneal, and ulnar nerves and greater than a 30 % increase for the tibial nerve [38]. Note that pure conduction slowing alone does not result in weakness, because the nerve action potentials eventually reach their destination, though not as fast. Slowing may result in depressed or absent myotatic reflexes and a perception of altered sensation. Also, if focal slowing is the only abnormality (i.e., without demyelinative conduction block or axonal loss), the entire needle EMG, including MUAP recruitment and morphology, remains normal.

Conduction block occurs when there is segmental demyelination resulting in loss of one or more internodal segment (internodal demyelination). To demonstrate a conduction block, the lesion of the affected nerve must be bracketed by two stimulation points, one distal and the second proximal to the lesion. Distal to the conduction block, the nerve conducts normally. However, with proximal stimulation, the nerve action potentials cannot traverse the area of demyelination resulting in a drop (or complete loss) of CMAP. This finding is similar to the pseudo conduction block encountered with acute axonal loss lesions (less than 4–5 days from injury), in which distal nerve conductions remain normal. However,

Table 7.12 Electrodiagnosis of conduction block

Definite in any nerve[a]
1. 50 % drop in CMAP amplitude with ≤15 % prolongation of CMAP duration
2. 50 % drop in CMAP area
3. 30 % drop in area or amplitude over a short nerve segment (e.g., radial across the spiral groove, ulnar across the elbow, peroneal across the fibular head)
Possible in median, ulnar, and peroneal nerves only
1. 20–50 % drop in CMAP amplitude with ≤15 % prolongation of CMAP duration
2. 20–50 % drop in CMAP area

Note: All amplitudes, areas, and durations reflect negative-peak areas, amplitudes, and durations

[a]Caution should be taken in evaluating the tibial nerve, where stimulation at the knee can be submaximal, resulting in 50 % or at times >50 % drop in amplitude, especially in overweight patients

unlike axonal loss lesions, the underlying axon remains intact and Wallerian degeneration never occurs. Hence, in demyelinating conduction bock, the distal CMAP does not decrease with time, as occurs with acute axon loss. Clinically, acute conduction block due to segmental demyelination of sensory and motor fibers results in sensory loss and weakness, respectively. The presence of conduction block implies that the clinical deficit (weakness and/or numbness) is secondary to demyelination and recovery may occur rapidly with remyelination.

Conduction block can be used to localize the lesion in compressive or entrapment mononeuropathies (e.g., ulnar neuropathy at the elbow, radial neuropathy at the spiral groove, or common peroneal neuropathy at the fibular head). Evaluation of the amplitudes and areas of the distal and proximal CMAPs is essential for the diagnosis of conduction block. Because there is substantial difference in the degree of CMAP amplitude and area reduction and CMAP duration prolongation with proximal stimulation among the various intact nerves and between healthy individuals, the criteria for conduction block continue to be debated [38–41]. Suggested working criteria are shown in Table 7.12.

On needle EMG, the recruitment pattern is decreased in a demyelinating conduction block because of a reduction in the number of conducting motor units. Because there is no Wallerian degeneration, however, no denervation or subsequent reinnervation occurs. Hence, MUAP morphology is normal and there are no fibrillation potentials. *Thus*, *reduced recruitment of MUAPs is the only abnormality on needle EMG in a pure demyelinating lesion with conduction block.* However, pure demyelinating lesions are rare. Most demyelinating lesions are accompanied by some degree of axonal loss. Hence, it is not uncommon to record fibrillation potentials, sometimes abundantly, in lesions where the NCSs suggest a purely demyelinative conduction block. This is due to the loss of a few, often clinically insignificant, number of axons in the midst of the demyelinating process.

Nonlocalizing Mononeuropathy

A nonlocalizing mononeuropathy is a familiar pattern in the EMG laboratory. This occurs primarily in axon-loss mononeuropathies examined after the completion of Wallerian degeneration. NCSs and needle EMG are normal throughout, except in the distribution of a single nerve. Sensory or motor nerve conductions, or both, may be abnormal depending on whether the involved nerve is a sensory, motor, or mixed nerve and on the severity of the lesion. In a nonlocalizing axon-loss lesion, the findings on NCSs reveal decreased CMAP or SNAP amplitudes, or both, with normal or slightly slowed distal latencies and conduction velocities. On needle EMG, neurogenic changes are limited to muscles innervated by the involved nerve distal to the site of the lesion. The mononeuropathy can only be localized at or proximal to the most proximal abnormal muscle identified on the needle EMG. Because there are usually no demyelinating findings on NCSs, such as focal slowing or conduction block, the lesion cannot be localized accurately. Common nonlocalizing mononeuropathies encountered in the EMG laboratory are axon-loss ulnar mononeuropathy or common peroneal mononeuropathy. Although the lesion is often across the elbow or fibular neck, respectively, the ulnar or peroneal conduction studies in these cases only show evidence of axonal loss, without slowing or conduction block.

Localizing Mononeuropathy

In a localizing mononeuropathy, NCS and needle EMG abnormalities are also limited to a single nerve. Definite localization is determined by electrophysiologic evidence of focal slowing or conduction block, or both, due to demyelination at the site of the lesion. Occasionally, axon-loss mononeuropathies may be localizing when examined by NCSs in the first 4–5 days by revealing a conduction block pattern similar to demyelination conduction block (see previous). Mixed lesions with low distal CMAPs and SNAPs with demyelinative conduction block or focal slowing, or both, are not uncommon. Localizing mononeuropathies are frequently seen in entrapment neuropathies in which the predominant underlying primary pathophysiology is demyelination (e.g., carpal tunnel syndrome, ulnar mononeuropathy across the elbow, radial mononeuropathy at the spiral groove, peroneal neuropathy at the fibular neck).

Radiculopathy

Radiculopathy is one of the most frequent patterns seen in the EMG laboratory. Because the lesion is at the level of the root (i.e., proximal to the dorsal root ganglia), sensory NCSs are always normal. Motor conductions are also generally

normal, although CMAP amplitudes may be low in severe radiculopathy, when the muscle(s) used for recording is innervated by the involved nerve root. With routine NCSs, this only occurs in the median and ulnar motor studies in C8–T1 radiculopathies, and in the peroneal and tibial motor studies in L5–S1 radiculopathies.

Because each nerve root innervates a segment of paraspinal muscles and several limb muscles, usually by way of several different peripheral nerves, a radiculopathy is recognized on needle EMG by neurogenic abnormalities in muscles that share the same nerve root innervation (i.e., myotomal pattern). Abnormalities are usually expected in distal and proximal limb muscles innervated by the same nerve root, but by different nerves. In addition, abnormalities in the paraspinal muscles are useful, but not required, in helping to recognize a radiculopathy. Similar to other axonal loss lesions, it is important to remember that the specific neurogenic abnormalities vary, depending on the time course of the radiculopathy (see previous).

In summary, two criteria are necessary to establish the diagnosis of radiculopathy. The first is denervation in a segmental myotomal distribution (i.e., in muscles innervated by the same roots via more than one peripheral nerve), with or without denervation of the paraspinal muscles. At least two muscles, and preferably more, should reveal evidence of denervation (fibrillation potentials, decreased recruitment or abnormal MUAP morphology, or both). The second criterion is a normal SNAP in the corresponding dermatome. For example, in a C7 radiculopathy, the flexor carpi radialis (median innervated C7 muscle) and triceps (radial innervated C7 muscle) may be abnormal on needle EMG, with or without the cervical paraspinal muscles, with the median SNAP (recording middle finger) being normal. The only exception to this rule is in some rare cases of L5 radiculopathy, wherein the superficial peroneal SNAP may be absent or reduced in amplitude (less than 50 % of the contralateral superficial peroneal SNAP). Although the reason behind this finding is not completely understood, it is thought that the L5 dorsal root ganglion is actually located proximal to the intervertebral foramen in a small percent of individuals, causing it to be susceptible to external intraspinal compression, for example, from a disk herniation [3].

Polyradiculopathy

The polyradiculopathy pattern is seen when multiple nerve roots are involved. This pattern may occur in diabetes, cervico-lumbosacral stenosis, or when multiple nerve roots are infected (e.g., from cytomegalovirus) or infiltrated (e.g., by tumor, granulomatous tissue). Similar to an isolated radiculopathy, sensory NCSs are always normal. Motor NCSs may show changes consistent with axonal loss if the recorded muscles are in the distribution of the abnormal nerve roots. On needle EMG, there are neurogenic changes in the limb muscles in the distribution of multiple myotomes with or without involvement of the paraspinal muscles. The EDX findings in polyradiculopathy are not fundamentally different from those of motor neuron disease. However, this differentiation is usually easily made on clinical grounds, as patients with motor neuron disease have no radicular pain and sensory manifestations and often have upper motor signs.

Generalized Disorders

Polyneuropathies

Peripheral polyneuropathies are recognized by characteristic widespread abnormalities on NCSs and neurogenic findings on needle EMG. A common pattern is the symmetric stocking-glove polyneuropathy in which abnormalities are length dependent. Because longer nerves are preferentially affected on NCSs and needle EMG, abnormalities are more prominent distally, worse in the legs than the arms, and more prominent in distal than proximal segments. The vast majority of polyneuropathies, especially those due to toxic, metabolic, or genetic factors, result in symmetric EDX findings. Side-to-side comparisons are often useful. Polyneuropathies may be demyelinating, axonal, or a combination of both. Symmetric polyneuropathies can result from either axonal loss or demyelinative lesions. Any significant asymmetry should make one question the diagnosis of an axonal symmetric stocking-glove polyneuropathy.

Symmetric Axonal Polyneuropathy

Axonal polyneuropathies are associated with a characteristic pattern on NCSs, provided that the polyneuropathy has been present long enough for Wallerian degeneration to have occurred (i.e., >10–11 days). In general, CMAP and SNAP amplitudes are low, with normal or only slightly slowed distal latencies, late responses, and conduction velocities (Fig. 7.71). These changes are always more marked in the lower extremities. Likewise, needle EMG reveals evidence of axonal loss that is more prominent distally than proximally and more pronounced in the lower than upper extremities. As with axonal loss lesions in general, the needle EMG findings depend on how long the polyneuropathy has been present. Although reduced recruitment of MUAPs develops in weak muscles acutely, fibrillation potentials typically develop within weeks, and reinnervated MUAPs become apparent within several weeks to months. Different patterns also develop based on the temporal profile of the illness. For example, if the process is relatively active and progressive, a combination of fibrillation potentials with reduced recruitment of reinnervated MUAPs will be seen, most prominent distally. If, on the other hand, the polyneuropathy is chronic

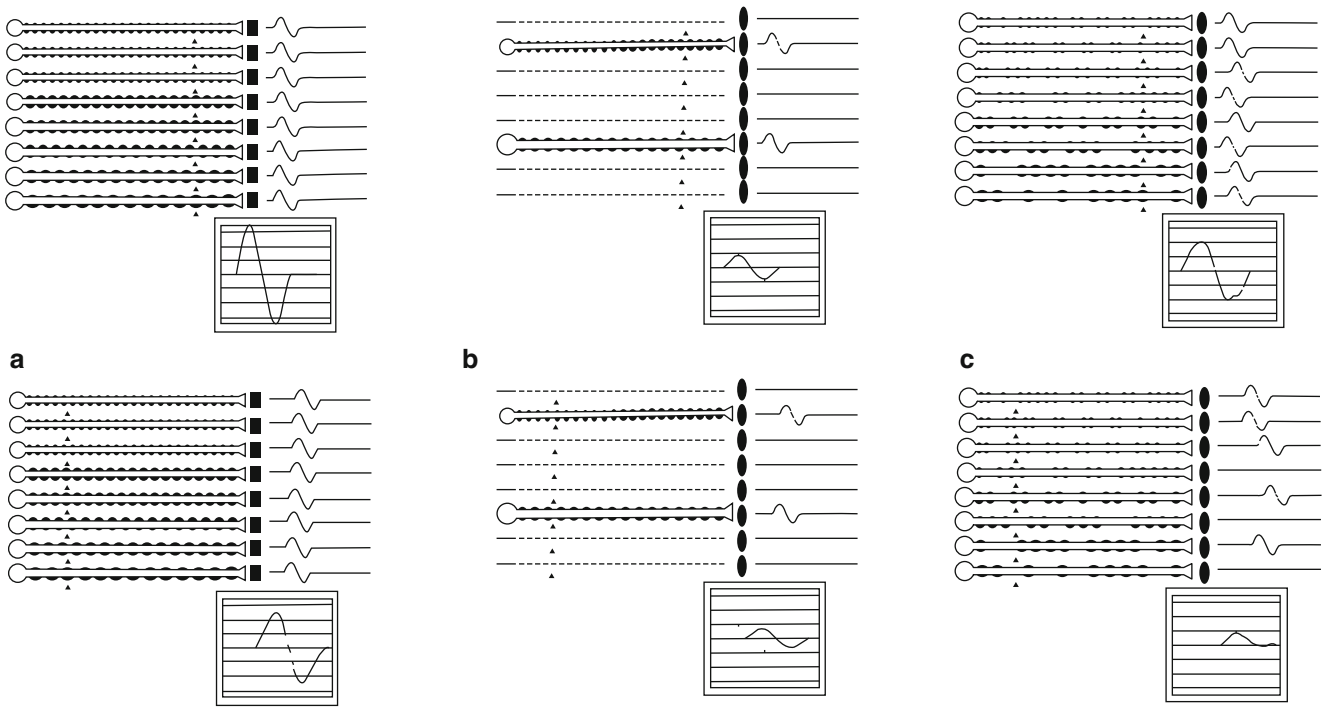

Fig. 7.71 Computerized model of peripheral motor nerve in normal nerve (**a**), axonal degeneration (**b**), and segmental demyelination (**c**) (Adapted from Albers [42], with permission)

and only very slowly progressive, reinnervation may completely keep pace with denervation. In such cases, there may be little or no fibrillation potentials, and the sole findings on needle EMG is reduced recruitment of reinnervated MUAPs.

Asymmetric Axonal Polyneuropathy

The presence of any significant asymmetry in an axonal polyneuropathy may have important diagnostic significance. In some cases, an asymmetric or a non-length-dependent pattern can be seen in typical, symmetric axonal polyneuropathies with superimposed mononeuropathies, plexopathies, or radiculopathies. For example, a diabetic patient with a distal symmetrical polyneuropathy may develop a diabetic amyotrophy (radiculoplexopathy) resulting in markedly asymmetric findings. More important, however, is that an asymmetric pattern may suggest underlying multiple mononeuropathies. Multiple mononeuropathies, as those occurring in mononeuritis multiplex, are a unique pattern in which individual peripheral nerves are affected in a stepwise manner. This pattern is most often seen in the context of an underlying vasculitic neuropathy. If the pattern is not recognized initially, as more nerves are affected, a confluent pattern of nerve involvement will develop, difficult to differentiate from a typical distal polyneuropathy. In these cases, asymmetrical EDX findings may be important clues to the true underlying mononeuritis multiplex pattern.

Demyelinating Polyneuropathy

Although axonal changes are present in all chronic polyneuropathies, few are due to primary demyelination. Demyelinating polyneuropathy is an important pattern to recognize. The differential diagnosis of such is narrowed further by the finding of uniform slowing versus nonuniform slowing and conduction blocks.

In demyelinating neuropathies, in which the process is uniform, all nerve segments are equally affected, often worse in the lower extremities. Consequently, demyelination results in marked slowing of conduction velocities (<75 % LLN), distal latencies, and late responses (>130 % ULN). This particular pattern of demyelination, symmetric uniform slowing without conduction block, is the pattern seen in the inherited demyelinating polyneuropathies (i.e., Charcot-Marie-Tooth disease type I).

The presence of conduction blocks has special diagnostic significance, as it helps to differentiate acquired from inherited demyelinating conditions. Conduction blocks at nonentrapment sites characteristically occur in acquired demyelinating neuropathies, such as Guillain-Barré syndrome or chronic inflammatory demyelinating polyneuropathy (CIDP), but are not seen in the inherited demyelinating neuropathies (e.g., Charcot-Marie-Tooth type I). One rare exception to this conduction block rule is in patients with hereditary neuropathy with sensitivity to pressure palsies (HNPP), an inherited demyelinating neuropathy, in which conduction blocks may occasionally accompany focal slowing at nonentrapment sites.

In summary, the cardinal feature of demyelinating polyneuropathies is marked slowing with relative preservation of CMAP amplitudes (see Fig. 7.71). In an inherited demyelinating neuropathy, there is symmetry comparing side-to-side and uniform conduction velocity slowing without conduction block. Also, the absence of conduction block at noncompressive sites is the key feature that separates inherited from acquired demyelinating polyneuropathies. In contrast, acquired conditions (e.g., CIDP) often have asymmetric nerve conductions when comparing side to side, even when there is no apparent clinical asymmetry. In addition, conduction block and excessive temporal dispersion at nonentrapment sites always mark the polyneuropathy as acquired, as they are not seen in inherited demyelinating neuropathies.

Anterior Horn Cell Disease

As the sensory system is spared in motor neuron disease, sensory conduction studies are usually normal. Motor NCSs may also be normal, but more often are low in amplitude consistent with axonal loss. No demyelinating features are seen on motor NCSs, an important feature because some demyelinating motor neuropathies can mimic motor neuron disease. However, these disorders are associated with conduction blocks and other signs of demyelination on NCSs. On needle EMG, the findings in motor neuron disease are similar to polyradiculopathy: neurogenic abnormalities are seen in the paraspinal muscles and in the distribution of multiple nerve roots. In addition, craniobulbar and thoracic paraspinal muscles may also be abnormal. Abnormalities in these latter areas are especially important, as they are not involved in cervical-lumbar spondylosis (i.e., cervico-lumbosacral polyradiculopathy), a common condition sometimes confused with motor neuron disease.

Myopathies

Myopathies result from loss or dysfunction of muscle fibers. The EDX of myopathy is usually based on needle EMG abnormalities alone. Sensory NCSs are normal, unless there is an associated neuropathy. Motor conduction studies are also normal in most cases, because distal muscles are often used to record during routine motor NCSs. These muscles are spared in most myopathies, which have a predilection for proximal muscles. In myopathies that are diffuse (e.g., critical illness myopathy), in their terminal stages (e.g., advanced Duchenne muscular dystrophy), or affect distal muscles preferentially (e.g., myotonic dystrophy type I), CMAP amplitudes may be decreased, but with normal latencies and conduction velocities.

On needle EMG, myopathy is usually diagnosed by changes in MUAP morphology and recruitment. In many myopathies, there is dropout or dysfunction of individual muscle fibers, which effectively decreases the size of the motor unit. In myopathy, MUAP morphology becomes short in duration, low in amplitude, and polyphasic. These changes result from dropout of individual muscle fibers and less synchronous firing of the remaining fibers. MUAP recruitment is usually normal, as the number of motor units remains intact. However, because each motor unit has fewer fibers than normal, it can generate less force. Consequently, more MUAPs than usual must fire to generate a particular amount of force. This results in a pattern of *early recruitment*, whereby an inappropriately large number of motor units must fire to generate a small amount of force. In severe myopathies where every muscle fiber in many motor units is lost, the number of motor units effectively decreases. This results in decreased recruitment which may be confused with a neurogenic disorder.

The analysis of spontaneous activity is also important in evaluating myopathic patterns. Certain myopathies are associated with abnormal spontaneous activity, including fibrillation potentials, myotonic discharges, or complex repetitive discharges (CRDs). Only a limited number of myopathies are associated with fibrillation potentials or myotonic discharges (Table 7.13). Fibrillation potentials in myopathies are due to segmental muscle fiber degeneration which results in effective denervation of some segments of muscle fibers (see Fibrillation Potentials).

A chronic myopathy with fibrillation potentials and denervating features is one of the most difficult patterns to recognize. Following denervation of muscle fibers in myopathies, some reinnervation normally occurs. In chronic conditions, this can lead to complicated needle EMG patterns, where both myopathic (short duration, low amplitude, and polyphasic) and neuropathic (long duration, high amplitude, and polyphasic) MUAPs are seen, often in the same muscle. In some cases, recruitment, which is usually normal or early in myopathy, may actually be reduced. However, the degree of neurogenic MUAP changes (large, long, and polyphasic) often appears out of proportion for the mild reduction in recruitment pattern, which is an important clue to a possible chronic myopathy.

Neuromuscular Junction Disorders

NMJ disorders often present in a similar fashion to myopathies, with proximal muscle weakness. They may be mistaken for myopathies on EMG as well, especially if repetitive nerve stimulation (RNS) is not performed. NMJ disorders result in different patterns on NCS-EMG, depending on whether the pathophysiology is presynaptic or postsynaptic. In all NMJ disorders, sensory conduction studies are normal. Motor NCSs always yield normal distal latencies, conduction velocities, and late responses.

In postsynaptic disorders (e.g., myasthenia gravis), CMAP amplitudes are usually normal, and slow RNS results in a decremental CMAP response (>10 %). Several minutes after exercise, the decrement becomes more marked (post-tetanic

Table 7.13 Needle electromyography findings in myopathies

exhaustion). As weakness and fatigue in myasthenia gravis affect extraocular, bulbar, and proximal muscles, decremental responses are more often seen with stimulation of more proximal nerves. It should be noted that slow RNS decrement correlates with disease severity and muscle weakness but is not a good objective measure of fatigue [44]. Single-fiber EMG is a more useful technique in assessing fatigue in patients with MG (see Chap. 8).

Presynaptic disorders (e.g., LEMS and botulism) have a different pattern. In these disorders, CMAP amplitudes are usually reduced at rest. There is a marked incremental CMAP response (typically >200 % in LEMS and >100 % in botulism) following rapid (30–50 Hz) RNS or brief (10 s) maximal voluntary exercise. Slow RNS also generally reveals a decremental CMAP response.

On needle EMG, abnormal spontaneous activity is not a common feature in NMJ disorders. However, in botulism or severe myasthenia gravis, NMJ blockade may be so severe that muscle fibers are effectively denervated, often resulting in fibrillation potentials. MUAP morphology in NMJ disorders is usually normal, including the recruitment pattern. However, the needle EMG may demonstrate unstable MUAPs, which vary in configuration (i.e., amplitude and phases) from potential to potential. If the severity of the disorder is such that blocking occurs, individual muscle fibers may drop out, thereby reducing the number of muscle fibers per motor unit. This results in short-duration, low-amplitude, polyphasic MUAPs, often accompanied by early recruitment, findings usually associated with myopathy.

Central Nervous System (CNS) Disorders

Patients with CNS lesions (i.e., brain and spinal cord) often present with weakness and numbness. They may have increased reflexes and muscle tone and other signs that mark the lesion as central. In an acute event, however, reflexes and muscle tone may be decreased, making it difficult to differentiate a central from a peripheral lesion. For example, in patients with new upper extremity weakness and numbness following open heart surgery, the differential includes a traction lesion of the lower trunk of the brachial plexus versus a stroke from a cardiac embolus. Acutely, both conditions may be associated with depressed reflexes and decreased muscle tone, along with weakness and numbness of the hand. In this type of situation, the EMG can easily differentiate between the two. In CNS disorders, motor and sensory nerve conduction studies are normal. There are no fibrillation potentials or reinnervation on needle EMG, and MUAP morphology remains normal. However, on voluntary contraction, the interference pattern is not full and often has an erratic or sputtering pattern of slow-firing MUAPs. This is due to decreased activation (i.e., reduced firing frequency), while the number of available MUAPs (i.e., the recruitment) remains appropriate for the level of activation.

Another CNS lesion that often creates confusion is a segmental lesion of the spinal cord. Muscles innervated below the level of the lesion display the typical CNS pattern of decreased activation. However, at the segmental level of the lesion, the anterior horn cells may be affected, leading to a lower motor neuron pattern in the muscles innervated by that segment. For example, in a patient with cord compression at C5–C6 resulting in quadriplegia, needle EMG of leg muscles and of muscles innervated by segments below the site of the lesion shows decreased activation. However, EMG of C5–C6 muscles (e.g., deltoid and biceps) shows decreased recruitment and active denervation or reinnervation, depending on the time course of the lesion. Muscles partially innervated by these segments (e.g., pronator teres, a C6–C7 muscle) show a combination of decreased activation and decreased recruitment, as well as other neuropathic changes.

Other Important Electrodiagnostic Patterns

Sensory Loss with Normal Sensory Nerve Action Potentials

When performing sensory NCSs, the electromyographer is occasionally presented with an apparent paradox: the SNAP is normal, yet the patient has clear sensory loss in the distribution of the normal SNAP that is being recorded. It is important to remember that there are only three possible explanations for this situation, provided the study is technically accurate (Fig. 7.72):

1. *The Lesion Is Proximal to the Dorsal Root Ganglion*. This includes structural lesions of the nerve roots, spinal cord, or brain, as well as psychiatric or factitious disorders. Because the dorsal root ganglion and peripheral nerve are intact, sensory responses remain normal on conduction studies.
2. *There Is a Proximal Demyelinating Lesion*. Because Wallerian degeneration does not occur with demyelination, the underlying axon remains intact. Thus, if the nerve is stimulated and recorded distal to the lesion, the distal segment continues to conduct normally and the SNAP will be normal, although effectively disconnected from its proximal segment.
3. *There Is a Hyperacute Axonal Lesion*. Immediately following an axonal lesion, the distal nerve continues to conduct normally for the first several days, before Wallerian degeneration occurs. During this time, if the nerve is stimulated and recorded distal to the lesion, it will conduct normally. This underscores the need for the electromyographer to know the temporal course of the clinical history before interpreting a study.

Low-Amplitude CMAPs with Normal SNAPs

A pattern of diffusely low CMAP amplitudes with normal SNAPs suggests a pure motor loss. Often, distal latencies,

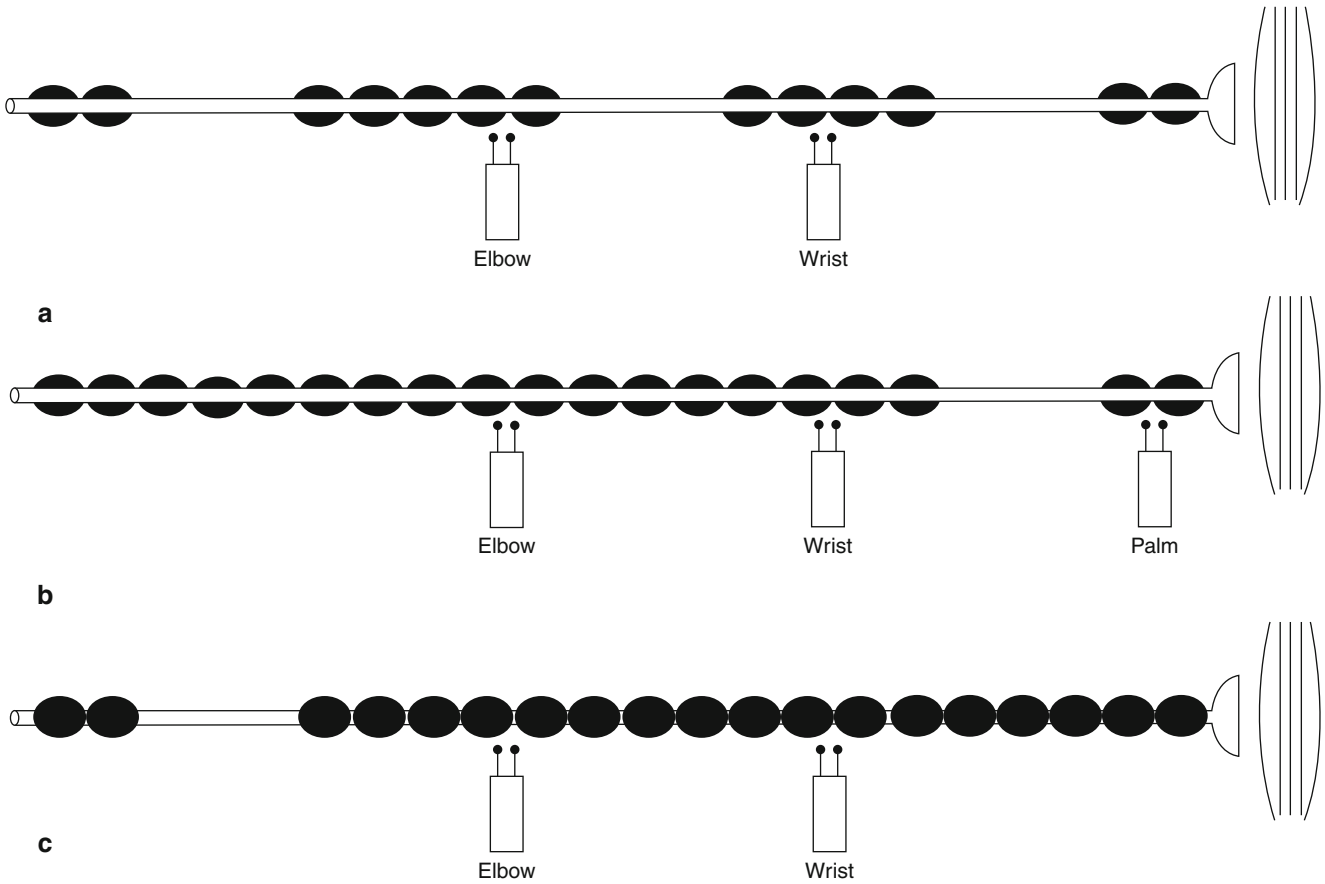

Fig. 7.72 Sensory loss and normal sensory nerve action potentials (SNAPs). When confronted with a patient with sensory loss, yet normal SNAPs in the distribution of the sensory loss, there are three possible explanations. (**a**) The lesion is proximal to the dorsal root ganglion (DRG). Because the DRG and peripheral nerve remain intact, SNAPs will be normal. This occurs in lesions of the brain (structural and psychiatric) and spinal cord, as well as lesions of the nerve roots. In nerve root lesions, Wallerian degeneration occurs centrally into the spinal cord and peripherally to the level of the DRG, leaving the DRG intact. (**b**) Proximal demyelination. Because demyelination leaves the underlying axon intact, subsequent Wallerian degeneration does not occur. If demyelination is proximal to the stimulation and recording sites, the SNAPs will be normal. (**c**) Hyperacute axonal injury. All peripheral axonal injuries result in abnormal SNAPs following Wallerian degeneration. If sensory studies are performed distal to the injury, and earlier than 4–7 days, before Wallerian degeneration has occurred, the SNAPS will also be normal (Reproduced with permission from Preston and Shapiro [1])

conduction velocities, and late responses are normal. This pattern may be seen in the following situations:

1. Anterior horn cell disease, such as amyotrophic lateral sclerosis
2. Polyradiculopathy, such as cervico-lumbosacral polyradiculopathies
3. Pure motor axonopathy (polyneuropathy) as seen with acute motor axonal neuropathy
4. Presynaptic NMJ disorders, such as LEMS
5. Myopathy (distal, diffuse, or terminal), such as critical illness myopathy, distal myopathies, or advanced Duchenne muscular dystrophy

Rapid RNS or postexercise CMAP evaluation should exclude LEMS. The needle EMG can be used to differentiate the neurogenic disorders (motor neuron disease, polyradiculopathy, axonopathy) from the myopathic ones (NMJ and myopathy). The differentiation between motor neuron disease and polyradiculopathy is difficult by EDX criteria but easily made clinically since polyradiculopathy is often associated with sensory manifestations or pain.

Single-Fiber EMG

8

James M. Gilchrist and Dinesh G. Nair

Introduction

Single-fiber electromyography (SFEMG) is the use of a special needle electrode to record electrical signals from single muscle fibers in vivo. The technique was originally developed by Drs. Erik Stalberg and Jan Ekstedt to study muscle fatigue. Their initial work was published as doctoral theses in 1966 [1] and 1964 [2], respectively. Dr. Stalberg has since become the primary proponent and researcher of SFEMG, and there is little regarding SFEMG he has not investigated, written about, or clarified. His textbook, now in its third edition, *Single Fiber Electromyography* [3], is the definitive monograph on the subject. The clinical and research utility of SFEMG has far outstripped the original intent of Drs. Stalberg and Ekstedt. SFEMG has become an important tool for assessing neuromuscular transmission and measuring reinnervation. It is the most sensitive clinical measure of dysfunctional neuromuscular transmission and an accurate electrical correlate of fiber-type grouping.

Basic Principles

The theoretical construct underlying SFEMG is the selective recording of a limited number of single muscle fiber action potentials (MUAP) from one motor unit. This requires a needle electrode with different specifications from a concentric or monopolar needle electrode. Single muscle fiber action potential amplitudes decrease exponentially with distance from the recording electrode. The motor unit action potential (MUAP) amplitude recorded by a needle electrode is therefore dominated by the nearest few muscle fibers, whereas MUAP duration correlates with the ultimate territorial spread of the motor unit. This amplitude differential between close and distant muscle fiber potentials is distorted, in part from the needle electrode itself, thus diminishing the amplitude gradient between closest and furthest fibers. This is particularly true for concentric needle electrodes which have a recording surface larger than individual muscle fibers. A smaller electrode will emphasize the amplitude difference between close and distant fiber potentials and, therefore, increase the near to far muscle fiber potential amplitude ratio. A smaller recording surface will also restrict the number of recordable muscle fiber potentials. In addition, muscle fiber potentials adjacent to the recording electrode will have high amplitudes and short duration and relatively more high frequency components compared to more distant potentials. Single muscle fiber action potential (MFAP) amplitude decreases exponentially with distance from the recording electrode. By using a high-pass filter of 500 Hz, much of the amplitude of distant muscle fiber potentials will be attenuated while preserving that of the near potentials. High-pass filtering and a small electrode recording surface, with the addition of bipolar recording, can then record and discriminate a single MFAP from the summated MUAP of which it is a part [3].

It therefore is logical that the caliber and the recording surface of a SFEMG needle are significantly smaller than of a concentric needle electrode (Fig. 8.1). A SFEMG recording surface is 25 μm in diameter with an effective recording area of 300 μm^3 [3], as compared with a concentric needle electrode which records from approximately 1 cm^3. Any needle point may mechanically deform muscle fibers, which would alter the muscle fiber potential and lead to potentially inaccurate waveforms and measurements. To avoid this, the active SFEMG electrode port is not at the end of the needle but rather 3–5 mm proximal to, and on the opposite side from, the beveled tip of the needle. The cannula serves

Fig. 8.1 Relative size and recording area of the SFEMG needle in comparison with two types of concentric needles. The recording area and the number of muscle fibers for each needle are approximate and not exactly to scale

as the reference electrode. Single-fiber EMG needles used for fiber density and jitter measurement contain a single electrode. Multielectrode single-fiber EMG needles are also possible and are useful for measurement of muscle fiber propagation velocity and volume conduction.

The small recording area of a SFEMG needle means it can only record signals from muscle fibers in its immediate vicinity, which limits the choice to 5–7 fibers at any time. Given the normal random distribution of muscle fibers within motor units, the 5–7 fibers within the SFEMG electrode recording area may be members of 5–7 different motor units. By using an amplitude threshold to trigger the oscilloscope trace on the closest muscle fiber potential (the potential with the sharpest rise time and the greatest amplitude), muscle fiber potentials from other motor units will be excluded from the oscilloscope screen. By counting the number of single muscle fiber potentials seen with each MUAP firing, one can determine the number of muscle fibers from that MUAP within the small recording territory of the SFEMG needle electrode. For the most part it should be one or two. By sampling 20 different sites in a muscle, an average number of single muscle fiber potentials per recording site can be calculated. This is called *fiber density*. In conditions with loss of random distribution of MUAP muscle fibers, such as reinnervation, fiber density will increase.

In those instances where two or more fiber potentials from a single MUAP are recorded, an interpotential interval (IPI) can be calculated. By recording multiple consecutive firings of the muscle fiber potentials, one can determine consecutive IPIs and, therefore, calculate the difference between consecutive IPIs. Comparison of consecutive differences will illustrate the variation between IPIs. This variation is called *jitter*. Jitter is most accurately determined by calculating a mean consecutive difference (MCD) [4] using the formula

$$\mathrm{MCD} = \frac{[\mathrm{IPI}_1 - \mathrm{IPI}_2] + \ldots + [\mathrm{IPI}_{n-1} - \mathrm{IPI}_n]}{n-1}$$

where IPI = interpotential interval.

Jitter is believed to derive from variation in the time it takes the neuromuscular junction end plate potential (EPP) to reach threshold for action potential generation at the postsynaptic membrane [5]. In disorders with disturbed neuromuscular transmission, there will be an increased variation in the time taken to attain an EPP capable of reaching threshold. This will lead to increased jitter (Fig. 8.2). Therefore, abnormal jitter is an indicator of abnormal neuromuscular transmission.

In those instances where an EPP fails to reach threshold for action potential generation, one of the muscle fiber potentials in the pair will be absent. This is called *impulse blockade* (Fig. 8.2c). It is another indicator of abnormal neuromuscular transmission, usually indicating a more severe disturbance than increased jitter alone. Impulse blocking, often referred to simply as blocking, is usually intermittent, with the affected fiber potential appearing and disappearing

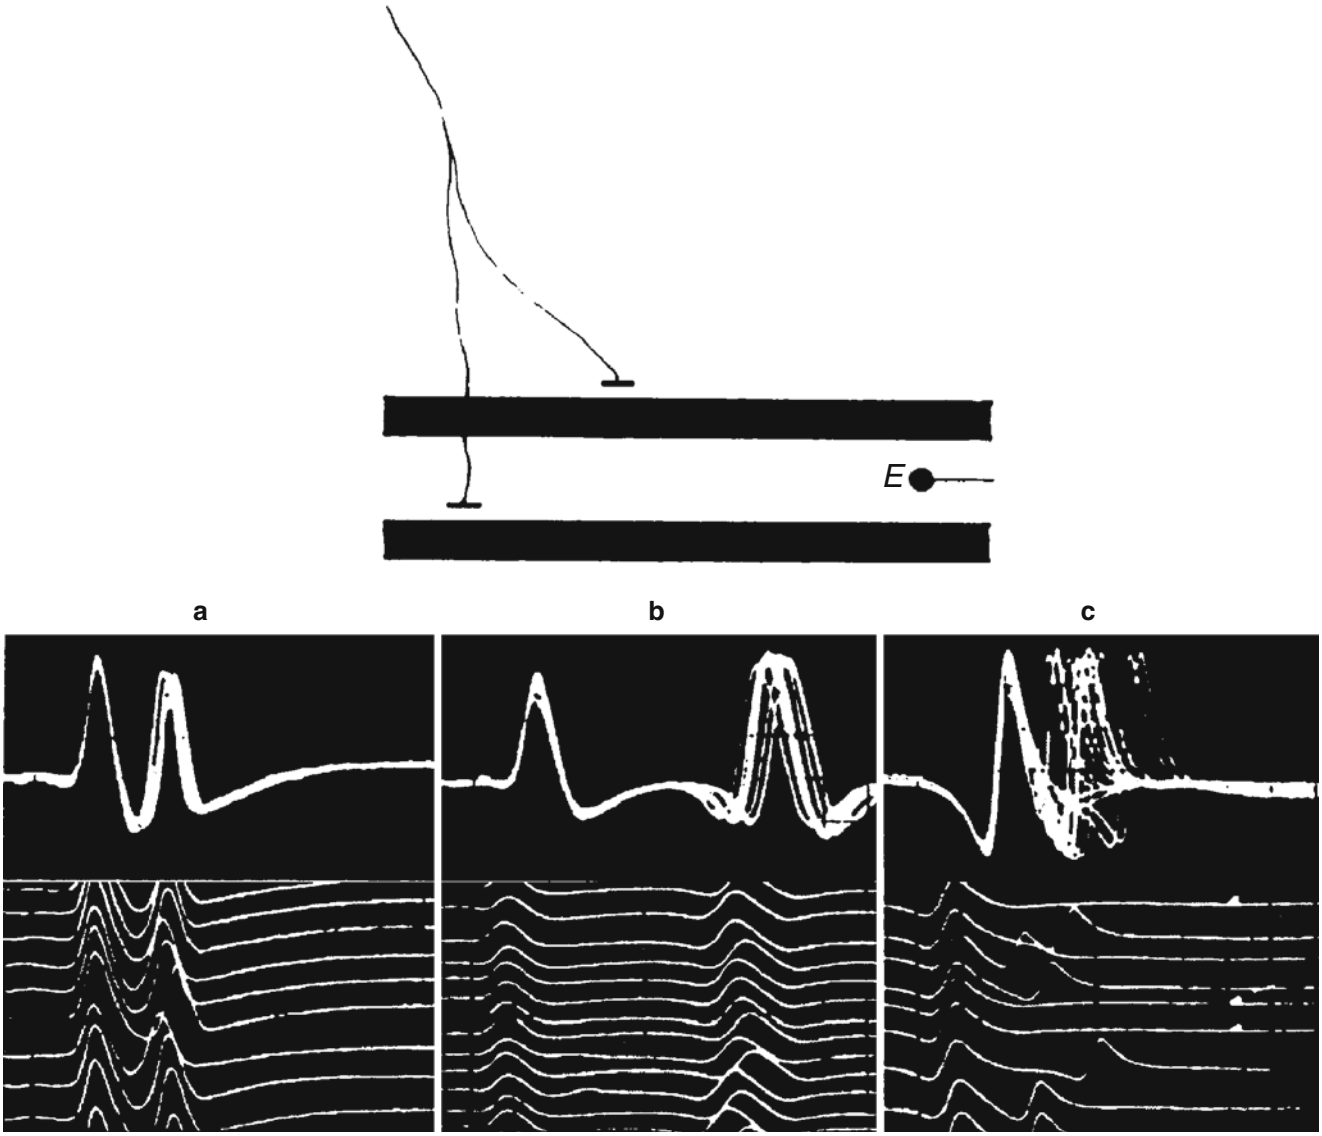

Fig. 8.2 Jitter as recorded using voluntary SFEMG technique. The electrode (*E*) is between two single muscle fibers. (**a**) Recording from a normal muscle, rastered traces on the *bottom*, superimposed traces on *top*. (**b**) Recording with increased jitter, indicating one or both of the motor end plates is abnormal. (**c**) Recording with increased jitter and blocking. Calibration 500 μs (Reproduced with permission from Stalberg [6])

in an unpredictable pattern. In my experience, blocking is uncommonly seen with jitter less than 100 μs.

SFEMG electrodes are expensive, get dull, develop increased impedance with use, and must be sterilized for reuse, which does not entirely eliminate concern for infections. Disposable concentric needle electrodes (CNE) provide an easy and probably acceptable alternative for single-fiber electrodes. The relatively larger recording uptake area of the CNE compared to the SFEMG electrode (see earlier part of this chapter for details and Fig. 8.1) creates different challenges, which in part can be allayed by increasing the low-frequency filter and using more restrictive selection of APs for analysis. The larger needle also causes a larger shunting effect of the electric field around the muscle fiber, and the recorded AP amplitude is smaller than when recorded using an SF electrode. The spikes obtained with a CNE do not represent a single-fiber AP but are rather a summation of action potentials from more than one fiber. Therefore, CNE cannot be used to measure fiber density.

Methodology

SFEMG for fiber density or jitter determination is performed by inserting a SFEMG needle into the muscle to be studied. A ground electrode should be nearby. The electrode is connected to an electromyograph machine with an amplitude threshold trigger and delay line. Filter settings should be set

at 500 Hz for the high-pass filter and 10–20 kHz for the low-pass filter. Selected single muscle fiber potentials should have a peak-to-peak amplitude of at least 200 μV with a rise time of 300 μs. The waveform should remain constant through consecutive recordings. For jitter analysis, at least 50 consecutive recordings should be made to allow for a statistically valid calculation. Paired fiber potentials with very short IPIs should have at least a 100 μV "notch" between them to count as two separate potentials.

When using a CNE for jitter analysis, the cutoff of the high-pass filter needs to be increased above 500 Hz in order to suppress activity of distant muscle fibers and decrease their contribution to the low-frequency components of the signal [7, 8]. If increased beyond 1,000 Hz, spikelike signal components appear, a phenomenon called ringing, and the amplitude of the signal further decreases. Also, summation of signals with similar latency may produce changes in individual waveforms and even result in a polyphasic MUAP, resulting in imprecise measurements. Hence, it is suggested that the best low-frequency filter setting for a CNE is likely 1,000 Hz [8]. In order to optimize the recording, a small CNE (30 G) with a recording area of 0.019 μm^2, often referred to as the facial electrode (Fig. 8.1), is recommended.

There are two commonly used methods for activation of muscle fibers when using SFEMG in a clinical setting. The first method is *voluntary*, in which the patient activates the muscle fiber (Fig. 8.2). This is the most commonly used method despite some drawbacks. The motor unit firing rate is dependent on the patient and may not be amenable to change or variation. The patient may not be able to cooperate in maintaining a constant firing rate (e.g., parkinsonian tremor) or may not be able to cooperate at all (child, comatose patient, patient with severe weakness). The second method is *axonal stimulation* (Fig. 8.3). This is performed by installing a monopolar needle electrode near the intramuscular nerve twigs and stimulating at a low current and constant rate [10, 11]. Disadvantages include a more technically complex procedure as you need to maneuver two needle electrodes, for stimulating and recording, while varying stimulation intensity to the appropriate level. Fiber density cannot be calculated, as the stimulated nerve twigs lead to muscle fibers from any number of MUAPs. In addition, direct muscle fiber stimulation may occur, leading to very low jitter, and if the nerve twig is not stimulated at the appropriate intensity (subliminal stimulation), jitter may be falsely increased. For the skilled electromyographer, stimulated SFEMG may be faster, as many single muscle fiber potentials can conceivably be analyzed at a time (Fig. 8.4). A primary advantage is that stimulation SFEMG requires no cooperation from the patient, and it is the preferred method in comatose or sedated patients, including children and the severely weak. Surface stimulation for SFEMG has also been done successfully [13].

One key difference in the two activation techniques is the number of end plates under study. In voluntary activation,

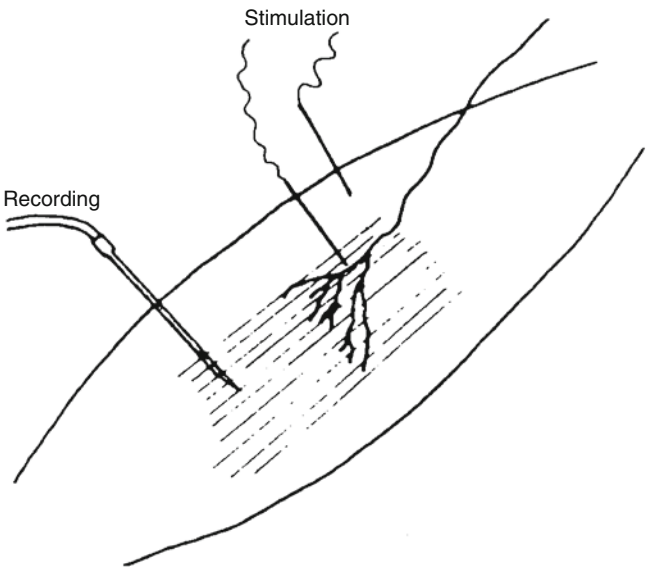

Fig. 8.3 Axonal stimulation SFEMG. The recording electrode is placed in the muscle, while the stimulating electrode is placed near the intramuscular nerve twigs (Reproduced with permission from Hilton-Brown et al. [9])

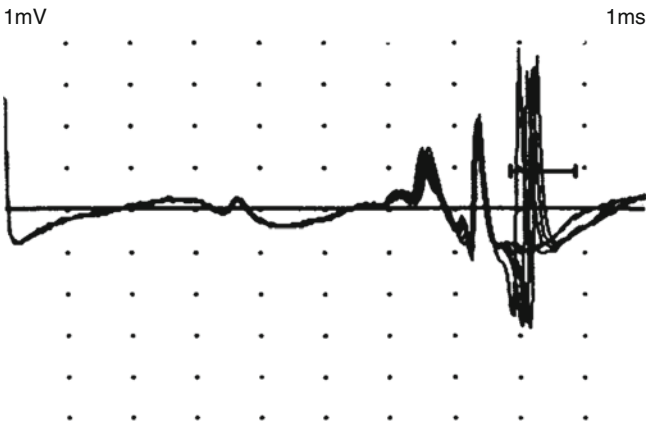

Fig. 8.4 Abnormal stimulated single-fiber electromyography of the extensor digitorum communis muscle. One of the advantages of stimulation single-fiber electromyography is the frequent recording of several muscle fiber action potentials (MFAPs). In this example, three separate MFAPs are recorded. The first MFAP shows a moderate amount of jitter (78 milliseconds [ms]), the second a normal amount of jitter (21 ms), and the third a large amount of jitter (165 ms), with blocking 30 % of the time (Reproduced with permission from Rivner and Swift [12])

jitter is calculated as the variation in IPIs between two muscle fiber potentials. As one of the potentials is time locked by the threshold trigger, all the variation of both end plates is expressed by the jitter of the other potential. In stimulation SFEMG, the IPI is measured as the latency between the stimulation and the single-fiber potential. Hence, only one end plate is involved.

Fiber density is easily calculated by hand, by averaging the number of single-fiber muscle potentials per recording site over 20 sites. Jitter can also be done by hand, but virtually

every EMG machine now manufactured has the capability for automatic measurement of jitter. All such programs should include methods for user intervention to delete extraneous or inaccurate data. Mean jitter should be calculated from 20 individual jitter measurements, and results are expressed as both the number and percentage of normal and abnormal fiber potential pairs and as mean jitter. The percentage of fiber potentials exhibiting impulse blockade, if any, is also an important measure of the health of neuromuscular transmission.

Normal values for fiber density and jitter are available from a multicenter international collaborative effort (Tables 8.1 and 8.2) [14]. Values differ between muscles and tend to increase with age, particularly over the age of 50 years. Fiber density values do not depend on the size of the muscle: a large biceps will have a fiber density comparable to a small biceps. As the values for jitter obtained by axonal stimulation are calculated on the basis of one end plate, the normal values are lower than those obtained by voluntary activation, theoretically by $1/\sqrt{2}$ or 71 % [10]. Normal values for axonal stimulation have been obtained for the EDC and the orbicularis oculi: they do not vary with age. The upper reference value for the EDC is 25 μs and for the orbicularis oculi is 20 μs [3]. The actual values were approximately 77 % of those obtained by voluntary activation.

The method used to record single-fiber activity with CNE is quite similar to that used for voluntarily activated SFEMG recordings. During voluntary contraction of the muscle, the electrode position is adjusted until two or more spikes are recorded. Jitter is measured between pairs of spikes. Axonal stimulation can also be used with CNE. The criteria for acceptable signals and normative values still remain untested, mainly due to variations in technique, filter settings, and needle size [3, 8]. Several studies have presented normative data for jitter using CNE [3], but the techniques, needle sizes, and filter settings were quite variable, and a larger database of normative values using standardized methods and equipment needs to be acquired. Thus, investigators should exercise caution before declaring a study to be abnormal, as several variables affect the criteria for identifying acceptable recordings [15]. Despite methodological concerns, however, the sensitivity and specificity of CNE SF studies appear to be comparable to studies using the SFEMG electrode [7, 8].

Findings in Neuromuscular Diseases

Disorders of the Neuromuscular Junction

Evaluation of neuromuscular transmission is the most common reason for performing SFEMG in most laboratories. The diagnosis of myasthenia gravis accounts for the bulk of such studies, and SFEMG can be very helpful in diagnosis and management. Less commonly, Lambert-Eaton myasthenic syndrome (LEMS), organophosphate intoxication, or botulism may be the referral diagnosis. Neuromuscular transmission is secondarily involved in anterior horn cell diseases, peripheral motor neuropathies, and myopathies, but those disorders will be discussed under more focused sections later.

SFEMG has been used in the diagnosis of myasthenia gravis since at least 1971, when Blom and Ringqvist examined 12 patients with MG [16]. Jitter and blocking improved after administration of anticholinesterase medication. Since then, there have been numerous studies of the sensitivity of SFEMG in diagnosing MG and comparisons to other diagnostic techniques. Sanders, Howard, and Massey published the largest series of SFEMG studies in MG by reporting the results on 788 patients [17, 18]. In their laboratories, the EDC was usually studied first; they found that the SFEMG of the EDC was abnormal in 85 % of all patients with MG at the time of initial examination. If the EDC was normal, and a second muscle was studied, 85 % of those patients had abnormal jitter studies. Thus, if two muscles were studied when the first was normal, SFEMG for jitter analysis was abnormal in 98 % of all patients with MG. This far exceeds the sensitivity of all other diagnostic tests for MG, as further illustrated by several comparative studies. Oh et al. [19] compared SFEMG of the EDC; repetitive nerve stimulation (RNS) of the ADQ, FCU, orbicularis oculi, trapezius, and deltoid; and acetylcholine receptor antibody testing in 120 patients with generalized MG. They found SFEMG to be the most sensitive at 92 % (testing just a single muscle), with RNS at 77 % (testing multiple muscles) and acetylcholine receptor antibody testing at 73 %. Gilchrist and Sanders [20] compared SFEMG of the ADQ, double-step RNS of the ADQ, and RNS of a proximal muscle in ten patients with normal RNS of the ADQ. SFEMG was abnormal in 90 %, RNS of the trapezius was abnormal in 3, and double-step RNS was abnormal in 3. In another study of patients with MG, SFEMG of any muscle in which at least one was abnormal had a yield of 99 %, SFEMG of the EDC was 89 %, RNS was 76 %, and acetylcholine receptor antibody was 80 % of patients with generalized MG [18]. SFEMG was sensitive regardless whether disease was generalized or ocular: the yield was 97 % even in ocular disease, if more than one muscle was studied.

The enhanced sensitivity of SFEMG makes physiologic sense: RNS will not be abnormal until at least 10 % of muscle fiber end plates undergo impulse blockade and, therefore, fail to generate or propagate a muscle fiber action potential. Muscle fibers with slowed and unstable neuromuscular transmission, but not so affected as to block, will count as normal. SFEMG not only can determine the fibers with impulse blockade but, by assessing jitter, allows those fibers with disturbed but still functional neuromuscular transmission to be measured. Support for this hypothesis comes from the study of Gilchrist et al. [21] in which RNS and SFEMG were done on the same muscle in 46 patients with MG. RNS was abnormal in 36 % of studies, SFEMG was abnormal in 86 %, and blocking was seen in 74 % of studies. All patients with decrement on RNS had abnormal jitter and all also had impulse blockade. No patient with decrement had a normal SFEMG exam, but there were many patients with normal RNS who had abnormal jitter.

SFEMG studies of jitter and impulse block also correlate well with the clinical severity of the disease [17, 22]. Sanders and Stalberg [18] found that changes in disease severity were accompanied by changes in SFEMG measurements. Mean jitter worsened by at least 10 % in two-thirds of patients whose disease worsened, and mean jitter improved by at least 10 % in 80 % of patients who clinically improved. Changes in jitter may therefore herald impending worsening or improvement but, more importantly, allow SFEMG jitter measurements to be used in the ongoing assessment of MG patients. Subjective fatigue often confounds the evaluation of fatigable weakness, rendering the patient's complaints of worsening difficult or impossible to accurately assess. Comparison of SFEMG jitter to prior studies allows a physiologic determination of worsening. Examples from my own practice include a patient with depression and MG: his complaints of worsening fatigue and weakness had to be discounted when his jitter studies remained stable or improved; another patient had ocular MG and severe mitral regurgitation and cardiomyopathy. His cardiologist felt his fatigue was due to his MG, but when his SFEMG jitter study was normal, a compelling case for cardiac asthenia was made.

The sensitivity of SFEMG to changes in neuromuscular transmission has led researchers to wonder whether it can predict progression of ocular myasthenia gravis to generalized disease [3, 23, 24]. The simple answer is no. Patients with purely ocular disease often have increased jitter in limb muscles, but neither its presence nor the degree of abnormality predicts which patients will go on to develop generalized myasthenia gravis.

SFEMG should be performed in a weak muscle if possible and, if normal, virtually excludes a diagnosis of MG. An abnormal SFEMG study by itself does not make the diagnosis of MG. Abnormal jitter remains a nonspecific finding and should be correlated with the history, examination, other diagnostic tests, and routine EMG. Its place in the diagnostic evaluation of MG is somewhat controversial. Some authors

consider SFEMG a last-ditch technique to make the diagnosis when MG cannot otherwise be confirmed, largely due to the relative unavailability of SFEMG [19]. I have found SFEMG to be better tolerated by patients than the Tensilon test or RNS, particularly of proximal muscles, and utilize it in preference to both. As mentioned above, I also consider baseline jitter studies useful as comparisons when difficult clinical questions arise later in the course. In those areas where SFEMG is not readily available, its use should be restricted to those patients whose diagnosis cannot otherwise be made. However, in centers with readily available SFEMG, it is the preferred electrodiagnostic method for confirming MG. Cholinesterase inhibitors can normalize jitter, and a normal exam on such drugs should be repeated off medications for at least 24 h if clinical suspicion of MG remains high [25]. Some practitioners use stimulation SFEMG routinely, finding it easier and quicker. I reserve stimulation for those patients who cannot cooperate, either due to age, infirmity, or level of consciousness. There is at least one study indicating voluntary SFEMG is more sensitive than stimulation SFEMG [26].

Ocular MG can be difficult to diagnose using other tests of myasthenia gravis, as AChR antibody has a low sensitivity in ocular MG, edrophonium test is not specific, and decrement during RNS is uncommonly observed in the ocular form of the disease. SFEMG of facial muscles in ocular myasthenia carries a sensitivity and specificity at least equal to that of generalized myasthenia gravis [27].

Over the last decade, muscle-specific tyrosine kinase (MuSK) antibody-positive myasthenia gravis (MuSK-MG) has been identified as a specific entity with unique clinical features and response to treatment, including resistance to anticholinesterases and usually requiring aggressive immunosuppression [28]. MuSK-MG patients, often women, present frequently with bulbar and facial weakness more so than limb weakness. As with acetylcholine receptor antibody-positive myasthenia gravis (AChR-MG), SFEMG is abnormal in MuSK-MG, though there is evidence that the neurophysiologic defect in neuromuscular transmission may not be as widely disseminated as in AChR-MG. Oh et al. [29] found SFEMG abnormalities in the EDC in 8/12 MuSK-MG patients, and Pasnoor et al. [30] reported SFEMG was abnormal in EDC in 18/21 cases, and in one patient whose EDC did not show abnormal jitter, the frontalis did. These results contrast with previous studies that reported a high diagnostic yield for SFEMG only when proximal muscles such as deltoid, frontalis, orbicularis oculi, and neck extensors [31, 32] were tested. Stickler et al. [31] reported that abnormal jitter by SFEMG in the EDC was relatively uncommon in MuSK-MG patients (59 %) compared to AChR-MG patients (91 %). Farrugia et al. [32] further addressed this by studying the different susceptibilities of the limb and facial musculature in both AChR-MG and MuSK-MG patients. In their study using concentric needle SFEMG, NM transmission abnormalities in the orbicularis oculi were found as frequently in the MuSK-MG patients (9/12) as in the AChR-MG patients (8/11) but were uncommon in the EDC in the MuSK group (1/13) compared to the AChR group (10/12). These results also bring up the interesting possibility that during development, MuSK may be differentially involved in postsynaptic differentiation and in agrin-induced clustering of ACh receptors at the end plate in facial and limb muscles. Taken together, results from previous studies highlight the importance of studying proximal muscles such as frontalis, orbicularis oculi, deltoid, or neck extensors with SFEMG in MuSK-positive patients, as SFEMG abnormalities are often not found in the EDC.

SFEMG jitter studies are also abnormal in LEMS, often more so than would be expected from the clinical picture. Large case series with SFEMG studies are not available, but virtually all patients reported have had markedly abnormal jitter and large percentages of blocking fibers [33–35]. Given the presynaptic nature of LEMS, a relationship between jitter and firing rate is expected. This relationship in reality is variable [33–36], but it is safe to say that a dramatic improvement in jitter and blocking with increasing firing rate is suggestive of a presynaptic defect in neuromuscular transmission.

Botulism arises from defective presynaptic release of acetylcholine caused by the toxin of *Clostridium botulinum.* Oh [37] reports SFEMG was abnormal in 95 % of 15 tested patients and in 100 % of patients with clinical weakness. Increased jitter and impulse blockade were seen, with decreasing abnormality at higher firing rates. SFEMG studies improved as the patient improved. Initially, fiber density was normal, but as botulism caused an irreversible block of acetylcholine release, patients improved by reinnervation and fiber density increased. Padua et al. [38] found similar abnormalities of SFEMG in each of seven cases of food-borne botulism. Studies after administration of botulinum toxin revealed increasing fiber density [39] and increasing jitter [40] over time, including muscles far removed from the injection site [40].

Anterior Horn Cells Disorders

Anterior horn cell disorders include amyotrophic lateral sclerosis (ALS), spinal muscular atrophy (SMA), and polio and post-polio muscular atrophy. All cause loss of lower motor neurons and are characterized by muscle weakness and atrophy. ALS is a progressive disease also involving upper motor neurons. By the time patients become symptomatic, they have already lost approximately 50 % of their motor neurons in affected muscles. Polio is an acute disease with a prolonged recovery. Post-polio syndrome is a

controversial entity suggestive of late worsening and loss of motor neuron function. Spinal muscular atrophy is a genetic degenerative disease, again with a chronic course and controversy over whether it is truly progressive. All share similar electrodiagnostic and pathologic features indicative of a mix of acute denervation and compensatory reinnervation. Needle EMG shows large, polyphasic, and rapidly firing MUAPs, while fibrillations, positive waves, and fasciculations are widespread. Muscle pathology shows fiber-type grouping and group atrophy, often involving entire fascicles. At the time of diagnosis, fiber density and jitter will both be increased. The degree to which fiber density, jitter, and blocking are abnormal depends on the pace of denervation and reinnervation and the duration and severity of motor neuron loss (Fig. 8.5). Rapidly progressive loss of motor neurons, such as in ALS, creates a milieu of constant denervation and compensatory reinnervation with either failing terminal motor axons or immature regenerating axons, both being a source of increased jitter and impulse blockade [42]. However, the fiber density may have little time to increase in such a scenario. In SMA, a usually slowly progressive motor neuron disease, fiber density will be markedly increased due to extensive reinnervation, but jitter may be less abnormal [42]. Post-polio muscular atrophy cannot be distinguished from stable old polio by SFEMG exam [43], but nonetheless patients with old polio complaining of recent change in strength tend to have greater abnormalities of jitter and fiber density than those without new weakness [44]. Fiber density will be increased, along with increased jitter and, often, blocking. These abnormalities increase as a function of the time since onset of polio. The etiology of the long-term instability of the motor end plate is still a matter of controversy but likely reflects continuing immaturity of end plate function as individual terminal axons in overstretched motor units fail and then reinnervate, repeatedly.

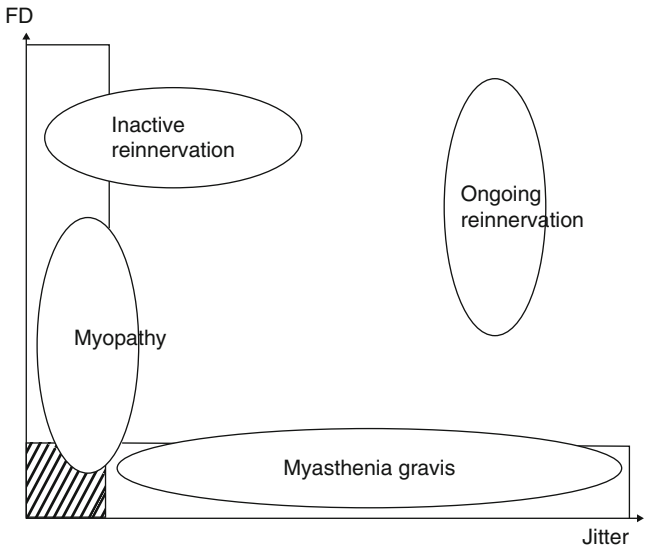

Fig. 8.5 The relationship between jitter and fiber density (*FD*) in myasthenia gravis, acute and chronic neurogenic disorders, and myopathies (Reproduced with permission Sanders and Stalberg [41])

Peripheral Nerve Disease

It comes as no surprise that peripheral neuropathy is associated with abnormalities of fiber density and jitter. Axonal degeneration leads to defective neuromuscular transmission with increased jitter and blocking from presynaptic failure, while immature end plates during reinnervation also have abnormal neuromuscular transmission, with resultant increased jitter and impulse blockade. Once reinnervation is complete, the fiber-type grouping which is typical of peripheral neuropathy results in abnormal fiber density. Jitter will be most abnormal in rapidly progressive neuropathies, reflecting the simultaneous loss of many presynaptic junctions (Fig. 8.5). Fiber density will be highest in chronic neuropathies with extensive reinnervation. SFEMG may even be abnormal in primary demyelinating neuropathies, indicating a degree of axonal degeneration.

Diabetic neuropathy has been the most studied of the peripheral neuropathies. Shields [45] found that abnormalities of fiber density and jitter were common in diabetics, even those without overt neuropathy. The degree of abnormality correlated with symptoms and signs of peripheral neuropathy. Bril et al. [46] also found a high incidence of SFEMG abnormalities in diabetic patients, with or without clinical neuropathy, and whether insulin dependent or not. The jitter increased as glycosylated hemoglobin increased, indicating SFEMG might be a sensitive measure of dynamic nerve changes in diabetic neuropathy [47].

Abnormalities of SFEMG have also been found in neuropathies due to uremia [48, 49], alcoholism [48], toxins [50], amyloidosis [51], Guillain-Barre syndrome (GBS) [52], chronic inflammatory demyelinating polyneuropathy (CIDP) [52, 53], and critical care multiorgan failure [54]. These abnormalities included increased fiber density (uremia, alcoholism, toxins, amyloidosis, GBS, CIDP) and jitter (critical illness neuropathy, alcoholism, CIDP). The only study to compare abnormalities among etiologies found that alcoholic polyneuropathy produced higher fiber densities than did uremic or diabetic neuropathy, despite (or because of) better nerve conduction velocities [48]. Jitter was only mildly abnormal in studies of alcoholic neuropathy and CIDP but was more abnormal in critical illness neuropathy, representative of its acute, monophasic nature.

Seventh cranial neuropathies have been studied using SFEMG as well. Takeda et al. [55] studied 36 patients with Bell's palsy (30 patients) or Ramsay-Hunt syndrome (6 patients). They found neuropraxic injuries with good

recovery and normal facial motor amplitudes had no abnormalities, while patients with facial motor nerve amplitudes less than 40 % of the unaffected side had increased fiber densities, consistent with axonal injury and collateral sprouting. Massey and Sanders [56] studied the frontalis muscle in a single patient serially over 3 years after an acute facial nerve injury. Fiber density and jitter were normal at onset; reached maximal abnormality at 37 days, coincident with the first clinical signs of recovery; and approached normal rapidly over the next 30 days, by which time the frontalis muscle had recovered completely. Even 34 months later, however, fiber density and jitter had not returned to baseline levels. This case illustrates how quickly collateral reinnervation can occur and how immature end plates with low safety factors can mature into normal neuromuscular transmission.

Muscle Disease

SFEMG can also be abnormal in muscle disease, particularly the destructive myopathies such as the muscular dystrophies and inflammatory myopathies (Fig. 8.5). The reasons for the abnormalities differ, however. Increased fiber density is less due to collateral reinnervation than to focal grouping of surviving muscle fibers, muscle fiber splitting, packing of muscle fibers from atrophy, and ephaptic recruitment of muscle fibers from other motor units [3]. Increased jitter is less common in muscle disease than nerve disease, and when seen is due to segmental denervation from muscle fiber necrosis and immature postsynaptic motor end plate function. Despite this, SFEMG can be useful in differentiating muscle from nerve disease. Shields found that SFEMG reliably confirmed the histopathologic diagnosis of either limb-girdle dystrophy (LGMD) or SMA and assisted in the differentiation of four patients with indeterminate diagnosis into one or the other category [57]. Fiber density is particularly helpful as it is usually lower in muscle disease than nerve disease. The anatomic distribution of jitter abnormalities may be more useful than the actual amount of increased jitter, which can overlap among neurogenic, neuromuscular transmission and myogenic disorders. Low jitter during voluntary SFEMG, i.e., less than 5 μs, indicates non-synaptic jitter and is seen with split fibers and ephaptically stimulated fibers [3]. Its presence is a sign of primary muscle disease.

Of the myopathies, the muscular dystrophies show the most abnormalities during SFEMG, and of the dystrophies, Duchenne dystrophy is the most abnormal [58]. Fiber density is frequently abnormal, often being greater than 3.0, which is in the range of peripheral neuropathy. Jitter is also often abnormal, being moderately increased in 20–40 % of patients with blocking in 5–10 %. Becker muscular dystrophy and LGMD are similarly affected but to a much less degree so that, as above, SFEMG can be used to distinguish them from a neurogenic process. Facioscapulohumeral dystrophy is very mildly abnormal by SFEMG, and myotonic dystrophy has abnormalities only slightly more interesting than that, being similar to LGMD. Oculopharyngeal muscular dystrophy may have increased jitter in an anatomic distribution, making differentiation from myasthenia gravis on a purely SFEMG basis impossible [59]. I have been fooled at least once and only made the correct diagnosis with further study of family members.

Mitochondrial myopathies are a diverse group, biochemically and clinically, and the results of SFEMG can be normal, mild to moderately abnormal, or, uncommonly, quite abnormal. Fiber density is slightly increased in a minority of patients and normal in the rest. One study of seven patients with Kearns-Sayre syndrome found normal jitter in all seven [60]. Other studies, including patients with chronic progressive external ophthalmoplegia, found increased jitter in most, with a range of abnormalities similar to that seen in myasthenia gravis, including the presence of blocking [59–62]. The difference in jitter results between the studies may be attributed to the latter groups having studied the frontalis muscle, whereas the Kearns-Sayre patients were studied only in an arm muscle.

Myotonia congenita demonstrates normal fiber density with 10 % of patients having slight increases in jitter. An interesting phenomenon is decreasing single-fiber action potential amplitudes during stimulation SFEMG [63]. One study [63] showed that Thomsen's disease patients had a rapid decrement between 40 and 70 % within 1 s of 20 Hz stimulation. Becker's disease patients had an even more profound decrement, often to zero, with 2 Hz stimulation for just 10–30 s. This decrement lessened with repeat trials, corresponding to the clinical improvement with warming up seen by these patients. Another channelopathy, hypokalemic periodic paralysis, showed no abnormalities of fiber density under the age of 40 [61] but increased fiber density over that age, corresponding with persistent myopathic findings on exam and histochemistry. Jitter was also increased in patients with persistent weakness, i.e., those patients with long-term disease and apparent permanent myopathy.

The SFEMG in patients with inflammatory myopathies is dependent upon the severity and stage of the disease but not on the cause or type of myositis. The abnormalities can be quite variable, but generally during the early stages of the disease, fiber density is only mildly increased whereas increased jitter and blocking are frequently encountered, due to either denervation of muscle fibers by segmental necrosis, immaturity of regenerating muscle end plates, or immature axonal sprouts [64]. As the disease enters a less progressive or arrested stage, the fiber density increases further and the jitter and blocking tend toward normal. The fiber density is highest in patients with the least atrophy and best return of strength, supporting the supposition their good result is due to effective reinnervation of new muscle fibers. Endocrine

myopathies, such as due to iatrogenic steroids, do not cause significant abnormalities of SFEMG [65]. As such, SFEMG may supplement needle electromyography in helping differentiate relapse or failure to respond to treatment in inflammatory myopathy from steroid myopathy.

Congenital myopathies are a mixed bag of SFEMG results. Central core disease [61], myotubular myopathy [3], and nemaline rod disease [61] have normal fiber densities, whereas type 1 fiber hypotrophy with central nuclei [61] has increased fiber density and, often, increased jitter and blocking, results which were not easily explainable by histochemical correlation [61].

Inborn errors of muscle metabolism show abnormalities to the degree that there are persistent structural muscle defects. In a case of late-onset McArdle's disease with proximal myopathy, fiber density and jitter were increased [66] and in acid maltase deficiency, which usually causes a permanent, progressive myopathy, fiber density was increased in more affected leg muscles [61]. Patients with myophosphorylase or phosphofructokinase deficiency have normal fiber density and jitter studies [61].

Quantitative EMG Analysis

9

Sanjeev D. Nandedkar and Paul E. Barkhaus

Introduction

In a clinical neurophysiology laboratory, nerve conduction studies are performed in a very objective fashion. The signals are recorded using standardized techniques, including the size and placement of electrodes, filter settings, and temperature control. The waveforms are often marked using automated algorithms to assess the latencies and amplitudes. Measurements are compared against appropriate reference values that take into account differences in age, height, temperature, and other variables [1–3]. In contrast, the needle electromyography (EMG) examination is based on subjective assessment of the waveforms on the display screen and from their sound on an audio monitor. One masters waveform recognition only by extensive training and practice. The routine needle EMG examination may be divided into four steps.

First, the electrical activity in response to the needle insertion and movement is assessed. The amplitude and duration of these potentials depend in part upon the vigor and degree of needle manipulation by the operator. In normal muscle, this *insertional activity* appears as a short-duration burst. In pathologic states, the needle movement may trigger potentials in the form of fibrillation potentials (FP), positive sharp waves (PSW), complex repetitive discharges (CRD), or myotonia. These are discussed in detail in Chap. 7.

In the second step, the needle position is held fixed by the clinician and the patient relaxes the tested muscle. In normal muscle, no electrophysiologic activity is expected. For patients with neurogenic and myopathic diseases, one may observe FPs, PSWs, CRDs, etc. generated in a spontaneous fashion. This is called *spontaneous activity*. It is assessed and graded subjectively based on its presence and persistence at different tested sites.

Next, the patient is asked to slightly contract the muscle. Motor unit action potential (MUAP) discharges of a few different motor units (MUs) will fire. The MUAP is assessed, subjectively and objectively, by its configuration (amplitude, duration, peaks, and phases). The MU discharge pattern is assessed for its *firing rate* in relation to the level of voluntary activation of the tested muscle as well as the firing rates of the other MUs activated. Finally, the patient slowly increases the force of contraction to maximal effort. The needle EMG signal, called the *interference pattern (IP)*, is assessed by its sound, the number of spikes, and their amplitude.

Insertional and spontaneous activities are recognized quite easily by their characteristic sound and waveform pattern. The assessment of FP and PSW is of great importance in assessing denervation in patients with neurogenic disorders. When MUAP shape or firing rate is significantly different from normal, it can be recognized very easily. But if the muscle is minimally affected by the disease processes, the needle EMG findings on subjective assessment may be equivocal. In these instances, quantitative analysis (QA) can help recognizing mild abnormalities. Quantitative measurements can also be used to assess disease progression. Combined with muscle biopsy studies and computer simulations, QA has given us a better understanding of the relationship between the EMG signals and their signal generators.

Most clinical electromyographers practice what might be described as subjective EMG waveform analysis. They insert the needle electrode into the muscle to be studied, place the electromyograph on free run, and attempt to assess the signals as they are acquired, in what might be further described as passive, "subjective" analysis. Essentially no change in the signal occurs between the display screen on the electromyograph and the operator's retina. QA of the EMG signal

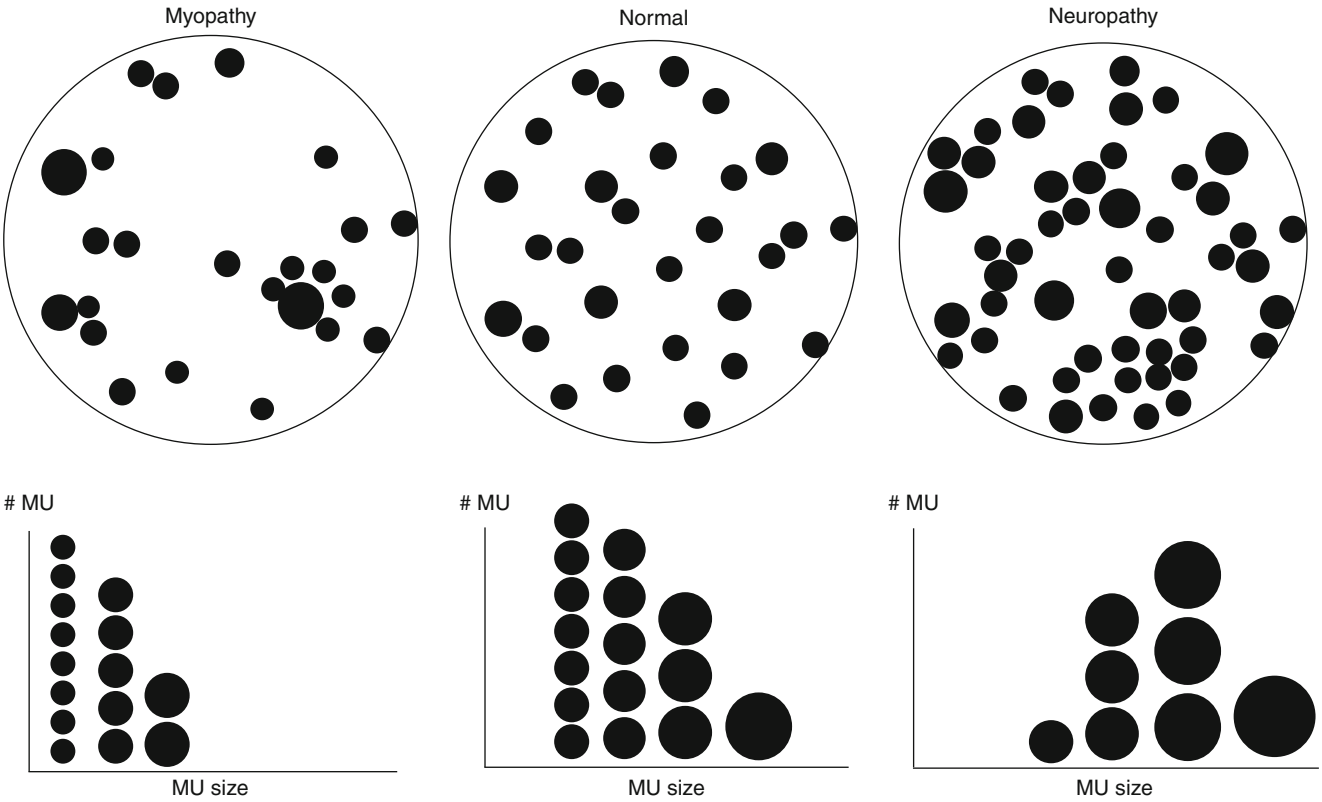

Fig. 9.1 The distribution of muscle fibers in a normal MU is shown schematically (*top row center*). The architecture of the same MU due to disease processes is shown for myopathy (*left*) and neuropathy (*right*). The concomitant change in the number and size of MU in the muscle is shown schematically below the MU schematic. In the *bottom row*, each *circle* represents one MU and its diameter reflects its size. See text for details

for many electromyographers implies long, tedious periods of signal acquisition followed by longer, labored times for analysis. Yet, it is in the fundamentals of quantitative EMG analysis that the impressions or gestalt for subjective assessment is grounded. One should not simply feel that the signal is not normal but rather have objective criteria for describing the signal as abnormal.

In this discussion of QA, the reader is encouraged to approach the EMG signal more objectively. The EMG signal should not simply be acquired in a passive manner but actively manipulated by the operator by changing the sensitivity setting, sweep speed, and low-frequency filter as needed to optimize the amount of information that can be derived from the signal. In other words, the operator should be interactive with the signal before final assessment. Practicing such quantitative procedures disciplines one to see and hear subtle abnormalities that would otherwise be missed. Additional recording techniques and manipulation of the EMG signal can easily be incorporated in the routine examination to document abnormalities. In other words, understanding QA improves the quality of the routine EMG examination by extracting more information from the signal at routine settings. We call this objective/interactive EMG [4].

The Motor Unit (MU)

A motor unit (MU) consists of all muscle fibers (MFs) innervated by one motor neuron (Fig. 9.1). The MFs of a MU are scattered through a large portion of the muscle cross section with no tendency to form groups. Most often, two MFs of the same MU are separated by more than 300 μm [5]. In large muscles such as the biceps brachii, the MFs of one MU may be distributed within a roughly circular territory of 5–10 mm diameter in a patchy mosaic pattern, such that MFs from the same MU are rarely contiguous or near one another. In a routine cross section of muscle at low power, only a few MFs from the same MU are likely to be visualized (approximately 2 MFs from the same MU for every 100 MFs seen) [6]. Thus, the MFs from more than 50 MUs may be visualized in a single low-power microscopic field. Larger MUs (i.e., those containing a greater number of MFs) have a larger MU territory. The end plates of a muscle may be distributed within a well-defined segment (typically at the midsection) along the long axis of the MFs [7]. This is called the end plate zone. Within the same MU, there is minimal variability in MF diameter. In the biceps brachii muscle, the mean MF diameter is 50–60 μm [8].

Based on metabolic properties, MFs may be divided into three groups: type I, type IIA, and type IIB. Type I MFs are fatigue resistant while type IIB MFs fatigue more easily. Type IIA MFs have intermediate characteristics. A MU contains MFs of only one type. In a normal muscle, a MF from a given MU is typically surrounded by MFs from other MUs, often with different MF types. Hence, on muscle biopsy, one obtains a random pattern of MF types without any tendency to form groups of MFs of the same type.

The MU size refers to the number and diameter of MFs in the MU (i.e., the number of MFs supplied by a single motor neuron or *innervation ratio*). The number and size of MUs vary among different muscles. Smaller muscles used in fine motor control and rapid movements (e.g., intrinsic hand muscles) tend to have smaller MUs, whereas larger muscles used in forceful activity (e.g., proximal limb muscles) have larger MUs [9]. A normal muscle contains more small, lower-threshold, fatigue-resistant MUs and fewer large, higher-threshold, rapid-fatiguing MUs (Fig. 9.1).

At minimal force of contraction, the smaller, type I MUs are activated first. These discharge at low rates. When MU firing rate increases, successive MU twitches will overlap and fuse to generate greater force from the same MU. This phenomenon is called *frequency modulation*. With further increase in force of contraction, more MUs are activated. This is called *recruitment*. A muscle uses a combination of these two processes to generate and maintain the desired force level. In many muscles, most MUs are recruited at moderate activation. Thus, maximal effort is primarily achieved through frequency modulation. Other muscles may recruit MUs until near maximal effort.

To reiterate, the MUs recruited at minimal effort are relatively small (i.e., type I), have few MFs, and are also fatigue resistant. When force is increased, the larger, type II MUs are recruited and tend to fatigue easily. This orderly recruitment of MUs based on their size is referred to as the *size principle* [10]. It should be noted that in using selective electrodes, i.e., concentric needle (CN) and monopolar needle (MN) electrodes, where the signal does not represent the electrical activity of the whole MU (i.e., the action potentials of all of the MFs from the MU), the MU size may not be proportionate to the relative size of the MUAP. In routine clinical EMG, patients activate their muscle by performing graded, low effort, isometric muscle contraction. For the purposes of this chapter, unless otherwise noted such as when discussing IP, this pattern of volitional activation should be assumed.

Disease Processes

In patients with neurogenic disease, the primary disease process affects the "neurogenic" portion of the MU resulting in the loss of that MU. This can occur due to loss of the motor neuron (e.g., polio, motor neuron disease) or the loss of its axon (e.g., trauma, diabetic distal symmetric axonal polyneuropathy). The denervated MFs atrophy and are recognized by their spontaneously generated action potentials: FP and PSW. Hence, assessment of insertional and spontaneous activity is essential to the electrodiagnostic examination. Also, the denervated MFs belonging to the lost MU can no longer be activated in voluntary contraction. Meanwhile, the surviving MUs in the immediate neighborhood generate collateral axon branches to reinnervate the denervated MFs. The net effect is a reduced number of MUs with an increase in MU size by virtue of the increased number of MFs innervated by that MU within its MU territory. In remodeling of the MU in reinnervation, the size of the MU territory per se is not increased, only a relative increase in the number of MFs within it (Fig. 9.1).

The MFs of the surviving MUs are no longer distributed randomly, such that the MFs of the MU are spatially isolated by MFs from other MUs, as in the normal state. Reinnervated MFs change their metabolic properties to conform to that of the motor neuron reinnervating it. On histological sections, small groups or clusters of MFs of the same metabolic type are seen. Thus, reinnervation is most characteristically recognized on muscle biopsy by MF type grouping [8]. Some MF loss may also be compensated for by MF hypertrophy. Denervated MFs on muscle biopsy are seen as small, angular, atrophic MFs. In the end stage of a chronic neurogenic process when large reinnervated MUs are being lost and further reinnervation is failing, the biopsy may show large groups of atrophic MFs corresponding to the loss of large reinnervated MUs. FP and PSW in such instances may be smaller in amplitude reflecting the smaller diameter of these angular, denervated MFs. These may be missed on routine instrument settings. It may be helpful to increase the low-frequency filter (e.g., to 100–500 Hz) and thus increase the sensitivity to better detect these FPs.

In patients with myopathy, the main disease process is the loss of MFs, thereby affecting the "myogenic" portion of the MU. Nonfunctional, affected MFs lost from MUs may be seen scattered throughout a cross section of muscle as small angulated MFs. High-resolution microscopy can reveal changes in the internal structures of the MFs, e.g., presence of chained nuclei. It is important to remember that in some myopathic processes, the predominant structure affected is the contractile mechanism; hence, the electrical signal may be relatively unaffected despite symptoms. Histologically, the response of the MFs to the myopathic process is variable. While MFs may typically atrophy, others may become hypertrophic. The latter, however, is not typically seen in polymyositis. Overall, this results in highly increased variability in MF diameter which is readily appreciated on muscle biopsy (Fig. 9.1) [8]. Hypertrophic MFs may eventually split into two or more smaller MFs. These will obviously be clustered together. Reinnervation may occur following segmental necrosis of a MF, isolating that segment from its end plate. New innervation may also occur in the process of innervating regenerated

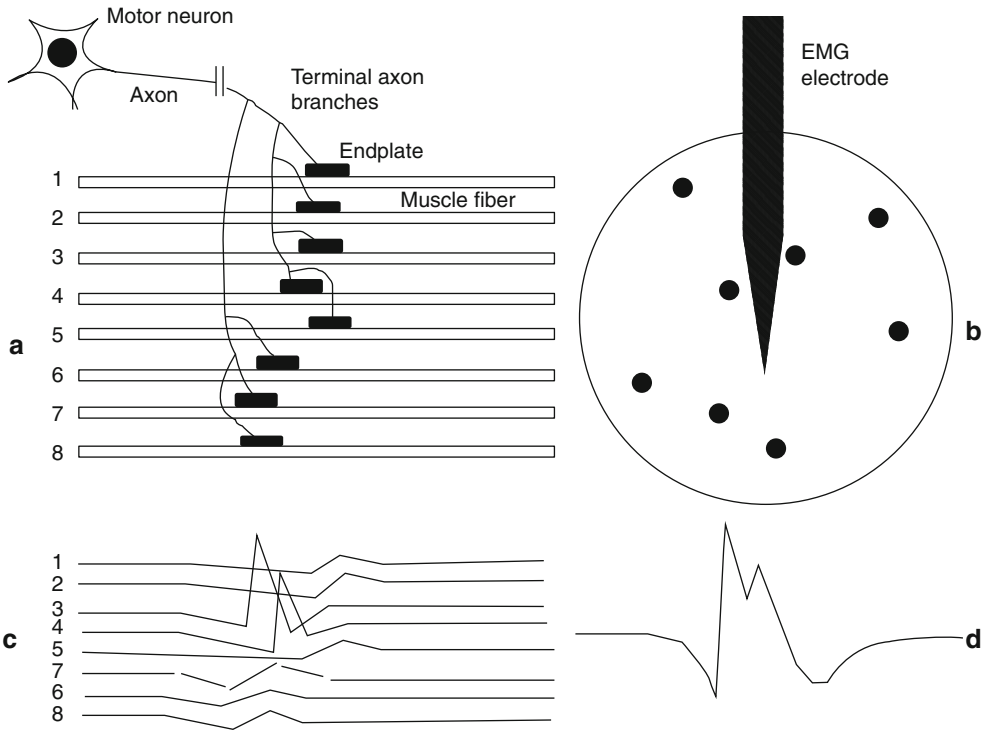

Fig. 9.2 The MU is described in (**a**). The muscle fiber distribution is shown in (**b**) along with a monopolar needle electrode. The individual muscle fiber APs (**c**) are summated to obtain the MUAP (**d**)

satellite cells forming new "nascent" MFs or innervating component MFs resulting from split hypertrophied MFs [11]. With severe loss of MFs, entire MUs may be lost and may slightly reduce the number of MUs. Thus, MU remodeling in myopathic processes affects not only the size of the MFs but also their distribution within the MU territory [12].

Muscle biopsy allows the most direct observations of MU abnormalities. A disadvantage is that it is invasive and expensive. In contrast, the EMG examination allows one to make inferences on changes in the MUs based on measurements of the signals recorded. It is therefore important to recognize the relationship between the EMG parameters and their generators, i.e., MFs and MUs. Although this is an indirect approach, EMG is relatively noninvasive and should complement the muscle biopsy. Other benefits of the EMG examination are that it can be performed in several muscles to confirm consistency in observations and can be repeated serially in the same muscle if needed. Thus, one may assess the topographic distribution of disease (e.g., distal, proximal, diffuse) as well as clinical progression. Needle EMG examination is also often used to select a muscle that is most suitable for muscle biopsy.

Motor Unit Action Potential (MUAP)

The MUAP is the quintessential building block of the EMG signal recorded during voluntary contraction (Fig. 9.2). When the motor neuron discharges, an action potential (AP) propagates through the axons and its terminal branches to reach the end plate, also called the neuromuscular junction or synapse. The arrival of the AP releases acetylcholine (ACh) from the nerve terminals in the end plate. The ACh diffuses through the synaptic cleft and binds to the receptors in the postsynaptic membrane. This produces a local depolarization called the end plate potential (EPP). When the EPP reaches a threshold level, a MF AP is generated that propagates bidirectionally toward the tendons. The AP initiates a chain of events leading to contraction of the MF.

An EMG electrode records the MF AP in the extracellular space (Fig. 9.2b). The extracellularly recorded MF AP, recorded away from the end plate region but along the length of the MF, has a triphasic waveform (Fig. 9.2c). The initial positive deflection represents the AP propagating toward the electrode. As the AP passes in front of the electrode, the main positive–negative deflection is recorded. When the AP propagates away from the electrode, the potential returns to the baseline. If the electrode is placed immediately over the end plate area, the initial positive defection will not be recorded. The potential will have a biphasic waveform with an initial negative deflection [13, 14].

The extracellular potential waveform also depends on the distance between the recording electrode and the MF. At a short distance, the potential has a short rise time and high amplitude (Fibers 3 and 4 in Fig. 9.2). The sound of the potential is described as "crisp" or "sharp." The potential recorded from a distant fiber has low amplitude with a high rise time. Such a potential sounds "dull" on the audio monitor. Regardless of the distance, near and far MFs have similar initial and terminal slow components of the potential (Fig. 9.2c).

The MF APs are dispersed (i.e., asynchronous) as they pass the electrode. This results from a variety of anatomic factors: (1) The nerve AP arrives at the end plate at different times due to differences in the length of terminal axon branches and their AP propagation velocity (Fig. 9.2a). (2) The time required for

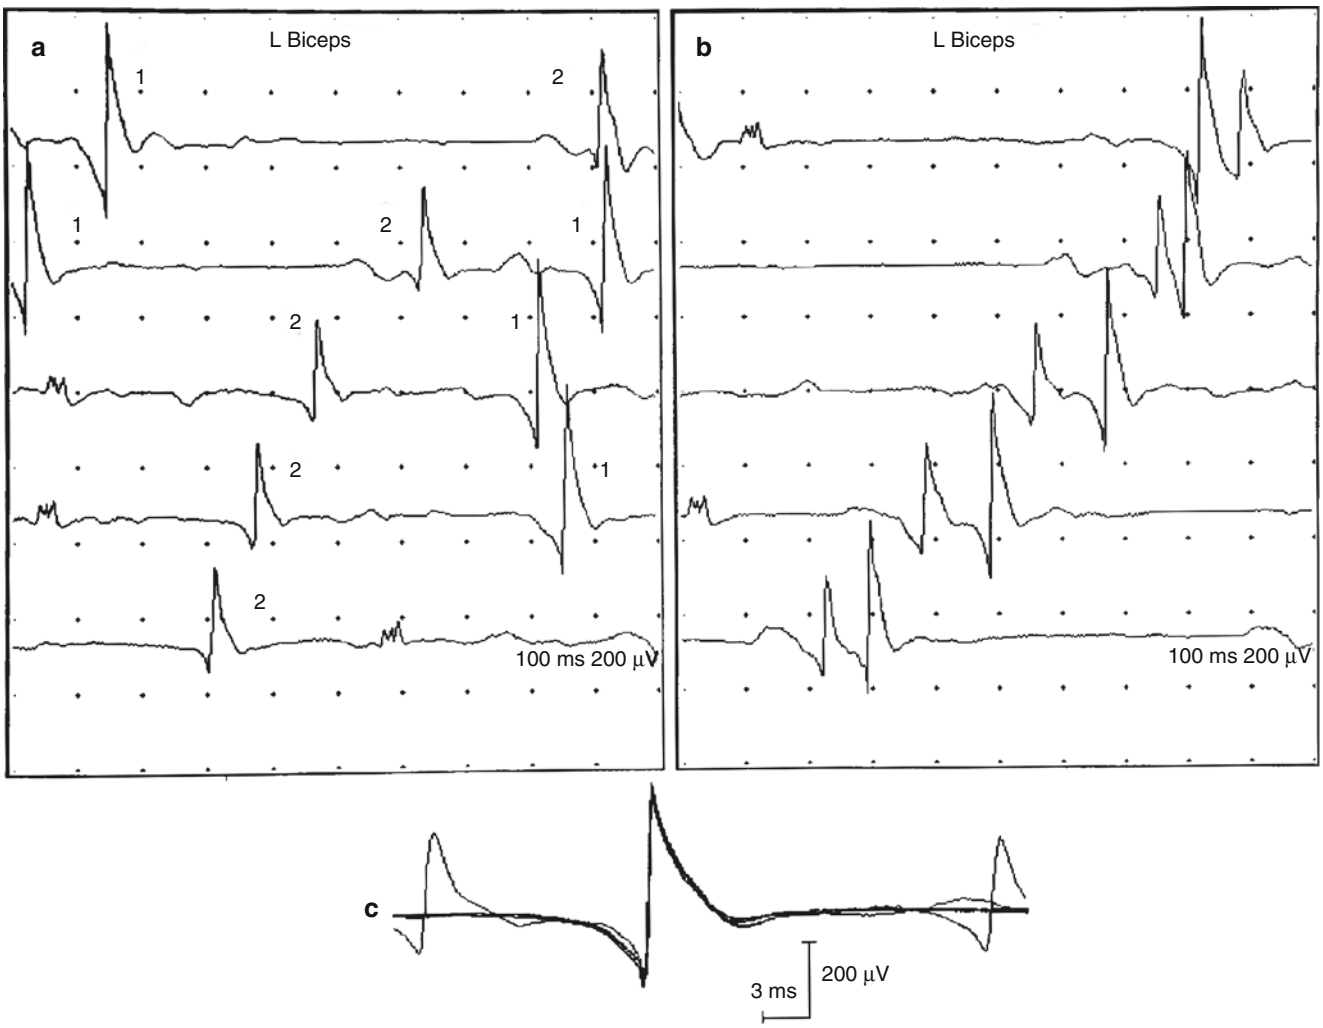

Fig. 9.3 Concentric needle EMG recording from the biceps muscle of a normal subject is shown in a free-running display mode (**a**, **b**). Five consecutive sweeps are presented. The traces are drawn from *top* to *bottom*. In (**a**), discharges of two different MUAPs are identified and labeled. Another portion of the same recording is shown in (**b**) where the two MUAPs superimpose each other. The resulting waveforms appear polyphasic with long duration. However, these waveforms are not seen in a recurrent fashion. Hence, they are not used for analysis. In (**c**), an amplitude triggered delay line is used to time lock the discharges of the larger MUAP on the screen. Five consecutive discharges are superimposed. The discharges of the smaller MUAP appear randomly in the traces. The MUAP features can be assessed after averaging these discharges. Even without the averager, we can easily assess its amplitude, duration, and phases

AP transmission across the neuromuscular junction is quite small but may vary from one discharge to another: This forms the basis for the jitter measurements in single-fiber EMG [5]. (3) The end plates are at different distances from the electrode. Thus, the APs travel varying distances to reach the electrode (Fig. 9.2a). (4) Finally, the AP propagation velocity varies among the MFs. Large MFs conduct APs faster than the smaller MFs [15]. The resulting variations in arrival times for the MF AP at the electrode is termed the "temporal dispersion."

The MUAP is the sum of all extracellularly recorded potentials of all MF APs within the MU (Fig. 9.2d). It is obvious that its shape depends on the MU architecture, i.e., number, size, and distribution of MFs, end plate zones, etc., and is altered in disease processes (Fig. 9.1). These changes in turn alter the MUAP waveform and form the basis for analysis in the needle EMG examination.

The MU abnormalities can be assessed using three different techniques: MUAP waveform measurements, MU firing rate analysis, and analysis of interference pattern recording at different force levels. We will now review these techniques.

MUAP Waveform Analysis

Recording Techniques

The needle is inserted in the muscle, while the subject exerts minimal effort. The needle position is adjusted to record "sharp" and "crisp" EMG activity. This usually coincides with increased amplitude and reduced rise time of the EMG signals. MUAPs can be extracted using a variety of techniques. In the manual method (Fig. 9.3a), a

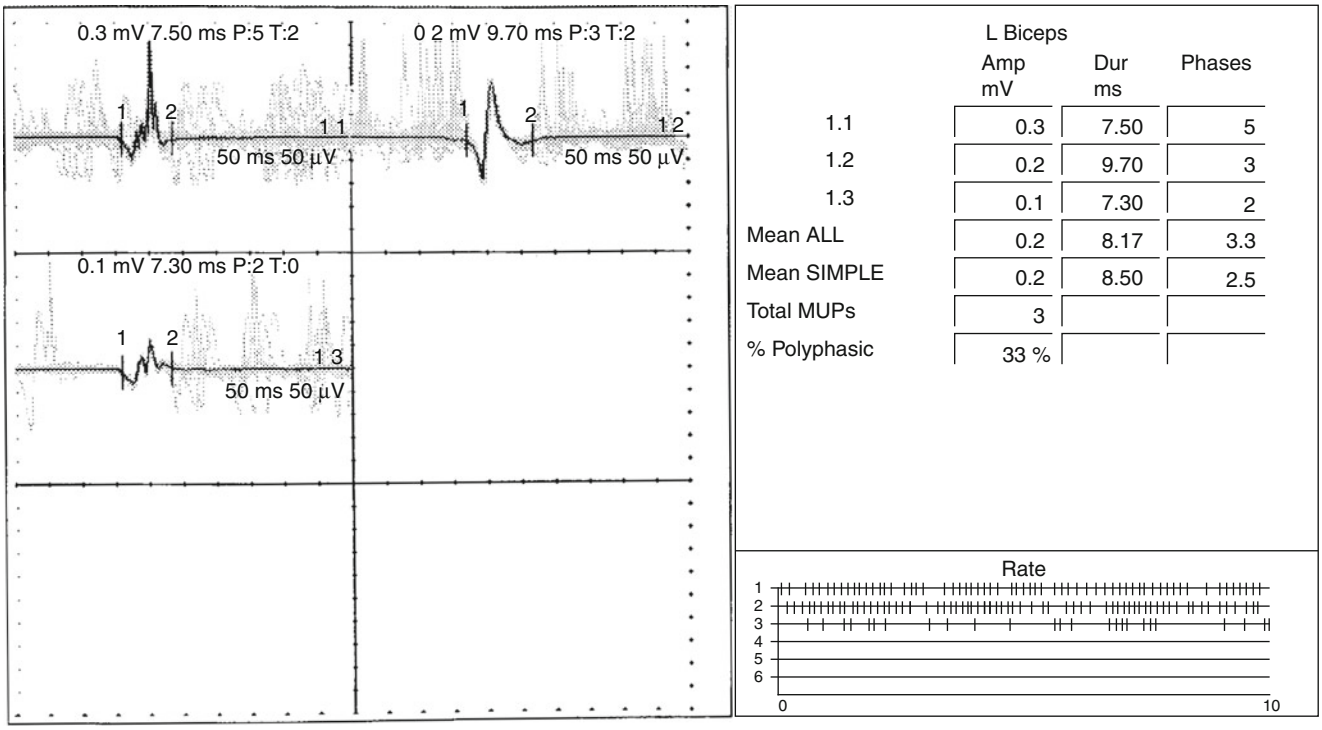

Fig. 9.4 A multi-MU analysis program was used to analyze CNEMG recording from the biceps muscle of a normal subject. From the 10 s epoch, the algorithm identified three different MUAPs. Their discharges are shown as if using an amplitude trigger and delay line. The dark trace is the averaged MUAP. The *vertical tick marks* labeled *1* and *2* are the beginning and end points of the MUAP. The amplitude, duration, and phases are measured automatically and tabulated to the right. The discharge pattern of each MUAP is shown in the *lower right corner*. The horizontal line represents time from 0 to 10 s. Each *vertical tick mark* is one MU firing. The gaps in the firing pattern represent MUAP superimpositions that were not resolved by the algorithm. It should not be misinterpreted as irregular MU firing. This analysis required the computer less than 1 s

500 ms EMG epoch is "frozen" on the display for visual assessment. A waveform occurring in a recurrent fashion is a MUAP. This is very easy when the signal contains discharges of a single MU. When two or more MUs are discharging, their MUAPs may superimpose by chance (Fig. 9.3b). The resulting waveform will not repeat consistently in the EMG record and should be therefore excluded from analysis. As a rule of thumb, one should see a waveform at least three times before calling it a MUAP [16]. The MUAP waveform is quantified manually. This technique can be easily performed on most modern systems.

A trigger and delay line device displays the EMG activity only when it exceeds a user-defined voltage level. If this level is adjusted so that only one MUAP crosses it, the EMG signals will be displayed only when that MUAP occurs. As a result, the MUAP waveform appears time locked in the display area (Fig. 9.3c). Activity from other low-amplitude MUAPs appears randomly. This makes it easier to assess characteristics of the triggering MUAP. On many instruments, one can average such time-locked discharges to improve the signal-to-noise ratio. After obtaining a relatively noise-free baseline, the MUAP measurements may be performed manually or automatically.

As computers and software have become more powerful, many have developed algorithms to decompose the EMG signal into the discharges of its constituent MUAPs (Fig. 9.4). Since several MUs are simultaneously acquired and analyzed, the method may also be called the "multi-motor unit analysis (MMA)" [17, 18] or "decomposition" [19, 20]. Because of minimal analysis time and a yield of one to four different MUAPs from each tested site, it is possible to analyze 20 MUAPs within only a few minutes, including muscles that are considered difficult to study, e.g., paraspinals [21].

The shape of the MUAP may vary depending on where it is recorded within the MU [6, 14]. Therefore, there is some risk that two presumably different MUAPs may actually represent signals from the same MU. To reduce the chance of this possibility, the following sampling technique is suggested. The needle electrode is inserted perpendicular to the long axis of the MFs. After recording the MUAPs at one site, the needle is inserted deeper along the same axis by 5–10 mm to the next recording site. This linear track is called a *corridor*. The rationale for moving 5–10 mm is to try to move away from a previously sampled MU's territory. With practice using the basic manual technique, it is possible to obtain two and rarely three MUAPs from one site, and each corridor of needle insertion typically yields 3–5 MUAPs. To avoid

unnecessary skin insertions, the needle electrode is withdrawn after recording from the deepest or most distal site in the muscle to just outside the muscle (i.e., still subcutaneous). The electrode is then angled 30–60 ° to one side of the original corridor yet remaining perpendicular to the long axis of the MFs, and a new corridor is explored. Since there is a greater risk of MU territory overlap in the superficial portion of this secondary corridor, recording MUAPs should initially start at a slightly deeper site. This process may be repeated using another corridor on the opposite side of the initial corridor. One usually obtains 20 or more MUAPs by investigating different corridors from different skin insertions. Stålberg and coworkers have shown differences in MUAP features when recorded from superficial and deeper portions of the muscle; hence, there should be some attempt not to bias the sampling to only superficial versus deeper portions of the muscle [13, 22].

When selecting a new skin insertion site, the needle is moved in a direction perpendicular to the long axis of the MFs. Inserting the electrode proximal or distal to the previous site along the long axis of the muscle (and therefore the MFs) will assure a high likelihood of sampling the same MUs but at a different site along the length of the MF. If the needle is angled less than 90° to the long axis of the MFs, then less efficient sampling of MUs occurs because fewer MFs are being traversed per unit length of the needle electrode. Sampling in the end plate zone should be avoided because it tends to be painful.

Use of a 50 mm CN or MN electrode offers the most flexibility in sampling (particularly in larger muscles) and has the same electrode diameter as its more commonly used counterpart, the 37 mm electrode. Recording areas on the CN and MN electrodes differ. The recording area on a 37 or 50 mm CN is the same regardless of length and the same applies for the 37 and 50 MN electrodes. Some of the shorter, 25 mm CN electrodes (i.e., the so-called facial CN needle electrode) have a smaller recording surface than the longer CN electrodes. This is important as amplitude values may differ between these electrodes.

Measurements

The technique of MUAP quantification was pioneered by Buchthal and coworkers beginning in the 1950s [23]. Those investigators measured the *amplitude* between the maximum negative to maximum positive peaks, i.e., peak-peak (Fig. 9.5). The MUAP onset occurs when it first deviates from the baseline. The MUAP terminates when the potential returns to the baseline and remains at that level until the next MUAP discharge. The time interval between these events is the total MUAP *duration*. The visual assessment of duration depends on the display sensitivity. At a setting of 1 mV/div

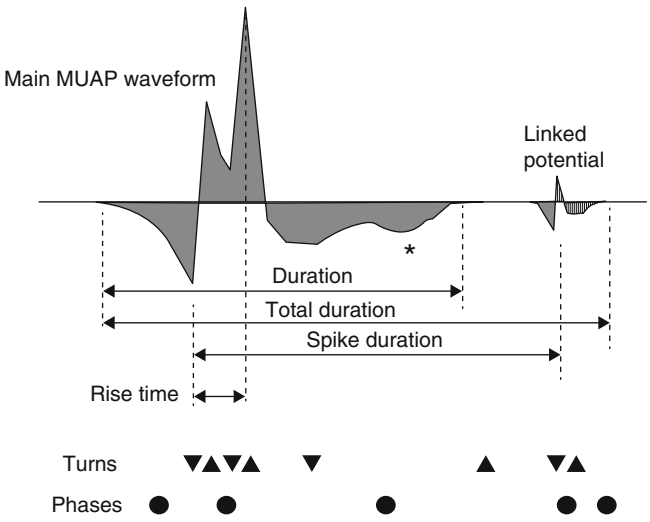

Fig. 9.5 A schematic is used to explain different features of the MUAP waveform. The *circles* and *triangles* project on to the phases and turns. The peak indicated by *asterisk* occurs when the APs reach the tendon. The amplitude of this potential in this schematic is less than the threshold for turns measurements. Therefore, those peaks do not generate turns. See text for details

or higher, the MUAP appears to have shorter duration. At a setting of 50 μV/div or less, the duration appears longer, perhaps also due to some baseline shifts. Hence, the duration is best assessed using a display setting of 100–200 μV/div. A *phase* occurs when the signal deviates from and then returns to the baseline. The number of phases can be quickly assessed by counting the baseline crossings in the MUAP and adding one. A MUAP is called simple when it has four or less phases. A *polyphasic MUAP* has five or more phases. Buchthal and colleagues measured the mean amplitude of all MUAPs and computed the percentage of polyphasic MUAPs in normal muscles. The mean duration was computed after excluding the polyphasic MUAPs.

With access to computers, algorithms have been generated to make automated measurements of the MUAP. Many such methods use "amplitude deviation from baseline" and/or "signal slope" criteria to detect the MUAP onset and end [18, 22]. Furthermore, the signal must cross the baseline by a threshold amplitude (e.g., 20 μV) before it is considered a phase. This will exclude spurious phases generated by noise near the baseline. A turn occurs at the peak of the MUAP. To exclude peaks generated by noise, the amplitude must change by a threshold value (40–100 μV) between successive turns. A *serrated MUAP* has more than five turns. A *complex MUAP* is either polyphasic or serrated [24]. Zalewska and Hausmanowa-Petrusewicz described the "irregularity factor" which also quantifies the complexity of the MUAP waveform [25].

The MUAP rise time is usually measured from the maximum negative peak to the maximum positive peak that precedes it. This definition may be unsatisfactory for

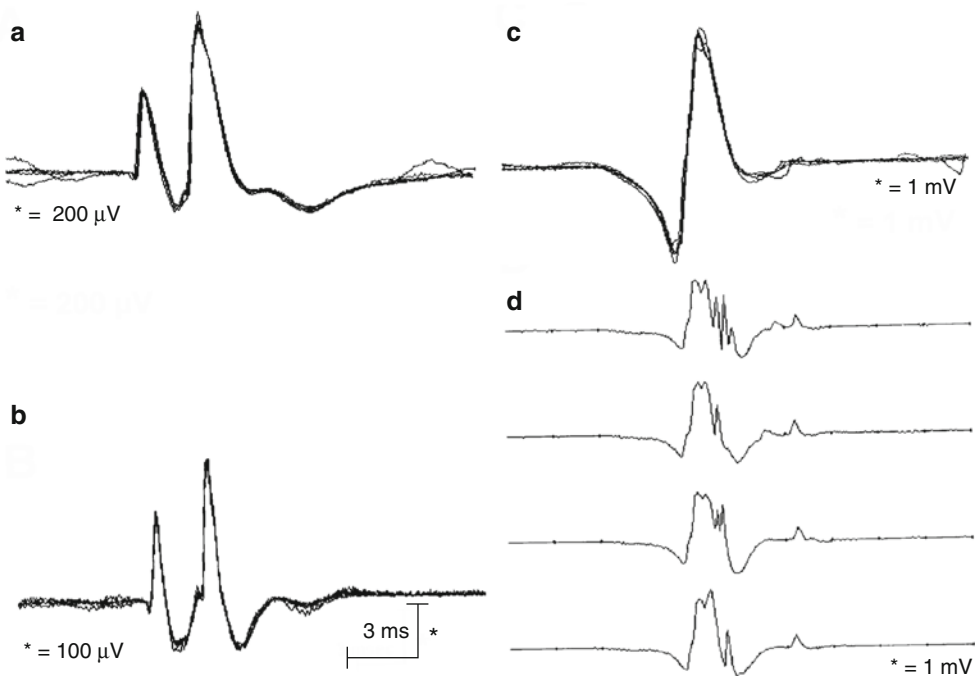

Fig. 9.6 Consecutive discharges of a stable (**a**, **b**) and unstable (**c**, **d**) MUAP are shown. The filter settings are 3–10,000 Hz in **a** and **c**, 500–10,000 Hz in **b** and **d**. The successive discharges superimpose extremely well for the stable MUAP (**a**, **b**). For the MUAP in **c**, the waveform appears significantly variable when the filter settings are changed (**d**). The amplitude calibration is indicated below the traces

polyphasic MUAPs (Fig. 9.5). Thus, MUAP rise time is not used in assessment of MUAP abnormalities.

Sometimes, a MUAP may be divided into two or more time-locked sections that are separated by baseline. In these recordings, the portion with the greatest duration or amplitude may be considered the main body of the MUAP. The remaining portions are called "linked" or "satellite" potentials. Although relatively easy to hear on the audio portion of the signal, these may easily be missed unless trigger/delay techniques are used. When such potentials occur, duration measurements can be tricky. Including the linked potentials may yield a very long-duration values that are "inconsistent" with the expected values or other measurements in the same muscle. One usually measures the duration from the main body of the MUAP only or may exclude these potentials from the analysis. The spike duration is usually measured between the first and last peaks of the MUAP. When linked potentials occur (Fig. 9.5), the spike duration may be longer than the duration of the main body of the MUAP [22].

The *MUAP area* is measured between the rectified signal waveform and baseline. The MUAP ratio, computed as area/amplitude, quantifies the MUAP "thickness" on visual assessment [26]. The MUAP size index is obtained by mathematically normalizing the MUAP ratio to its amplitude [27]. The mean values of these features are used for analysis.

When the MUAP waveform configuration is relatively constant during successive discharges, it is called a *stable MUAP* (Fig. 9.6a, b). An *unstable MUAP* reveals a significant change in the waveform from one discharge to another (Fig. 9.6c, d) that results from abnormalities of neuromuscular transmission. "Jiggle" is a quantitative measurement of this change [28]. Stability is a subjective measurement which should be assessed from potentials that are within 3–4 ms of the trigger point. Potentials that are farther away from the trigger point may appear unstable due to other phenomena, such as velocity recovery function [15]. The percentage of unstable MUAPs may be computed. MUAP instability can be better appreciated when the low frequency of the band-pass filter of the EMG instrument is set to 500 Hz or higher. This was originally described as the "Blanket principle" [29].

Assessment Strategies

Buchthal and coworkers defined reference values for the mean amplitude, mean duration, and percentage of polyphasic MUAPs in normal subjects (Tables 9.1 and 9.2) [30]. Durations that differ by more than 20 % from the normal mean are considered abnormal. Many investigators have used a similar approach and described upper and lower normal limits of amplitude and duration [20, 24].

Analysis based on mean values is quite different from subjective MUAP assessment. By visual inspection, one can easily recognize rare MUAPs that are quite abnormal in normal subject (e.g., a MUAP with eight phases). Stålberg and coworkers referred to these MUAPs as "outliers" [31]. If such MUAPs are seen occasionally, they are taken as a statistical anomaly and ignored. However, if such outlier MUAPs occur with greater frequency, then we would suspect an underlying disease process. To mimic this approach, Bischoff and coworkers defined normal limits of amplitude and duration for individual MUAPs [17]. A study is considered

Table 9.1 Mean values of MUAP duration (ms) in normal muscles are tabulated

Data from Buchthal [30]

abnormal when the mean values are outside the normal range or when more than 10 % MUAPs have measurements outside the individual normal limits (Table 9.3). Those investigators found a similar diagnostic sensitivity using either criterion of abnormality. Furthermore, they did not find a significant change in MUAP duration with age for subjects less than 60 years old [17, 31, 32].

The advantage of outlier-based analysis is that the third abnormal MUAP (i.e., >10 % when the sample size is 20 MUAPs) may occur within the first 2 or 3 min of the examination. At this time, the study has already reached diagnostic significance, and one may terminate the MUAP analysis in that muscle. However, a large sample of MUAPs must be obtained if the goal of the examination is to assess disease progression. The outlier approach, although new to MUAP analysis, is used quite successfully in single-fiber EMG and macro EMG [5, 33].

Findings in Normal Subjects

In normal subjects, large muscles tend to have a long-duration MUAPs (Tables 9.1 and 9.3). MUAP duration increases with age after the sixth decade. MUAP amplitude is often high in small distal muscles (Tables 9.2 and 9.3). This variation reflects the differences in the MU size and architecture among normal muscles. One must recognize this difference (Tables 9.1 and 9.3) not only in quantitative analysis but also in the routine needle EMG examination.

The reference values depend upon the technique of recording. Using an amplitude trigger delay line always selects the highest amplitude MUAP in the signal (Fig. 9.3). Hence, the mean MUAP amplitude values will be higher compared to other techniques [18, 24]. The amplitude is higher when the examiner makes a conscious effort to reduce the MUAP rise time to less than 500 μs. Slight needle movements can significantly affect the MUAP amplitude and rise time;

Table 9.3 Reference values for individual and mean values of MUAP features are tabulated. These investigators did not find age-dependent variation in normal subjects until the sixth decade of age

	Amplitude (μV)			Duration (ms)			Thickness		
Muscle	Mean ± SD	Minimum	Maximum	Mean ± SD	Minimum	Maximum	Mean ± SD	Minimum	Maximum
Deltoid	550 ± 110	162	1,531	10.4 ± 1.3	4.2	18.4	1.56 ± 0.22	0.65	2.94

Data from Bischoff et al. [17]

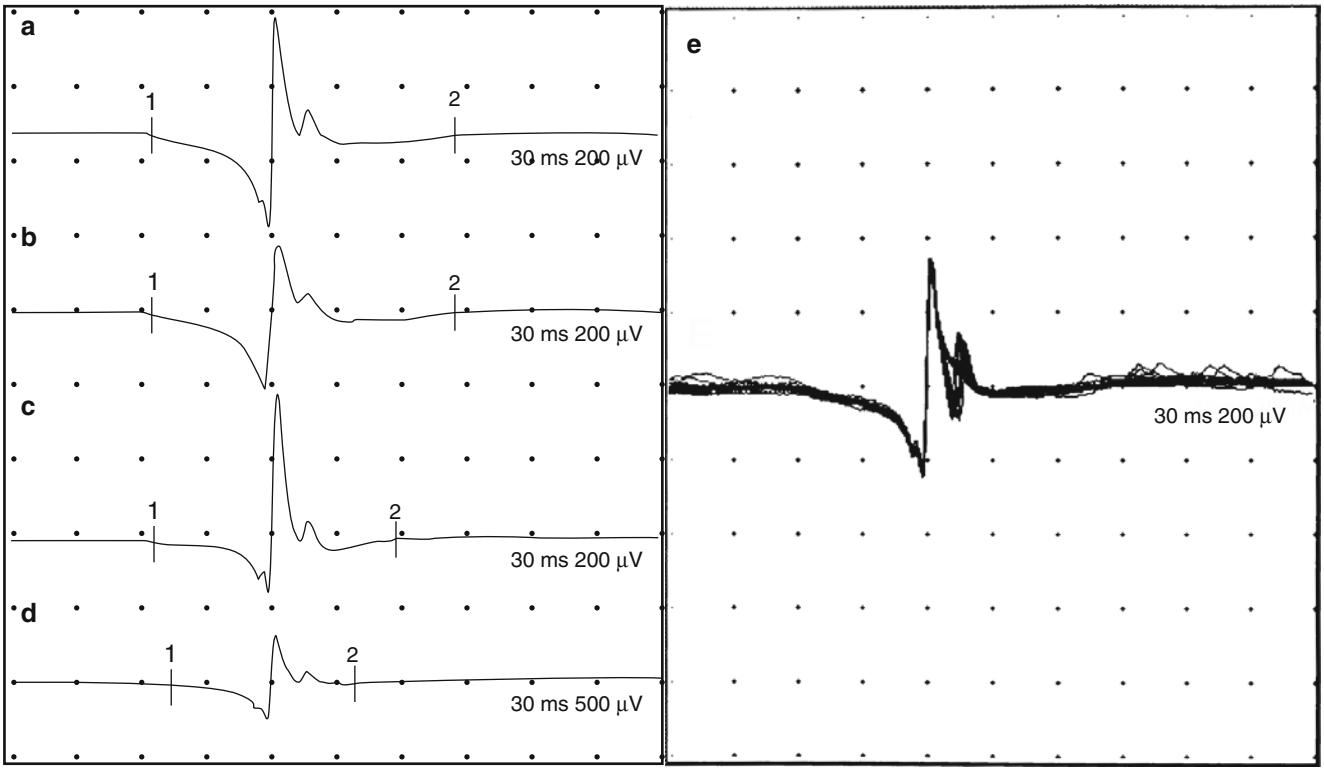

Fig. 9.7 The change in MUAP waveform and its assessment due to technical factors is illustrated. The *vertical tick marks* labeled *1* and *2* represent the onset and end of the MUAP by subjective assessment. See text for details

however, the duration remains relatively constant [34]. Hence, the MUAP duration is considered a "robust" MUAP feature. The duration values also appear quite similar among different methods. This results from two factors. The duration is far less sensitive to electrode position within the MU compared to the amplitude. Secondly, many algorithms developed for duration measurements were deliberately tuned to match measurements by Buchthal and coworkers [30].

MUAP measurements are also affected by technical factors (Fig. 9.7). Averaging unstable MUAPs will reduce the amplitude of different peaks. In Fig. 9.7e, the individual MUAP discharges demonstrate jitter and blocking of one muscle fiber in the MU. On averaging the discharges, that component appears with reduced amplitude (Fig. 9.7a). Reducing the high-frequency setting (e.g., 10,000 Hz in (a) to 2,000 Hz in (b)) decreases the MUAP amplitude and increases its rise time. The smaller peaks are attenuated. Increasing the low-frequency setting (e.g., 3 Hz in (a) to 100 Hz in (c)) reduces the MUAP duration. Subjective duration assessment depends upon the display setting. Reducing the display gain (e.g., changing from 200 μV/div in (a) to 500 μV/div in (d)) will give the perception of a short duration to the same MUAP. Automated measurements may be also incorrect due to poor signal-to-noise ratio.

Monopolar needle EMG usually gives MUAPs with higher amplitude and a greater incidence of polyphasic

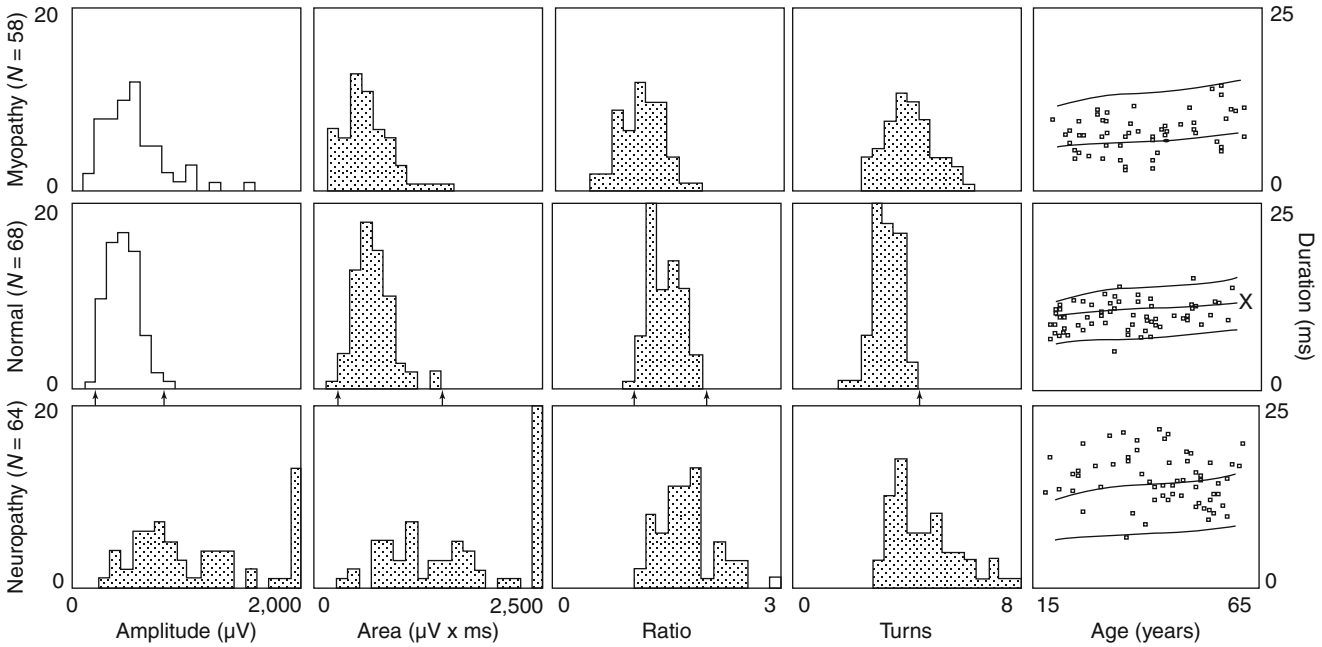

Fig. 9.8 Amplitude triggered delay line and averager was used to record MUAPs from the biceps muscle. The mean values of amplitude, area, area/amplitude ratio, turns, and duration of simple MUAPs were computed. The histogram of these measurements in normal subjects is shown in the *middle row*. The *arrows* indicate the upper and lower normal limits. The duration values are plotted against the patient's age. The *horizontal line* indicated by *X* depicts the slight trend in the mean MUAP duration with age. The other *two horizontal lines* indicate upper and lower normal limits. These limits were used to assess MUAP recordings from the biceps muscle of patients with myopathy (*top row*) and neuropathy (*bottom row*). Observe the typical patterns and also some less recognized abnormalities. See text for details (Reproduced with permission from Stewart et al. [24])

waveforms [35–38]. In our hands, monopolar and concentric needle MUAPs have similar duration. However, some investigators found a longer duration for monopolar recordings [35]. If the temperature is reduced, the MUAP duration and amplitude increase.

Findings in Patients with Nerve and Muscle Diseases

As described earlier, the absolute values of the MUAP measurements vary considerably among different laboratories. However, the pattern of abnormalities on MUAP analysis is quite similar for different research groups [13, 24, 39–42]. In patients with neuropathy, the mean amplitude, mean duration, percentage of polyphasic MUAPs, and incidence of unstable MUAPs are increased. In contrast, the MUAP mean duration and amplitude are reduced in patients with myopathy. The incidence of polyphasic MUAPs is also increased, and unstable MUAPs may be seen. In patients with neuromuscular junction diseases, the MUAPs show prominent instability which is the sine qua non for such diseases as myasthenia gravis. In severely affected muscles of patients with neuromuscular junction diseases, the MUAP duration may be reduced. These are the classical patterns of MUAP abnormality that are used routinely in the day-to-day needle examination. QA also reveals many other patterns and combinations of abnormalities that do not fit the above criteria. With QA, subtle changes in the MU architecture and MUAP waveforms may be seen that are often not appreciated.

- The MUAP duration is increased in patients with neuropathy and decreased in patients with myopathy. Because of this contrasting pattern, this feature is useful for differential diagnosis. Changes in duration are considered "specific" to the underlying disease process. In patients with myopathy, one may record complex long-duration MUAPs with linked potentials and also short-duration simple MUAPs in the same muscle. Together, they may give a normal mean MUAP duration. In some cases, one may incorrectly infer a neurogenic disease process based on the complex and long-duration MUAP. Therefore, we exclude the polyphasic MUAPs from the calculations of mean MUAP duration. This increases the diagnostic sensitivity of the technique [42, 43, 43a, 44, 45].
- Increased MUAP amplitude is usually associated with a neurogenic disease process. QA reveals that some patients with myopathy also have a mild increase in amplitude. In our studies [24, 42], the mean MUAP amplitude in myopathy was never greater than twice the upper limit in our normal subjects (Fig. 9.8). Since a mild increase is seen in both patient groups (i.e., myopathy and neuropathy), this finding is considered a nonspecific abnormality. When

amplitude is significantly increased (more than twice the upper normal limit), we consider this as a specific abnormality indicating a neurogenic disease process.

- When the amplitude is increased in patients with myopathy, the waveform appears "thin" by visual assessment. This gives a reduced area/amplitude ratio (Fig. 9.8). This observation is a specific abnormality for myopathy, since the ratio is normal or increased in patients with neuropathy. Thus, the MUAP "thickness" is useful for differential diagnosis when the MUAP amplitude is mildly increased (Fig. 9.8) [26].
- The incidence of polyphasic MUAPs is increased in all patient groups. In myopathic processes, this is primarily due to increased variation in MF diameter [13]. In neurogenic processes, this is considered to be a result of collateral reinnervation of denervated MFs by surviving motor neurons. Therefore, this is a nonspecific finding on MUAP analysis.
- Although MUAP duration differentiates between myopathic and neurogenic disease processes, it is not a diagnostically sensitive feature. When the muscle is minimally involved based on muscle strength assessment, duration values may be normal. In those patients, one may find abnormalities in other MUAP features. In our experience, an increased incidence of polyphasic MUAPs is the earliest abnormality by QA [24, 42]. When the muscle is moderately or severely affected, the duration is likely to be abnormal. This implies that we should sample moderately weak muscles and select muscles that demonstrate MUAP duration abnormalities for biopsy studies.
- It is not uncommon to record high-amplitude and long-duration MUAPs in muscles that are apparently not weak or involved in the disease process. This reflects an earlier insult to the MUs and a full recovery by collateral reinnervation. During reinnervation, the newly formed end plates are immature and demonstrate poor efficacy of neuromuscular transmission which result in unstable MUAP waveforms. When the end plates mature, the MUAPs are stable. Thus, MUAP stability is useful to assess whether reinnervation is complete and makes a distinction between an acute and chronic disease process [5, 29]. Theoretically degenerating end plates would also have inefficient neuromuscular transmission and therefore unstable MUAPs. However, degeneration takes only a few days compared to several weeks for reinnervation. Hence, unstable MUAPs are attributed mainly to ongoing reinnervation even in progressive motor neuron diseases.
- In a slow progressive neurogenic disease, reinnervation may adequately compensate for MU loss. Previous studies suggested that in a slow chronic neurogenic process, approximately 1/3–1/2 of motor neurons (and therefore MUs) may be lost before clinical weakness is manifest. In such instances, high-amplitude MUAPs are readily noted. Amplitude measurements are easy to perform even when the signals are displayed in a free-running sweep. This is the parameter of choice to investigate chronic neurogenic changes in the muscle.
- The aforementioned patterns of abnormalities are seen in muscles with minimal to moderate weakness. In severely weak muscles, one may observe atypical MUAP waveforms. Following a severe trauma such as when all motor axons are severed from the nerve trunk, all MUs in the muscle may be lost. As the nerve regenerates and forms new "nascent" MUs (as opposed to collateral sprouting when axonal loss within a muscle is patchy), the MU size will be initially small. Their MUAPs will have low amplitude, reduced duration, and a polyphasic waveform. In many respects, they appear similar to the MUAPs seen in patients with myopathy. Therefore, we recommend that one should describe and interpret the MUAP waveform instead of characterizing them as "myopathic" or "neurogenic." While the reinnervation continues and the MUs are rebuilt, the MUAP waveform is unstable. This potentially implies a good prognosis, i.e., ongoing reinnervation. In contrast, stable MUAPs indicate that MU remodeling, and hence reinnervation, is complete, although the degree of clinical recovery may be variable.

Based on the above considerations, we recommend that one should describe and interpret the MUAP waveform rather than characterizing them as "myopathic" or "neurogenic." To apply labels to MUAPs that imply an etiology or causation is to oversimplify MUAP analysis and in turn potentially mislead the referring physician in their evaluation of the patient.

Computer simulations indicate that the CN MUAP amplitude depends upon the number and size of fibers within 500 μm of the recording tip [46]. The MUAP amplitude is greatly affected by the size and distance to the closest MF. Therefore, slight changes in the needle position can significantly affect MUAP amplitude. This explains the great variability of MUAP amplitude among different recording techniques. Furthermore, a single MF close to the recording tip may result in normal MUAP amplitude.

The number of phases and turns depends upon the temporal dispersion of the APs of MFs within one mm of the recording electrode. The dispersion is affected by action potential propagation in terminal nerve branches and in the MFs as described earlier (Fig. 9.2). When there is an increased number of MFs from a single MU in this area, we have a better chance of observing their temporal dispersion. However, it is quite possible that the potentials will summate to produce large amplitude simple MUAPs. In contrast, if there is a severe loss of MFs, this area may contain just one fiber that gives a simple small waveform.

MUAP duration depends on MFs that are up to 2.5 mm from the recording tip. This represents a significant portion of the MU territory. In a large muscle, such as the biceps

Table 9.4 The MUAP abnormalities are related to underlying disease processes

MUAP abnormality	Myopathy	Neuropathy
Increased amplitude	MF hypertrophy	MF hypertrophy
	Slight MF grouping due to reinnervation, regeneration, and split MF	MF grouping due to reinnervation
	Synchronous MU firing (tremor)	Synchronous MU firing (tremor)
		Synchronous MU firing due to ephaptic transmission in nerves
Reduced amplitude	Loss of MF	Atrophy of MF
	Atrophy of MF	Unstable waveform
	Fibrotic tissue attenuates potential	Fibrotic tissue attenuating potential
Increased phases and turns	Increased temporal dispersion due to	Increased temporal dispersion due to
	Slow conduction in atrophic MF	Slow conduction in new collateral nerve branches
	Fast conduction hypertrophic MF	Slow conduction in newly reinnervated MF that are atrophic
	Increased variability of MF diameter (atrophy and hypertrophy)	Fast conduction in hypertrophic MF
	Synchronous MU firing (tremor)	Synchronous firing of MUs (tremor)
		Synchronous MU firing due to ephaptic transmission in nerves
Increased duration	Increased temporal dispersion (see above) giving long-duration polyphasic waveform	Increased number of fibers in MU after reinnervation
	Synchronous MU firing (tremor)	Increased temporal dispersion (see above)
		Synchronous MU firing (tremor)
Reduced MUAP duration	Loss of MF	Newly formed MUs
	MF atrophy	MF atrophy
		Poor neuromuscular transmission fails to elicit MF AP
Unstable MUAPs	Formation of new end plates after necrosis	Formation of new end plates during reinnervation
	Changes in MF AP propagation velocity during successive MUAP discharges (velocity recovery function)	Abnormal AP propagation in terminal axon branches
		Velocity recovery function

When MUs fire synchronously due to tremor, the resulting waveforms appear to have long-duration and complex waveform. A closer inspection may reveal that the waveform does not replicate and hence does not qualify as a MUAP

brachii which has a rough MU area of 5–10 mm in diameter, MUAP duration reflects about 25–50 % of MU territory. Hence, change in the MUAP duration reflects changes in the MU size. When the temporal dispersion is significantly increased, one may record long-duration MUAPs with linked (satellite) potentials. In such MUAP, a single MF AP may significantly change the duration, which does not reflect the actual MU size (Fig. 9.5) [47]. Therefore, one is justified to exclude these from duration analysis to increase the diagnostic sensitivity of the technique [42, 45]. MUAP duration is relatively constant when the needle electrode position is changed slightly within the MU territory that occurs naturally in MUAP recordings. This makes the MUAP duration a robust feature for assessment.

Based on computer simulations [46, 47], the relationship between disease processes and MUAP abnormalities is summarized in Table 9.4.

The above relationship also applies to monopolar needle electrodes. Note that the spike component of the CN MUAP is generated by only those fibers that are in front of the needle tip. Hence, the recording area is semicircular. In contrast to the concentric needle, the monopolar electrode has a spherical uptake area for the amplitude and spike component of the MUAP (Fig. 9.9) [48, 49]. The uptake area for the duration is circular for both electrodes [50], which explains similar values of MUAP duration for these electrodes.

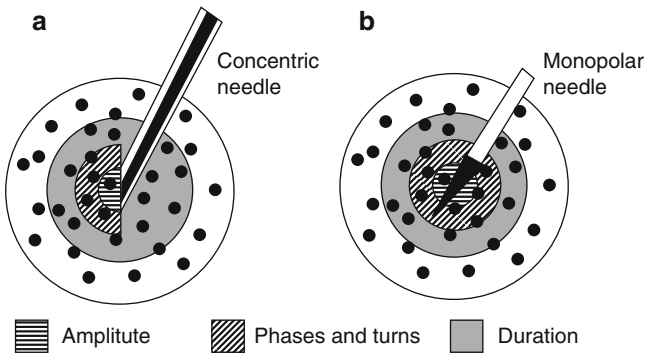

Fig. 9.9 The distribution of muscle fibers in the cross section of the MU is shown schematically. In (**a**), the *semicircles* around the concentric needle tip enclose fibers that define the MUAP amplitude and spike component. The uptake area for duration is *circular*. These relationships are based on computer simulations. The uptake area for monopolar MUAP features is shown in (**b**)

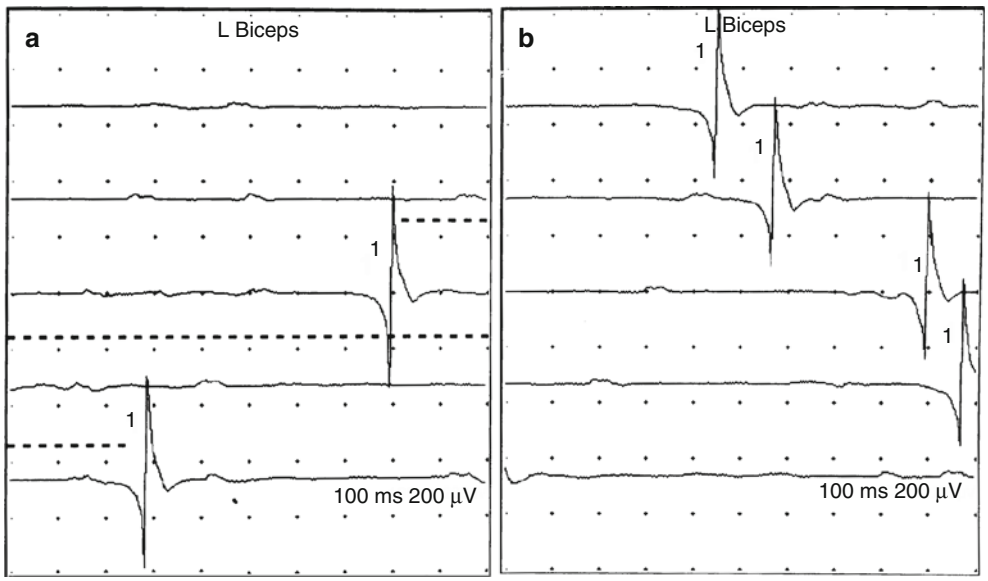

Fig. 9.10 CNEMG signals were recorded from the biceps muscle of a normal subject. Five consecutive sweeps of 100 ms duration are shown. The traces are drawn from *top* to *bottom*. In (**a**), there is no EMG activity in the first three traces. As the subject gradually increased the force, recruitment of a MU is inferred from its MUAP discharges. The inter-discharge interval (IDI, *dotted line*) is 150 ms which corresponds to an onset frequency of 6 Hz. In (**b**), the MU firing rate is increased due to further increase in force. The 500 ms epoch contains four MUAP discharges. Multiplying by 2, we estimate the firing rate of 8 Hz. The continuation of this recording is shown in Fig. 9.11

MU Firing Rate Analysis

How to Measure the Firing Rate

The MU firing rate is equal to the number of MU discharges in a 1 s time interval and is measured in Hertz (Hz). The first step in MU firing rate analysis is to identify a MUAP and its discharges. Thus, all techniques of MUAP waveform analysis can be adapted to firing rate analysis. In the manual method, a 500 ms epoch is "frozen" on the display screen (Figs. 9.3, 9.10, and 9.11). Such epochs usually contain adequate MUAP discharges to identify and validate the MUAP waveform. The number of discharges of a MUAP in the epoch is multiplied by two to obtain the MU discharges in 1 s epoch, i.e., the MU firing rate (Fig. 9.10).

The time interval between successive MUAP discharges is called the *inter-discharge interval (IDI)*. The IDI is measured in milliseconds (ms). It is inversely related to the firing rate by the following formula

$$\text{Firing rate (Hz)} = \frac{1{,}000}{\text{IDI}}, \text{ OR } \quad \text{IDI (ms)} = \frac{1{,}000}{\text{Firing rate}}$$

When the sweep duration is 100 ms and successive sweeps are shown in a raster fashion, MU firing rate can be estimated by very simple rules. If the MU firing rate is 10 Hz, the IDI will be 100 ms which equals the duration of one sweep. The MUAP will appear at roughly the same location on successive sweeps (MUP #2 in Fig. 9.11a). If the rate is less than 10 Hz, the IDI is more than 100 ms. The discharges are separated by more than one sweep. The successive discharges will appear to shift to the right in the recording (first four traces in Fig. 9.10b). On some sweeps, the MUAP may not be seen at all (last trace in Fig. 9.10b). Conversely, when the rate exceeds 10 Hz, the MUAP will appear to shift left (Fig. 9.11, MUAP #1). On some occasions, the MUAP discharge is seen twice on a sweep (Fourth trace in Fig. 9.11b). When the firing rate is 20+ Hz or more, each sweep will contain two MUAP discharges. At 30+ Hz, each sweep will contain 3 MUAP discharges and so on.

Manual analysis of MU firing rate is quite easy when the signal contains discharges of just one MU (Fig. 9.10b). When more MUs are discharging, their MUAPs superimpose. This makes MUAP identification and firing rate analysis tedious and time consuming (Fig. 9.3b). Automated methods can analyze an epoch that contains discharges of several MUAPs in just a few seconds [18, 19]. These methods use the IDI values to compute the MU firing rate. Unfortunately, the algorithm may fail to resolve the MUAP superimpositions. When a MUAP discharges are missed, the algorithm will calculate IDI values that are roughly integer multiples (e.g., twice, three times) of the true IDI value (Fig. 9.4). This will increase the mean IPI and artifactually yield lower rates. The median value is less affected by the spuriously high or low values. Hence, the median IDI value may be optimal in aforementioned formula to compute firing rate.

Recording Technique

The MU firing rate varies with the force of contraction. Even when the subject maintains a relatively constant effort, the IDI changes slightly from one discharge to another. Therefore, different protocols have been developed to study the MU firing rate that gives different physiologic information [1, 51–53].

In the traditional methods of MUAP analysis, the subject exerts a relatively constant effort. The average firing rate of each MU during the analysis epoch is measured. The

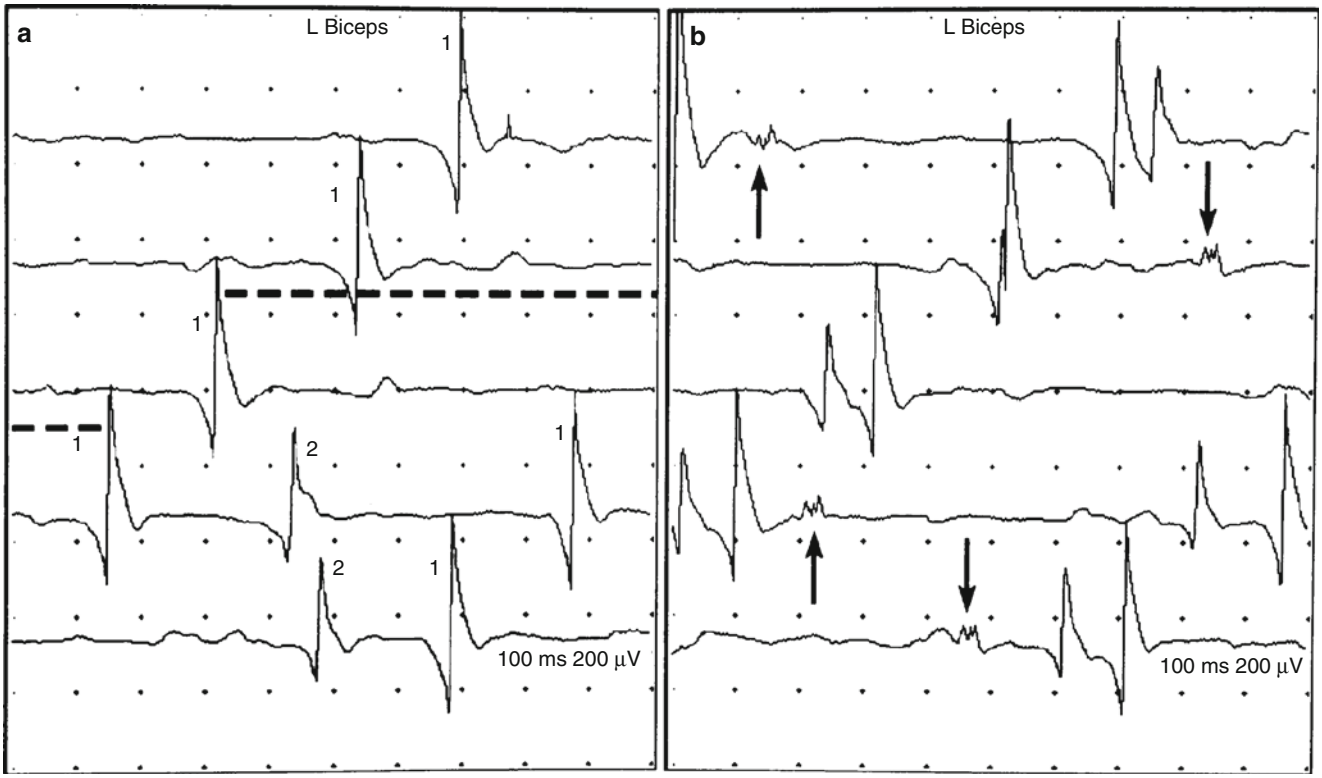

Fig. 9.11 This is a continuation of the recording in Fig. 9.10. When the force was further increased, the firing rate of the first recruited MU (#1) increased, and a new MU (#2) was recruited. This is detected from its MUP discharges in the fourth and fifth trace (**a**). The two discharges of MU #2 are seen roughly at the location on the sweep, which gives it an onset frequency of roughly 10 Hz. The *dotted line* indicates the recruitment interval of roughly 80 ms. This corresponds to a recruitment frequency of 12.5 Hz. In (**b**), the force of contraction is increased further. Careful examination reveals discharges of three MUAPs in this recording. The third MUAP (indicated by *arrows*) has low amplitude and serrated waveform. The MUs are discharging at 12 Hz or less. This gives a recruitment ratio of 3 for this recording. Waveforms in (**b**) appear polyphasic with long duration due to superimposition of the MUAPs

recruitment ratio is obtained by dividing the rate of the fastest discharging MU by the number of MUs [1].

The dynamic change in MU firing rate is investigated when the subject gradually increases the force of contraction. At rest, the EMG contains no MU activity. When the force is gradually increased, one MU will be recruited and its discharges recorded by the needle electrode. The MU firing rate when it begins to discharge is called its *onset frequency* (Fig. 9.10a). When the force is further increased, the MU firing rates increase (Fig. 9.10b), and eventually, a second MU will be recruited (Fig. 9.11a). The EMG will contain discharges of two MUAPs. The firing rate of the first MU just before the recruitment of the second MU is called the *recruitment frequency* (Fig. 9.11a) [53].

The instantaneous variability of a single MU discharge rate may be calculated from the IDI values. In a simple method, the mean and standard deviation values of firing rate are used to compute the coefficient of variation. In a more elegant method [54], successive IDIs are correlated (a data point (X, Y) is constructed where X and Y are successive IDI values, and a plot of these (X, Y) is constructed to study the correlation between Y and X).

The changes in the MU firing rate of all discharging MUs are investigated by a technique called *precision decomposition* [55, 56]. A special electrode is used to record three-channel EMG activity when the subject gradually increases force to moderate levels and then relaxes the tested muscle. Almost every discharge of several different MUs is identified. The instantaneous firing rate and the force of contraction are plotted against time to study their relationship (Fig. 9.12).

Findings in Normal Subjects

At minimal effort, the average MU firing rate varies among muscles. The MU onset frequency is usually 6–10 Hz (Fig. 9.10). The recruitment frequency varies significantly among different muscles [53] (Table 9.5). It probably reflects the difference in the force generation mechanism among the muscles. Muscles requiring for fine control (e.g., facial muscles) use frequency modulation to adjust force. Hence, they often have higher range of discharge frequency. In contrast, the larger muscles used for forceful activity rely on recruitment of motor units. Their motor units have smaller

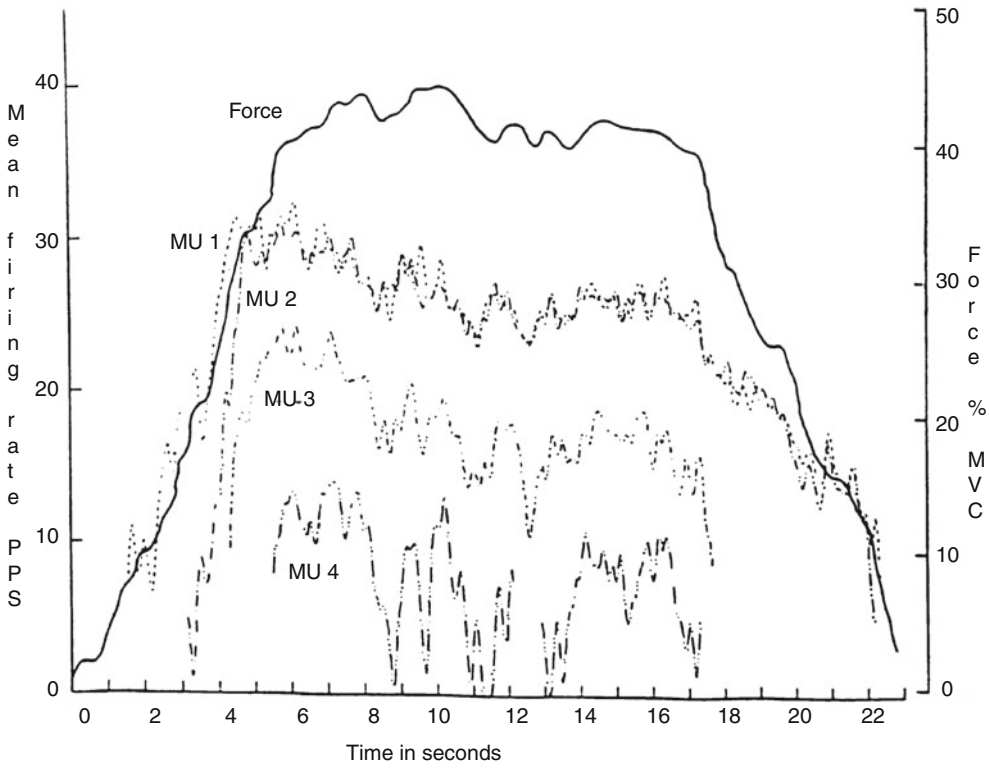

Fig. 9.12 Results of precision decomposition from the first dorsal interosseus muscle of a normal subject are shown. The time is indicated along *X* axis. The *Y* axis shows change in the force of contraction and firing rate of individual MUs. Observe the orderly recruitment of MU. When the force is reduced, the MUs are released, i.e., stop discharging, in reversed order of recruitment. The last recruited MU is released first. The first recruited MU is last to stop firing. The firing rate of these normal MUs at high force levels is 25+ Hz which is well above the commonly observed rate of 10–15 Hz. Finally, the rate changes in parallel for all MUs (Reproduced with permission Stashuk and Deluca [56])

Table 9.5 Onset and recruitment interval/frequency in normal muscle

	Onset		Recruitment	
Muscle	Interval (ms) mean (standard deviation)	Frequency (Hz)	Interval (ms) mean (standard deviation)	Frequency (Hz)
Frontalis	102 (29)	9.8	46 (16)	21.7
Orbicularis oris	79 (19)	12.7	34 (10)	29.4
Deltoid	116 (23)	8.6	84 (16)	11.9
Biceps	124 (21)	8.1	86 (14)	11.6
Pronator teres	132 (38)	7.6	88 (19)	11.4
First dorsal interosseous	142 (39)	7.0	98 (21)	10.2
Multifidus	152 (33)	6.6	102 (20)	9.8
Vastus lateralis	126 (30)	7.9	88 (18)	11.4
Tibialis anterior	124 (26)	8.1	90 (13)	11.1

Table constructed using data from Petajan and Phillips [51]. The rates are computed using the mean interval value

range of firing rate. The recruitment ratio is less than 5 and corresponds to 3 MUs discharging at less than 15 Hz (Fig. 9.11b) [1].

In normal muscles, successive IDIs exhibit a negative correlation [54]. It corresponds to the subjective observation that a long IDI is followed by a short IDI and vice versa. We can often hear this pattern when double discharges occur in MUAP recordings. Precision decomposition demonstrates MU firing at 25+ Hz in normal muscles (Fig. 9.12). Although individual MU firing rates differ, all MUs change their rate in parallel. In other words, when one MU increases the firing rate, other recruited MUs also discharge faster [56]. This is called the *central drive.*

Findings in Patients with Nerve and Muscle Diseases

In patients with neuropathy (Fig. 9.13), routine MUAP analysis at minimal effort shows increased MU firing rate. Recruitment frequency is increased. This corresponds to the usual visual assessment of single fast-firing MU (Fig. 9.13a). The recruitment ratio is increased and corresponds to two MUs firing at more than 15 Hz (Fig. 9.13b). These observations are described as *reduced recruitment* on the routine EMG. The term "reduced" expresses the lack of other MU activity in the recording. In patients with upper motor neuron lesions, MU firing rate is reduced [20]. The IDI shows

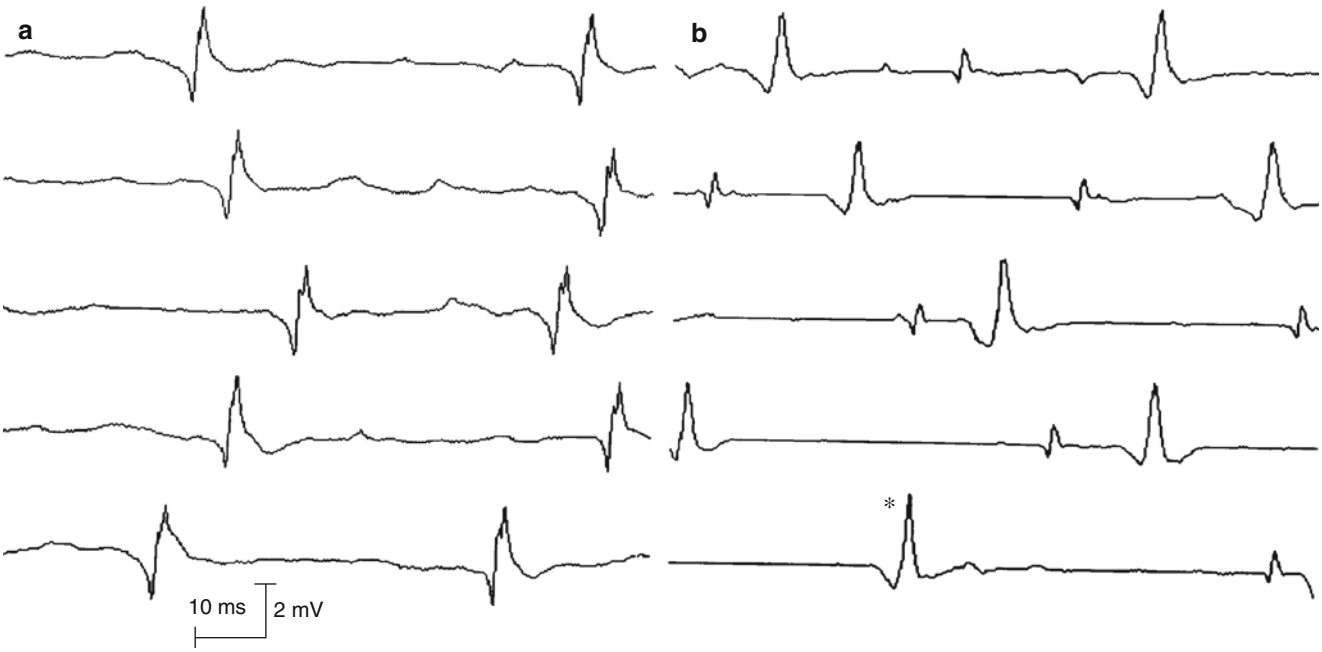

Fig. 9.13 CNEMG recordings from the biceps muscle of a patient with neuropathy are shown in raster mode. Traces are drawn from *top* to *bottom*. In (**a**), two discharges of a MUAP are seen on each sweep. This gives it a firing rate of 20+ Hz. There is no other MU activity seen. This indicates increased recruitment frequency. In (**b**), discharges of two MUs are seen. The eight discharges of each MU in a half-second epoch give them a firing rate of more than 15 Hz. This corresponds to increased recruitment ratio. The waveform indicated by * represents a superimposition of both MUAPs

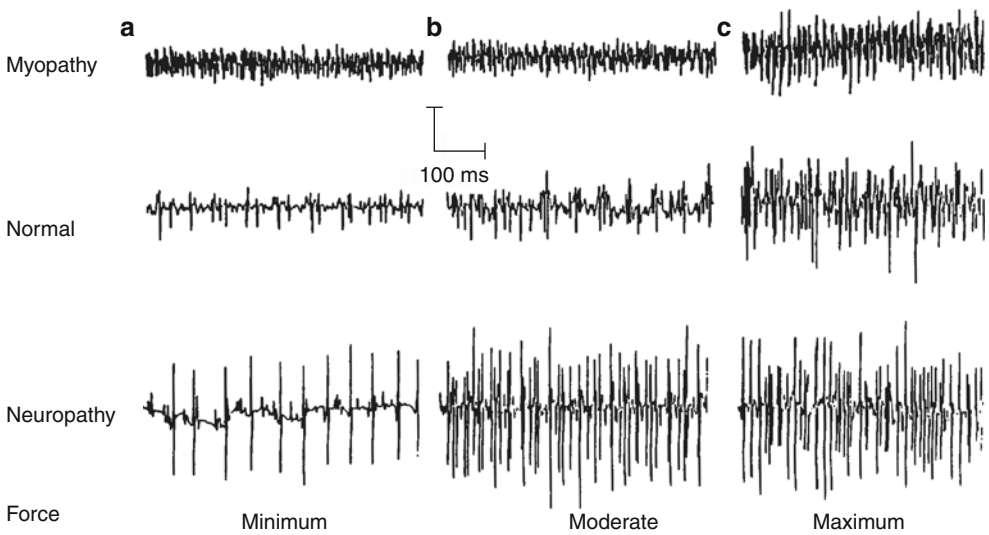

Fig. 9.14 EMG IP was recorded at minimal (**a**), moderate (**b**), and maximal (**c**) effort of the biceps muscle in a patient with myopathy (*top row*), a normal subject (*middle*), and a patient with neuropathy (*bottom*). Observe the increased recruitment at minimal effort in the patient with myopathy. At maximal effort, the pattern is full with reduced amplitude. In neuropathy, the amplitude is increased with reduced number of spikes (Reproduced with permission from Nandedkar [4])

considerable variability from one discharge to another. The plot of sequential IDIs may not show a negative correlation.

In patients with myopathy, routine MUAP analysis also shows a slightly higher MU firing rate. Several MUs discharge even at minimal effort (Fig. 9.14). This offsets the higher firing rate and may give a reduced recruitment ratio. This observation is described as *increased* or *early* recruitment of MUs. These terms refer to the greater than expected number of discharging MUs for force of contraction [3]. Recruitment frequency may be increased in some recordings [43a].

Disease Processes and Firing Rate

The technique of precision decomposition is relatively new. However, it should give valuable information about motor control in neuromuscular diseases. In normal subjects, one can visually assess the MU firing rate only at a minimal force of contraction. Precision decomposition reveals that normal MUs do discharge at rates of 25+ Hz at higher forces of contraction (Fig. 9.12). Therefore, the high MU firing rate per se seen in patients with neuropathy is not an abnormality of

MU discharge frequency. Rather, it reflects the loss of MUs and allows us to view the surviving MUs discharging at a higher rate. The greater the loss of MUs, the easier it will be to recognize fast-firing MUs. Reduced MU firing rate and higher variability are characteristic of an upper motor neuron lesion.

Recruitment of a MU is easily recognized when the MUAP has a high-amplitude spike component. As discussed earlier, this is defined by the few muscle fibers closest to the recording electrode. If there is a significant loss of MFs, the MUAP spike component will have a lower amplitude. We may then fail to fully recognize the MU recruitment (Fig. 9.11b). This results in higher values of recruitment frequency in some recordings of patients with myopathy [43a, 53].

Assessment Strategies

The MU firing rate analysis requires identification of individual MUAP discharges. When the signal contains discharges of three or more MUAPs, this process can be time consuming and laborious. Hence, in our opinion, firing rate analysis is not quite suitable for patients with myopathy. In patients with neuropathy, loss of MUs makes it easier to assess the MU firing rate. Increased recruitment frequency is easily recognized when a single MU discharges at 20+ Hz. This results in two discharges of the same MUAP on every sweep of 100 ms duration (Fig. 9.13a). Recruitment ratio abnormalities must be assessed with caution. To show that a muscle is normal, one must demonstrate three MUs in the recording. (In a normal muscle, one can easily record two MUs firing at 12 Hz which would correspond to an increased recruitment ratio.) In contrast, to demonstrate increased ratio, it is adequate to show one or two MUs firing at more than 15 Hz (Fig. 9.11b).

Variability of firing rate is best assessed by the sound of the EMG signal when the patient tries to maintain a steady force of contraction.

MUAP Assessment at High Force: Analysis of Interference Pattern

At minimal force of contraction, the EMG may contain discharges of a single MU. The MUAP waveform and its firing rate can be easily assessed. As the force of contraction is increased, the firing rates of the MUs also increase, and new MUs are recruited. At moderate to high activation, the EMG becomes a complex signal in which individual MUAPs can no longer be readily recognized. Therefore, the MUs recruited at higher force cannot be easily studied using the earlier described technique. To reflect the summation and cancellation of individual MUAP waveforms (i.e., phase interaction), this signal is called the *interference pattern (IP)*. The term "interference" usually refers to undesired signals derived from external sources, e.g., the main power supply. However, in this context of EMG assessment, the term is well recognized. The IP signal contains information about the number of MUs, their firing rate, and their waveform characteristics. These characteristics are assessed indirectly from measurements of the IP signal. Because of the complexity of the signal, the manual methods of analysis are rather simplistic. All quantitative methods require automation by computers. These techniques also use different features of the signal for assessment. These are discussed individually.

Subjective Assessment at Maximal Effort

Buchthal and coworkers proposed a simple technique to assess IP signals recorded at maximal effort using two features: *fullness* and *envelope amplitude* (Fig. 9.14) [30, 40]. In a full pattern, the signal baseline is completely obscured by MUAPs. In a discrete pattern, one can recognize individual MUAPs even at maximal effort. The signal usually contains discharges of just one or two MUs. To measure amplitude, one draws an imaginary line connecting together the positive peaks and a similar line connecting the negative peaks. The amplitude difference between these lines is the envelope amplitude. Solitary peaks are excluded from envelope measurements. The criteria for abnormality are as follows (Fig. 9.14):

- If the IP is full in a weak or wasted muscle and the envelope amplitude is reduced, the abnormalities are consistent with myopathy.
- A discrete pattern with increased amplitude is consistent with a neurogenic disease process.

The normal envelope amplitude varies among different muscles but is usually greater than 1.5–2 mV. This assessment is subjective and hence numerical measurements of the same signal made by different operators may differ slightly. Furthermore, the criteria should not be used if the patient fails to exert maximal force (e.g., due to pain and discomfort, somatoform disorders).

Frequency Domain Measurements

The sound of EMG signals has a high pitch in patients with myopathy. Walton demonstrated this shift using an audio spectrometer [57]. With access to computers, spectrum analysis is relatively easy [58]. The basic concept is as follows: Any signal can be represented as a sum of harmonically related sinusoids of different amplitudes and phases. The power in each sinusoid is proportional to the square of its amplitude. A plot of power versus the frequency of the

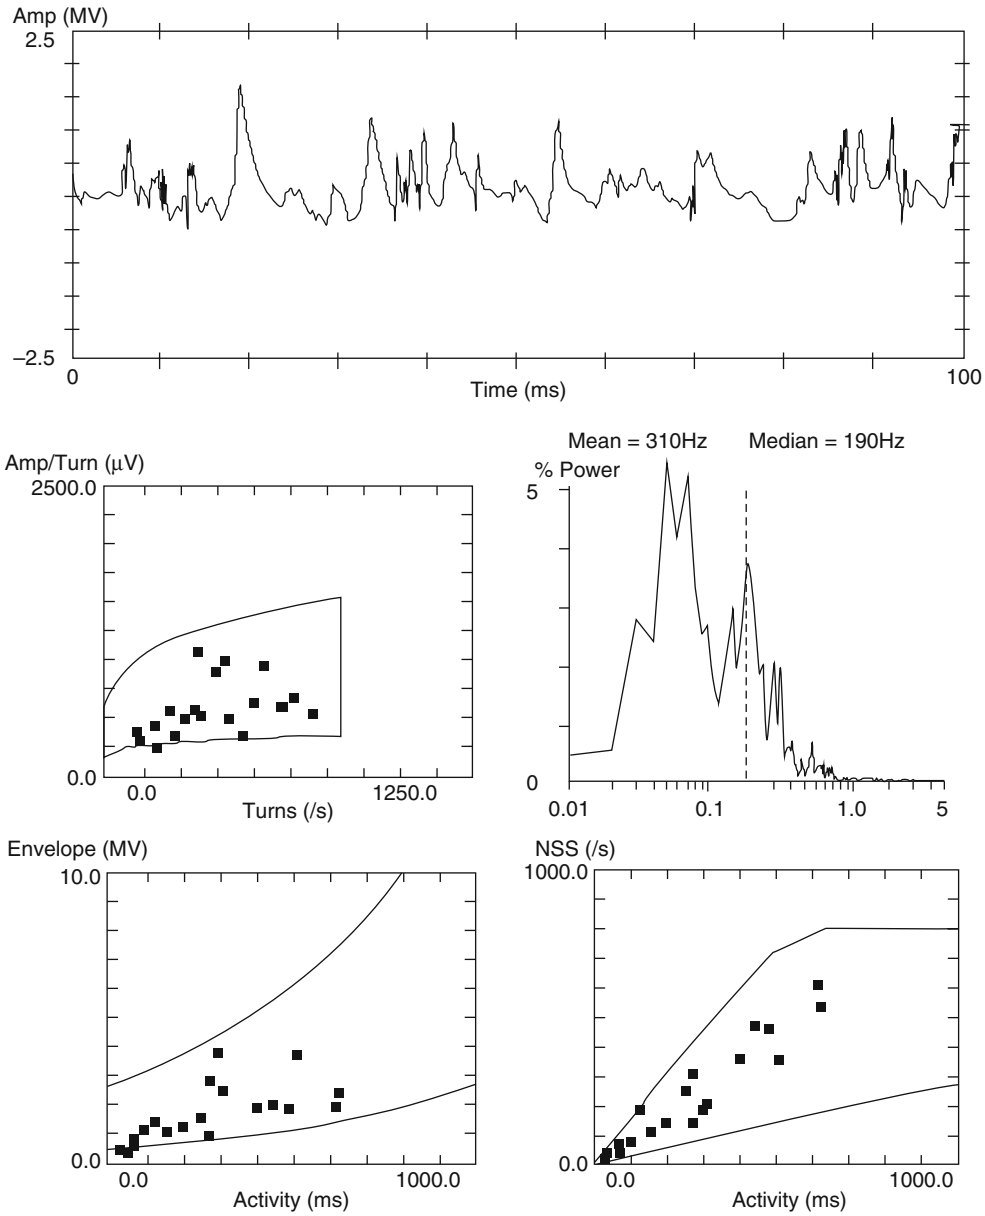

Fig. 9.15 Different techniques of IP analysis are demonstrated from IP recordings in a normal subject. An EMG signal is shown at the *top*. The power spectrum of this signal is shown below to its *right*. The results of "turns and amplitude" analysis are shown to *left* in the *middle*. The *bottom* two plots describe findings on EQUIP analysis. These three plots contain more than 90 % of the data points in the tested muscle. See text for details (Reproduced with permission from Sanders et al. [61])

sinusoid is called the power spectrum (Fig. 9.15). To accommodate a wide range of frequencies and power, logarithmic scales may be used. The calculation of the power spectrum is often facilitated by the fast Fourier transform (FFT). The spectrum is quantified by the sum of power in all sinusoids. This is also called the *total power*. The frequency that contains 50 % of the power below it and 50 % power above it is called the *median frequency*. The *mean frequency* is computed by summating the product of frequency and power and then dividing the sum by the total power. A shift to high frequencies will give higher numerical values of the mean and median frequencies. Changes in signal amplitude will affect the total power.

Power spectrum analysis offers a very high-resolution technique to measure energy in narrow bands of frequency. This is often not necessary. Therefore, one may use broadband filters to measure power in a few frequency ranges, e.g., low, mid, and high. The power in these bands is normalized to measurements in normal subjects. Therefore, in a normal muscle, the resulting values are close to unity. If the spectrum shifts to right, the normalized power will be greater than one for the high-frequency band and less than one for the low-frequency band. Opposite pattern will result when the spectrum shifts to low frequency [59].

In patients with neuropathy, the power spectrum shifts to low frequencies giving a low pitch sound. The mean and median frequencies are reduced (Fig. 9.16). Conversely in patients with myopathy, the spectrum shifts to high frequency. The mean and median frequencies are increased

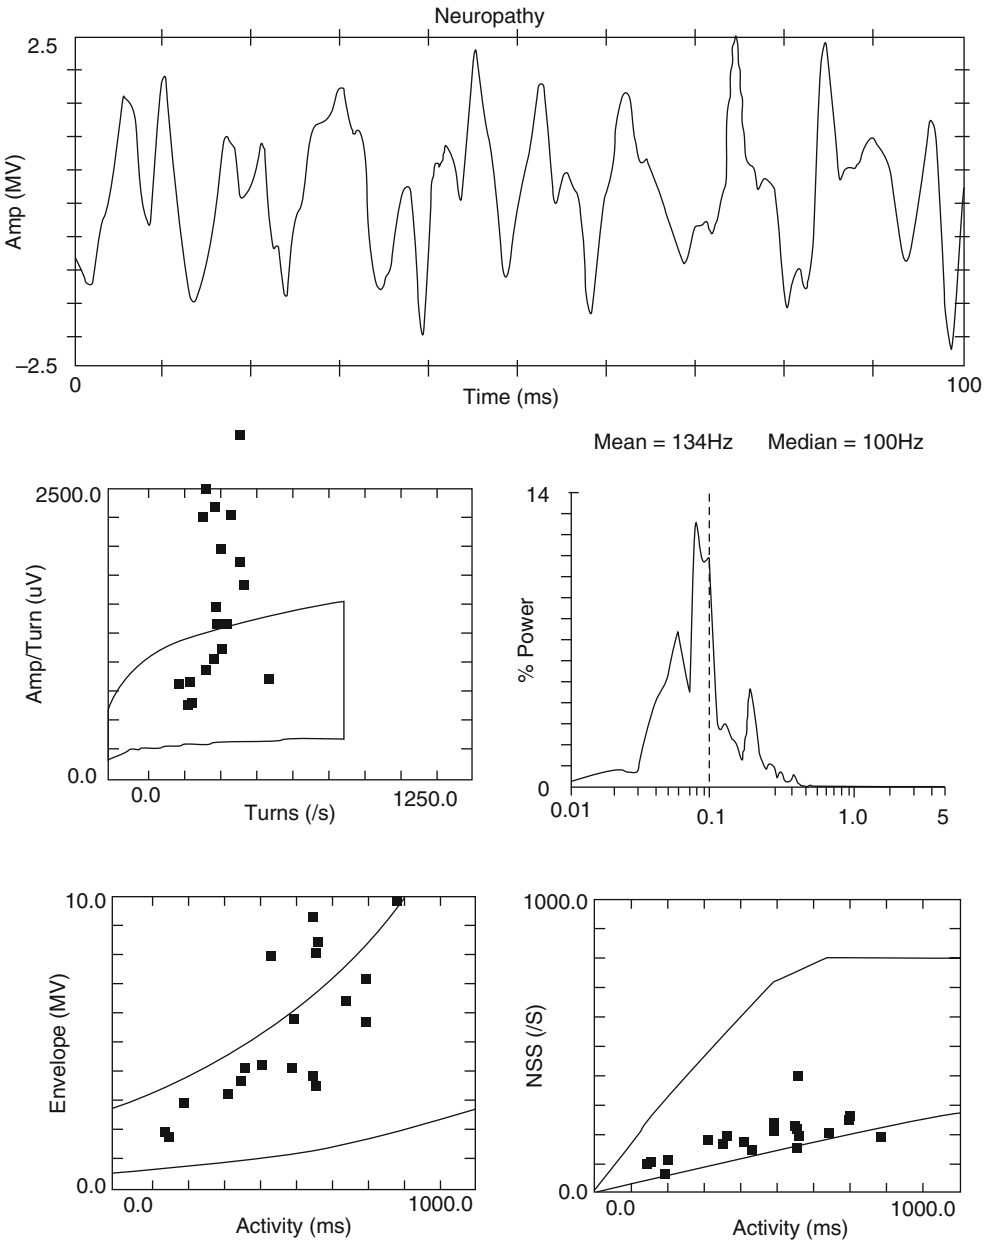

Fig. 9.16 Different techniques of IP analysis are demonstrated from IP recordings in a patient with neuropathy. An EMG signal at the *top* shows reduced number of spikes. The mean and median frequencies are reduced compared to Fig. 9.15. The turns and amplitude plot shows data points outside and on the *upper side* of the normal cloud. EQUIP also shows increased amplitude and reduced NSS values (Reproduced with permission from Sanders et al. [61])

(Fig. 9.17). Reduced signal amplitude will give less power. With fatigue, the spectrum shifts to low frequencies, and the total power is increased [60].

Turns and Amplitude

The computation of spectrum is a rather abstract way of quantifying the IP signals. If the spectrum shifts to high frequency, we expect the signal to contain more peaks. To exclude peaks generated by noise, Willison defined a "turn" of the IP signal (Fig. 9.18a) [61, 62]. A turn occurs at a peak of the signal. If a turn occurs on a positive going peak, then the immediately following and preceding turns occur on negative going peaks and vice versa. Finally, successive peaks are separated by at least 100 μV difference. The number of turns (NT) is used to quantify the IP. The mean amplitude change between successive turns (MA) is used to assess the amplitude changes.

The NT and MA values depend on the force of contraction (Fig. 9.18b). NT increases with force until it is about 50 % of maximum. With further increase in force, the NT increases mildly or may even decrease slightly. The MA increases with force at all levels of activation. Since the IP measurements depend on the force, the recordings are performed when the subject exerts a standard force. Signals are recorded from different sites, and the mean values of IP measurements are compared against normal.

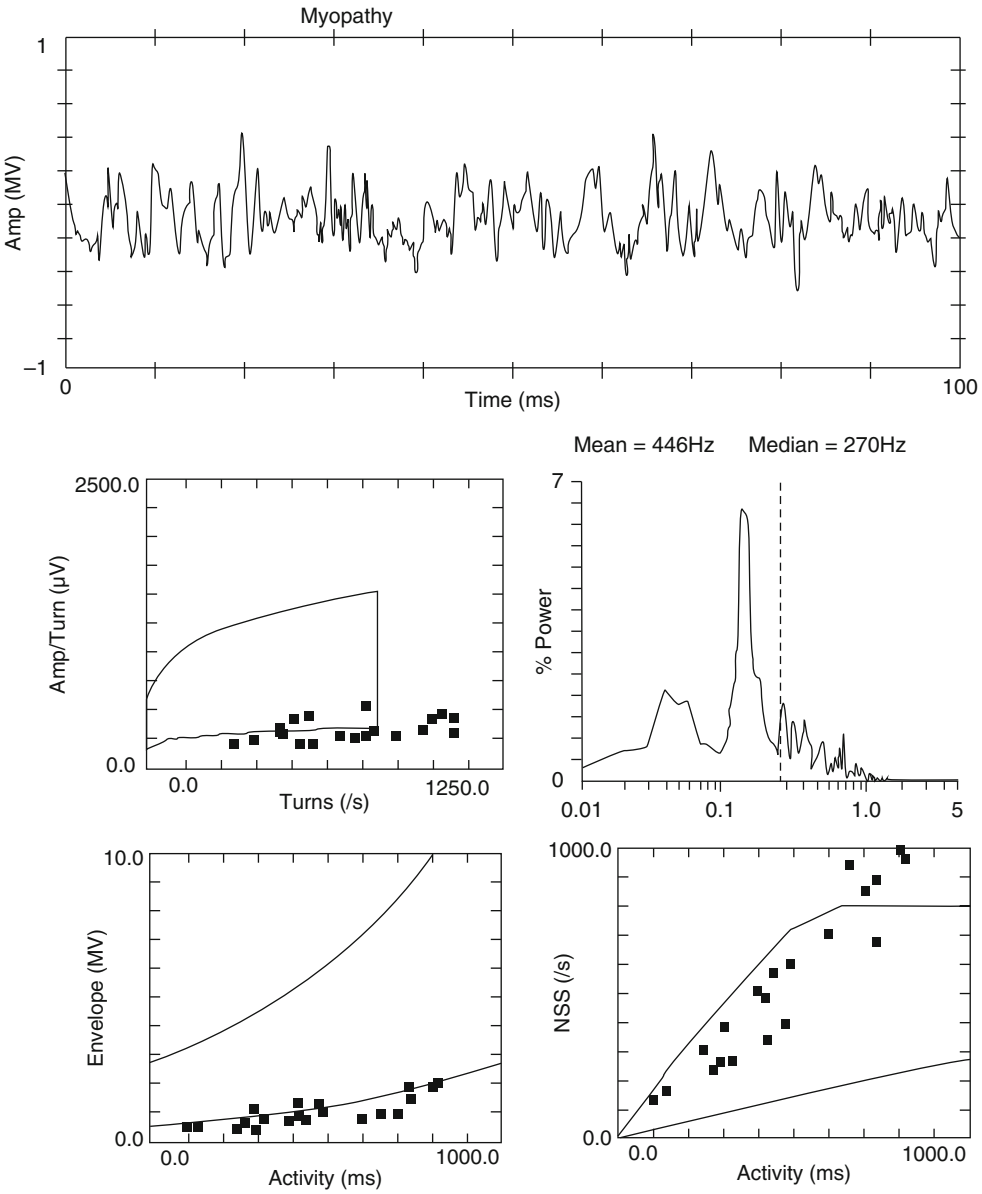

Fig. 9.17 Different techniques of IP analysis are demonstrated from IP recordings in a patient with myopathy. An EMG signal at the *top* shows increased number of spikes and reduced amplitude. The mean and median frequencies are increased compared to Fig. 9.15. The turns and amplitude plot shows data points outside and on the lower side of the normal cloud. EQUIP also shows reduced amplitude and increased NSS values (Reproduced with permission from Sanders et al. [61])

Willison, Hayward, and coworkers used a fixed load, e.g., 2 kg for biceps, and demonstrated increased NT in patients with myopathy [63–65]. The MA was increased in patients with chronic partial denervation. Fuglsang-Frederiksen and coworkers standardized the force to 30 % of patient's maximal effort [66–68]. Besides abnormalities of MA and NT, they also found reduced NT/MA ratio in patients with neuropathy and increased NT/MA ratio in patients with myopathy. Patients with myopathy also had a higher incidence of short-duration intervals between successive turns. The diagnostic sensitivity of IP analysis was similar to MUAP waveform analysis. When used together, they increased the overall diagnostic sensitivity.

This approach to IP analysis has several limitations. It requires force monitoring and hence additional hardware. In many muscles, force cannot be measured easily. Finally, it requires patient cooperation. Smyth analyzed IP in children who were referred for EMG. The force of contraction was not measured. The mean ratio of NT to MA was computed from several different sites with different levels of activation. Later, those children with no evidence of a neuromuscular disease were defined as the reference population [69]. Analysis based on the mean gave a modest diagnostic yield in the patient group [70]. Gilchrist and coworkers also demonstrated usefulness of the mean NT/MA ratio without force monitoring in adult subjects [71].

Stålberg and coworkers also ignored the force of contraction but used a novel way to assess the abnormalities [72]. Their analysis, now called *turns and amplitude (TA)*, is performed as follows: The IP signal is recorded from six to ten different sites. At each site, the signal is analyzed at three to four different force levels that range from minimal to

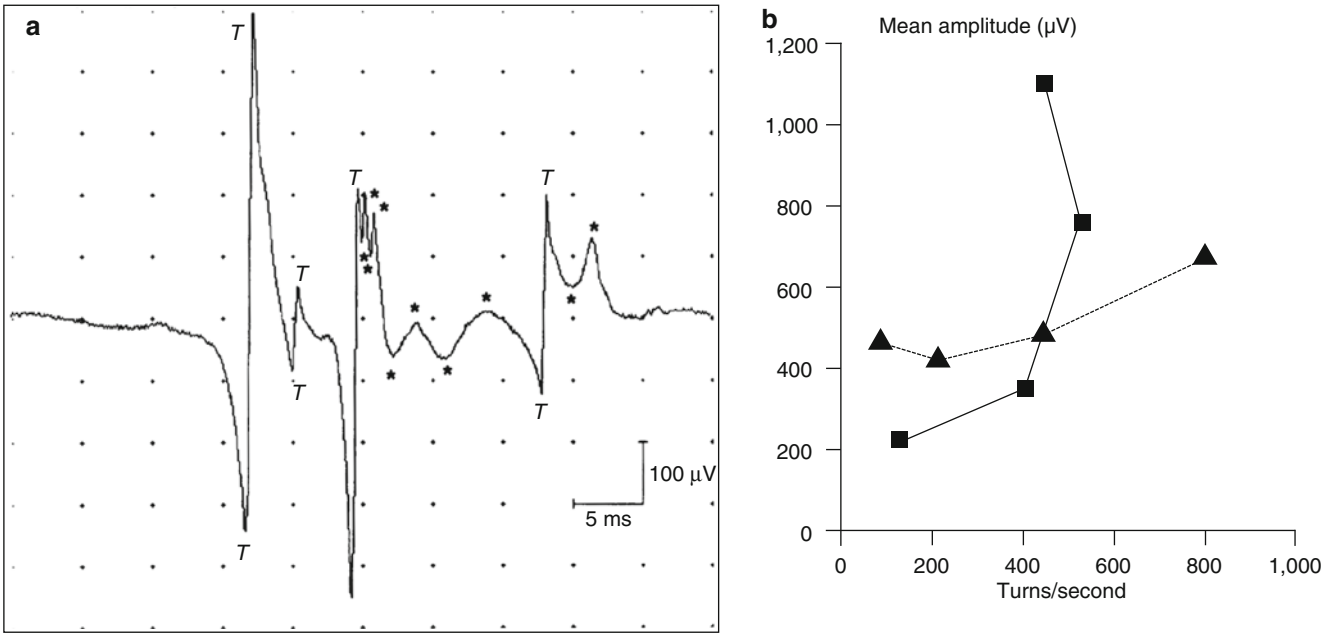

Fig. 9.18 In (**a**), 50 ms epoch of EMG signal is used to identify the turns (indicated as *T*) based on 100 µV amplitude threshold level. Peaks indicated by * did not qualify as turns. They include small peaks in the MUAP and also peaks generated by noise and baseline fluctuations. In (**b**), IP signals were recorded from two sites in the biceps muscle of a normal subject when the force of contraction was mild, moderate, submaximal, and maximal. A plot of mean amplitude (MA) versus number of turns (NT) is constructed. Data points from each site are connected by *straight lines*. Note the change in NT and MA with the force of contraction

maximum. The force is varied when the patient matches the resistance offered by the clinician. A plot of MA versus NT is created. An area on this plot is defined which contains more than 90 % of data points in normal subjects. The boundary of this area is called the *normal cloud* (Fig. 9.15). A typical investigation acquires 20 data points. Hence, the study will be abnormal when three data points are outside the normal cloud. This can occur within the first 2 or 3 min. If so, the test has now reached diagnostic significance and may be stopped. In patients with neuropathy, the data points fall on the upper side of the normal cloud (Fig. 9.16). In contrast, some data points occur below or to the right of the normal cloud in patients with myopathy (Fig. 9.17).

The IP quantification described so far is quite different from the subjective assessment that is based on IP fullness, amplitude, and sound. To mimic this assessment, Nandedkar and coworkers defined three IP parameters that were derived from the turns [73, 74]. *Activity* defined the number of milliseconds from a 1 s signal that contained "spiky" MUAP activity. When activity was more than 500 ms, the IP appeared full by visual assessment. The amplitude was measured from the envelope of the signal [75]. The *number of small segments (NSS)* measured the frequency of short-duration low-amplitude portions between successive turns. This quantifies the high-frequency component that is heard but not recognized easily by visual inspection. When the force of contraction is increased, activity and amplitude increase. NSS also increases initially and then remains constant or decreases slightly at high force. Signals were recorded from different sites and at different force levels. Two plots were constructed along with their normal clouds: envelope amplitude versus activity and NSS versus activity (Fig. 9.15). In patients with neuropathy, the data points fell above the amplitude-activity cloud. The activity was less than 500 ms in many patients indicating a reduced pattern. NSS values fell below the cloud indicating reduced high-frequency components (Fig. 9.16). In contrast, patients with myopathy showed a full pattern with activity values well in excess of 500 ms. The amplitude data fell below the normal cloud indicating reduced values. The NSS are increased and fall above the normal cloud. This corresponds to a high pitch sound of the IP (Fig. 9.17).

Many other modifications to the NT and MA analysis were described and are reviewed by Fuglsang-Frederiksen [76] and Gilai [77]. However, it is beyond the scope of the current discussion to review their details.

Interference Pattern Features and MUAP Waveform

When force of contraction is increased, the number of MU discharges increases due to recruitment and increased firing rates. Therefore, the NT, activity, and NSS increase with force. Some of the newly recruited MUs have MFs close to the recording surface. Hence, they will have large amplitude MUAPs. This will increase the envelope amplitude and MA. Recruitment of

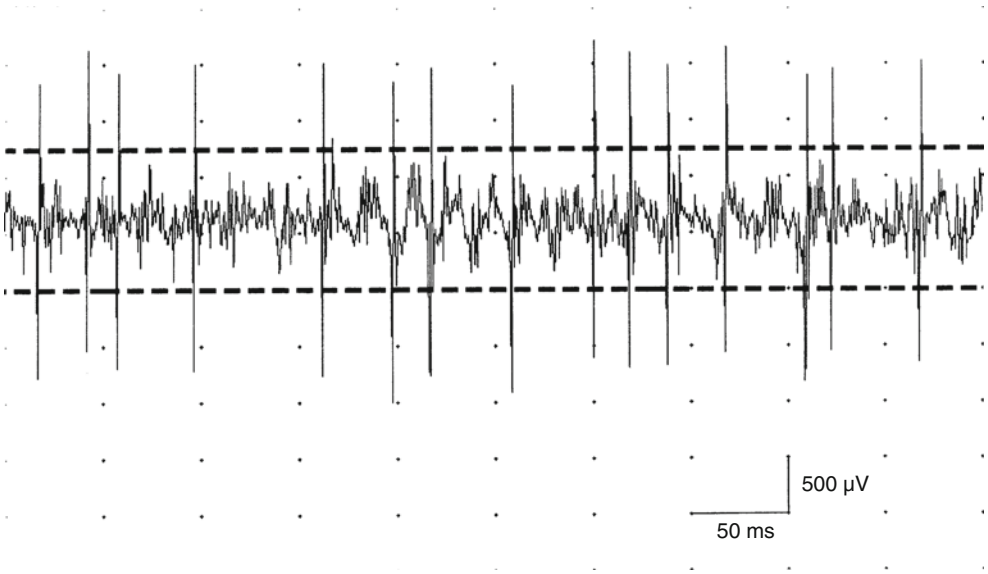

Fig. 9.19 The IP was recorded at maximal effort of the biceps muscle in a patient with myopathy. The spikes exhibit a bimodal distribution of amplitude. Majority of the spikes have low amplitude. However, the signal also contains discharges of a high amplitude, thin MUAP that appears to discharge quite rapidly. See text for details

high-amplitude MUAPs is recognized quite easily by visual assessment. Some newly recruited MUs may not have MFs close to the recording electrode. Their MUAPs will have a low amplitude (Fig. 9.11b), and their recruitment is recognized from an increase in NT, NSS, and activity. When several MUs are discharging, their MUAPs will superimpose each other. Their waveforms may interfere to generate higher amplitude signals. Computer simulations, however, indicate that the chance summation of several MUAPs to produce high-amplitude signal is rather low [73]. Therefore, the envelope amplitude mainly reflects the upper limits of the highest amplitude component MUAPs. Simulations indicate that summation of one large and one small MUAP often results in a signal that is very similar to the larger MUAP. Smaller MUAPs are masked and cannot contribute to the turns (Fig. 9.13b). Therefore, NT and NSS may decrease slightly at maximal effort.

Interference Pattern Features and Disease Processes

In normal muscles, the intramuscular needle may record from over 10–15 different MUs that are near the needle tip. In patients with neurogenic disease, the interference pattern is reduced due to loss of MUs. If the IP is discrete and contains MUAPs from only one or two MUs, this implies a significant MU loss.

The IP pattern may be spuriously reduced when the patient fails to exert the desired force due to pain and discomfort. However, this should not cause confusion. In normal subjects, the MUAP waveform and MU firing rate at minimal effort will be normal. In patients with neurogenic diseases, the MUAP waveform is altered as described earlier. Furthermore, the MUs appear to fire at higher rates (Fig. 9.13).

In patients with only upper motor neuron disease, the number of MUs may be normal, but the patient cannot activate them. The MUAP waveform may also be normal. The abnormality in these recordings is mainly the reduced and variable MU firing rate which is typically slowed for level of effort [20]. Obviously, one needs to combine different approaches in MUAP analysis to identify the underlying abnormality [61].

As stated previously, the EMG envelope amplitude is increased in patients with neurogenic diseases due to increased MUAP amplitude following reinnervation. In patients with myopathy, the amplitude is reduced due to loss of MFs and MF atrophy. In some patients with myopathy, one may record an IP that contains mainly low-amplitude MUAPs but also high-amplitude spikes (Fig. 9.19). These spikes are generated by discharges of a single MUAP when the needle electrode is close to a hypertrophied MF. These spikes appear thin by visual assessment, which is a specific finding in myopathy. Because of their high amplitude, they can be easily recognized when they discharge at higher rates. These fast-firing high-amplitude MUAPs should not be misinterpreted as evidence of neuropathy [43].

The high pitch sound in myopathy reflects the short-duration, short rise time, and polyphasic MUAPs. In neuropathy, the long-duration simple MUAPs with long rise time give a dull sound. In the very early stages of reinnervation, MUAP amplitude and duration may be normal, but the waveform is polyphasic and unstable. This may impart a high pitch sound to the IP signal.

Practical Considerations

The IP assessment at maximal effort is usually performed as part of the routine needle EMG examination. The criteria

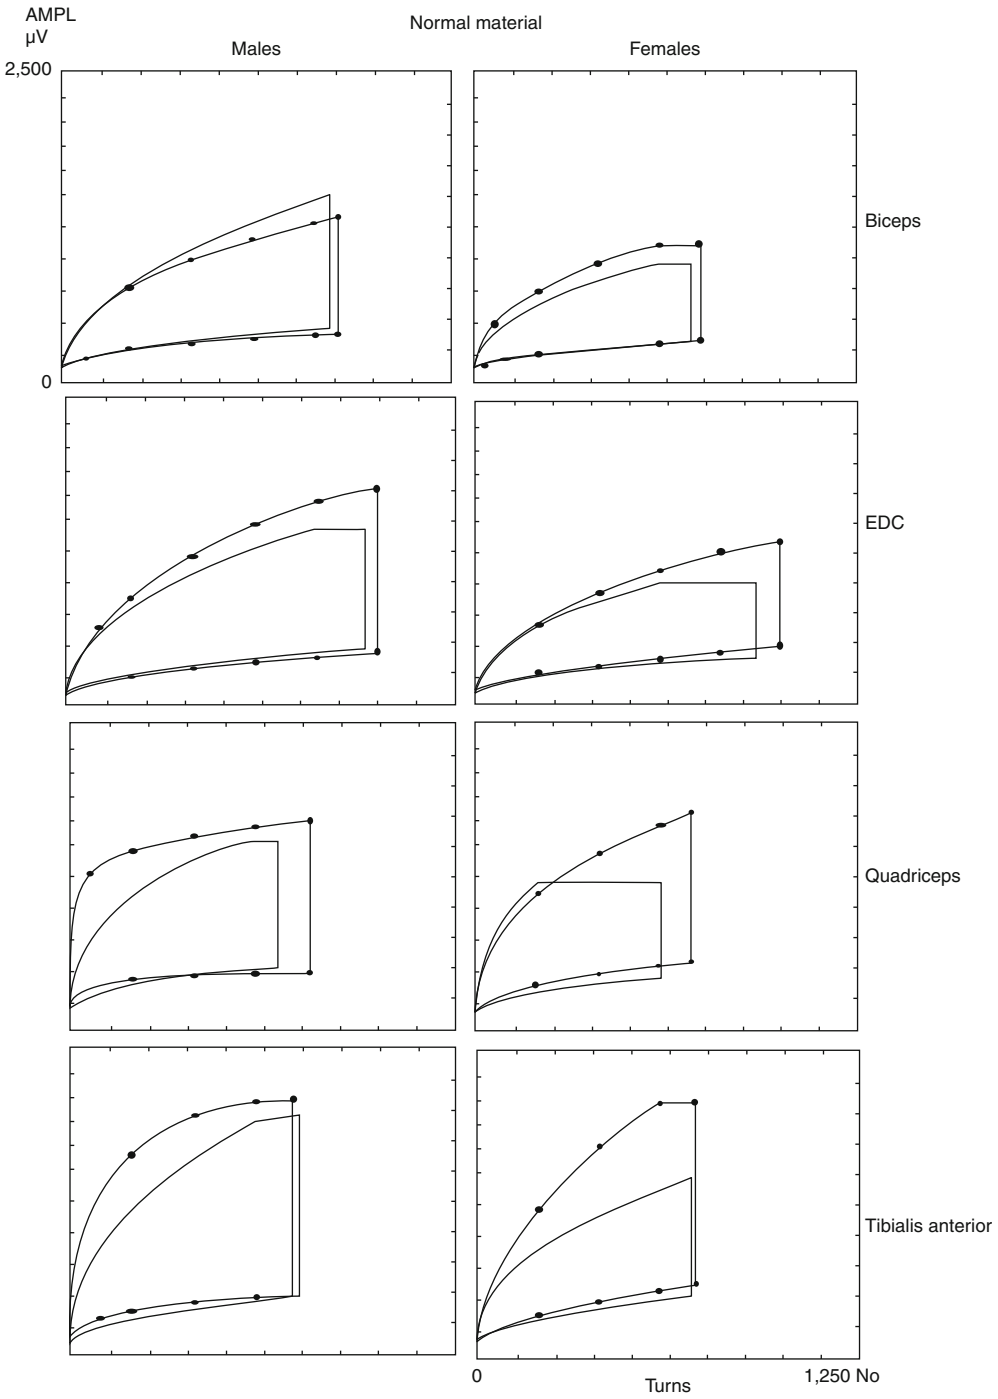

Fig. 9.20 Normal clouds for four different muscles in male (*left*) and female (*right*) subjects. The *lines* connecting the *symbols* define the cloud for subjects over 60 years. The other cloud is for subjects below 60 years. A concentric needle was used in this study (Reproduced with permission from Stålberg et al. [72])

described by Buchthal can be quite helpful in this analysis [30, 40] and should be used only when the patient exerts maximal effort.

The techniques based on spectrum analysis require special software on the EMG instrument. The measurements are not intuitive like time domain features (e.g., amplitude). We are not aware of well-defined reference values for different muscles.

The techniques of TA or EQUIP also require special software. The technique of IP recordings is relatively simple compared to MUAP analysis. The quantitation requires little time. Hence, the test can be performed "online" and completed within 5 min. The contrasting pattern of data distribution in neuromuscular diseases makes it useful in electrodiagnosis. The diagnostic yield is similar to MUAP analysis, but the sensitivity is increased when both analyses are used. The only significant limitation of these techniques is the relative paucity of reference values. The normal clouds vary among different muscles. The clouds also depend on the needle electrode type (concentric versus monopolar), patient age (below or above 60 years), and gender (Fig. 9.20) [72].

The maximal force generation (manual resistance versus a strain gauge) also affects the cloud boundaries for high turns values [78]. Hence, at present, these methods have limited clinical usefulness.

Motor Unit Number Estimation

Loss of motor units is a key feature in patients with a neurogenic process. Therefore, it has always been of long-standing interest to estimate the number of MUs in a muscle, which McComas and coworkers pioneered in the early 1970s [79]. Due to technical problems encountered with the method, interest in MU counting declined. With access to fast computers, there has been a renewed interest in *motor unit number estimation (MUNE)*.

Principle of MUNE

MUNE is a three-step process. First, the *compound muscle action potential (CMAP)* of the tested muscle is recorded using standard motor nerve conduction techniques (Fig. 9.21a). The premise is that the CMAP represents the sum of MUAPs of all MUs in the muscle recorded by the surface electrode. Next, the same surface electrode is used to estimate single *surface-recorded MUAP (SMUAP)* amplitudes (Fig. 9.21b). Finally, to obtain the number of MUs, the CMAP amplitude is divided by the SMUAP amplitude (Fig. 9.21c). MUNE techniques differ mainly in the second step. Furthermore, one may use CMAP and SMUAP area in lieu of amplitudes for computations.

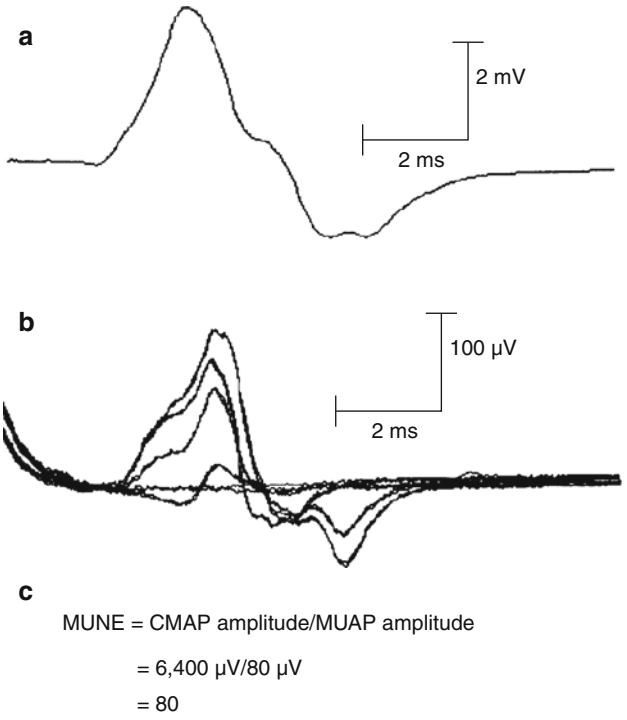

Fig. 9.21 The principles of MU counting technique are illustrated using the method described McComas. In (**a**), the CMAP of the abductor pollicis brevis muscle is recorded by supramaximal stimulation of the median nerve at the wrist. Its peak-peak amplitude is 6.4 mV. In (**b**), the responses recorded by incremental stimulation are shown. In each case, two trials are superimposed. The largest response represents a sum of 4 surface EMG MUAPs. Dividing its peak-peak amplitude by 4 gives the average MUAP contribution to the CMAP, i.e., 80 µV. In (**c**), their ratio is computed to obtain the MU count of 80. Ideally, the mean MUAP amplitude should have been estimated from 10 MUs

Estimation of SMUAP

McComas and coworkers used a so-called incremental stimulation technique to estimate single SMUAP amplitude [79–83]. This method uses a standard motor nerve conduction setup, by recording the muscle action potential when the stimulus intensity is increased. At very low stimulus intensity, none of the axons are stimulated. As stimulus intensity is increased, a stage is reached when an axon will depolarize and generate an AP. The SMUAP of that MU is then recorded. When the intensity is varied slightly, that axon will either be stimulated or not stimulated. Hence, the response contains either the SMUAP or the baseline. No intermediate response is observed. This is called the "all or none" phenomenon (Fig. 9.22). The signal represents one SMUAP.

When the intensity is increased further, the response will not change until another axon is stimulated (Fig. 9.21b). The response represents a sum of two SMUAPs. When the intensity is changed slightly, we record either the baseline, the first SMUAP, or a sum of the two SMUAPs. No intermediate response is seen. When the intensity is increased further, the response changes in a stepwise fashion whenever another axon is stimulated (Fig. 9.21b). The procedure is continued until about ten steps are recorded. The last response represents the sum of all ten SMUAPs. Dividing the amplitude of the last response by the number of steps gives individual SMUAP amplitudes.

This method is conceptually simple but has several pitfalls. If the newly stimulated axon gives a very small SMUAP, we may fail to recognize its stimulation. This will overestimate the SMUAP amplitude and yield a smaller MU count. In some instances, two axons may have a very similar stimulation threshold. The evoked response will then exhibit three different possible waveforms that correspond to stimulation of the first axon, the second axon, or both axons. If this is interpreted as stimulation of three axons, we will underestimate SMUAP amplitude and get a larger MUNE. This phenomenon is called *alternation.* By subtracting the successive incremental responses, we obtain the SMUAP amplitudes of the stimulated MUs. By adding these SMUAPs in different

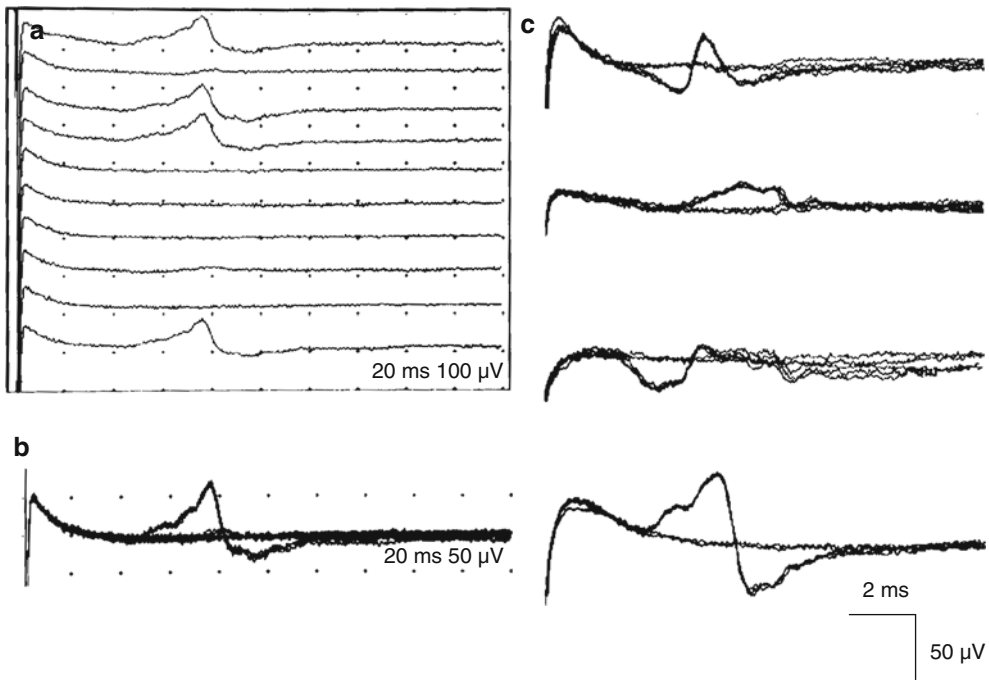

Fig. 9.22 The muscle action potential was recorded from the abductor pollicis brevis muscle when the median nerve was stimulated at the wrist. Results of ten stimuli are shown in (**a**) raster and (**b**) superimposed fashion. At this low setting of stimulus intensity, the response contains either the baseline or small amplitude potential. When present, this potential has the same shape as seen by superimposing the traces. No intermediate waveform configurations are seen making this an "all or none" phenomenon. The SMUAP recorded from different stimulation sites, i.e., multipoint, are shown in (**c**)

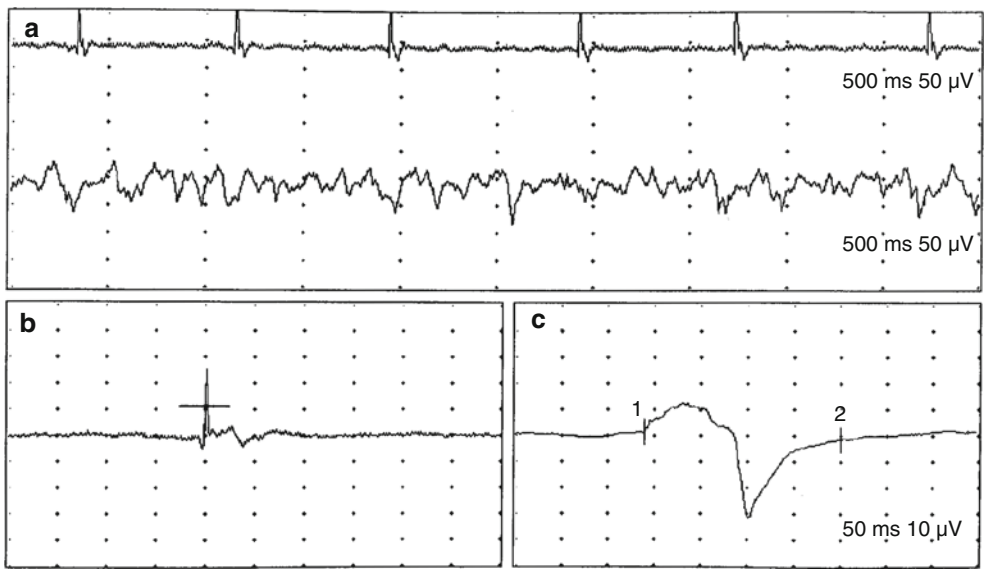

Fig. 9.23 In (**a**), EMG signals are recorded simultaneously using a surface and an intramuscular needle electrode. The needle EMG signals are used to identify and trigger from a single MU discharges (**b**). The time-locked and delayed surface EMG signals are averaged to obtain the MUAP (**c**). This procedure is similar to the macro EMG recordings

combinations, alternation can be resolved [84]. Needless to say, this requires special analysis and software.

In the *multipoint stimulation (MPS) method*, the stimulus intensity is increased to identify only the first stimulated MU (Fig. 9.22a, b) [85]. This allows one to avoid the technical pitfalls of the incremental stimulation method. The stimulator is then placed at a different position along the nerve to record another SMUAP and so on (Fig. 9.22c). It may be possible to get perhaps two or three different SMUAPs from each stimulation site by careful comparison of the evoked responses (Fig. 9.21b). Many such derivatives of the MPS have been developed, e.g., motor unit number estimation based on stochastic activation (MUESA) [86] and adaptive MPS [87]. In another technique, the nerve is stimulated at submaximal intensity to record a few hundred F waves. Repeating F waves are considered to be individual SMUAPs [88].

SMUAPs may also be recorded without using electrical stimulation. In a two-channel recording technique, called *spike-triggered averaging (STA)* [89–91], an intramuscular needle electrode is used to identify activity from a single MU (Fig. 9.23). This is used to trigger the display sweep and the averager. The delayed surface EMG signals are averaged to obtain the SMUAP. The position of the needle is

Fig. 9.24 Signals recorded from the hypothenar muscle at submaximal stimulus intensity demonstrate variability of amplitude. Responses from 30 stimuli are superimposed (*top left*). The largest amplitude signal is the compound muscle action potential. The area distribution from 120 stimuli (i.e., 4 runs) is shown as histogram (*top right*). The variability is used to estimate the mean MUAP amplitude and hence estimate the MU count (Table in *bottom right*). The results of three such runs are shown in the table in *bottom left*

then changed to record from another MU. The STA technique has been modified in several ways. Fang and coworkers used a separate surface electrode instead of the intramuscular needle to identify individual MU activity [92]. DeKoning et al. used the macro electrode instead of surface electrodes for the recordings [93]. Stein and Yang measured the force generated by the MU and the muscles to estimate the MU count [94].

Other than the incremental stimulation technique, all methods record individual SMUAPs. When two SMUAPs are summated, the amplitude of this combined SMUAP is less than the sum of their individual SMUAP amplitudes. This results from phase cancellation of their SMUAP waveforms. In other words, a MU contributes less amplitude to the final CMAP amplitude than its individual SMUAP amplitude recorded by the above techniques. Using an averaged SMUAP amplitude gives a smaller MU count. To include phase cancellation, one may summate the waveforms by aligning them at their onset point. The amplitude of the resulting response is divided by the number of constituent SMUAPs to estimate a "phase-corrected" SMUAP amplitude [88]. This adjusted calculation is then used for MUNE. It is important to recognize that individual SMUAPs have different latencies within the CMAP. In the neural network-based method, the CMAP is synthesized by summating the SMUAPs by offsetting their onset points. The number of SMUAPs required for the synthesis of the CMAP is the MUNE [92].

At submaximal intensity, some axons may not depolarize with each stimulus. As a result the evoked response varies

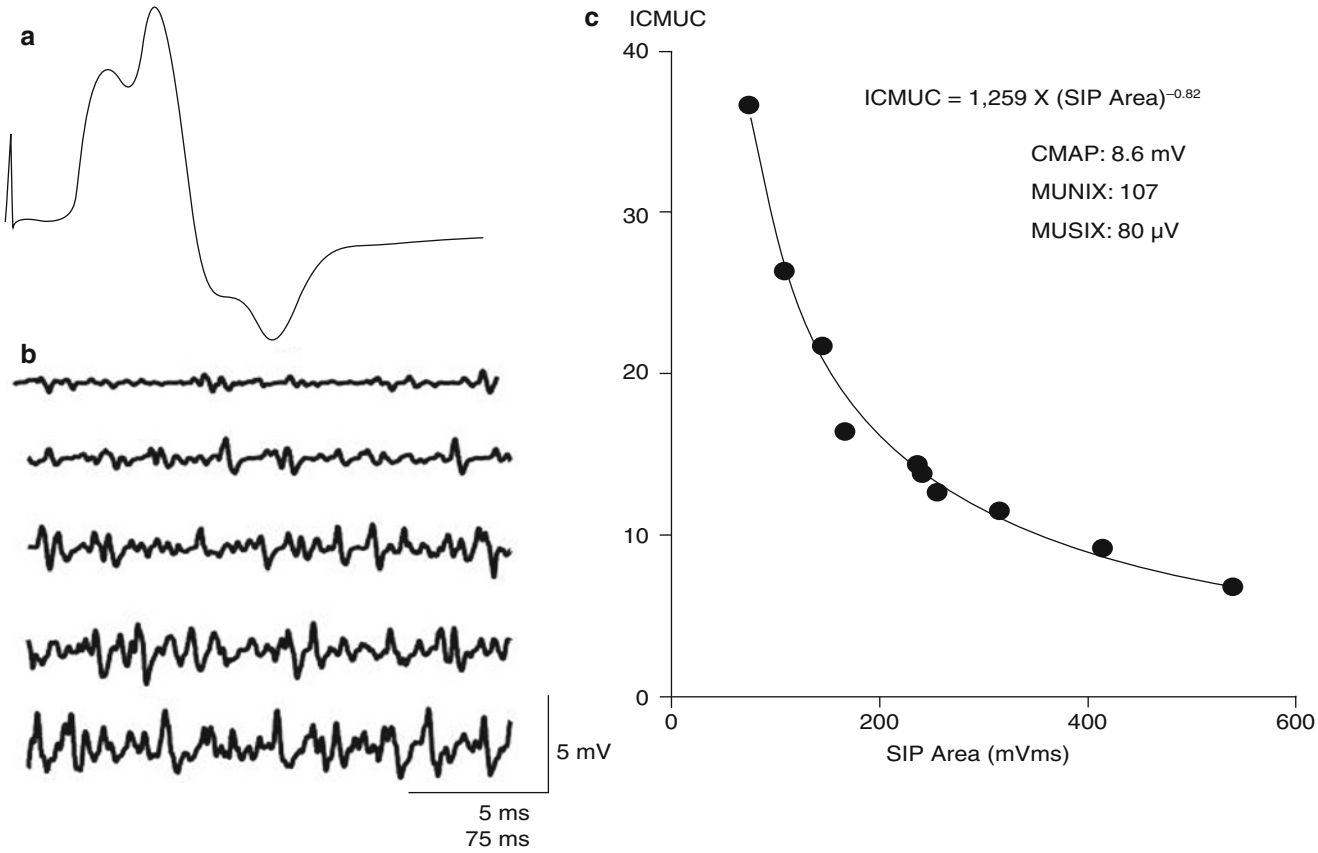

Fig. 9.25 The MUNIX method is illustrated with recordings from a healthy subject. The abductor digiti muscle was tested. (**a**) CMAP, (**b**) SIP at different force levels. Only 5 of 10 recordings are shown. (**c**) The data is analyzed to compute MUNIX and MUSIX

from one discharge to another (Fig. 9.24). Daube assumed a Poisson distribution for the number of stimulated axons at submaximal intensity [95]. The nerve is stimulated 30 times at submaximal intensity. Collectively, the 30 responses are called a "group." The variance of the evoked response amplitude (or area) is used to estimate the individual SMUAP amplitude (or area). The technique does not give individual SMUAP waveforms. The number of MUs is estimated. The process is then repeated until the coefficient of variation of MUNE from the groups is less than 10 % or ten groups are acquired (Fig. 9.24, Table in bottom right). This completes a run at the selected level of stimulation. One may perform additional runs by using another stimulus intensity level (Fig. 9.24, Table in bottom left). Shefner and coworkers have modified the technique by combining the results from the different runs. This increased the reproducibility of the technique [96].

Motor unit number index (MUNIX) is a newer technique that computes an index which reflects the number of motor units [97]. The CMAP is recorded using the standard nerve conduction methods (Fig. 9.25a). The same electrodes are used to record the surface EMG interference pattern (SIP) at different isometric force levels ranging from slight to maximum (Fig. 9.25b). A mathematical model is used to compute MUNIX as follows. First, the so-called ideal case motor unit count (ICMUC) is computed for each SIP signal by the following formula:

$$\text{ICMUC} = (\text{CMAP power} / \text{CMAP area}) \times (\text{SIP area} / \text{SIP power})$$

Next, the relationship between ICMUC and SIP area (used as in indicator of force) is modeled by a power regression as below:

$$\text{ICMUC} = A \times (\text{SIP area})\alpha$$

In Fig. 9.25c, each data points shows the area and ICMUC value for each SIP epoch. The solid line shows the power regression line. It shows a very good fit to the data. Once the parameters A and α are computed from the recordings, MUNIX is computed as

$$\text{MUNIX} = A \times (20)\alpha$$

The "motor unit size index (MUSIX)" is computed by dividing MUNIX in to the CMAP amplitude. It is an estimate of average surface-recorded motor unit potential amplitude

Data from Daube [95]
The level represents the evoked potential as a percentage of the compound muscle action potential at supramaximal stimulation. Each cell of the table shows mean/minimum normal MU count. Note the higher number of MUs estimated at low level of stimulation

which reflects MU size. In Fig. 9.25c, the MUNIX is 108 and MUSIX is 87 μV.

Findings in Normal Subjects and Patients with Neuromuscular Diseases

McComas and coworkers investigated the MU count in the extensor digitorum brevis muscle and reported a mean count of 210 MUs in healthy subjects [80]. In normal healthy subjects, the MU count was reduced and attributed to the normal aging. In patients with neurogenic diseases, the MU count was reduced, as expected. Surprisingly, they also found a reduced MU count in patients with muscular dystrophy. This led them to propose a neurogenic basis for muscular dystrophy [80]. Panayotopoulos and coworkers demonstrated that small MUs may be missed in the incremental stimulation method [98]. This in turn would yield a reduced MU count in dystrophy. While neurogenic processes may be seen in patients with dystrophy, the primary disease process is still consistent with a myopathic process.

The aforementioned MUNE techniques have been used primarily to study healthy subjects and patients with neurogenic diseases [83–97, 99–103]. The findings are summarized in Tables 9.6, 9.7, and 9.8. The data in healthy subjects shows significant difference among estimates made by

Table 9.8 MUNIX and MUSIX values in healthy subjects. The 5–95 % range is shown

Muscle	MUNIX	MUSIX (μV)

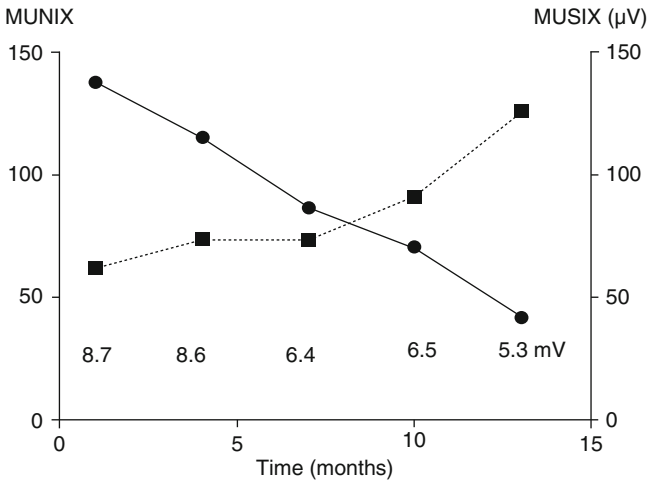

Fig. 9.26 Serial MUNIX studies in a patient with amyotrophic lateral sclerosis. The MUNIX and MUSIX are plotted against time. The CMAP amplitude is also listed for each study. The MUNIX decreased more than CMAP amplitude indicating disease progression

different techniques. In the statistical method, the estimates also depend on the choice of stimulation range (Table 9.7). In general, the number of motor units is slightly reduced in older subjects. In patients with neuropathy, the number of motor units is reduced depending on the severity of the disease. A serial MUNIX study demonstrates the process of MU loss and reinnervation (Fig. 9.26). In this patient, the MUNIX decreased by 70 % over the study period. Due to reinnervation, the MUSIX almost doubled. However, reinnervation of all denervated muscle fibers was not possible, and hence, the CMAP amplitude decreased by 30 %.

Limitations of MUNE

Perhaps the development of so many techniques of MUNE has occurred due to inherent limitations and pitfalls of each method. We have already considered the problems with small SMUAPs and alternation phenomenon with the incremental stimulation method. The multipoint stimulation technique and its derivatives can be tedious to acquire a large sample of SMUAPs. Furthermore, it does not adequately account for phase cancellation of the SMUAPs comprising the CMAP. The statistical method uses variability in the signal for analysis. When variations occur due to abnormalities of neuromuscular transmission, the MUNE values may remain high and normal despite MU loss. In general, stimulation-based methods for SMUAP recognition are limited to muscles where the nerve supplying the muscle is easily accessible for repeated stimulation, e.g., distal hand and foot muscles. Large proximal muscles have not yet been studied extensively using these methods.

SMUAP identification based on needle EMG recordings is conceptually simple. It can be performed in any muscle as long as a CMAP can be recorded, e.g., large proximal muscles. On the negative side, it is invasive and also fails to account for phase cancellation. The techniques based on multichannel surface recordings are noninvasive [92], but the neural network algorithm for MUNE is not readily available. The MUNIX method is being tested for proximal and distal muscles [103]. It requires very little time to perform. But it does require patient cooperation. Furthermore, it is not very intuitive. Many MUNE methods are not commercially available and not automated. This makes the technique time consuming.

The surface electrodes record mainly from the fibers that are within 2 cm of the skin surface [104]. This is sufficient to include small muscles such as the thenar, hypothenar, and extensor digitorum brevis muscles. However, in large muscles, like the biceps, the electrode records much smaller SMUAPs amplitudes from deeper MUs. This perhaps explains the larger MUSIX in distal hand muscles (Table 9.8). Using the deep MUs to estimate SMUAP in the spike-triggered averaging method will give a much higher MU count.

Finally, all methods are based on recording the CMAP [105]. Any variability in CMAP can affect the MUNE, the MU size estimation, or both. To assess the disease progression, it is necessary to study the MUNE and MU size together (e.g., Fig. 9.26). In serial studies, changes in CMAP due to technical factors, e.g., electrode placement, electrode size and geometry, skin temperature over the studied muscle, and limb and digit position (i.e., MF length), may affect results [106]. Therefore, in our serial MUNIX studies, we always display the recordings from previous and current investigation in superimposed manner at the time of the study. This is not possible on many commercially available systems. In demyelinating diseases, some axons may require very high stimulus intensity for depolarization. If one fails to excite them, the CMAP is underestimated. This may result a reduced MU count.

Clinical Utility

The MUNE is of interest mainly in patients with neurogenic disorders. It is hoped that MUNE will be useful to study

disease progression in degenerative diseases like amyotrophic lateral sclerosis. That could allow one to utilize MUNE as a surrogate marker in studying the effectiveness of the new therapies. However, at this point of time, MUNE methods remain mainly in the research domain. Currently, the loss of MUs is assessed indirectly in the routine electrodiagnostic studies, e.g., from reduced pattern at maximal effort (Fig. 9.14).

Other EMG Techniques

The MU architecture and resultant remodeling in neuromuscular diseases may also be studied using special techniques, such as single-fiber EMG (SFEMG) and macro EMG. The fiber density measurements on SFEMG are most sensitive in detecting reinnervation changes. Jitter analysis is most sensitive in demonstrating abnormalities of the neuromuscular junction. SFEMG is very nonspecific since jitter abnormalities may be found in a variety of neuromuscular diseases [107]. Macro EMG electrode records from the entire MU. Hence, macro MUAP amplitude and area depend on the MU size. They demonstrate increased MU size in patients with neuropathy. In patients with myopathy, MU size is normal or reduced [12]. Thus, macro EMG may be used for differentiating between myopathic and neurogenic disease processes. However, it is diagnostically less sensitive than other methods, reflecting the lesser selectivity of this electrode. While the macro electrode records from the entire MU, the SFEMG electrode records mainly from MFs that are within 300 μm of the recording electrode. This makes it the most selective of readily available recording electrodes. As described in Fig. 9.9, concentric and monopolar electrodes have an intermediate uptake area (and thus intermediate selectivity). This is a fortuitous coincidence which offers the sensitivity and specificity that enhances and is needed in clinical electrodiagnosis. By combining these different techniques, we can better understand the pathophysiology and progression of neuromuscular diseases [39, 44, 108].

Using Quantitative Analysis

Quantitative analysis in needle EMG examination is not performed in many clinical EMG laboratories. This is largely due to the time required for the study, availability of reference values, diagnostic sensitivity and specificity, special instrumentation, etc. We agree that every patient does not need quantitative analysis. But knowledge, understanding, and skills used for quantitation can be used in the routine EMG examination performed in every patient. This is particularly useful when the signals have atypical characteristics. We will illustrate this using two examples.

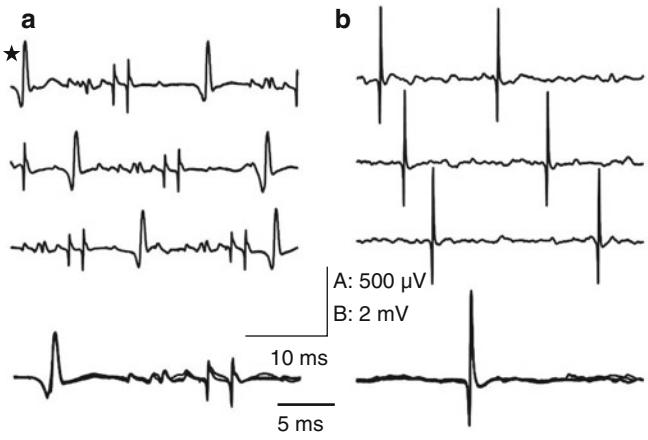

Fig. 9.27 Atypical MUP recordings in (**a**) neuropathy and (**b**) myopathy. In (**a**), discharges of a complex potential give appearance of increased recruitment. In (**b**), large amplitude fast-firing MUAP suggests possibility of a neurogenic disease. Note the different amplitude calibrations in (**a** and **b**). Also the sweep speed is different for free-running versus triggered sweeps. See text for details

The signals recorded, using a free-running sweep, are shown in the top portion of Fig. 9.27a. The subject was exerting low force of contraction. By a quick glance, one can see several small MUAPs in this signal that suggests "early" recruitment as seen in myopathy. However, the sound of the EMG signal was not what one would expect from discharges of multiple MUs. It sounded more like a complex repetitive discharge. The signal was, however, not generated spontaneously. When the amplitude trigger and delay line were used, we find that the signal contains discharges of a single, long-duration, complex MUAP with linked potentials. Polyphasic potentials are nonspecific abnormality as they can be seen in patients with myopathy and neuropathy. Next, we recognized that the potential appears twice on each sweep. This is easily seen by following one part of the potential marked by an asterisk on the top trace. The sweep duration is 100 ms. The two discharge per sweep give this potential a firing rate of roughly 20 Hz. There is no other active MU. Hence, this represents reduced recruitment. The polyphasic MUAP waveform can be due to reinnervation. Therefore, we feel quite comfortable in considering this as evidence of a neurogenic process.

The signals in the free-running display of Fig. 9.27b also have a MUAP discharging at 20 Hz. There appears to be no other MU activity. Finally, the amplitude of this MUAP is increased compared to normal. This appears to suggest a neurogenic abnormality. However, the MUAP appears very thin (i.e., lack of expected area or "thickness" in the main spike). Using trigger and delay line, one can demonstrate that it has a very short duration (less than 5 ms). This reduced duration is specific for myopathy. Note that the display setting is 2 mV/div. At this instrument setting, smaller amplitude MUAPs may not be visually detected. If there were no other MUAPs, the baseline would be smooth. But the "rough"

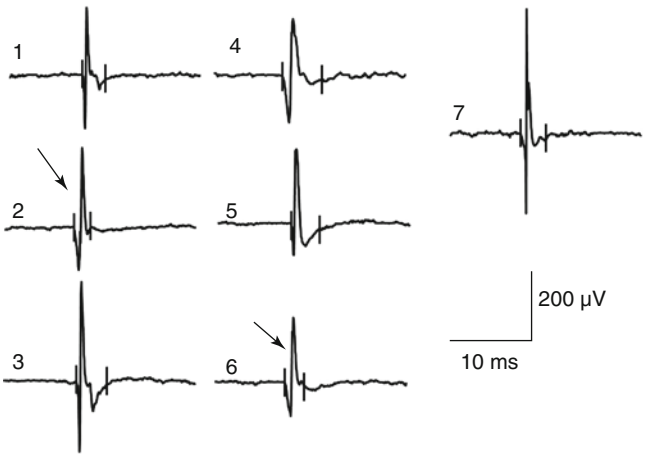

Fig. 9.28 Multi-MUP analysis is used to document short-duration MUPs in a patient with myopathy. *Arrows* indicate MUAPs with reduced duration, i.e., outliers

baseline seen, however, indicates that there are low-amplitude MUAPs. Indeed, smaller amplitude MUAPs are more easily seen when the display sensitivity is changed to the customary 100 μV/div setting for analysis. Such high MUAP amplitude can occur if the recording electrode is close to a hypertrophic MF (Table 9.4). Therefore, this atypical MUAP signal is still consistent with myopathy.

The modern multi-motor unit analysis or decomposition methods are very fast. One can easily acquire over 25 MUAPs in less than 5 min. A single 5–10 s epoch is analyzed in a fraction of a second. Therefore, these algorithms can also be used to document abnormal waveforms. Figure 9.28 shows 7 MUPs recorded from two different sites in the vastus lateralis muscle. The short duration is recognized quite easily. The waveform looks "thin." The MUAPs with duration less than 5 ms are indicated by the arrows. Note that these MUAPs are abnormal using the limits shown in Table 9.3. The process of analysis added only a minute or two to the examination, and it provided very objective evidence of abnormality.

Single-fiber EMG is the most sensitive test to detect abnormalities of neuromuscular transmission. When jitter is significantly increased and there is blocking, one can also visualize this as a variable MUAP waveform on routine EMG study. One can demonstrate this quite easily using the trigger and delay line and enhancing it by increasing the low-frequency filter to single-fiber EMG settings (e.g., 500 or 1,000 Hz) (Fig. 9.6). When unstable potentials are found on the routine EMG examination in a patient suspected of a neuromuscular junction disease, SFEMG jitter analysis may not add much for diagnosis. After one has experienced the audio quality of increased jitter on SFEMG, one becomes more sensitive to the sound of an unstable MUAP at both routine and increased low-frequency filter settings. In patients with neuropathy, unstable potentials indicate ongoing compensatory reinnervation which is a good sign for recovery.

Quantitative analysis may be useful for monitoring diseases [109]. New methods are being developed to quantify severity of the disease using combined analysis of many different MUAP measurements [110, 111]. Serial MUAP studies show decrease in CN MUAP duration and also the macro EMG amplitude [44]. SFEMG jitter may be used to follow patients with neuromuscular junction diseases [107]. Macro EMG MUAPs may be used to follow changes in MU size in neurogenic diseases [39]. MUNE can be used to study the MU loss and compensatory reinnervation [81, 102]. The MU size and the MU count may be used to define the exercise program for patients with old poliomyelitis [112].

Quantitative analysis measures many different features of the EMG signal, e.g., amplitude, duration, and phases. The normal limits of each feature are defined such that there is only a slight chance (often <2–3 %) that the measurements in healthy subjects are outside the normal range. As more and more measurements are made, there is a greater chance that at least one feature has abnormal values. This occurs not due to pathology but due to inherent statistical analysis. Therefore, one should not overestimate isolated mild abnormalities. Having marked abnormalities on a specific feature (e.g. duration) and/or abnormalities on two or more features is more consistent with a pathologic muscle [113].

Each laboratory should develop its own reference values. This is not always possible. When using published reference values [17, 114], the examiner should perform studies in a few healthy subjects to confirm their suitability and reproducibility for their particular laboratory. Attention should also be paid to instrumentation and accessories. As example, the so-called facial needle electrode is used extensively in routine EMG examination since it has a smaller diameter and may cause less pain. However, this electrode also has a smaller recording surface. Hence, it tends to record slightly higher amplitude MUAPs compared to the longer needle electrodes with slightly larger diameter [115]. Furthermore, its length limits the evaluation of larger muscles or in large individuals.

Conclusion

The shape of the MUAP depends on the MU architecture. The MUAP features give complementary information about remodeling of the MU due to disease processes. MU firing rate is useful to study loss of MUs and upper motor neuron lesions. IP analysis gives information about the number of MUs and their waveforms. It also allows the study of high force threshold MUs. Collectively, these techniques offer useful information about the underlying disease processes. By understanding and including quantitative EMG techniques and principles in the routine EMG examination, we may better document abnormalities and extract more information about the severity, duration, activity, and prognosis of the disease. MUNE

techniques are an exciting development in electrophysiologic testing. However, these methods are in an evolutionary stage. When the MUNE techniques are improved, they may be of great value in monitoring disease progression. While quantitative analysis of the EMG signals may appear esoteric and time consuming, it is nevertheless critical to understand their principles in order to perform competent routine EMG.

Testing of Autonomic Function

10

Kamal R. Chémali and Thomas C. Chelimsky

Introduction

In recent years, objective testing of the autonomic nervous system (ANS) has acquired a new dimension. After being generally underrecognized, disorders of the ANS now constitute a major component of neurological dysfunction and neuromuscular diseases in particular. For example, peripheral neuropathy due to diabetes mellitus (DM), which accounts for a large number of neuromuscular consultations, is frequently associated with dysautonomia. Several recent studies concluded that diabetic cardiac autonomic neuropathy contributes to arrhythmia or silent myocardial infarction and is the major predictor of death ahead of coronary artery disease and by far outweighing the prognostic value of the somatic peripheral neuropathy [1–5]. One study established a correlation between the presence of ANS dysfunction and a poor response of DM to insulin treatment [6]. These reports led several experts to argue for a systematic detection of dysautonomia in DM through the use of autonomic testing [7]. Furthermore, in nondiabetic patients who suffered a myocardial infarction, decrease in heart rate variability increases arrhythmic complications and mortality [8]. A large prospective long-term study demonstrated the value of markers of cardiac autonomic tone in identifying infarct survivors at risk for malignant ventricular tachyarrhythmias and sudden death [9]. As much as large (myelinated) fiber neuropathy is well detected by conventional electrodiagnostic studies and electromyography [10], small-fiber (unmyelinated or thinly myelinated) neuropathy often cannot be detected by this technique [11] and requires autonomic testing for diagnosis [12]. Thus, the unique early involvement of small fibers in diabetic peripheral neuropathy cannot translate into early diagnosis without the help of the autonomic laboratory.

Since autonomic dysfunction may remain asymptomatic for a long period of time, it is of utmost importance not only to test the ANS qualitatively, i.e., to determine whether autonomic dysfunction is present or absent, but also to quantitate the deficit and to localize the site of the lesion within the ANS. With this perspective, testing the ANS becomes an indispensable part of the evaluation of many secondary neuromuscular diseases but also of primary diseases affecting the peripheral nervous system where dysautonomia or distal pain is a major component of the clinical picture.

Autonomic testing, alone or in combination with other tests such as skin biopsy, should ideally be able to (1) establish the presence or absence of small-fiber involvement in the diagnosis of a neuropathy, distinguish subtypes of neuropathy (e.g., pandysautonomic, cholinergic, adrenergic, or sympathetic), and localize the process as pre- or postganglionic; (2) assess cardiovascular risk factors associated with certain disorders, such as in DM, and evaluate the risk for syncope and sudden death; (3) diagnose syndromic or central autonomic disorders such as the postural orthostatic tachycardia syndrome (POTS), multiple system atrophy, or diffuse Lewy body disease (presenting with isolated end-organ failure, such as impotence, constipation, incontinence, or orthostasis); and (4) delineate the role of the ANS in focal disorders associated with pain as seen in the complex regional pain syndrome (CRPS) also referred to as reflex sympathetic dystrophy.

Basic Principles and Anatomy

Autonomic homeostasis depends on a state of equilibrium between the effects of the two major components of the ANS, the parasympathetic nervous system (PSNS) and sympathetic nervous system (SNS), upon the organs they innervate.

Since each of these systems follows a separate well-defined pathway, little, if any, neuronal interaction occurs between them. Rather, their competitive antagonism occurs at the level of the effector organs. Therefore, most autonomic tests aim at monitoring the response of the effector organ to different maneuvers or stimuli. Test combinations should be selected for optimal dissection of the ANS into its different components and evaluation of as many of its branches as possible. In focal disorders, testing the ANS also allows more precise localization of the geographic distribution of the autonomic disturbance and the site of the lesion.

Basic Anatomy of the Autonomic Nervous System

Every neural system, however simple or complex, comprises of an input (the afferent limb), some decision-making component (an integrator), and an output (the efferent limb). For autonomic function, the afferent limb consists of information regarding the state of the particular end organ of interest conveyed through visceral afferent nerve fibers. This portion of the circuit is often not termed "autonomic" but rather "visceral afferent." Strictly speaking, according to this framework, the autonomic system begins with the central nervous system (CNS) integrators, and proceeds outward, to include the efferent connections, classically divided into parasympathetic and sympathetic branches. The two branches differ in the site at which the signal exits the CNS; the parasympathetic branch is craniosacral, while the sympathetic is thoracolumbar. Acetylcholine activates nicotinic receptors at the ganglia for both systems. The postganglionic segment innervates the end organ through a cholinergic muscarinic connection for the parasympathetic branch and a noradrenergic connection for the sympathetic branch.

The Parasympathetic Nervous System

General Concepts

The PSNS is responsible for maintenance of homeostasis when the organism is at rest. The PSNS is divided into two major segments: preganglionic and postganglionic. The preganglionic segment refers to first-order neurons whose cell bodies lie in the CNS. This includes the brainstem nuclei, such as the Edinger-Westphal nucleus, the salivary nucleus, the dorsal motor nucleus, and the nucleus ambiguus, and the ventral horns and intermediolateral columns of the sacral segments (S2–S4) of the spinal cord. The cranial preganglionic axons travel along cranial nerves III, VII, IX, and X and synapse in parasympathetic (PS) ganglia, in the vicinity or within the target organs, with short second-order neurons that innervate these organs. The sacral preganglionic axons travel with the pelvic nerve to the inferior hypogastric plexus. Most synapse on PS ganglia within the target organs and some on neurons in the myenteric and submucosal plexuses of the enteric nervous system, also with short second-order neurons.

Parasympathetic Ganglia and Effector Organs

Preganglionic fibers arising from the brainstem synapse in the following PS ganglia (Fig. 10.1):

- The *ciliary ganglion* receives PS fibers arising within the Edinger-Westphal nucleus in the midbrain and traveling with the oculomotor nerve (III). Postganglionic fibers innervate the pupillary constrictor and ciliary muscle.
- The *pterygopalatine ganglion* receives PS fibers arising within the lacrimal nucleus in the pons and traveling with the facial nerve (VII). Postganglionic fibers innervate lacrimal glands and palatal, pharyngeal, and nasal mucous glands.
- The *submandibular ganglion* receives PS fibers arising within the salivary nucleus in the pons and traveling with the facial nerve. Postganglionic axons innervate submandibular and sublingual glands and mucous glands of the oral cavity.
- The *otic ganglion* receives PS fibers arising in the inferior salivary nucleus in the medulla and traveling with the glossopharyngeal nerve (IX). Postganglionic fibers innervate the parotid glands and mucous glands of the oral cavity.
- The *visceral ganglia* receive PS fibers arising in the dorsal motor nucleus of X and nucleus ambiguus in the medulla and traveling with the vagus nerve (X). Postganglionic fibers innervate the bronchi and lungs, the heart, the gastrointestinal tract from the esophagus to the descending colon, the liver, the gallbladder, the pancreas, the kidneys, and the intestines.
- Fibers arising from the *sacral spinal cord* (*S2–S4*) travel with the pelvic nerve and synapse in the pelvic plexus (inferior hypogastric), where pre- and postganglionic sympathetic and parasympathetic fibers intermingle. Postganglionic fibers innervate the bladder, descending colon, rectum, and genitalia.

The enteric nervous system, which innervates the gastrointestinal tract, pancreas, and gallbladder, is considered a third and separate division of the ANS [13–16]. Its neurons are interconnected in a complex meshwork forming two major plexuses: the myenteric (Auerbach's) plexus and the submucous (Meissner's) plexus. This system is particularly sensitive to fluctuations of the chemical environment of the gut and to variations in the tension of the gut wall and reacts autonomously to establish homeostasis. However, even though this system can act independently, it is largely controlled by CNS reflexes through both the PSNS and the SNS [13].

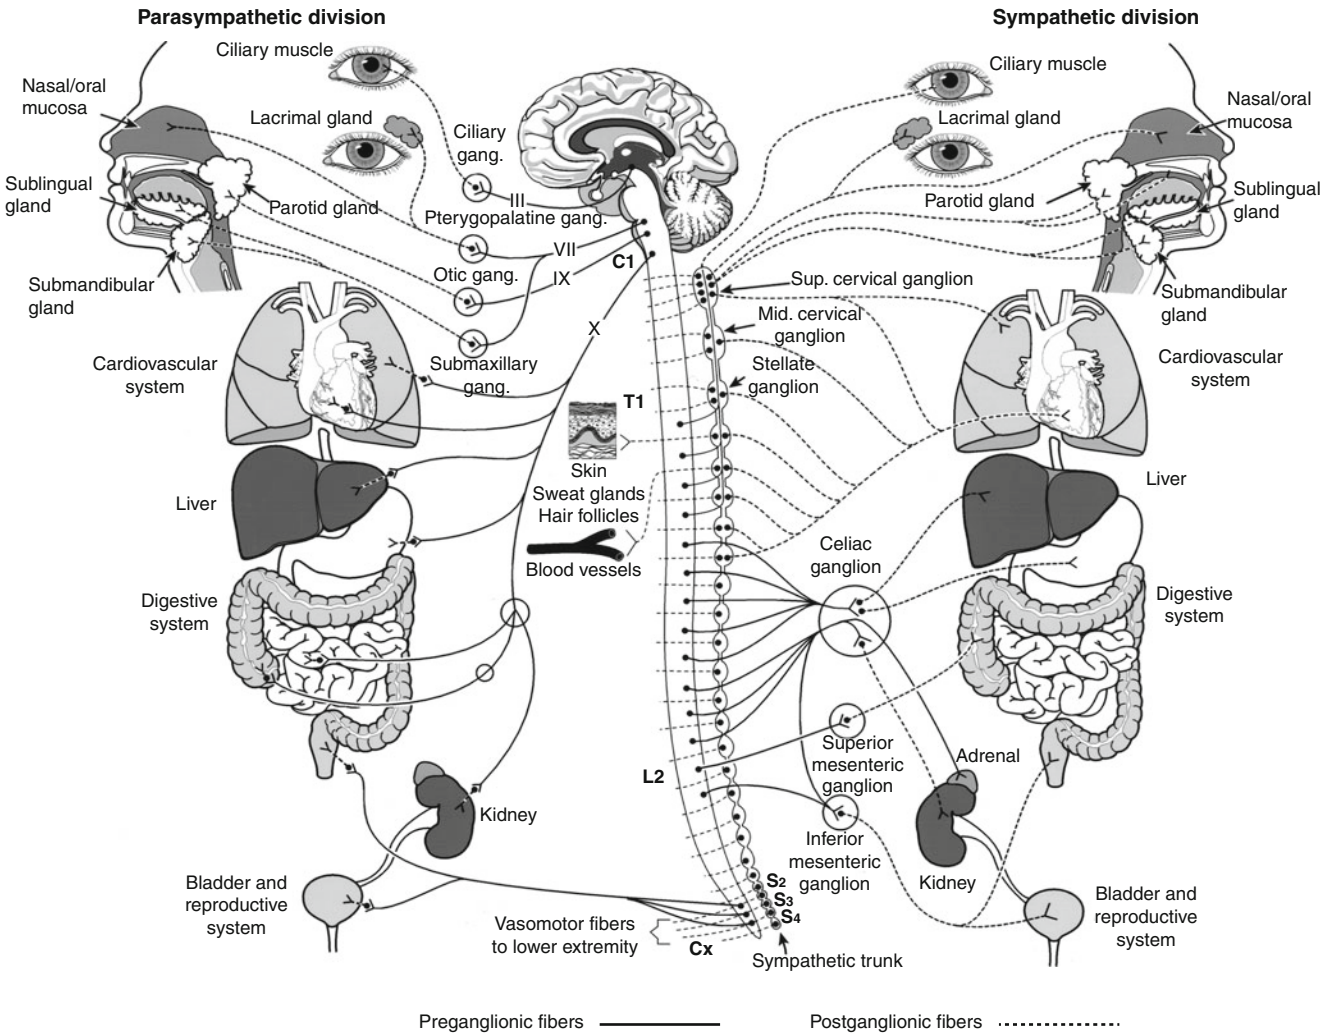

Fig. 10.1 The efferent parasympathetic and sympathetic autonomic systems (Copyright Cleveland Clinic foundation 1999)

The Sympathetic Nervous System

This division of the ANS is mainly responsible for the reestablishment of homeostasis, disturbed by exposure of the organism to external challenges and stimuli. As the PSNS, it arises in the CNS and makes its way to the periphery to innervate target organs. It is also divided into preganglionic and postganglionic compartments.

The sympathetic fibers originate from the hypothalamus, which may be divided into three functional zones: periventricular, medial, and lateral. Each of these zones is formed of nuclei which give rise to neurons that project to autonomic centers in the brainstem: the periaqueductal gray matter in the midbrain, the parabrachial region in the pons, and the intermediate reticular formation of the medulla (ventrolateral medulla). Projections from these structures terminate primarily in the sympathetic preganglionic neurons located in the T1–L2 segments of the intermediolateral cell column of the spinal cord (lamina VII) [17]. These neurons have short myelinated axons that leave the spinal cord through the ventral roots and exit, close to where the ventral root meets the dorsal root to form the spinal nerve, via white rami communicantes to project to the 22 pairs of paravertebral sympathetic trunk ganglia which lie close and parallel to the vertebral column (Figs. 10.1 and 10.2). Here, the preganglionic axons synapse with postganglionic neurons whose long unmyelinated axons travel through gray rami communicantes and join the ventral ramus where they travel along peripheral spinal nerves and innervate target organs (Fig. 10.2). Some preganglionic fibers pass through the paravertebral sympathetic ganglia and branches of the splanchnic nerves to synapse on neurons of the prevertebral (or collateral) ganglia, which include the coeliac ganglion and the superior and inferior mesenteric ganglia. These ganglia innervate the gastrointestinal system and other abdominal organs such as the kidneys, pancreas, and liver. They also provide the major sympathetic innervation to the bladder and external genitalia [16]. One exception is the adrenal medulla, which receives

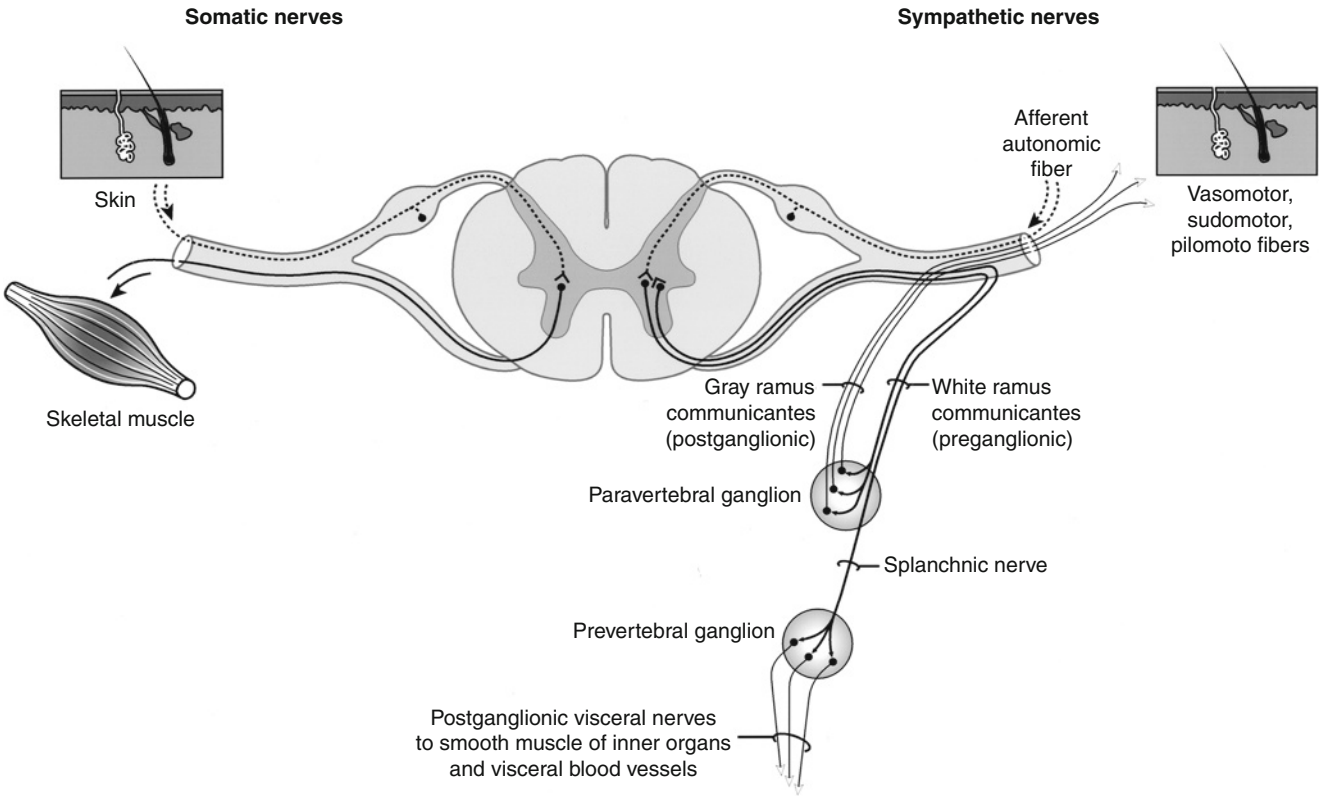

Fig. 10.2 The course of the sympathetic outflow fibers from the spinal cord and roots

only preganglionic fibers, with the medulla being equivalent to a ganglion. Although there is a lot of cross-innervation, it would be fair to presume that fibers originating from T1 segment innervate the head, fibers from T2 the neck, fibers from T3 to T6 the thorax, fibers from T7 to T11 the abdomen, and fibers from T12, L1, and L2 the pelvis and the legs [18].

Cholinergic and Adrenergic Neurons

Acetylcholine is the neurotransmitter for all preganglionic neurons (sympathetic and parasympathetic) and for the parasympathetic postganglionic neurons. For practical purposes, one can simplify the system and conceive the ganglionic acetylcholine receptors as nicotinic and target organ cholinergic receptors as muscarinic, although, in reality, there is a mixture of both at each level. Norepinephrine (noradrenaline) is the transmitter in the postganglionic neurons of the sympathetic nervous system. One exception is sympathetic nerve fibers to the sweat glands, which display acetylcholine as a postganglionic transmitter. Dozens of peptides also modulate synaptic transmission at the autonomic ganglia or act as co-transmitters, but so far, these transmitters do not play a major role in autonomic testing. Some of the most important are substance P, which is mainly found in the intestine where it may play a role in the myenteric reflex. Vasoactive intestinal polypeptide (VIP) is concentrated in the sacral cord and other parts of the CNS and might be co-released with acetylcholine at cholinergic muscarinic junctions, while neuropeptide Y is co-released with norepinephrine. Somatostatin is released in the hypothalamus. Calcitonin gene-related peptide (CGRP) is widely distributed throughout the central, peripheral, and autonomic systems and seems to play a major role in non-cholinergic and non-adrenergic vasodilation [18].

Effects of the Autonomic Nervous System on Target Organs

Cardiovascular System

Activation of sympathetic nerves increases heart rate and contractility of the ventricles and the atria. It causes vasoconstriction of all blood vessels with the exception of some arteriovenous anastomoses in the skin and skeletal muscle vessels, which receive cholinergically mediated sympathetic vasodilators. Activation of the parasympathetic system decreases heart rate and contractility of the atrium only.

Sweat Glands

Sweat secretion is under the control of sympathetic postganglionic fibers with acetylcholine as principal terminal neurotransmitter. However, other neurotransmitters are localized in the periglandular nerves, including catecholamines

[19–22], VIP [23, 24], CGRP, atrial natriuretic peptide (ANF), galanin [25], oxytocin, and ATP [26, 27]. The exact role of these substances in sweat excretion is not fully understood.

Pupils

Activation of the peripheral sympathetic innervation of the radial smooth muscle of the pupil produces dilation of the pupil. Dilation also occurs by central inhibition of the Edinger-Westphal nucleus, via fibers originating from the posterior thalamus. The postganglionic nerves release norepinephrine on to alpha-adrenergic receptors on the dilator pupillae [28]. Constriction of the pupil occurs when it is exposed to light or with near vision. Both reflexes are mediated by the activation of parasympathetic preganglionic neurons whose cell bodies lie in the Edinger-Westphal nuclei. Because afferent impulses are carried to these nuclei by crossing fibers on both sides, illumination of one eye produces constriction of both pupils. Postganglionic nerves release acetylcholine and activate muscarinic receptors on the sphincter pupillae [28].

Bladder

Activation of the sympathetic fibers to the bladder is mediated by norepinephrine, which elicits relaxation of the detrusor muscle and contraction of the trigone, which includes the internal sphincter (bladder neck), and exerts primarily inhibitory effects on synaptic transmission in parasympathetic ganglia. Activation of the parasympathetic fibers utilizes acetylcholine, ATP, and NO as neurotransmitters. Acetylcholine promotes contraction of the detrusor muscle and inhibits release of norepinephrine from sympathetic terminals, ATP promotes bladder contraction, and NO elicits relaxation of the urethral smooth muscle [29].

Salivary Glands

Sympathetic activation produces only weak serous secretion of the submandibular gland, while parasympathetic activation produces copious serous secretions of all salivary glands.

Gastrointestinal System

Sympathetic activation decreases the motility of the gastrointestinal tract by inhibiting the contraction of the longitudinal and circular smooth muscles and causes contraction of the sphincters. In contrast, parasympathetic activation increases the motility of the gastrointestinal tract through the contraction of the longitudinal and circular muscles and relaxes the sphincters.

Autonomic Tests

Although many tests have been devised to assess autonomic function over the last 50 years, certain ones have retained utility, while others have faded. Both economic forces and simple expediency have led autonomic laboratories across the USA to increasingly adopt a fairly standard battery of tests. These include the cardiac response to deep breathing, Valsalva maneuver or handgrip, the cardiovascular response to tilt table test, and one of the several different ways to measure sweat function (axon reflex testing by capsule, direct sweat testing by capsule, thermoregulatory sweat testing, or sweat droplet quantitation using a Silastic imprint).

Testing the ANS in our laboratories includes the following: (1) a measure of cardiac parasympathetic function through the cardiac response to deep breathing; (2) a measure of cardiac sympathetic and parasympathetic functions as well as vasomotor sympathetic function through the Valsalva maneuver; (3) an analysis of the separate arteriomotor and venomotor systems through the tilt table test; (4) a quantitative axon reflex sweat testing (QSART), assessing postganglionic sympathetic cholinergic sudomotor function; and (5) the thermoregulatory sweat test (TST) which is recommended in situations where the first four tests provide ambiguous results. The three tests of cardiovascular function combined with one of the tests of sudomotor function form a commonly used and powerful screen of the ANS, because it evaluates four organ systems (cardiac, arteriomotor, venomotor, and sudomotor) and three physiologically distinct systems (sympathetic adrenergic, sympathetic cholinergic, and parasympathetic cholinergic) and assesses the risk for the most severe complication of autonomic dysfunction, syncope.

Pupillometry has come into greater use recently, as equipment now permits non-pharmacologic analysis of the function of the different ANS branches. This test holds promise, and the evolution of its use will eventually determine its role in autonomic testing.

Finally, direct quantitation of sudomotor fibers was made possible by the development of skin biopsy techniques, which demonstrate both somatic and autonomic sudomotor small-caliber unmyelinated C fibers.

From a practical perspective, interpretation of autonomic studies utilizes each of the tests in a specific way (Tables 10.1, 10.2, and 10.3). The three cardiovascular tests (heart rate variability to deep breathing, the Valsalva maneuver, and the tilt table test) provide a system view, determining which autonomic branches are affected, parasympathetic, sympathetic, or both. In contrast, the sudomotor tests provide information about neuraxis localization, both through the presence or absence of the QSART response and the pattern of the thermoregulatory sweat test (Table 10.3). Tilt table testing also assesses the risk of syncope. When assessing heart rate changes, and determining whether a particular effect is primarily sympathetic or parasympathetic, it should be kept in mind that the parasympathetic system (given a normal heart and sinus node) acts between the heart rates of 40 and 100 beats per minute (bpm), whereas the sympathetic system acts

Table 10.1 Neural pathways of autonomic reflexes

Test	Stimulus	Afferent limb	Central integrator	Efferent limb	Effector organ
Deep breathing	6 deep breaths during 1 min	Vagus nerve, baroreceptors, glossopharyngeal nerve	NTS; hypothalamus	Vagus nerve	Heart
Valsalva maneuver	Forceful (40 mmHg) expiration for 15 s	Glossopharyngeal and vagus nerves	NTS; hypothalamus	Vagus nerve; sympathetic efferents	Heart, blood vessels
Response to standing	Standing up from a supine position	Baroreceptor and muscle	NTS; hypothalamus	Vagus nerve; sympathetic efferents	Heart, blood vessels
Sustained handgrip	30 % of maximal handgrip power for 5 min	Muscle afferent; central command	Cortex; hypothalamus	Sympathetic efferents; vagus nerve	Blood vessels, heart
QSART	Acetylcholine iontophoresis	Axon of postganglionic sympathetic sudomotor nerve	None	Branching axon of postganglionic sudomotor nerve	Sweat glands
TST	Heat	Pre- and postganglionic sudomotor nerves, intermediolateral columns, bulbospinal pathways	Hypothalamus	Sympathetic efferents, pre- and postganglionic sudomotor fibers	Sweat glands
Pupillometry	Brief light	Optic nerve	Edinger-Westphal nucleus	Parasympathetic efferents within oculomotor nerve	Constrictor of the pupil

Modified from Low: Clinical Autonomic Disorders

Table 10.2 Specific information regarding particular autonomic functions derived from cardiovascular autonomic tests

	Parasympathetic cardiac	Sympathetic cardiac	Sympathetic arteriomotor	Sympathetic venomotor	Syncopal risk
Test 1	Cardiac response to *deep breathing* reduced for age	Blunted heart rate increase during *Valsalva phase II*	Diastolic BP drops with *tilt*	Pulse pressure drops *during tilt*	Mean BP < 70, or drops >70 mmHg *during tilt*
Test 2	Blunted heart rate reduction during *Valsalva phase IV*	Cardioacceleration during *tilt* blunted (if BP drops)	Diastolic BP drops with *Valsalva phase II*		BP drop accompanied by HR drop at *end of tilt* (vasodepressor syncope)

Table 10.3 Findings of sweat tests in autonomic disorders

Sweat test	Postganglionic lesion	Preganglionic lesion
Quantitative sudomotor axon reflex test (QSART)	Abnormal with distal > proximal reduction in sweat output	Normal
Thermoregulatory sweat test (TST)	Abnormal with peripheral (stocking-glove) pattern	Abnormal with central (reverse stocking-glove) pattern

between 85 and 160 bpm. Outside the overlap zone between 85 and 100 bpm, the particular branch responsible for an action is clear. In the low range, the parasympathetic system is excited or inhibited to reduce or increase heart rate, and in the high range, the sympathetic system is inhibited or excited for the same effects.

Assessment of the complex regional pain syndrome (CRPS) requires a search for asymmetry with the uninvolved limb, rather than a search for impaired function in comparison to established norms. As a guide in the diagnosis of CRPS, we utilize asymmetry in sudomotor nerve fibers and intraepidermal nerve fiber density on skin biopsy at the zones of maximal allodynia and at the exact contralateral areas of the uninvolved limb [30, 31], asymmetry in resting sweat output and QSART output across two sites in the affected limb compared to the unaffected limb, and asymmetry in resting skin temperature to assist in determining probable response to a sympathetic block [32].

Autonomic testing is indicated (1) to establish a specific ANS diagnosis, such as multiple system atrophy, autonomic neuropathy, or CRPS; (2) to determine whether the ANS is involved in a particular disorder and, thereby, guides the diagnostic process, such as in patients with polyneuropathy or polyradiculopathy of unknown cause, or with parkinsonism; (3) to assess the severity of dysautonomia in disorders known to have a predilection to involve the ANS, such as diabetes mellitus or multiple system atrophy; (4) to evaluate for the possibility of a generalized autonomic disorder in a patient presenting with single-organ failure, such as erectile or sphincteric dysfunction, gastroparesis, or orthostasis; (5) to assess the risk and mechanism of syncope; and (6) to establish the mechanism of orthostatic symptoms (e.g., venomotor vs. arteriomotor failure vs. non-autonomic) and guide management.

Tests of Sudomotor Function

Quantitative Sudomotor Axon Reflex Test

The quantitative sudomotor axon reflex test (QSART) evaluates the postganglionic sudomotor (sympathetic

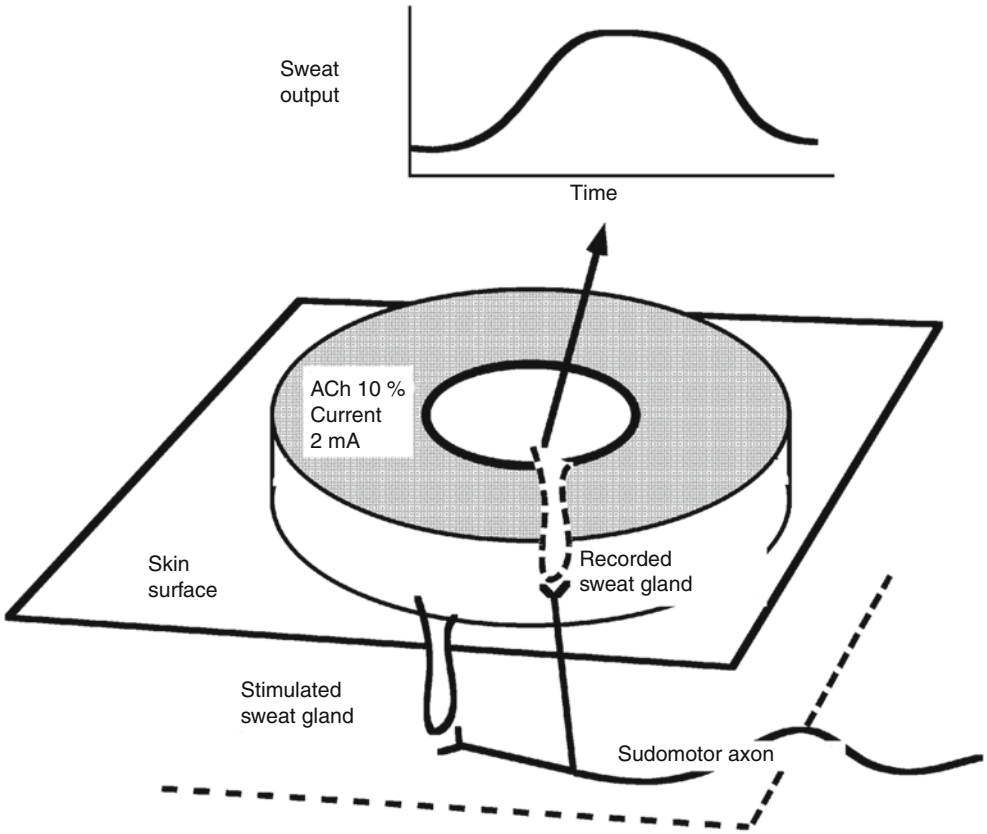

Fig. 10.3 Schematic view of axon reflex sweat test. Ten percent of acetylcholine is applied across the outer chamber of the capsule, stimulating a set of sweat glands, as shown. Sweat output is recorded from the central chamber

cholinergic) nerve fibers. As its name implies, it consists of stimulating the sudomotor nerve in one location and recording the sweat response at a distance. The principle of the test is that stimulating the nerve terminal (innervating a sweat gland) will produce a retrograde action potential along the axon until it reaches a collateral (branching) axon that innervates a different sweat gland. The action potential will then spread along this collateral and induce a release of acetylcholine at its terminal, which in turn will produce a sweat response that is recorded and quantitated (Fig. 10.3). An abnormal QSART can therefore be produced by an abnormality at any of the following five anatomical locations:

- Point 1: the stimulated presynaptic sudomotor nerve terminal
- Point 2: the postganglionic sudomotor nerve axon
- Point 3: the collateral axon
- Point 4: the collateral axon terminal or the synaptic cleft
- Point 5: the sweat gland from which the sweat response is recorded

QSART is widely employed as a sensitive marker of distal autonomic neuropathy, as the response depends on the integrity of the postganglionic segment of the sudomotor nerve. Because it is quantitative, distal-to-proximal gradients can also be detected, giving it good resolution for early disease, such as small-fiber neuropathy where the QSART is abnormal in 60–80 % of patients [33–35]. This test is abnormal in the following conditions:

- Small-fiber sensory neuropathy, such as with diabetes where it is quite sensitive [33]
- Complex regional pain syndrome (CRPS or reflex sympathetic dystrophy) where it may be exaggerated or reduced [32]
- Atopic dermatitis [36]
- Aging (only mildly decreased responses) [37]
- Generalized conditions affecting the ANS, such as generalized autonomic failure [38], postural orthostatic tachycardia syndrome (POTS) [39], parkinsonism-plus and cerebellar disorders with dysautonomia [40], multiple system atrophy (MSA), and pure autonomic failure (PAF) [41]
- Concomitant use of certain medications, particularly anticholinergic medications and tricyclic agents [42]

The test is gender-sensitive. Generally, women have lower sweat responses than men [43]. Table 10.4 lists the normative QSART values adjusted to age and site.

QSART is considered the most sensitive test for the detection of a postganglionic autonomic neuropathy. However, it is time-consuming and necessitates special equipment [45]. Practically, sweat is produced by the iontophoresis of acetylcholine through the skin, using a small-intensity electrical current. It is collected into a two-chambered cell (the sweat

Table 10.4 Normative data for quantitative sudomotor axon reflex test (QSART)

Age	20 years			40 years			60 years

cell) that is strapped to the skin [43]. The sweat response is quantitated by a sudorometer that detects the change in humidity of a nitrogen (or normal air) current flowing in and out of the capsule. The response overtime is a sweat curve, with a typical morphology (Fig. 10.4).

Resting Sweat Output

Measurement of baseline or resting sweat output (RSO) uses the same methodology as the QSART, except that there is no stimulation of sweat response. RSO is measured using larger sweat cells than those used for the QSART. Recording of sweat output is generally made over 5 min. It is important to measure RSO before proceeding with the QSART. The combination of both tests increases the specificity of autonomic testing for the diagnosis of CRPS type I [32]. Table 10.5 lists the normative values of RSO adjusted to sites.

Thermoregulatory Sweat Test

The thermoregulatory sweat test (TST) evaluates the integrity of the entire central and peripheral sudomotor pathway. The term "central" includes the hypothalamus, the bulbospinal pathways, the intermediolateral cell columns, and the preganglionic sympathetic fibers. The term "peripheral" encompasses the sympathetic chain and the postganglionic sudomotor fibers. TST is based on the following assumption: the maximal sweat response is directly proportional to the local skin temperature and the central temperature [46]. Therefore, the test consists of passively raising the body core temperature and the skin temperature in a sweat chamber, under constant conditions of ambient air temperature and humidity using infrared lamps, and visually evaluating the distribution of sweat production by the different regions of the body ("sweat pattern"). An indicator powder, usually Alizarin red mixed with cornstarch and sodium carbonate spread over the body, changes color when it becomes wet (Fig. 10.5) [46]. The powder that is orange when dry turns purple when wet.

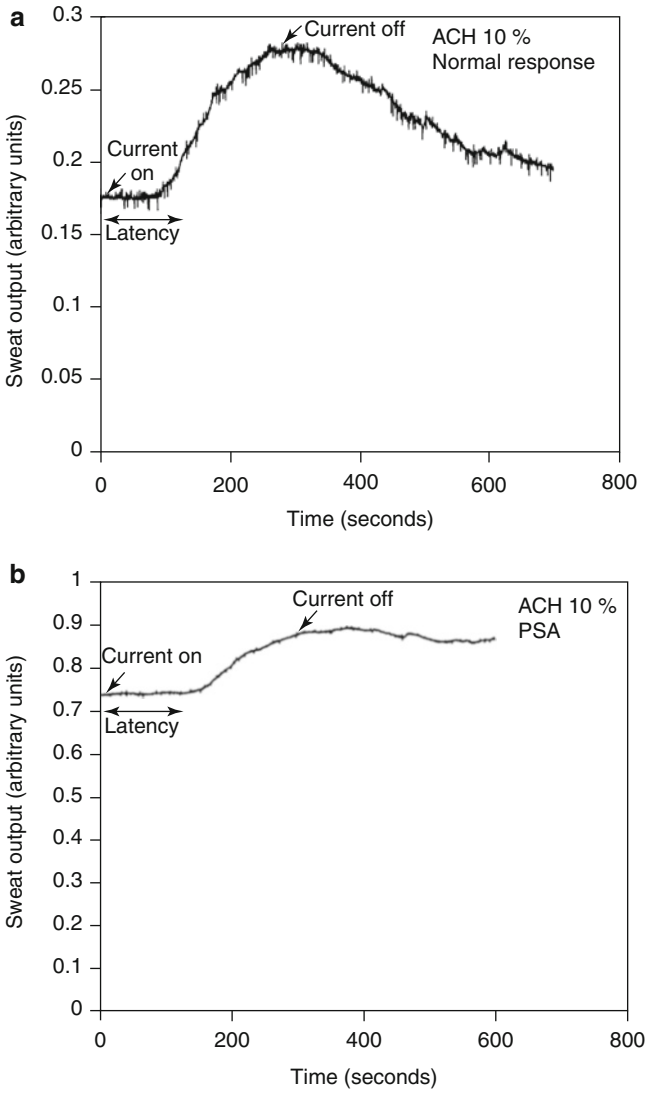

Fig. 10.4 Quantitative sudomotor axon reflex test (QSART). (**a**) Normal response. The tracing represents voltage output proportional to moisture level by an apparatus that senses humidity. Dry air is channeled through a capsule over the surface of the skin and returned to the apparatus for a moisture level assessment. After a baseline reading, current is turned on ("current on"), iontophoresing acetylcholine (10 %) across the skin all the way around the recording site. As a result sweat rate rises, after a 90 s latency. The sweat rate returns to baseline once current is turned off. Note the monophasic appearance of the normal response. (**b**) Abnormal response; "persistent sweat activity (PSA)". Two basic patterns of abnormality occur. The response may be reduced or absent, or (as in this figure) the response may persist excessively. Note the prolonged latency to onset, nearing 200 s, and the absence of clear drop in sweating after the current is turned off. Such a pattern may reflect early denervation and consequent supersensitivity

The TST is age- and sex-dependant [46]. Several sweat patterns are described in normal individuals and in different dysautonomias, and knowledge of these patterns is important for a correct diagnosis [46]. The most typical patterns are the *peripheral pattern*, indicating loss in a stocking-glove distribution, and its mirror image, the *central pattern*, with

Table 10.5 Normative data for resting sweat output (RSO)

Sites	Values		
Hypothenar	0.53	0.49	0.20–0.87
Forearm	0.08	0.10	0.06–0.12
Distal leg	0.12	0.12	0.09–0.72
Proximal foot	0.16	0.16	0.12–0.58

Modified from Low [44]
Values are for mean, 5th, and 95th percentile values

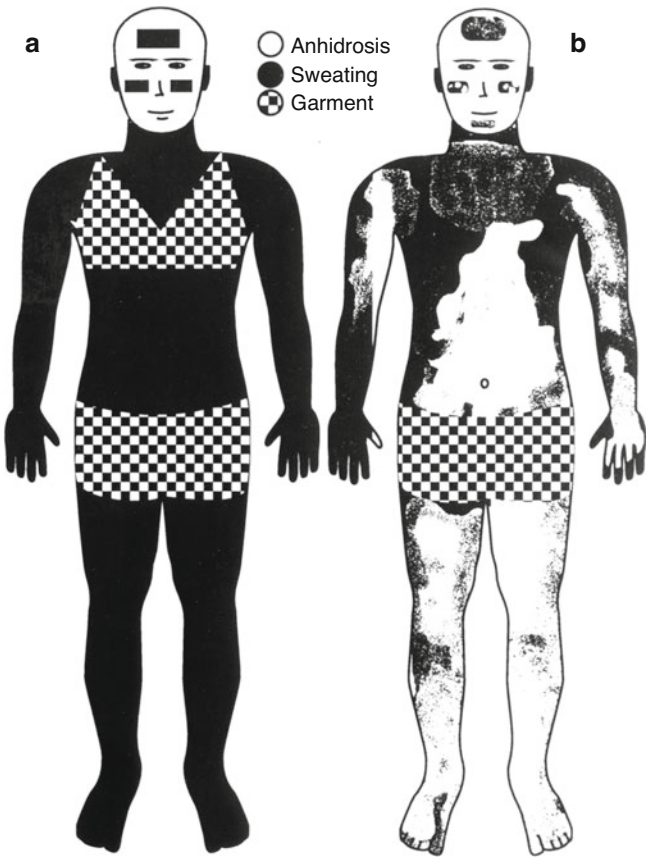

Fig. 10.5 Thermoregulatory sweat test. (**a**) Normal study. (**b**) Reduced sweating (60 % anhidrosis). Note the preservation of sweating along the lateral thigh, anterior leg, upper medial foot, and great toe, suggesting an L5 distribution. This finding would suggest a polyradiculopathy, rather than a peripheral neuropathy, in which one would expect a pure distal-to-proximal gradient of anhidrosis

preservation of sweating over the distal extremities. Other patterns include *radicular pattern*, with stripes of absent sweating marking particular dermatomes, particularly over the thorax, as seen in a ganglionitis or radiculitis, and a *patchy pattern*, with loss of sweating in patches as would occur in leprosy. A *myelopathic pattern* indicates loss of sweating clearly demarcated below a particular level.

Silastic Imprint Technique

The Silastic imprint technique consists of quantitating a local sweat response by iontophoresing pilocarpine into the skin and applying over the area a soft Silastic impression mold that shows the sweat droplets' imprint. The droplets are then counted using light microscopy or through computerized analysis of the molds, which allows automatic sweat gland counts and estimations of the secretion volume of each sweat gland [47]. This technique does not test any specific pathway of the sudomotor system. By directly stimulating the muscarinic receptors, it reflects the integrity of the sweat glands. Nonetheless, because the sweat gland undergoes denervation hyposensitivity (the denervated gland does not respond to pharmacologic stimulation), the Silastic imprint technique is sensitive for detection of sympathetic nerve involvement, even in asymptomatic patients. Its sensitivity and accuracy has been enhanced by the computerized analysis of the molds [47].

Sympathetic Skin Response

The sympathetic skin response (SSR) is of special interest to electromyographers, since it allows the assessment of the integrity of the peripheral sudomotor sympathetic nerve in the setting of an EMG laboratory, using standard EMG equipment and electrodes. The test is expected to be abnormal (reduced amplitude or absent) in diseases affecting the peripheral nerves such as peripheral neuropathies and distal small-fiber neuropathies and possibly (exaggerated) in diseases with sympathetically maintained pain (e.g., in CRPS) [48], but also in central autonomic disorders [49]. The physiologic principle of the test is based upon the observation that an electric potential recorded on the skin (termed "electrodermal activity") reflects the potential generated by sweat glands and the adjacent epidermis and dermis, in response to different stimuli [49, 50]. This potential can be evoked by microneurographically stimulating cutaneous nerve fascicles or postganglionic sympathetic efferent fibers [50] and be suppressed by sympathectomy [51], section of the peripheral nerve that innervates that portion of the skin [52], regional anesthesia of major nerve trunks, and administration of atropine [53]. SSR can be considered a test of sudomotor function, but it should be kept in mind that only a portion of the response (the early fast changes) is due to sweating, whereas the rest of the response (later changes) are due to skin potential changes which were present in patients with congenital absence of sweat glands [54]. SSR is simple to perform. The potential may be recorded by applying a recording (active) disc electrode (similar to the electrodes used in nerve conduction studies) on the palm of the hand or sole of the foot and a reference electrode (inactive) on the dorsum of these two body parts. The patient is stimulated electrically and strongly enough to cause a startle or induce pain. Stimulation is applied to a sensory nerve in the digit, ipsilateral or contralateral to the recording site. Other stimuli that produce a startle reaction can also be used (e.g., a loud noise). A cough or an inspiratory gasp is another acceptable stimulus.

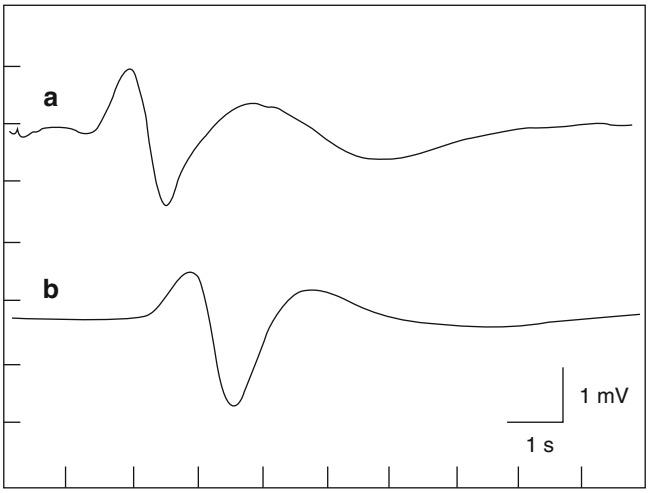

Fig. 10.6 Sympathetic skin response. A shock at the median nerve initiates the sweep. Recording occurs at the contralateral palmar (*A*) surface and contralateral sole (*B*). The response is assessed for latency, amplitude of the initial wave (peak to peak), and morphology. Evidence strongly suggests that this response reflects a wave of sweat secretion, with consequent alteration in surface potential

The amplitude of the SSR is generally variable (between 500 μV and 3 mV, peak to peak) due to the variable morphology of the potential (Fig. 10.6). Although controversy exists about the usefulness of this parameter, it is generally agreed that the latencies are not meaningful since they are produced by conduction along unmyelinated C fibers [48]. The amplifier low-frequency filter (high pass) should be set as low as possible (0.1–0.5 Hz). If it is higher, it attenuates the potential. High-frequency filter should be set between 500 and 1,000 Hz. The disadvantages of the method are that the response is only semiquantitative, can be difficult to elicit and habituates with repetition, and can therefore lead to false-positive results. Another drawback of this test is that it is not specific to the postganglionic portion of the sudomotor nerve and therefore cannot localize an abnormality.

Skin Biopsy

Even though this test is not technically part of the regular armamentarium of an autonomic laboratory, skin biopsy is a useful addition to the above-described sweat tests, as it allows direct visualization of autonomic sudomotor fibers surrounding sweat glands. As the only available quantitative test (as opposed to the above tests being qualitative tests), it can be considered a very useful complement to physiological testing of sudomotor function.

In the past decade, reports of the use of punch skin biopsy and the quantification of intraepidermal nerve fiber (IENF) density as a diagnostic tool in peripheral neuropathy started to flourish. This technique was first developed at the Karolinska Institute in Sweden [55] and then further developed and refined by the major centers that pioneered its use in clinical practice, mainly the University of Minnesota [56] and the Johns Hopkins University [57]. This technique allows the visualization of epidermal, dermal, and autonomic sudomotor nerve fibers surrounding sweat glands (see Chap. 13).

More recently, guidelines on the use of skin biopsy in peripheral neuropathy came out of a task force under the auspices of the European Federations of Neurological Societies (EFNS) [58]. We reproduce some of their major recommendations:

1. The EFNS task force recommends a 3 mm punch biopsy be performed. This biopsy is safe, causes minimal bleeding, and does not need stitches if proper care is taken. The recommended biopsy sites are the distal leg and the proximal thigh. These sites allow the assessment of a distal peripheral neuropathy and give information about a length-dependent process.
2. The recommended staining agent is the protein gene product (PGP) 9.5, a ubiquitin carboxyl-terminal hydrolase. It stains all types of axons. The biopsy specimen is immediately fixed in a cold fixative (2 % PLP) for up to 24 h at 4 °C, then kept in a cryoprotective solution for one night and serially cut with a freezing microtome or a cryostat. Each biopsy yields about 55 vertical 50 μm sections. The immunostaining methods commonly used are bright-field immunohistochemistry and indirect immunofluorescence with or without confocal microscopy. Quantification of IENF density is performed on images stacking 16 sections of consecutive 2 μm sections for a standard linear length of epidermis from 1 to 3 mm. IENF should be counted at high magnification (40×) in at least 3 sections per biopsy. Only fibers that cross the dermis-epidermis barrier should be counted, excluding secondary branching. This is controversial as some centers include free nerve fragments within the epidermis in the count, even if they do not cross the barrier. In order to calculate the IENF density, the number of counted fibers in a section is divided by the length of the section and expressed as #IENF/mm [59].
3. Diagnostic efficiency and predictive values of skin biopsy with linear quantification of IENF in the diagnosis of SFN are very high. Bright-field microscopy was used in order to determine cutoff values or epidermal densities, but immunofluorescence is an acceptable method for counting fibers. Normative data which is age, gender, ethic, and anatomical site-matched is available and should be used. Normal IENF density in the lower leg ranged in different studies between 17.4 ± 7.4 and 33.0 ± 7.9/mm.
4. Morphological changes of small fibers can also be assessed, such as axonal swellings, branching, and fragmentation. Axonal swellings in the lower limb are thought to have a predictive value to the progression of

the neuropathy. Whether or not one can diagnose a SFN based on swellings alone is not clear.

5. There is a correlation between skin biopsy and other neurophysiological tests, mainly sural nerve conduction studies, in large-fiber neuropathies, whereas IENF density is more sensitive than EMG in diagnosing SFN. A linear correlation between the medial plantar sensory nerve potential amplitude and IENF density has been reported [60]. IENF density inversely correlated more closely with warm and heat-pain threshold than with cooling threshold on quantitative sensory testing (QST) [61, 62]. A significant correlation was found between the decrease of IENF density and abnormal QSART [63], which is also our own experience.

The above recommendations and most of the experience gained in skin biopsy focused on the precise quantitation of somatic small nerve fibers. This is unfortunately not the case with sudomotor nerves. The complexity of their anatomical distribution around sweat glands has made it difficult to devise a simple generalizable technique for counting these nerve fibers, and as a result, normative data still do not exist. Most of determinations regarding the normality or abnormality of the test are based on a subjective impression of decreased or normal numbers of sudomotor fibers surrounding sweat glands. Therefore, caution is to be exerted in the interpretation of this test and it is important not to conclude hastily that an abnormality in IEFND necessarily reflects an abnormality in C-fiber autonomic function.

Cardiovascular Autonomic Tests

The heart is innervated by the PSNS and SNS. Similarly, the peripheral vasculature receives fibers from both arms of the ANS. However, sympathetic fibers have a predominant action at the level of the peripheral vasculature, whereas the parasympathetic has little influence. The responses of the heart and peripheral blood vessels to the autonomic tests described below are reflex compensatory responses. For example, a decrease in blood pressure (BP) leads to a reflex increase in heart rate (HR) and a reflex vasoconstriction, whereas the opposite is true with an increase in BP. Afferent fibers of this reflex pathway originate at the level of the baroreceptors of the carotid sinus, arterial walls, aortic arch, cardiac mechanoreceptors, and pulmonary stretch receptors. An increase in afferent activity leads to a decrease in sympathetic efferent activity, an increase of parasympathetic efferent activity, or both and vice versa [47]. *Photoplethysmographic blood pressure recordings*, also called the *Finapres* technique, is a noninvasive method of measuring BP with every heartbeat (BPBB). It consists of an infrared sensor that is applied to the finger within a finger cuff and records its blood volume. Through a computerized servo system, the blood pressure is recorded beat to beat and accurately reflects intra-arterial pressures [43]. This technique is useful in detecting sudden changes in hemodynamics as a result of the autonomic compensatory reflex. It is commonly used in the Valsalva maneuver, the deep breathing test, and the tilt test.

Heart Rate Response to Deep Breathing

Heart rate variability with deep breathing (HRDB) is one of the most commonly performed tests to evaluate the autonomic innervation of the heart. It is simple to perform and provides a sensitive, specific, and reproducible indirect measure of cardiovagal nerve function [64].

Basic Principles

The physiologic principle of the test is thought to be based on the following mechanisms that occur during the respiratory cycle (see Table 10.1):

- Inhibition of vagal efferent activity with inspiration [65].
- Baroreceptor reflex (carotid sinus reflex) (Fig. 10.7): changes in baroreflex sensitivity with respiratory phases and consequent variations in arterial BP [66, 67]. The variation in BP (mainly increases) also stimulates these receptors, which send impulses along the afferent limbs of the glossopharyngeal nerve (nerve of Hering) and vagus nerve to the nucleus tractus solitarius (NTS) in the medulla. The central-caudal area of the NTS also receives input from the hypothalamus. The response then decreases sympathetic activity, which, in turn, decreases HR [68].
- The Bainbridge reflex: responds to changes in the right atrium (RA) volume or central venous pressure via stretch receptors located within the RA wall and cavo-atrial junction. Increases in intravascular volumes or right-sided filling pressures stimulate these receptors, which also send their impulses through vagal afferents to inhibit PS activity and to increase HR [68].

The "time domain" measure of HR is a commonly used term that refers to statistical measures of HR variability with respiration. These measurements are derived from a regular strip of an electrocardiogram (EKG) performed while the patient is breathing deeply in the supine position. The most commonly used are maximum minus minimum HR difference and inspiratory/respiratory (I/E) ratio (i.e., the shortest RR interval during inspiration to the longest RR interval during expiration). We note that the duration of the RR interval is inversely proportional to the HR.

Practical Considerations

The patient is asked to take six deep breaths during 1 min (inspiratory and expiratory cycles of 5 s each). The procedure is repeated after 2 min of rest. An EKG recording is made during deep breathing and the previously described parameters are calculated by a computer (Fig. 10.8). Though

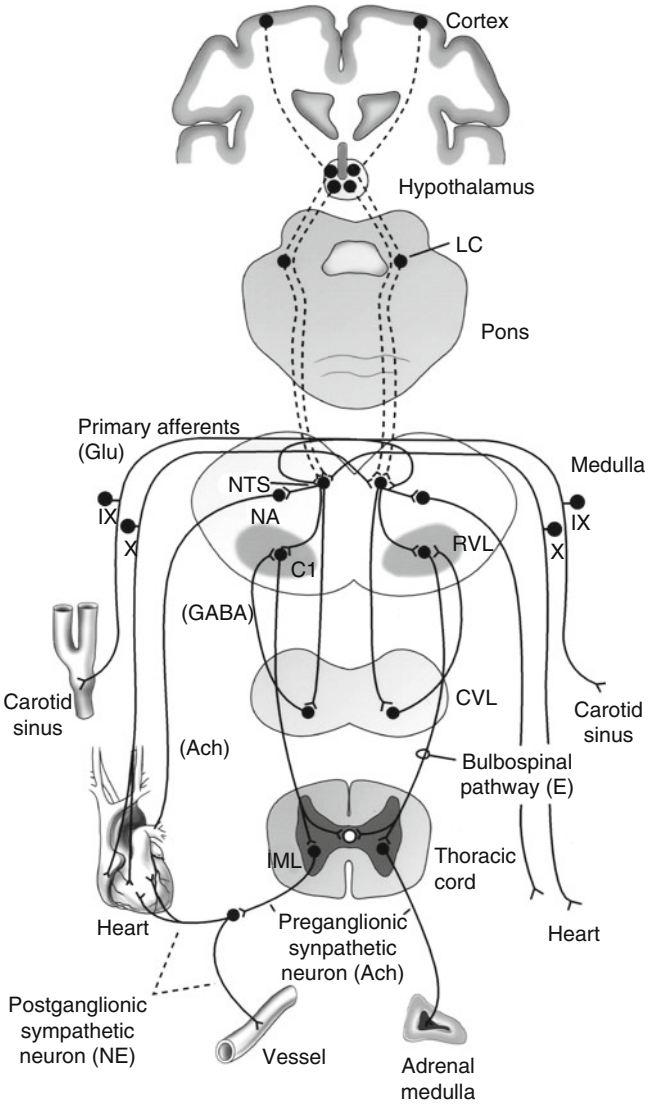

Fig. 10.7 Proposed pathways and neurotransmitters of the baroreceptor reflex. *NTS* nucleus tractus solitarius, *NA* nucleus ambiguus, *CVL* caudal ventrolateral medulla, *RVL* rostral ventrolateral medulla, *Cl* ventrolateral epinephrine cell area, *IML* intermediolateral cell column, *IX* glossopharyngeal nerve, *X* vagus nerve, *LC* locus ceruleus, *GABA* gamma-aminobutyric acid, *Glu* glutamic acid, *E* epinephrine, *Ach* acetylcholine, *NE* norepinephrine (Copyright Cleveland Clinic foundation 1999)

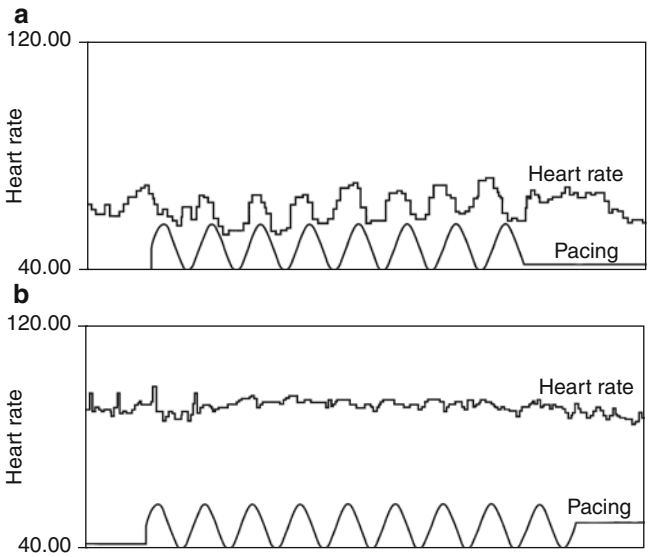

Fig. 10.8 Cardiac response to deep breathing. (**a**) Normal response. Breathing is paced at 6 breaths per minute (8 breaths are shown, *lower trace*). Heart rate is shown in the *upper trace* and increases with each inspiration. The difference in heart rate within each respiratory cycle is averaged for the five best responses. (**b**) Abnormal response. A patient with moderately severe autonomic failure demonstrates little to no heart rate variation with deep breathing. Note also that the baseline heart rate is higher than in **a**, a finding suggestive of cardiac denervation

Table 10.6 Variation in heart rate with deep breathing

Age (years)	Heart rate variation
20	13–43
40	9–36
60	7–29
80	7–29

Modified from Low [44]

other parameters are described [64], the HRDB test is the most commonly used and reproducible test of parasympathetic cardiac nerve function.

Pitfalls

Limitations of the HRDB involve the following factors:

1. *Age*: RR variation with respiration has been shown to vary with age in a linear fashion [37]. Therefore, normative data adjusted to age groups should be used in order to avoid false-positive or false-negative results (see Table 10.6).
2. *Time of testing*: there is a circadian variation of HRDB variability, this being largest at night and smallest in the morning [69].
3. *Medications*: Drugs, especially those with anticholinergic side effects, can alter the accuracy of the testing [42]. We recommend stopping them at least five half-lives prior to the test.
4. *Other factors*: body weight and body mass index [70], hypoxia [71], physical condition [72], and others [64] have an effect on HRDB variability.

The Valsalva Maneuver

Another commonly used test of parasympathetic cardiovascular autonomic function is the heart rate response to the Valsalva maneuver (VM). It consists of a precisely timed forced expiration against resistance, which leads to a series of hemodynamic changes.

Basic Principles

The hemodynamic changes induced by the VM are classically divided into four phases of which only phase II and IV

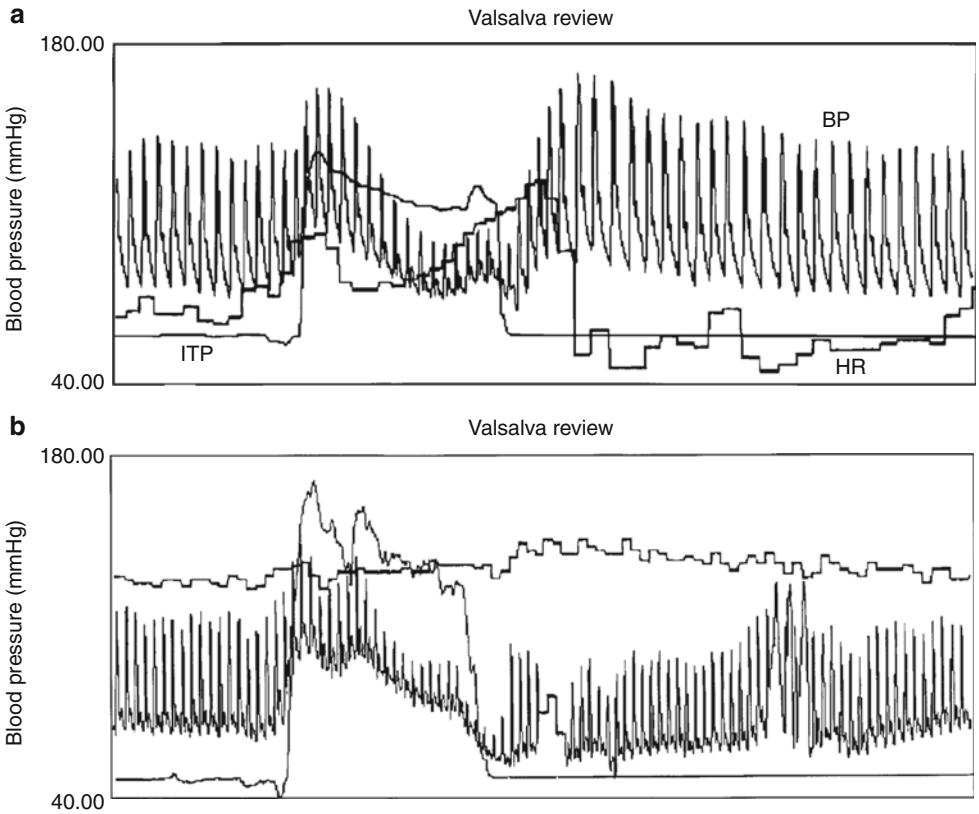

Fig. 10.9 Valsalva maneuver. (**a**) Normal response. The recording totals 60 s. The lowest trace shows oral/intrathoracic pressure maintained as recorded at the mouthpiece. The middle trace records heart rate, and the *upper trace* displays beat-to-beat blood pressure. About 12 s into the recording, the patient holds 40 mmHg and maintains pressure for 15 s. As a consequence of reduced venous return, blood pressure and pulse pressure drop, and heart rate rises in compensation. The Valsalva ratio is obtained by dividing the highest heart rate during pressure holding (phase II) by the lowest heart rate after release (phase IV). (**b**) Abnormal response. The heart rate is rapid at start and does not change, while the blood pressure drops without a plateau

are clinically significant (Fig. 10.9). Variation of BP during the test reflects the integrity of sympathetic adrenergic cardiovascular function [73]. Heart rate variation (Valsalva ratio) is a compound of heart rate acceleration in phase II (sympathetic) to heart rate deceleration in phase IV (parasympathetic). The ratio reflects the integrity of the parasympathetic cholinergic and the sympathetic adrenergic cardiovagal function. If the ratio is low, one then determines if the problem is in phase II or IV to conclude whether the SNS or PSNS is impaired (see Table 10.2).

Phase I: A transient increase in BP and drop in HR occurs at the start of the expiration. This phase is purely mechanical and not controlled by the ANS. It consists of a transient rise in BP and fall in HR due to the sudden increase in intrathoracic pressure, which leads to a transient compression of the aorta and propulsion of blood into the periphery.

Phase II: Early in phase II, there is a decrease in BP and increase in HR. The decrease in venous return caused by the increase in intrathoracic pressure leads to a decrease in cardiac output (drop in BP) with a compensatory increase in HR, through the activation of the low-pressure atrial receptors, and the integrator of this information is the nucleus tractus solitarius. Late in phase II, and with continued straining, there is a return of BP to normal and continued increase in HR. The BP normalizes due to peripheral vasoconstriction, which occurs secondary to activation of the muscular and vascular sympathetic systems. This normalization is sympathetic as it is blocked by the administration of phentolamine, an alpha-blocker. The early heart rate increase is vagally mediated, while the peak of phase II is sympathetic.

Phase III: There is a transient fall in BP and increase in HR, which corresponds to cessation of expiration. The release of the strain causes mechanical displacement of blood to the pulmonary vascular bed, which was under increased intrathoracic pressure, resulting in a transient drop in BP. Like phase I, this is mechanically induced and not mediated by the ANS.

Phase IV: There is a large increase in BP (overshoot) and fall in HR due to the return to normal of the venous return, leading to a return to normal of the cardiac output while peripheral vasoconstriction is still present. The accompanying bradycardia is a baroreflex-mediated response (see Fig. 10.7) [74]. The BP overshoot is sympathetically mediated through cardioacceleration as it is decreased by propranolol (a beta-blocker) and unaffected by phentolamine (an alpha-blocker) [73].

The analysis of VM is mainly based on the "Valsalva ratio" (VR). This is the ratio of the shortest RR interval (maximal tachycardia) in phase II to the longest RR interval (maximal bradycardia) during phase IV. This ratio is a sensitive, specific, and reproducible measure of autonomic, mainly cardiovagal, functions [64].

Practical Considerations

The patient is asked to blow into a bugle with an air leak (so that pressure really comes from the chest and the abdomen) for 15 s and maintain a pressure of 40 mmHg. BPBB and HR are recorded during the maneuver. The maneuver should be repeated until two responses of similar BPBB and HR are obtained. Typically, in cardiovascular dysautonomia, there is loss of the BP overshoot and the reflex bradycardia in phase IV. Table 10.7 lists normative data for the VR.

Pitfalls

Several factors can affect the accuracy of the Valsalva ratio. As with most tests of the ANS, gender and age are important considerations before interpreting the test. Medications, especially those with anticholinergic or anti-adrenergic effects, should be stopped five half-lives before the test. Patient position during the test and the duration and quality of the expiratory effort significantly affect test results. Another important pitfall was described in patients with isolated sympathetic vasomotor lesions but intact cardiovagal function [75]. In such patients, because of poor peripheral vasoconstriction in phase II, BP falls excessively and reflex tachycardia is also excessive, whereas BP overshoot is decreased in phase IV and consequently bradycardia does not occur. This situation yields a misleading normal VR.

Table 10.7 Valsalva ratio normal values

Age		20 years	40 years	60 years	80 years
Values	Men	1.50–2.97	1.36–2.60	1.21–2.23	1.21–2.23
	Women	1.41–2.97	1.47–2.88	1.36–2.65	1.36–2.65

Modified from Low [44]

Conclusion

The VM is a good indicator of both parasympathetic and sympathetic failure. The VR is thought to reflect the status of the cardiovagal system although this is controversial [76, 77]. The variation of BP during the maneuver, especially BP overshoot in phase IV, is indicative of the integrity of the sympathetic fibers to the heart and vessels.

Heart Rate Response to Standing

This simple test to perform is part of the routine autonomic screening of cardiovascular function. As in the VM, monitoring heart rate variation with standing reflects the integrity of parasympathetic cardiovagal function and sympathetic cardioadrenergic function, whereas BP variation reflects the state of sympathetic cardiovascular function.

Basic Principles

As in the VM, two major events occur during the test: an initial drop in BP and increase in HR, followed by a relative BP overshoot and bradycardia. The first event or phase 1 occurs within the first 15 s after standing up, and the second, or phase 2, at approximately 30 s after standing up (Fig. 10.10). The initial drop in BP is thought to be caused by

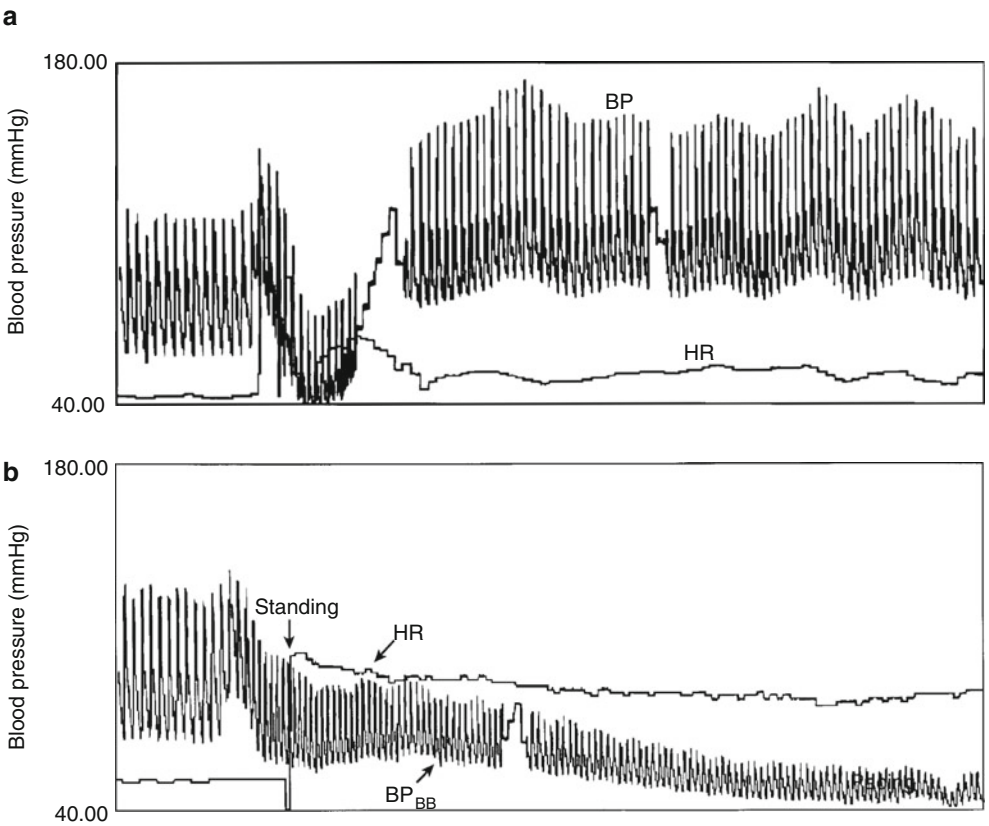

Fig. 10.10 Standing test. (**a**) Normal response. The *lower trace* shows heart rate, the *upper* beat-to-beat blood pressure. Total recording time is 1 min. At 10 s, the patient stands. Blood pressure drops and heart rate rises temporarily. Return to a new plateau occurs promptly, with a slightly higher heart rate and blood pressure. (**b**) Abnormal response. Heart rate rises and blood pressure drops as before, but return to near-baseline values does not occur. Blood pressure continues dropping, and the patient would have lost consciousness if the stand had continued

Table 10.8 Principal indications of head-up tilt test for evaluation of syncope

Tilt table testing is indicated
Recurrent syncope or single syncopal episode in a high-risk patient with or without structural cardiovascular disease, in which cardiac, cerebral, or cerebrovascular causes have been excluded
Further evaluation of patients with a structural cardiac cause of syncope (e.g., asystole, atrioventricular block), in whom the demonstration of a susceptibility to neurally mediated syncope would alter treatment
Evaluation of exercise-induced or exercise-associated syncope
Tilt table testing not indicated
Single syncopal episode with clear-cut vasovagal clinical features, without injury and not in a high-risk patient
Syncope in which an alternative specific cause has been established and in which additional demonstration of a neurally mediated susceptibility would not alter treatment
Relative indications
Differentiating convulsive syncope from seizures
Evaluating patients with recurrent unexplained falls
Assessing recurrent dizziness or presyncope
Evaluating unexplained syncope in the setting of peripheral neuropathies or dysautonomia
Follow-up evaluation to assess therapy of neurally mediated syncope

the orthostatic stress produced by standing up and a reflex release of vasoconstrictor tone. In one study, standing elicited a transient 25 % fall in mean blood pressure as a result of a 36 % fall in total peripheral resistance [78]. The initial increase in HR is thought to be due to 2 physiological events: (1) an "exercise reflex" triggered by standing up and caused by muscular contractions and (2) withdrawal of vagal tone. A more gradual increase in HR is caused by a reflex increase in sympathetic activity and further vagal inhibition. The later increase in HR occurs through a baroreflex-mediated mechanism in response to the transient hypotension. The second phase of the response occurs around 30 s after standing up and is characterized by a return to baseline of HR and BP followed by a BP overshoot and a reflex bradycardia.

Practical Considerations

The patient is kept at rest in the supine position for at least 20 min before standing. This is because shorter periods lead to different standing responses [79]. Continuous EKG and BP recordings are made during rest and for 1–3 min after standing up. The EKG allows calculation of the 30:15 ratio. This test allows determination of orthostatic hypotension (OH). Its hallmark in autonomic failure is the absence of compensatory tachycardia [47]. This diagnosis should only be made after ruling out all other possible medical causes of OH.

The principal measurement from the standing test is the 30:15 ratio. This is made by dividing the longest RR interval that occurs at or around 30 cardiac beats after standing (reflects the minimum HR) by the shortest RR interval that occurs at or around 15 s (reflects the maximum HR). With a lesion of the parasympathetic cardiovagal fibers, phase 2 bradycardia does not occur, hence decreasing the ratio. This ratio provides a measure of cardiovagal function.

Pitfalls

Caution should be taken in interpreting the standing test as its results can vary according to the technique used. For example, it is important to specify the starting point for measuring HR after standing: onset of standing or a complete erect position. Age and medications are other factors to be considered before the interpretation of the test. Finally, as with the VM, patients with an isolated sympathetic vasomotor lesion with intact cardiovagal function can display a decreased 30:15 ratio due to failure of the BP to increase during phase 2 of the response, leading to an absence of the reflex bradycardia. Therefore, this ratio should not be interpreted as a cardiovagal failure. For this reason, it is always important to assess HR variation in relationship to BPBB during the interpretation of the test [53].

Head-Up Tilting

Basic Principles

Head-up tilting represents a passive form of standing, and therefore, the initial hemodynamic events differ from the standing test. The initial drop in BP is less marked or absent. Instead, there is a slow increase in BP, mainly the diastolic. Similarly, HR increases gradually and the initial increase seen during active standing is not observed. This difference is probably due to the absence of "exercise reflex" produced by the orthostatic stress and activation of the muscle pump, during passive tilting [80]. Because the above-mentioned event induces a series of neurally mediated changes, active standing is preferred over head-up tilting as a way to assess orthostatic neural control in the initial phase. However, during the later phases, head-up tilting and active standing induce similar hemodynamic adjustments. Head-up tilting remains a more advantageous technique in patients with severe OH since it provides the possibility of returning quickly to the supine position.

Practical Considerations

Despite controversies about the degree of tilting and the positive endpoints, this test constitutes the gold standard in assessing neurocardiogenic syncope (Table 10.8) [81, 82]. Most authors agree that the angle of tilt should be at least of 60°. Most laboratories use 70° or 90°, which produce similar hydrostatic effects. The speed of tilting has little or

no influence on the initial orthostatic response to upright tilting [81]. Reproducing syncope is the ultimate positive endpoint of the tilt test. Also, a cardioinhibitory response (bradycardia or asystole) and a vasodepressor response (hypotension without bradycardia) are equally positive endpoints.

Power Spectral Analysis of Beat-to-Beat Heart Rate Variability Signal (Valsalva and Tilt)

Basic Principles

A power spectrum graphically displays the prevalence of particular frequencies in a signal. For example, if a recording lasting 150 s comprises 100 s of 0.5 Hz signal (one occurrence every 2 s) and 50 s of a 0.1 Hz (one occurrence every 10 s), the power spectrum would show a peak over the *x*-axis at 0.1 and a larger peak over the *x*-axis at 0.5 (larger, because it occurred during a larger portion of the total signal). Heart rate naturally varies at two frequencies: a relatively higher frequency which matches breathing frequency and usually falls around 0.15 Hz and a lower frequency related to heart rate changes with activity, around 0.06 Hz. The higher frequencies are thought to represent parasympathetic cardiac influence, while the lower frequencies reflect sympathetic cardiac influence. Detailed reviews of this method are available [83–87].

Practical Considerations

The patient should be quiet and supine for 10 min of EKG recording. Respiratory rate should be monitored and recorded, as low-frequency respiration will cause the respiratory frequency to drop into the non-respiratory range. Data acquisition should proceed at a sampling rate of at least 250 Hz, and artifacts, such as extrasystoles and muscle "noise," are removed. Several functions then need to be applied to the data, including resampling for equidistant data presentation, with some filtering and smoothing, before computation of the Fourier power spectrum. Low frequency is defined as 0.04–0.15 Hz and high frequency as 0.15–0.4 Hz [85].

Pitfalls

The seeming simplicity of this method is deceptive. The power spectrum represents highly transformed data, and the method should not be used without clear and consistent evaluation of the raw data and great familiarity with the method. Absence of these safeguards results in, what the 1970s programmers call, "GIGO" (garbage in, garbage out) and has resulted in much retrospective criticism of the published literature. Two factors cause most of the misinterpretations: (1) inadequate control and recording of respiratory rate, with consequent inability to determine the expected high frequency, and (2) failure to adequately handle artifacts, such as extrasystoles and muscle, in addition to other factors.

Pupillometry

The use of pupillometry for testing the ANS is the object of renewed interest after the emergence of new-generation infrared dynamic pupillometers, which are reliable, relatively easy to use, and commercially available instruments [88–95].

Anatomy

The pupil is innervated by both the SNS and the PSNS. Preganglionic parasympathetic fibers travel along the third cranial nerve and synapse in the ciliary ganglion. Postganglionic fibers innervate the constrictor of the pupil through the short ciliary nerves. Activation of this smooth muscle produces constriction of the pupil. This is mediated by the release of acetylcholine at the synaptic junction and the interaction of the neurotransmitter with muscarinic ACh receptors.

Sympathetic innervation to the pupil is composed of three neurons designated first-, second-, and third-order neurons. The first two are preganglionic neurons, whereas the third-order neuron is postganglionic. Preganglionic first-order neurons emerge from the hypothalamus and their axons descend in the brainstem into the spinal cord where they synapse in the ciliospinal center of Budge, in the intermediolateral column, with the cell bodies of second-order neurons. Axons of second-order neurons exit the spinal cord through the ventral roots of the T1–T2 segments and enter the cervical sympathetic trunk at the level of the inferior cervical ganglion. They then take an upward course, traversing the inferior and middle cervical ganglions to the superior cervical ganglion where they synapse with the cell bodies of the third-order neurons. These postganglionic neurons project their axons along the course of the internal carotid artery and then join the ophthalmic branch of the trigeminal nerve to enter the orbit through the superior orbital fissure. These fibers finally enter the eye with the long ciliary nerves and innervate the dilator pupillae muscle by releasing norepinephrine that binds to mainly alpha-adrenoreceptors on this muscle.

Basic Principles

The principle of *dynamic infrared pupillometry* consists of quantifying the change of the pupil diameter during the course of a light reflex and dividing it into several kinetic parameters, which are analyzed separately (Table 10.9). These parameters reflect the activity of the two branches of the ANS in response to a light stimulus resulting in pupillary constriction and redilation phases (Fig. 10.11). The term "infrared" refers to illuminating the tested eye in a dark environment by an IR light that is reflected by the iris into the pupillometer, allowing this device to estimate the variation in pupil diameter.

Table 10.9 Some pupillometric parameters and their significance

Parameters	Initial diameter (ID)	Minimal diameter (MD)	Reflex amplitude (RA)	Constriction velocity (CV)	Redilation velocity (RV)	Latency
Definition and significance	Dark-adapted pupil diameter prior to light reflex. Reflects sympathetic-parasympathetic balance	Minimum diameter reached by pupil during light reflex. Reflects parasympathetic function?	ID – MD Depends on ID. Reflects parasympathetic function?	Reflects parasympathetic function	Reflects sympathetic function	Time between onset of flashlight and start of pupillary constriction. Unclear significance.[a] Reflects number of sphincter pupillae acetylcholine receptor? Parasympathetic function?

[a]Seems to be prolonged in myasthenia gravis (personal observation)

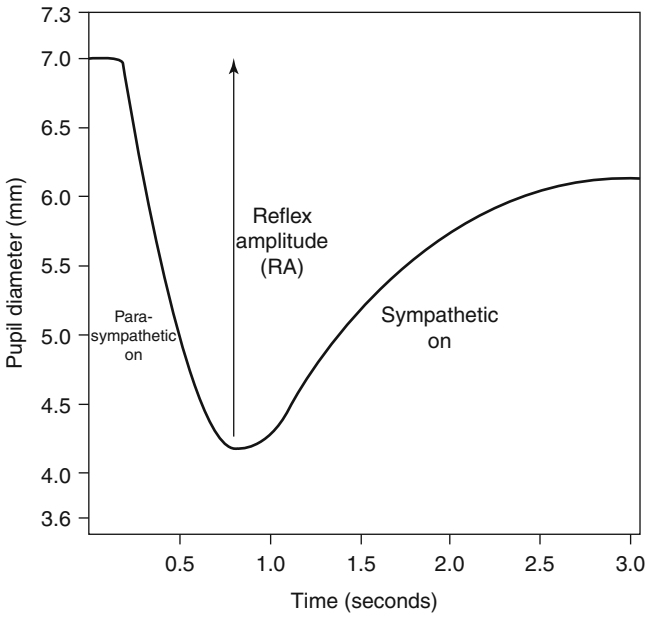

Fig. 10.11 Pupillometry. A 200 ms pulse of light shines into the eye at time 0. As a result, the pupil constricts and subsequently dilates (since the light turns off). This simple procedure yields the following information: (1) latency to onset of dilation, (2) slope of constrictive (parasympathetic) phase, (3) reflex amplitude, and (4) slope of redilation (sympathetic) phase

Pitfalls

Care should be taken in the interpretation of pupillometric data, taking into account multiple factors which could interfere with pupillary function. For example, patients with diabetes have abnormalities of pupillary reaction to light (near-light dissociation) and an increased incidence of cataracts which interfere with pupillary function.

Pupillary initial dark-adapted diameter and consequently reflex amplitude decrease with age, and the time to 75 % redilation increases with age [28]. Latency seems also to be affected by age and gender. Drugs, caffeine, nicotine, lack of sleep, and fatigue may also play a role in modifying pupillary kinetics (authors' unpublished observations). Normative data are lacking for most pupillometric parameters and studies of normal subjects and patients with dysautonomia are needed.

Table 10.10 Supine and standing norepinephrine levels by disease subtype

Position	Normal	Preganglionic lesion	Postganglionic lesion
Lying	X	X	0.25 X
Standing	X	1.25 X	0.5 X

In the normal state, the baseline value is assumed to be an arbitrary number (varies by laboratory) "X." This usually doubles after 10 min of standing. The disease states are assumed to have reduced the respective neuron population by 75 %. In a preganglionic disorder, baseline norepinephrine is unaffected because postganglionic release does not depend on central stimulation. In the upright position, since 75 % of the preganglionic neurons are gone, only 25 % of the postganglionic neurons receive a signal, and norepinephrine level rises by 25 % instead of 100 %. For a postganglionic disorder, only 25 % of terminals are left, reducing baseline norepinephrine by 75 %. However, those remaining have intact central connections, with normal doubling of value

Plasma Catecholamines

Supine plasma norepinephrine (noradrenaline) blood level is dependent on its release by unstimulated sympathetic postganglionic noradrenergic terminals. In contrast, the standing value reflects activation of these terminals by central command. Table 10.10 delineates the change in norepinephrine level after 10 min in each position. These levels are useful in large population studies, but the variation across individuals is such that the pre-/postganglionic distinction is often difficult to make. Levels can also be useful in the postural tachycardia syndrome in distinguishing the subset of patients who may have a norepinephrine transporter deficiency [96].

Skin Blood Flow

Skin blood flow has been vigorously explored by several groups as a measure of autonomic function. Several excellent laser devices range from the ability to measure a single point or an average of multiple points on the skin, to maintain skin at a steady predetermined temperature throughout the study, and to differentiate flow, volume, and velocity of red cells. Despite the constant improvement in the reliability and reproducibility of these measurements,

skin blood flow has not yet caught on as a clinical tool, except perhaps in assessing the diagnosis of complex regional pain syndrome. The main reason is probably that although these measurements are conceptually very attractive and simple, they are actually fraught with significant complexity. The skin vessels are highly localized, and enormous variability exists from point to point, even in a 250 μm distance, so that any physical disturbance of the laser probe will change the entire recording. Second, skin blood flow depends on more than just skin temperature. As with any autonomic measurement, one cannot interpret a random steady state recording, but rather one needs to measure the response to a specific stimulus, such as a change in skin temperature, ischemia, or iontophoresis of an agent. However, this is difficult to interpret without knowing the maximum and minimum physiologic blood flows at the point being measured, to provide a backdrop against which to compare the observed change. This adds one more step and is itself not easy to obtain. Finally, there are two types of vessels in the skin, nutritive vessels and arteriovenous shunts which help with dissipation of heat. It is difficult to determine which type of vessel is being recorded, and their responses to sympathetic stimulation differ considerably.

Anatomy

Like blood flow in most regions, skin flow is primarily controlled by the sympathetic nervous system through its influence on vasoconstriction. The contribution of sympathetic or parasympathetic cholinergic dilator fibers continues to be debated today. Constrictor fibers release norepinephrine or neuropeptide Y to activate the muscle cells in the vessel walls to produce constriction. In contrast, putative dilator fibers will release acetylcholine or vasoactive intestinal peptide (VIP) to activate the nitric oxide system and induce dilation. Dilation may also occur as a result of neuro-inflammatory activation of afferent C fibers releasing substance P or CGRP. An excellent review details factors influencing blood flow [97]. Sympathetic nerve fibers are controlled by postganglionic neurons, in turn under the influence of intermediolateral cell neurons, in turn controlled by hypothalamic activity and feedback from the various temperature centers in the brain, as well as emotional activity and local factors.

Basic Principles

Most devices are composed of two parts, a probe that is applied to the skin, usually composed of optic fibers that carry the laser signal to and from the skin surface, and a box of some type that generates laser light at a specific frequency and measures the frequency of returning light. Many devices also come with a probe housing that can maintain constant skin temperature during flow measurement, a vital aspect since skin temperature is one of the most important determinants of skin flow. As the name implies, laser Doppler technology uses the amplitude and change in frequency of reflected light from red blood cells coursing through vessels in the skin to determine blood volume and velocity, respectively. Flow is calculated by a formula that includes multiplication of these two parameters (flow = velocity × volume). Most devices provide only a flow display, but some will also provide primary velocity and volume measurements.

As with most other autonomic tests, a specific stimulus is usually applied to the skin and the resulting change in skin blood flow is determined. Examples include the iontophoresis of a dilating or constricting agent such as nitroprusside or phenylephrine [98], the application of a cooling or heating stimulus, or ischemia and reperfusion, depending on the approach. The inspiratory gasp is the best way to vasoconstrict the skin [99].

Pitfalls

In contrast to other tests of autonomic function, there are no absolute norms for skin blood flow, so it is difficult to know if a given measurement falls in or out of the range of normal. The laser probes cannot be moved since flow may be vastly different even a few microns away from any given location. Any protocol involving the application of a stimulus with comparison pre- and poststimulus cannot include moving the probe. Finally, the probes are mechanically quite delicate, and the optic fiber can break inside the plastic lining and still seem to be providing information when it is not.

Quantitative Sensory Testing

11

Pariwat Thaisetthawatkul

Basic Principles in Sensory Physiology

The sensory system integrates and perceives sensory stimuli from the outside world. The sensory perception starts with a physical stimulus reacting on a sensory receptor. The receptor has an intrinsic mechanism to transform the physical stimulus into a nerve impulse. The nerve impulse reaches the central sensory system for integration and interpretation and becoming a perception. The modality of sensory perception is determined by the type of sensory stimuli and their specific receptors mediating nerve impulses along specific nerve fibers. There are five modalities of somatosensory system: vibration, touch, proprioception, pain, and temperature senses. These modalities are determined by specific receptors to mediate each type of sensory perception. There are three types of sensory receptors in the somatosensory system: mechanoreceptors, thermoreceptors, and nociceptors. The mechanoreceptors mediate vibration, touch, proprioception, and joint position senses. The nociceptors mediate pain, and the thermoreceptors mediate temperature senses. Each specific type of sense is mediated through a specific receptor. Most receptors are located in the skin with less or no hair (glabrous skin). The mechanoreceptors have two types of adaptation (decrease firing potentials with time even with constant stimuli): rapidly adapting (Pacinian and Meissner's corpuscles and most hair follicle receptors) and slowly adapting (Merkels discs and Ruffini end organs). Rapidly adapting mechanoreceptors responds best to rapidly changing stimuli such as swift movement (touch) or rapidly changing stimuli in sinusoidal wave forms (vibration). Slowly adapting mechanoreceptors respond better to continuous stimuli such as prolonged stretch or pressure [1]. Each of these receptors responds best to specific ranges of stimuli. For example, Pacinian corpuscles respond best to vibration stimuli with frequency range of 60–400 Hz, while Meissner's corpuscles are more sensitive to midrange stimuli of 20–50 Hz and Merkel discs to very low frequency of 5–15 Hz [2]. Because of these, humans are most sensitive to vibration at frequencies of 200–250 Hz, and vibration stimuli whose frequencies fall out of these ranges need higher intensity to be felt. Also, a sensory stimulus is felt best within the receptive field (the area where the density of the receptors is highest) of that particular modality. Proprioception sense is mediated through receptors outside the skin including muscle spindles, Golgi tendon organs, and receptors within the joint capsules. Thermoreceptors respond to changes in skin temperatures, resulting from the external temperature touching the skin, from baseline temperature, usually at 34 °C. Cool receptors respond most at 25 °C and stop responding at 5 °C, below which the cold nociceptors start responding. Warm receptors are most active at 45 °C, above which heat nociceptors start responding [2]. There are three types of nociceptors: mechanical, thermal, and polymodal. The mechanical nociceptors respond to painful tactile stimuli, often associated with tissue damage, and the thermal nociceptors respond to extreme changes in skin temperatures (<5 °C or >45 °C). Polymodal nociceptors respond to destructive mechanical, thermal, and chemical stimuli [2]. Not only the sensory modality depends on the sensory receptors, but also its nerve impulse is conducted via specific types of nerve fibers. Vibration, touch, and proprioception senses are conveyed through fast-conducting, large-diameter, myelinated (Aα or Aβ) nerve fibers while temperature and pain sensations are conveyed through slow-conducting, small-diameter, myelinated (Aδ) or unmyelinated (C) nerve fibers. The first group of the nerve fibers is often called "large fibers" and the latter "small fibers."

Sensory Evaluation in Clinical Neurology

The examination of the sensory system is a very important part of clinical neurology. The results can confirm the presence, determine the localization, identify the cause, and grade the severity of the neurologic problem. Because the sensory system is organized by different modalities as mentioned above, the clinical exam is usually performed to check on each modality separately by utilizing different tools that can give different type of stimuli aimed to stimulate each type of sensory receptors. A tuning fork is commonly used to check on the *vibration sense*. The frequency of the tuning forks can vary from 64 to 165 Hz [3, 4]. However, the most commonly used frequency of a tuning fork is 128 Hz [5]. The method can be all-or-none response, where the subject reports whether he or she feels the vibration sense, or graded response, where the duration of the feeling of vibration is recorded, or comparative, where the sensation on one side is compared to the other corresponding side. Some type of tuning fork can be used quantitatively such as Rydel-Seiffer type [6]. The *touch sense* is checked on by swift touch on the skin by a cotton wool, tissue, or even a finger. Quantitative assessment of touch sense can be considered by using Semmes-Weinstein monofilaments [7]. This is noninvasive, rapid, and low-cost test that can be used in a clinical exam room. The filament is applied to the skin until it bends, and the patient will acknowledge each time he or she senses the monofilament. The touch threshold is determined by which filament can be sensed. The use of the filaments has been adopted widely. It is considered by some authors to be a good screening method to identify diabetic patients who are at risk of developing foot ulcers and having peripheral neuropathy [8, 9]. *Pain sensation* is tested most commonly by using a sharp object such as a safety pin, and *temperature sense* can be checked by using a warm or cold flask containing warm or cold water.

Even though routine sensory exams are used widely in clinical practice, the methods mentioned above are not usually quantifiable or, at most, semiquantitative. The intensity of stimuli and the methods of delivery of stimuli differ significantly between each test performance. In day-to-day experience, interobserver and intraobserver variability in routine sensory exam is frequently observed and makes the results of the exam not reproducible. Besides, different institutions may adopt a different approach for the assessment of the same sensory evaluation. A tuning fork has also been shown to overestimate vibration assessment compared to a more quantitative assessment [10]. Quantitative method of bedside sensory assessment such as the use of 64-Hz Rydel-Seiffer tuning fork may have a good correlation with sensory nerve action potential amplitudes on nerve conduction studies [3]. However, the use of Semmes-Weinstein monofilaments has been more controversial. It can be more or less specific for the diagnosis of peripheral neuropathy based on nerve conduction study [11, 12]. Moreover, if sensory assessment is used as an end point in a clinical trial, there will be a need for a more validated, gender- and age-control, quantifiable, and sensitive technique.

Method of Automated Quantitative Sensory Testing

An automated system to evaluate the sensory function has been designed. The concept of the system is to deliver each sensory stimulus, including touch-pressure, vibration, thermal, and heat-pain sensory stimuli, in a quantifiable and reproducible manner [13]. The system requires an apparatus that can deliver specific type of sensory stimuli in a method that is best time-efficient and accurate and employ the best method of presentation of stimuli to the subjects. At the same time, the method should be able to score the result by defining the threshold of each sensation and establishing normal values and validating them to a large number of normal subjects and adjusting them according to age, gender, and test site. In general, these methods will be categorized into the following: presentation of stimulus, subject's response, and method of threshold determination [14].

Presentation of Stimulus

There are two methods of the presentation of stimulus: method of limits and method of levels. In *method of limits*, the stimulus increases (such as in warm stimuli) or decreases (such as in cool stimuli) until the subject starts feeling the appearance or disappearance of stimuli, in which case, the subject will press a response key and that will stop the stimulation. This type of stimuli is also called dynamic stimuli [15]. The sensory threshold (appearance threshold) is the intensity of the stimulus at which the subject acknowledges the feeling. A good example of how dynamic stimuli work is to look at the Marstock method demonstrated by Verdugo and Ochoa [16]. This method delivers hot and cold stimuli by changing the direction and intensity of electrical currents applied to a thermostimulator. A thermostimulator creates changes in the temperature of a thermode attached to the skin. Incoming currents cause increase in the skin temperature and outgoing currents decrease in the temperature. Heat ramp is kept from 5 to 50 °C to prevent tissue damage and damage to the thermode itself, in which case, the direction of the currents is automatically reversed when those temperature limits are reached. Baseline skin temperature is kept at 32 °C. This method can evaluate warm and cool threshold (when the subjects start to feel the first change in skin temperature) and heat-pain and cold-pain threshold (when the

feeling of pain starts). Thresholds are expressed in the physical unit (temperature) at which the subjects acknowledge the change. An advantage of using dynamic stimuli is that this method is time-saving. However, the subject's response always includes reaction time which makes the subject overestimate the sensory threshold. To overcome issues on reaction time, trapezoid-shaped stimuli are recommended instead of the usual triangular-shaped stimuli [17]. Besides, the sensory threshold determined by this method can be affected by "learning effects" [18].

In the *method of levels*, the changes in the level of sensory stimuli happen in a stepwise manner. In each step, the stimulus is given with predetermined intensity and duration depending on the stimulus "step." The step is usually numbered from small to large with corresponding low and high level of stimulus, respectively. The duration and intensity of the stimulus at each step is quantified and reproducible. The intensity or duration of the stimulus at the next level depends on the response of the subject to the preceding stimulus. This method is reaction-time exclusive and, therefore, minimizes test response variability. However, it is more time-consuming. This type of the stimuli is called static stimuli [15]. The sensory threshold is the intensity level that is perceived by the subject 50 % of the time. Compared to static stimuli, using dynamic stimuli tends to overestimate sensory threshold, especially fast- and high-intensity stimuli, and also creates a sense of "expectation." These effects have been shown in vibration [19], temperature, and heat-pain testing [20]. To deliver static stimuli, a good example is to look at the use of Computerized Assessment of Sensory Examination (CASE IV®; WR Medical) QST equipment [21]. There are two methods or algorithms to deliver static stimuli: a *forced-choice* technique [19] and a *4-2-1 stepping algorithms* [22]. For either technique, a subject sits in front of a visual cuing device and will be let alert of a time period when the stimuli may be delivered (yellow light = get ready, green light = test in progress). In general, the time period when the stimuli may be delivered will be displayed in number 1 or 2. The stimuli are delivered randomly. Null stimuli are used only in 4-2-1 stepping algorithms. Null stimuli are delivered randomly in between to assure alertness and attentiveness of the subject. When and how many the null stimuli are delivered are unknown to the subject. The subject is, by that time, already attached to either vibration or thermal transducers depending on which modality of sensation is being tested. In a force-choice technique, the subject is forced to acknowledge at which time period (1 or 2) the stimuli are present after the last (2) period indicator appears in the visual cue. Even if the subject is not sure, he or she will still have to choose a "most likely" time period in which the stimuli might be. Null stimuli are not used in forced-choice method. The stimulus will never be delivered in both periods, only in period 1 or 2. Because the subject will have a 50 % chance of guessing where the stimulus is, a sensory threshold determined by a forced-choice method is set as the stimulus level at which a subject is correct 75 % of the time. In a 4-2-1 stepping algorithms, the subject acknowledges the presence of each stimulus at the time right when he or she feels it (in either 1 or 2 time period). The subject acknowledges the response by pressing a response key (yes = felt, no = not felt). The advantage of using a force-choice technique is that it eliminates the indecisiveness (slow reaction) from the subject and can help in discriminating "internal" sensation (if this sensation is there already) from external stimuli. The disadvantage of the force-choice technique is that it is more time-consuming and requires more understanding of the test and more attention from the subject. It is also easier for a subject to make mistakes in forced-choice methods. If done right, the thresholds estimated from 4-2-1 stepping algorithms are comparable to those from a forced-choice method [22].

In CASE IV, the magnitude of stimulus is measured not in physical units (displacement or temperature) but in a unit called *JND* (*just-noticeable difference*). One JND unit is the minimal difference of the intensity between two stimuli to make a subject feel different during the stimulation. The sensory perception is governed by psychophysical laws [23]. According to psychophysical laws, the relationship between the sensory perception and stimulus strength is not linear but exponential. Therefore, it is more accurate if the stimulus strength is expressed as JND, not physical units, when the numerical value of threshold is used for statistical calculation [4].

In delivering static stimuli (both vibration and thermal) with CASE IV, the magnitude of each step of stimuli has been discretely defined and set up as 25 JND steps(ranging from step 1 JND (smallest magnitude) to step 25 JND (largest magnitude)) [21]. For vibration testing, the stimulus is created from a stimulating probe, which is placed over the skin. This probe is part of a vibration stimulator set at precisely 125 Hz of vibration and has displacement between 0.1 and 576 μm [21]. In CASE IV, step 1 is defined as displacement of <1 μm and step 25 as 315 μm [4]. A 30-g preload weight is used to balance the movement so that there is no non-stimulus vibration. In vibration testing, the stimulus is shaped into sinusoidal curves wrapped in an exponential envelope. For thermal testing, a thermode is placed over the skin. This thermode provides a ramp of increasing (heat) or decreasing (cool) temperatures in a precise manner. The shape of the stimulus is either triangular or trapezoid. The lowest temperature is set at 10 °C and the highest 50 °C [4]. If more strength of stimulus is required for a higher or lower JND step after the highest or lowest temperature has been reached, the duration of the stimulus can be kept longer to increase the strength without causing tissue damage.

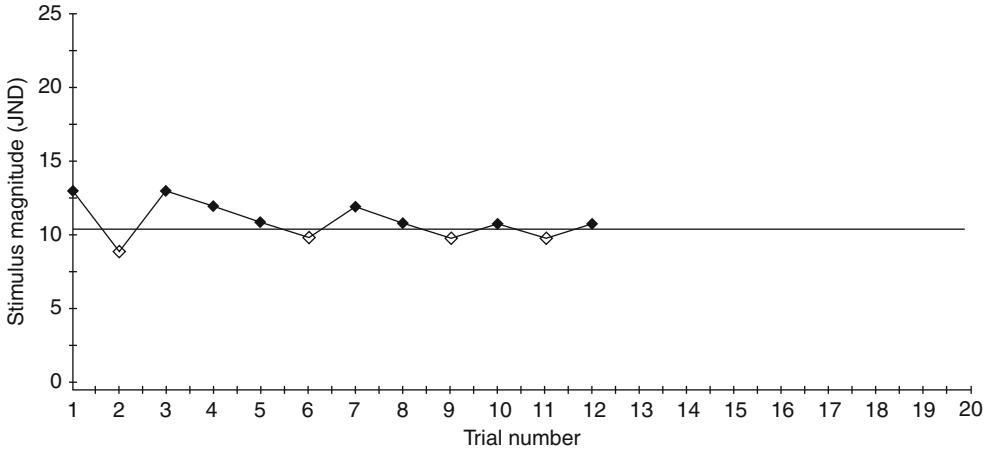

Fig. 11.1 Forced-choice algorithm. The diagram illustrates the sequence of a force-choice technique on vibration threshold testing performed on a subject using CASE IV device. The test was done at the fingertip of the left index finger. The test starts with JND 13. The ● represents success. The ○ represents failure. Success is defined as correct identification of a stimulus pair six of seven times or five of the first six times and seven times incorrect and the eighth and ninth time correct according to Dyck et al. [4]. Step 1(●, JND 13) = ssssss, step 2 (○, JND 9) = sfssf, step 3 (●, JND 13) = ssssss, step 4 (●, JND 11) = ssssss, step 5 (●, JND 10) = ssssss, step 6 (○, JND 9) = ff, step 7 (●, JND 12) = ssssss, step 8 (●, JND 11) = fssssss, step 9 (○, JND10) = ff, step 10 (●, JND11) = ssssfss, step 11 (○, JND10) = ff, step 12 (●, JND11) = sfssssss. The changes in stimulus level follow 4-2-1 rules. Null stimulus is not given in forced-choice algorithm. In this subject, the vibration detection threshold is 10.5 JND and 92nd percentile

Subject Response and Method of Threshold Determination

Either in forced-choice or 4-2-1 algorithms, the test usually starts with an intermediate JND step (step 13) delivered to the subject. The next level of JND delivered depends on the response from the subject. In general, the stimulus delivery follows the rule of up-down transformed rule described by Wetherill [24]. This rule dictates that every step of "felt" stimulus will be followed by the next stimulus of lesser strength until the subject no longer feels. Then, the next step will be of a stimulus of increasing strength (up-turnaround point). Similarly, every "not felt" stimulus will be followed by the next stimulus of greater strength until the subject starts to feel. Then, the next step will be of stimulus of lesser strength (down- turnaround point). In forced-choice algorithms, step 13 will be followed by larger or smaller steps depending on the response of the subject and the rule described by Dyck et al. [4]. At each stimulus level, the subject will be tested up to eight times before the next level of stimulus is given. If the subject answers correctly, the next stimulus level will be decreased. If the stimulus is identified incorrectly, the next stimulus level will be increased. The threshold is determined from the mean JND at the last six turnarounds. The sequence of testing results is shown in Fig. 11.1. In 4-2-1 stepping algorithms, the stimuli are similarly divided into 25 discrete JND steps. In this algorithm, null stimuli will be given randomly with the real stimuli. After the initial step (13), the next stimulus will depend on the subject's response and follow the rule above. The stimulus level will be changed by 4, 2, and then a sequence of 1 JND step change. Again, the threshold is determined by the mean JND at the last six turnarounds. The sequences of testing result are shown in Fig. 11.2. In 4-2-1 algorithms, if a subject gives affirmative responses to two or more of null stimuli, the test is not considered valid and needs to be retested, and if this happens again for two more subsequent occasions in the same subject, a forced-choice technique is recommended. If step 25 is not repeatedly felt (at least three times), the subject is considered "insensitive" (Fig. 11.3), and if step 1 is recurrently felt (at least three times), the subject is considered "hypersensitive." Some responses are not considered legitimate. For example, if the subject identified the same level of stimuli as "felt" one time and "not felt" another time, the subject may have not paid enough attention to the test. One possibility is that the subject fell asleep or his/her mind was occupied by other issues, not the test at hand (Fig. 11.4). In this case, the test needs to be repeated or switched to the force-choice technique.

Forced-choice and 4-2-1 stepping algorithms are not used in testing heat-pain threshold. These algorithms can produce overstimulation and cause tissue damage in this category of sensation test [25]. Instead, the method employs a series of non-repeating heat ramps of increasing level to stimulate pain sensation with null stimuli [25]. In CASE IV, the subject will be presented with a visual analog pain scale with pain level ranging from 1(least) to 10 (most), with 0 level indicating no discomfort or pain. At the level 0, the subject may feel only warm or hot feeling but still no pain feeling. When the subject starts feeling pain (minimal), the subject will choose level 1 and will report this to the operator. When the subject feels that he or she no longer wants the thermal stimulus to

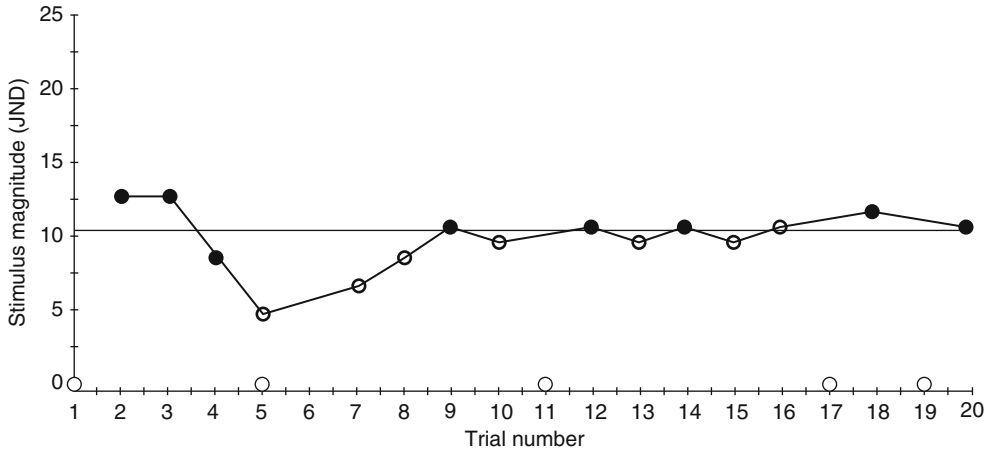

Fig. 11.2 4-2-1 stepping algorithm with null stimuli. The diagram illustrates the sequence of a 4-2-1 stepping algorithm on vibration threshold testing performed by the same subject as in Fig. 11.1 using CASE IV device. The test was done at the fingertip of the left index finger. The test starts with JND 13. The ● represents "felt." The ○ on the graph represents "not felt." The ○ on the trial number axis represents null stimuli. Please note that the changes in the stimulus level follow 4-2-1 stepping rule described in the text. In this subject, the vibration detection threshold is 9.8 JND and 89th percentile

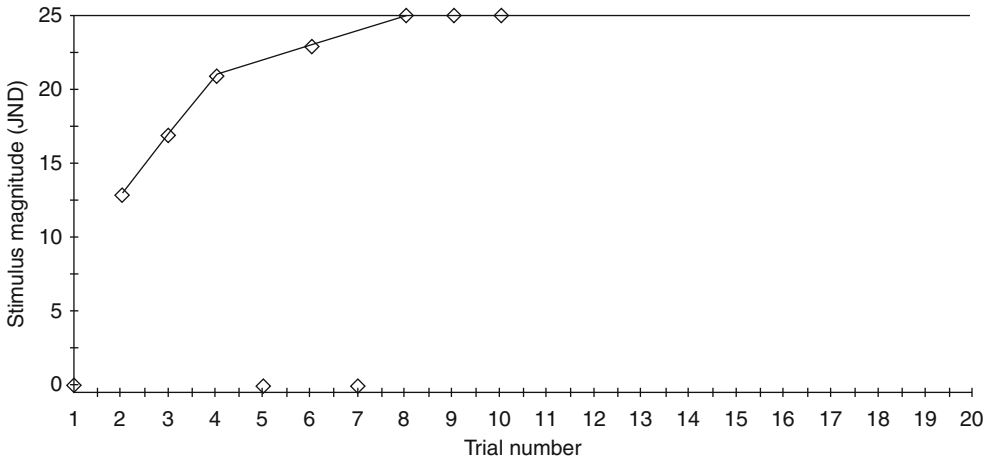

Fig. 11.3 Vibration insensitivity. The diagram illustrates the sequence of a 4-2-1 stepping algorithm on vibration threshold testing performed by another subject using CASE IV device. The ○ represents "not felt" as mentioned under Fig. 11.2. In this subject, the vibration sensate was not felt even though the stimulus level was raised to JND 25. When the subject did not feel JND 25 level for three consecutive times, the test was terminated and the subject was declared "vibration insensitive"

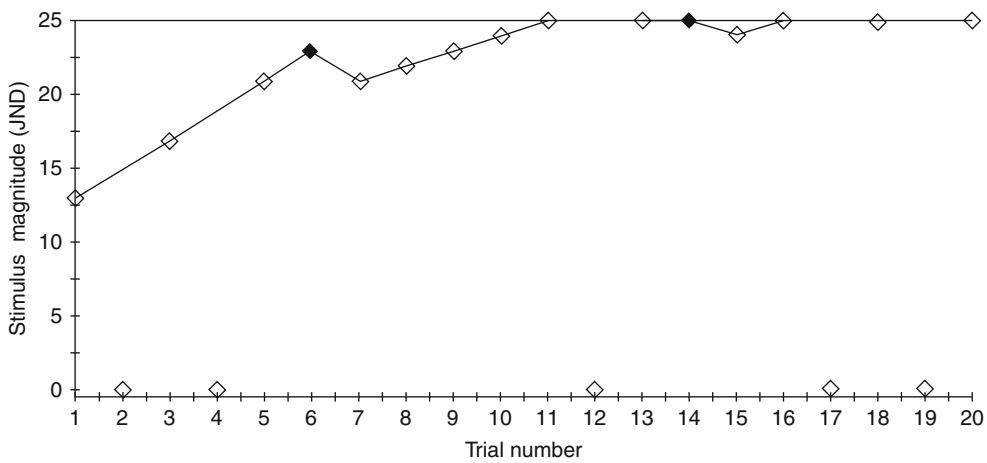

Fig. 11.4 Unacceptable result of testing. The diagram illustrates the sequence of a 4-2-1 stepping algorithm on vibration threshold testing performed by a subject using CASE IV device. In this subject, the step 6 (JND 23) was felt. However, subsequent steps with JND 23 or higher were not felt. With a pattern like this one, the threshold cannot be determined, and the test should be repeated. The ● represents "felt." The ○ represents "not felt"

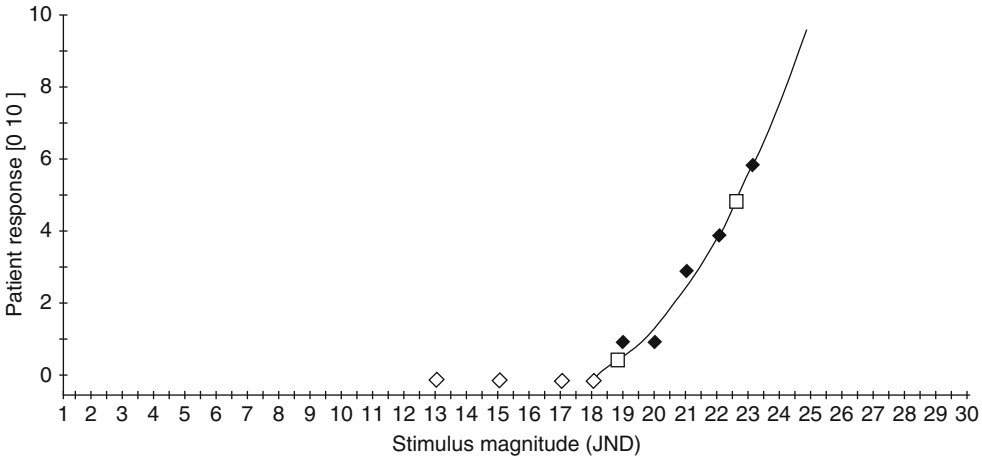

Fig. 11.5 Non-repeating heat-pain algorithm with null stimuli [4]. The diagram illustrates the sequence of steps to determine HP threshold by a subject using CASE IV device. The test starts with JND 13. The ● represents "pain feeling." The ○ represents "warm feeling only." The □ represents HP 0.5 and HP 5.0. The difference between HP 5.0 and HP 0.5 is HP 5.0-0.5. In this subject, HP 0.5 =18.8 JND (12th percentile), HP 5.0 = 22.5 JND (47th percentile), and HP 5.0-0.5 = 3.7 JND (88th percentile)

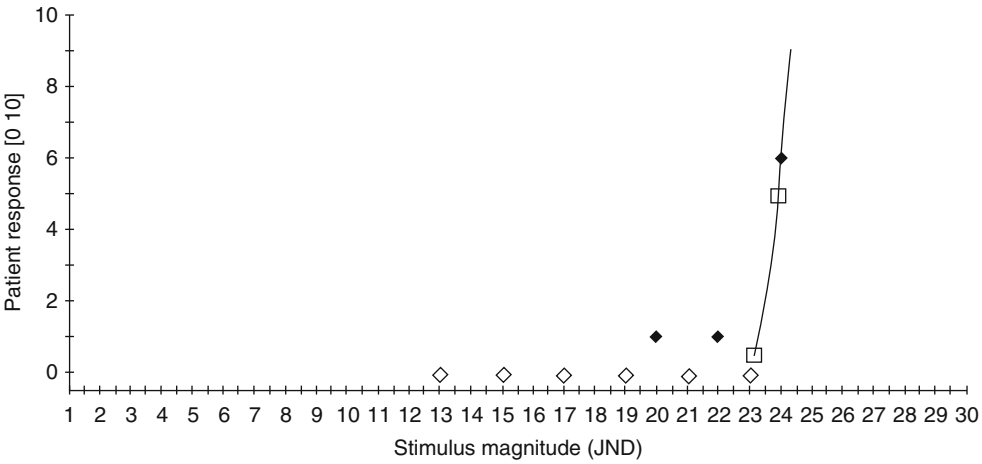

Fig. 11.6 Heat-pain hypersensitivity. The diagram illustrates the sequence of steps to determine HP threshold by a subject using CASE IV device. The test starts with JND 13. In this subject, HP 0.5 = 23.2 JND (97th percentile), HP 5.0 = 23.9 JND (75th percentile), and HP 5.0-0.5 = 0.7 JND (1st percentile). The ● represents "pain feeling." The ○ represents "warm feeling." The □ represents HP 0.5 and HP 5.0

increase, the subject will report level 10 (most discomfort). Because heat-pain threshold is the thermal level at which the subject feels pain 50 % of the time, the levels 0.5 (HP 0.5) and 5 (HP 5.0) are used for threshold description [25]. The sequence of test results is shown in Fig. 11.5. HP 0.5 is considered to be the heat-pain threshold, and HP 5.0 is the intermediate pain level. The difference between the threshold (HP 0.5) and the intermediate step (HP 5.0) is named HP 5.0-0.5. HP 5.0-0.5 indicates tolerability of a subject to increasing pain stimulus. In heat-pain testing, not only elevated thresholds (hypoalgesia) but also decreased thresholds (hyperalgesia) can be established (Fig. 11.6). Using this method, only erythema of the skin can happen, but tissue damage (burns) is not expected.

When performing automated quantitative sensory testing, vibration threshold estimation is usually done first, followed by thermal (cool and warm), then heat-pain threshold estimation the last. In all these tests, normal values controlled for age, gender, test sites, methods of tests, and stimulus presentation are available [4]. The threshold is usually reported in percentile value compared to the results obtained from normal populations. Elevated thresholds are considered when the thresholds obtained are >95th percentile compared to normal population. In evaluating heat-pain sensation, decreased thresholds or hypoalgesia is considered when the thresholds are <5th percentile. However, for more restricted criteria, especially for a research purpose, the cutoff points of >97.5th or >99th and <2.5th or <1st percentile may be considered [26]. Normal values for different type of equipment may not be applicable to CASE IV and have been established [27]. Normal values for children and adolescents are also available for a different type of equipment [28]. Cautions need to be taken on choosing normal values because this may change according to type of equipment, test methods chosen, and stimulus types.

Limitations of Quantitative Sensory Testing

Even though quantitative sensory testing (QST) is very helpful for the reasons mentioned above, the technique has some disadvantages or shortfalls. First of all, QST requires a special equipment and needs to be done in a quiet environment without distraction such as in a separate, quite room. The

subject needs to be alert, pay attention to the instructions, cooperative, and follows the testing protocol closely until the test ends. If the subject becomes drowsy, falls asleep, or is under influence of psychotropic drugs, the test results may deviate. However, a small dose of simple analgesics does not affect the test outcome [29]. Secondly, QST cannot differentiate between peripheral and central causes of sensory deficits. QST by itself has no anatomical-localizing value apart from telling which fiber types (large, small, or both) are involved. For example, QST is used to evaluate central pain syndrome after stroke [30]. Thirdly, the subject may deliberately alter the results, especially in a medicolegal case, so that they appear abnormal or more abnormal than what really is [31]. Fourthly, because it is a psychophysical testing, the response is always subjective.

Clinical Applications of QST

Because QST is a standardized, quantified, reproducible sensory testing with validated normal values, the use of QST has been adopted in many clinical situations [32]. QST can be used in establishing a diagnosis, quantifying severity, identifying fiber type involved, following up a patient after the use of medications or other treatment intervention, and following up the subjects participating in a research project if the research project uses QST as an end point [33]. In establishing the diagnosis of peripheral neuropathy, one has to keep in mind that an abnormal QST result is not by itself diagnostic of peripheral neuropathy but QST is a helpful tool when used in combination with another diagnostic test in defining the diagnosis of peripheral neuropathy.

The Role of QST in Generalized Peripheral Polyneuropathy

QST has been used mostly to evaluate generalized polyneuropathy. Diabetic distal sensorimotor polyneuropathy is the most common neuropathy that uses QST as a diagnostic and evaluating tool. QST assessing vibration and cooling threshold has been incorporated into diagnostic criteria to diagnose diabetic neuropathy in a large longitudinal study [34]. On long-term follow-up, it has been shown that vibration detection threshold was a good measure showing the worsening of diabetic neuropathy even though monotone worsening was better shown by the neuropathy impairment composite score of the lower limbs [35]. In diabetic patients without polyneuropathy, however, QST showed no monotone worsening toward the development of neuropathy, compared to a composite score from the nerve conduction study attributes [36]. The abnormalities in the patterns of QST, especially vibration (VDT), cooling (CDT), and heat-pain (HP 0.5 and HP 5.0) detection thresholds, correlate with the severity of diabetic polyneuropathy [37]. When using ≥97.5th percentiles as abnormal, patients with diabetic polyneuropathy who have abnormal VDT, CDT, HP 0.5, and HP 5.0 have more severe symptoms. HP 5.0-0.5, which indicates pain-stimulus response slope, if it is in the ≤2.5th percentile or suggests hyperalgeisa, was also correlated with the severity of diabetic polyneuropathy [37]. The use of QST has been accepted as a method of assessment of response to treatment in clinical trials on polyneuropathy [38]. In a clinical trial evaluating recombinant human nerve growth factor in patients with diabetic polyneuropathy, QST assessing CDT and HP 5.0 were used as a second end point to indicate the effect of the treatment and placebo on the studied subjects [39]. Likewise, QST was also used as a secondary end point in clinical trials assessing the use of antioxidant, alpha lipoic acid [40, 41], and aldose reductase inhibitor [42] in diabetic polyneuropathy. However, the centers participating in a clinical trial have to use the same QST device because different devices do not share the same normal values and the results may not be comparable [43]. When QST is used in that manner, the results are found to be reproducible [44].

The other common clinical application of QST is to assess and diagnose small fiber neuropathy (SFN). SFN is a very common sensory neuropathy seen in clinical practice. A patient is suspected to have SFN when one presents with positive sensory and pain symptoms but routine electrophysiologic studies are normal or minimally abnormal [45]. The diagnosis is based on demonstration of abnormal small fiber nerve functions and/or pathology [46]. Because QST can evaluate each modality of sensory function separately, QST has a role in diagnosis of SFN when abnormality is seen in cooling, warm, or heat-pain detection threshold while vibration detection threshold is normal [47]. The other diagnostic tools for SFN include skin biopsy to study intraepidermal nerve fiber density [48] and the assessment of sweat output by quantitative sudomotor axon reflex testing (QSART) or thermoregulatory sweat test [49]. In a large study on painful sensory neuropathy, the sensitivity of QST (abnormal cooling threshold) in diagnosing SFN was about 72 %, ranked between skin biopsy and QSART [50]. In the other study, the sensitivity of QST in SFN was up to 100 % [51]. In most cases, abnormal VDT can be allowed due to mild coexisting involvement of large fiber nerves [50]. QST abnormalities do not predict pain symptoms in sensory neuropathy [52, 53] suggesting that the mechanism of pain symptoms in sensory neuropathy, especially SFN, may have other associated mechanisms rather than small fiber dysfunction alone [54].

Assessment of sensory abnormalities by utilizing QST has been commonly used in cancer and chemotherapy researches to identify cancer subjects who have abnormal

sensation at baseline before, during, or after chemotherapy [55–59]. In some of these studies, QST alone was performed either to screen the patients before chemotherapy or to follow up on the patients after chemotherapy, especially when they developed neuropathic symptoms. However, without a gold standard of the nerve conduction studies, the validity of QST alone as a test to identify peripheral neuropathy is in doubt. Besides, the methods and devices of QST in these studies were different making comparison between studies impossible. In a study on subclinical peripheral neuropathy in colorectal cancer, touch detection was done by Semmes-Weinstein monofilament and BUMPS device while thermal detection was done by heat ramps with dynamic stimuli [59]. Another study on neurotoxicity of paclitaxel in patients with breast cancer used handheld biothesiometer to assess vibration threshold [58]. In a study on suramin-induced neuropathy after the use of the agent to treat prostate cancer, QST by CASE IV was incorporated into Total Neuropathy Score to categorize the patients along with standard electrophysiological studies and other clinical assessment [60]. In that study, QST showed good correlation with the presence of peripheral neuropathy after the treatment [60].

In diseases that have high prevalence of SFN, such as human immune deficiency (HIV)-associated sensory neuropathy and Fabry disease, QST has been widely used to assess and diagnose SFN. Heat-pain threshold (HP 0.5) and epidermal nerve swelling seen from skin biopsy were found to predict the development of HIV distal sensory neuropathy [61]. There was also a good correlation between the swelling of the intraepidermal nerves and HP 0.5 and HP 5.0 [62]. In a study with a longer follow-up, an abnormal CDT, HP 0.5, and leg intraepidermal nerve fiber density were found to predict transition to symptomatic HIV distal sensory neuropathy [62]. QST has been shown to add significantly to the research diagnosis of HIV-associated sensory neuropathy [63]. QST was included in a study on an antiretroviral medication, 2′,3′ dideoxycytidine (ddC), and its role in sensory neuropathy in HIV patients [64]. In this study, abnormal vibration detection threshold was found to precede the occurrence of clinical symptoms. Fabry disease is an X-linked metabolic disease caused by deficiency of alpha-galactosidase resulting in accumulation of galactosyl conjugates, especially globotriaosylceramide, in vascular endothelial cells in various organs. QST has an important role in identifying SFN related to this disorder [65]. QST was one of the outcome measures in a clinical trial assessing enzyme replacement therapy in Fabry disease, showing significant reduction in warm and cooling detection threshold after 3 years of treatment [66].

QST has also been used in the assessment of abnormal sensibility in many other disorders that cause predominantly sensory neuropathy or SFN such as uremia [67], leprosy [68], familial dysautonomia [69], and hypothyroidism [70].

The Role of QST in Focal Peripheral Neuropathy (Such as Carpal Tunnel Syndrome)

Because of its noninvasiveness, QST has been tried to identify cases of entrapment neuropathy, especially carpal tunnel syndrome. If QST is going to be helpful in carpal tunnel syndrome, the sensory threshold at the tip of the second digit should be higher than the fifth digit, and the sensitivity of abnormal QST should be at least equal to or, better, higher than the nerve conduction study that is already the gold standard diagnostic test for carpal tunnel syndrome. However, many studies that were done to look at these particular issues failed to support the use of QST as a diagnostic test for carpal tunnel syndrome. One study looked at vibration threshold at the second and fifth finger tips on 28 affected limbs in 17 patients with carpal tunnel syndrome [71]. The VDT was compared to the standard nerve conduction studies. Even though there was a good correlation between elevated VDT at the second digit and abnormal nerve conduction study indicating a median mononeuropathy across the wrist, concomitant elevation of vibration threshold was found in 36 % of the patients [71]. Another study looked at thermal (hot and cold) threshold using automated force-choice procedure at the second and fifth finger tips on 24 patients with carpal tunnel syndrome and 25 controls [72]. Again, the thermal threshold detection was compared to the standard nerve conduction studies. Abnormal thermal (both hot and cold) threshold was found to correlate well with the nerve conduction studies. However, abnormal thermal threshold, especially cold threshold, was found frequently on the fifth digit [72]. The sensitivity of abnormal vibration and thermal threshold in carpal tunnel syndrome was unacceptably low [73], especially when compared to the nerve conduction studies [74]. Similar findings were found in a large study using vibrometry and electrophysiologic testing in 130 factory workers for carpal tunnel syndrome [75]. In a large study using vibrometry with different frequency to screen for carpal tunnel syndrome compared to the nerve conduction study in 169 industrial workers, vibration threshold was found to correlate poorly with the nerve conduction studies when the carpal tunnel syndrome was mild or early thus precluding a vibrometer as a good screening method [76].

The Role of QST in Central Nervous System Disease

The role of QST in diseases of the central nervous system is limited. Neuroimaging studies such as magnetic resonance imaging study or computerized tomography scan and electrophysiologic studies such as somatosensory evoked potential study already are efficient in demonstrating a lesion within or detecting objective physiologic changes in the

central nervous system, respectively. QST is not usually used to diagnose central nervous system diseases. However, QST has an advantage of detecting functional abnormalities in spinothalamic- or posterior column-specific modality of sensory system separately. So, its use has been limited to study sensory abnormality in the central nervous system pertaining to specific modality of sensory function. QST has been used to study sensorimotor dysfunction in patients with multiple sclerosis correlated with magnetization transfer imaging of the spinal cord [77]. QST was also used in the study of the mechanism of central pain in patients with syringomyelia [78] and stroke [79]. The other use of QST in central nervous system diseases can be demonstrated by the use of QST in studying sexual dysfunction in female patients with multiple sclerosis [80] and the use of QST in studying recovery of sensory symptoms in acute stroke [81].

Acknowledgment The author wants to thank Ken Maurer, manager of the neurophysiology laboratory at the Nebraska Medical Center, and Debi Kibbee, research assistant at the Department of Neurological Sciences, University of Nebraska Medical Center, for their contribution to all the figures.

Nerve and Muscle Biopsies

12

J. Douglas Miles and Mark L. Cohen

Peripheral Nerve Biopsy

Several texts, small monographs, and reviews give comprehensive accounts on the surgical techniques of nerve biopsy, the specialized procedures required to process the biopsy, and the pathology of peripheral nerve disease [1–13]. As is the case with neuropathology in general and neuromuscular pathology in particular, the interpretation of histopathologic and molecular biologic findings derived from examination of the nerve and muscle biopsies always requires detailed correlation with information on the patients' clinical status. This brief account will give an overview of the topic; for in-depth information, the reader is referred to the references noted above.

The distal sural nerve on the lateral aspect of the ankle, posterior and just superior to the lateral malleolus, is the most common site of nerve biopsy. There are several reasons that the sural nerve is a favorite site: surgical sampling is easily accomplished with a superficial skin incision, the clinical deficit is limited to a small patch of sensory loss on the skin of the foot, and there is extensive morphometric data at this site. Since the sural nerve is a sensory nerve, the information derived from the study of the biopsy must be extrapolated to apply to any type of peripheral nerve. As sensorimotor neuropathies are so common, compared to pure motor neuropathies, this expediency is justified.

General Remarks

Peripheral neuropathy is a very common disorder in clinical practice and its causative factors numerous. On the other hand, the need for nerve biopsy in the diagnosis of peripheral neuropathy is uncommon. History, physical exam, electrodiagnostic testing, and laboratory workup are sufficient in the majority of cases to reach a diagnosis. But there remain cases when nerve biopsy is essential, and in those cases, it is imperative for the physician reading the nerve biopsy to be cognizant of all the available clinical, laboratory, and neurophysiologic information. Dialogue between the neuropathologist and the neurologist will bring out essential clinical data such as the time of onset of the patient's peripheral neuropathy, the duration and rate of progression of the illness, and the anatomic distribution of the involved nerves.

As described fully in other portions of this text, *acute neuropathy* is characterized by an abrupt onset over the course of several days; at times, the patient may point a single day when the symptoms began. *Subacutely evolving neuropathy* occurs more slowly, becoming manifest over an interval of several weeks. *Chronic neuropathies* develop insidiously over months or years and may either have a slow, relentlessly progressive evolution or follow a relapsing course, with episodes of partial improvement followed by variable, gradual deterioration. The distribution of symptoms and signs may take on a symmetric or asymmetric pattern, affect the most peripheral portions of the limbs ("stocking–glove" distribution), or involve a single or multiple nerves or roots. *Mononeuropathy* refers to involvement of a single nerve, *radiculopathy* to injury affecting one or multiple spinal roots, *plexopathy* to damage to a nerve plexus, and *multiple polyneuropathy* or "*mononeuropathy multiplex*" to disease of multiple individual nerves [14, 15].

Processing Peripheral Nerve Biopsies

Optimal processing of a peripheral nerve requires that the biopsy be as free as possible from artifactual distortion. This goal is difficult to attain because peripheral nerve is particularly susceptible to damage from handling at the time of biopsy; such iatrogenic injury may render the biopsy findings uninterpretable. Surgical access to the sural nerve is gained through a superficial skin incision just posterior to the lateral malleolus. The surgeon must take special care to avoid applying traction or pressure on the nerve and not to infiltrate the nerve itself with local anesthetic. A segment of nerve, about 4 cm long, is carefully dissected out and then removed in continuity. It is recommended to use intraoperative frozen sections to make certain it is the sural nerve itself which has been obtained rather than a neighboring sclerotic vein. This practice is especially valuable in children where the smallness of the nerve within fibroadipose connective tissue renders dissection difficult or in elderly patients with disease states which may cause the nerve to be embedded in dense aggregates of connective or inflamed tissue. The pathologist should be notified from the operating room to be prepared to receive the biopsy promptly after surgery. Transport of the specimen to the laboratory can be carried out by wrapping the nerve in a saline-moistened gauze; some prefer to bring a tray with necessary materials to the operating room so that the tissue can be processed immediately after biopsy. An effective technique is to place the length of nerve onto a strip of dental wax and then with a very sharp blade, divide the specimen into four roughly equal segments. The specimens from both ends (i.e., those that might have been clamped by the surgeon at the time of removal) are frozen, and those from the middle are fixed. Specimens designated for fixation are pinned (or clamped) at both ends to ensure that the nerve remains stretched during fixation. One of these linear mid-specimens is placed in a container filled with formalin: this specimen will be embedded in paraffin, and transverse and longitudinal sections can be stained with H&E, Masson trichrome (connective tissue), stains for myelin and axons, immunohistochemistry, and other special stains as needed. The other stretched midportion of the specimens is quickly flooded with cold glutaraldehyde and later cut in smaller fragments to be embedded in plastic (resin) for semi-thin sections and subsequently, electron microscopic examination according to standard protocols. If nerve teasing studies are anticipated, a 1-cm segment of formalin- or glutaraldehyde-fixed tissue should be set aside for this purpose. Tissue segments designated for freezing can be embedded on a chuck for frozen section, thereby permitting immunofluorescence studies and special stains for metachromasia, or can be quick-frozen in liquid nitrogen for biochemical and genetic studies [16, 17].

The disposition of the biopsy does, of course, vary from case to case depending on clinical considerations. When the amount of tissue is limited, such as when dealing with a nerve biopsy in an infant, the procedure of choice may be resin embedding rather than paraffin embedding. Paraffin embedding with routine H&E staining is the most efficient method to evaluate tumors of peripheral nerve or to identify interstitial lesions such as vasculitis, granulomas, and amyloid. When the reason for the biopsy is to address the possibility of vasculitis, it can be argued that it is best to process all of the tissue for paraffin embedding with step sections, as this approach is the most sensitive way to detect focal lesions [18, 19]. On the other hand, paraffin embedding has limited utility in assessing properties of individual axons, whereas plastic embedding is indispensable to determine the extent of axonal loss, the specific populations of damaged axons, or abnormalities of the axon or myelin sheath. Teased-fiber analysis is performed on glutaraldehyde-fixed segments of peripheral nerve after osmication. Teased-fiber preparation is most helpful in the identification of demyelinating neuropathies, which typically have slowed nerve conduction velocity. Examples include suspected cases of chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) or hereditary neuropathy with liability to pressure palsies. Assessment of the status of unmyelinated fibers or evaluation of peripheral nerve in hereditary metabolic disease ordinarily requires ultrastructural study.

Normal Nerve Histology

In the central nervous system, axons are enveloped by myelin derived from oligodendroglia. In the peripheral nervous system, myelin is derived from Schwann cells. The Redlich–Obersteiner zone or central-peripheral transitional zone is that boundary between the central and peripheral nervous systems where the one form of myelin transitions to the other. In spinal sensory and motor nerve roots, this is about 2 mm distal to the cord root entry/exit point. The site of the transitional zone in cranial nerve roots varies considerably: in the eighth cranial nerve, it is at the level of the internal auditory meatus (i.e., 8–10 mm from the nerve's point of entrance in the brainstem); in the fifth cranial nerve rootlets, it is well out into the subarachnoid space; in the lower cranial nerves, it is just a few millimeters off the brainstem [8, 20, 21].

Peripheral nerves are organized as multiple fascicles within connective tissue sheaths (Fig. 12.1) [22]. The *epineurium* is the outer sheath of connective tissue that defines the macroscopic structure of the entire nerve. It contains the large blood vessels which supply the nerve, variably dense connective tissue, and adipose tissue. The *perineurium* is composed of skeins of concentrically arranged layers of specialized perineurial cells which enclose the nerve fibers of each fascicle. In addition to this role serving as the

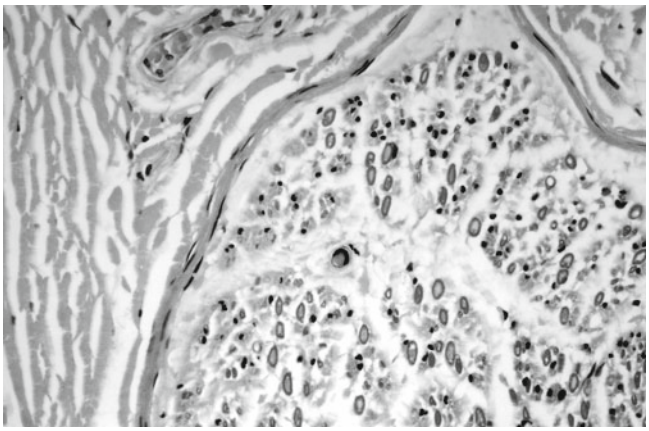

Fig. 12.1 Normal nerve. The fascicles are surrounded by perineurial layers. The epineurium is the condensation of connective tissue external to the perineurial layers, and the endoneurium is composed of axons and Schwann cells within each fascicle

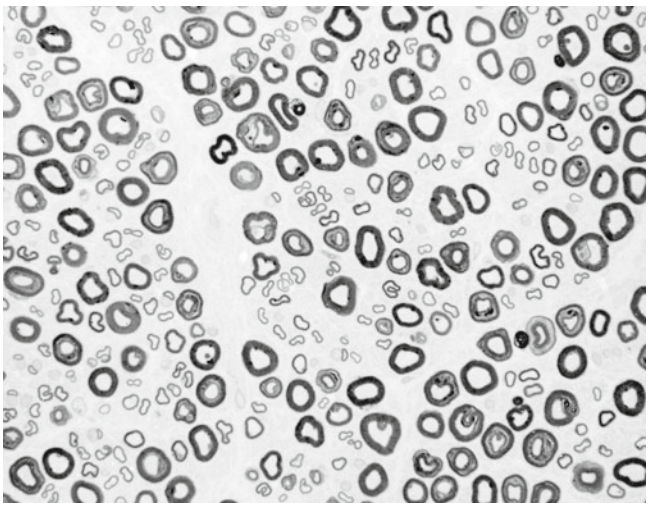

Fig. 12.2 Normal nerve. The endoneurial compartment is populated by myelinated fibers with a bimodal distribution of fiber diameter

structure responsible for the anatomic compartmentalization of fascicles, the perineurium also functions as a physiological barrier that regulates the microenvironment of the endoneurial space. The number of perineurial layers is directly related to the diameter of the fascicle. The *endoneurium* is the supporting tissue that surrounds individual axons and their Schwann cells, forming the interstitial connective of each fascicle.

Nerve fibers are the principal components of the endoneurial compartment. Nerve fibers can be demonstrated histologically in paraffin-embedded sections, resin-embedded semi-thin sections, electron microscopy, and by teased nerve fiber preparations. The latter three are by far the best methods to carefully analyze them, although general information can be gleaned also from the study of paraffin-embedded sections.

Plastic-Embedded Semi-Thin (1–2-μm-Thick) Sections

Transverse sections of plastic-embedded nerve are the best method of evaluating peripheral nerve fibers (Fig. 12.2); longitudinal sections can also be prepared to yield additional information. The sections are ordinarily stained with toluidine blue, though other suitable dyes also can be applied. This method beautifully demonstrates the orderly array of small myelinated and large myelinated fibers as well as, to a lesser extent, the unmyelinated fibers. The myelinated axon fiber diameters range from 2 to 12 μm. There is a bimodal distribution of small and large fiber diameters; small myelinated fibers are about two to four times as numerous as large myelinated fibers (Fig. 12.3). Small-caliber myelinated axons range from 2 to 6 μm; large-caliber myelinated axons range from 6 to 12 μm in diameter. The relationship between axonal diameter and myelin thickness is relatively constant; accordingly, large myelinated fibers have a thicker myelin

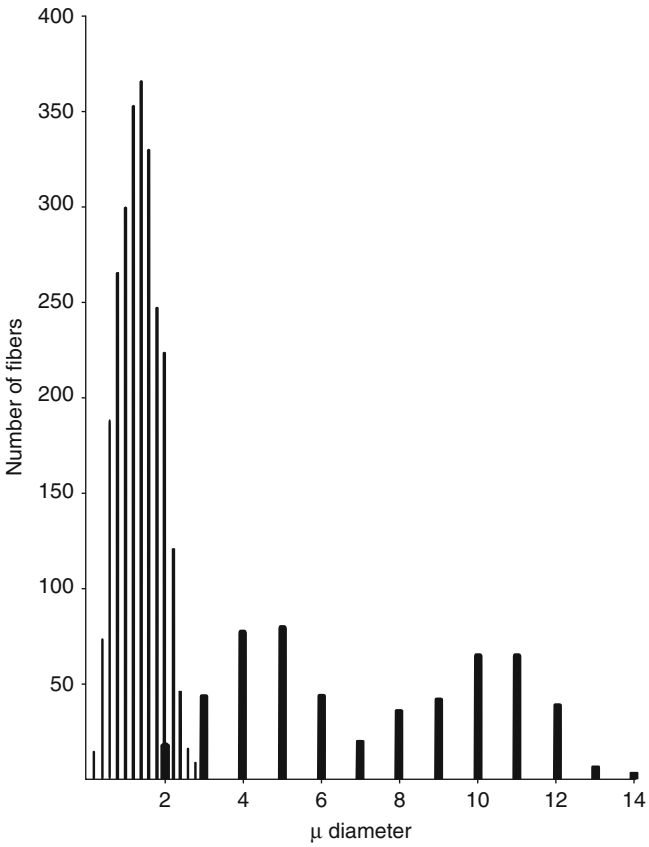

Fig. 12.3 Morphometric analysis of the normal human sural nerve. In addition to the bimodal population of myelinated fibers (*thick bars*), there is a unimodal population of unmyelinated fibers (*thin bars*) (Reproduced with permission from Ochoa and Mair [23])

sheath in comparison to that of small myelinated fibers. The *G ratio* (axonal diameter/fiber diameter) is 0.5–0.7 over a large range of axonal diameters. Plastic-embedded sections

also beautifully demonstrate the connective tissue sheaths of peripheral nerve and all of the cellular components of the endoneurial compartment.

Electron Microscopy

Electron microscopy may be an integral part of the evaluation of a sural nerve biopsy, especially in children. Detailed information on the fine structure of the myelin, axon, and supporting cells is obtainable with this technique (Fig. 12.4). Axons have a lucent cytoplasm that contains microtubules and neurofilaments. Neurofilaments, unlike intermediate filaments in other cell types, are oriented along the long axis of the axon and are evenly spaced throughout the axoplasm with perpendicular side arms. In myelinated fibers, the outer surface of the axonal plasma membrane is immediately adjacent to the innermost membrane layer of Schwann cells, with multiple concentric layers forming myelin membranes. Small portions of Schwann-cell cytoplasm, known as Schmidt–Lanterman incisures, are sequestered between the layers of myelin. The cytoplasm of Schwann cells contains intermediate filaments, microtubules, mitochondria, and occasional cytoplasmic multilayered membranous structures (known as pi, or Greek letter π, granules). The entire external surface of the Schwann cell is surrounded by a condensation of extracellular matrix, the external lamina.

Fig. 12.4 Electron micrograph of a normal myelinated axon. The Schwann-cell nucleus is visible just below the axon

Teased-Fiber Preparations

Precise longitudinal sections of peripheral nerve are very difficult to prepare since the plane of section is usually not perfectly parallel to the long axis of the axons. To circumvent this problem, single fibers need to be teased apart from their connective tissue sheaths within the fascicles. This is accomplished as follows: after fixation with aldehydes, osmication, and treatment with glycerin (or cedar oil), large-caliber axons are teased apart with fine needles under direct visualization with a dissecting microscope; they are then lined up in parallel for detailed examination and measurement under the light microscope (Fig. 12.5). Under the light microscope, the teased fibers appear as stretches of darkly stained myelin internodes interrupted by short gaps (nodes of Ranvier) wherein course pale, barely discernible axons. The external contour of the myelin sheath is usually smooth or slightly corrugated. The nodes of Ranvier are short discontinuities of the myelin sheath where "naked" axons can be seen to course through the fiber. The length of a myelin internode varies in proportion with cross-sectional diameter of the fiber. In large-caliber fibers (around 10 μm thick), they are approximately 1 mm in length. In the peripheral nervous system, a given myelin internode corresponds to a segment of the axon that is myelinated by a single Schwann cell. In general, the internodal length and myelin thickness within the internode is constant along the length of any one fiber.

Morphometry

Transverse, plastic-embedded sections through nerve fascicles clearly demonstrate the array of seemingly randomly distributed myelinated nerve fibers of varying sizes. Morphometric methods can provide precise quantitative data concerning the density of axons within fascicles. Histograms of the human sural nerve reveal a bimodal distribution of myelinated fibers, with an overall density of 7,000–20,000 myelinated axons/mm^2. Of these, small myelinated fibers outnumber large myelinated fibers two to fourfold (see Fig. 12.4). Several excellent accounts are available on the topic of normal sural nerve morphometry in adults and children including analyses of both unmyelinated and myelinated fiber populations at different ages [6, 23–32].

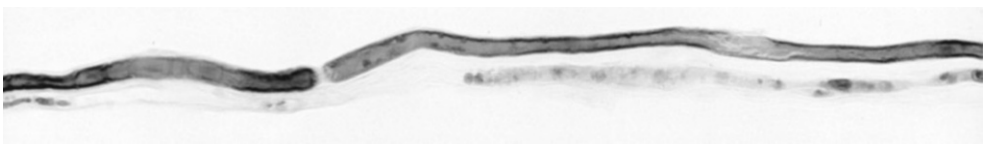

Fig. 12.5 Teased-fiber preparation of a normal nerve. The node of Ranvier is visible as the gap between internodes in the upper fiber. The lower fiber is undergoing axonal degeneration

Artifacts and Structures of Uncertain Pathologic Significance

Several artifacts may be introduced during the handling of nerve biopsies, the most common being compression, or crush artifact. With the low resolution afforded by H&E sections, the problem is less apparent; however, on resin-embedded sections and teased-fiber analysis, crush artifacts may hamper the interpretation. The large-caliber fibers show coiled myelin layers and distorted axoplasm, findings which may be confused with axonal degeneration. However, the distortion is often limited to one region of the cross section or to one region of the individual teased fibers, an important point for its recognition. Fixation of nerve biopsies without pinning down the specimen is another common problem. It may be impossible to obtain cross sections if the specimen is coiled, and the resulting resin-embedded sections show axons cut tangentially with elliptical profiles aligned parallel to each other. The effect of coiling on teased-fiber preparations may be even more dramatic. Extensive coiling precludes any effort to untangle individual fibers and eliminates the option of teased-fiber analysis. In less extensively coiled specimens, the individual fibers can be identified and separated, but the fibers have a saw-toothed appearance. Nodes of Ranvier may be identifiable, but the analysis is often hampered by frequent breaks of the fiber within the saw-toothed regions. Hypo-osmolar solutions may cause axons to swell and yield a uniformly rounded population of axons. These biopsies may be interpretable, but morphometry and other measurements may not be accurate since the axonal caliber has been altered. In addition, Schmidt–Lanterman incisures may be prominent, appearing as concentric rings within the myelin layer on cross sections and as periodic, symmetric clefts along the lengths of fibers on longitudinal sections or teased-fiber preparations.

Renaut bodies are subperineurial, loosely textured, fibrous whorled structures; they are believed by some investigators to develop in response to mechanical pressure on the nerve [33]. *Polyglucosan bodies* (*Lafora bodies*) are round or oval concentrically laminated acellular structures, ranging between 2 and 20 μm in diameter, and are located within axons and in others cells within the endoneurial compartment. They are composed largely of glucose aminoglycans. They are especially common in older individuals but are seen as well in some hereditary metabolic diseases which affect the central and peripheral nervous systems [34].

Basic Peripheral Nerve Pathology

The general pathologic processes involving peripheral nerve fibers may be subdivided into two broad categories: those primarily affecting the axon (*axonal neuropathies*) and those primarily affecting the Schwann cell or its myelin sheath (*demyelinating neuropathies*) (Fig. 12.6). It is worth noting that even when the primary pathology is demyelinating, subsequent axonal loss may sometimes occur. The neuropathologic findings of axonal loss may be further subdivided into those characteristic of the acute phases of the illness (*Wallerian degeneration*) and those that are observed in long-standing disease (*chronic axonal degeneration*).

General tissue reactions of peripheral nerve may also be viewed from the perspective of processes which cause peripheral neuropathy secondary to damage to the connective tissue elements of peripheral nerves (e.g., vasculitic neuropathies, compression neuropathies).

Acute Axonal Degeneration (Wallerian Degeneration)

When a peripheral axon is cut (or damaged in such a way as to interrupt its continuity), the portion distal to the cut undergoes a series of changes that are collectively designated as Wallerian degeneration after the original descriptions of experiments by Augustus Waller in 1850 [36]. The distal axon remains morphologically intact for a period of 3–5 days, depending on the length of the severed part (distal stump) of the axon (longer in long distal stumps than in short ones). The first discernible changes in the distal stump require electron microscopy for visualization; these consist of disintegration of cytoskeletal structures (neurofilaments and microtubules), with accumulation of granular debris in the axoplasm. Soon, the cell membrane disappears, and the axon undergoes fragmentation, whereas the myelin remains intact for a while, enclosing the remnants of the axon. The myelin then rapidly disintegrates, forming strings of round or oval fragments (ovoids, ellipsoids) (Fig. 12.7a, b). Accompanying the breakdown of axons and myelin, there are changes in the Schwann cells of the distal stumps. Within the first and second weeks, the Schwann-cell processes increase in number and fill with intermediate filaments. In addition, the Schwann cells proliferate actively, dividing longitudinally within the tubes formed by the intact basal laminae. Ultimately, these proliferated Schwann cells within the encirclement of the original basal laminae form long cellular chains known as the bands of Büngner [37]. Meanwhile, macrophages become increasingly evident at the site of fiber degeneration and are the principal cell responsible for myelin removal [38]. Although there normally are a few macrophages in the walls of the endoneurial blood vessels, most of those participating in the reaction to nerve injury are derived from the blood stream. Their numbers increase greatly, and then they pass through the intact Schwann-cell basal lamina and actively phagocytose the remains of the myelin and the axons.

The morphologic findings can be summarized as follows:

In the first days following transection of a peripheral nerve, there is (1) initially swelling of axon with disintegration

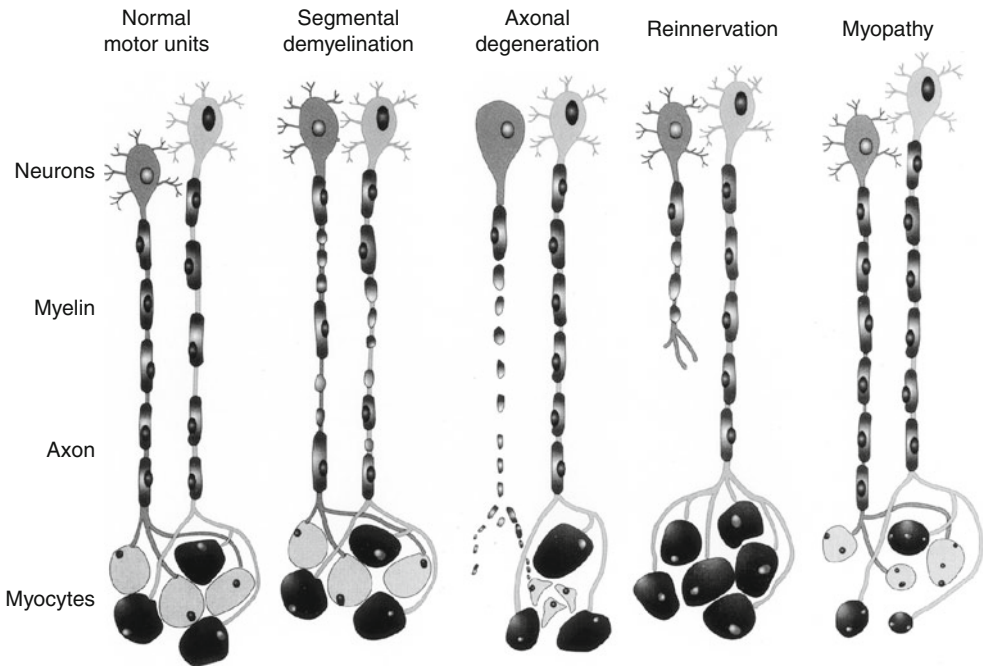

Fig. 12.6 Diagram of normal and abnormal motor units. The normal motor units show myocytes whose fiber type is determined by the axon which innervates them. Segmental demyelination results in the loss of myelin, followed by remyelination over distinct segments of the axon. Axonal degeneration, the process of the anterograde degeneration of an axon from a single point, is followed by atrophy of the myocytes within that motor unit. Reinnervation results from both sprouting of axonal termini, with grouping of muscle fibers of a single fiber type (type grouping), and from sprouting and elongation of the distal stump of the degenerate axons. In contrast, myopathies are characterized by retention of the fiber-type distribution with atrophy of scattered individual myocytes (With permission from De Girolami et al. [35])

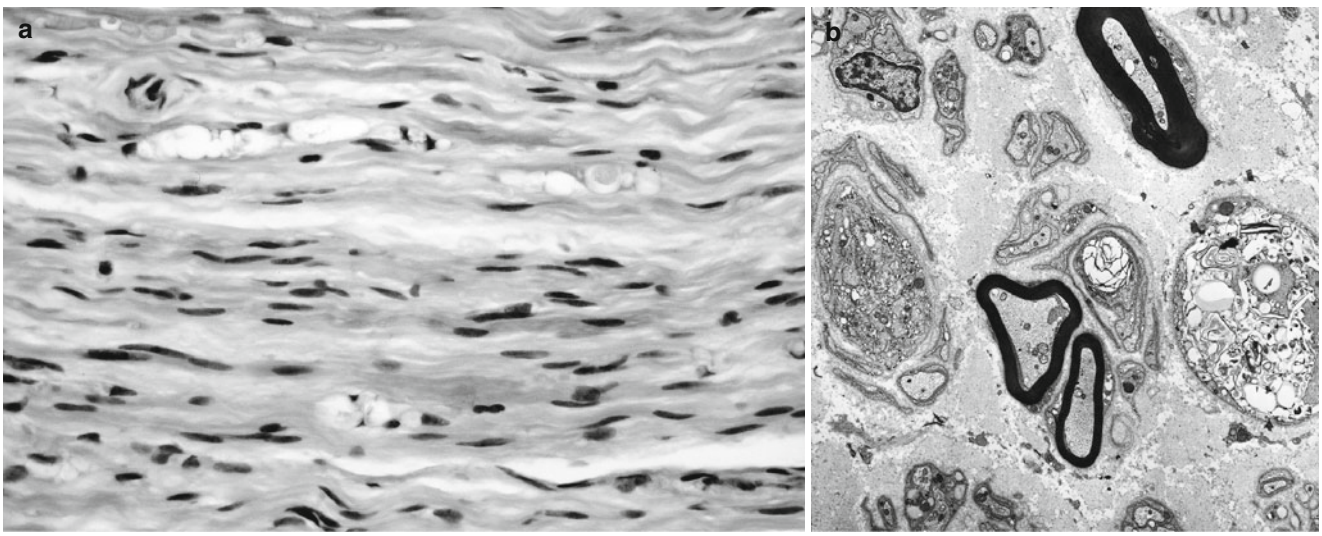

Fig. 12.7 Wallerian degeneration. (**a**) Light microscopic appearance of degenerating axons, with ovoid vacuoles arranged in a row. (**b**) Electron micrograph showing several normal myelinated axons and two degenerating axons

of tubules and filaments in the distal segments, (2) retraction and disintegration of myelin at nodes of Ranvier, (3) accumulation of vesicles and degenerating mitochondria at the proximal stump, and (4) progressive disintegration of both the axon and myelin at all points distal to the site of transection. Subsequently, but within the first weeks following transection of a peripheral nerve, there is (5) phagocytosis of axon and myelin debris by macrophages, (6) regeneration, consisting of thinly myelinated axonal sprouts, and (7) proliferation of Schwann cells along the course of the disintegrated axon.

Chronic Axonal Degeneration

Unlike Wallerian degeneration, which is the result of an abrupt interruption of the continuity of a nerve, chronic axonal degeneration characteristically proceeds slowly, with

little interstitial cellular response. Loss of the axon leads to breakdown of the myelin sheath, which undergoes fragmentation, and is ultimately removed by phagocytosis. Examination of tissue preparations of nerves in a chronic axonal neuropathy often shows no evidence of active breakdown of any component of the nerve. This is because the damage occurs in widely scattered individual fibers and therefore may not be contained in a particular tissue sample. The presence of axonal degeneration is established by the finding of decreased numbers of myelinated or unmyelinated axons in a cross section of nerve and an increased amount of endoneurial connective tissue.

Comparative counts of the numbers of fibers in the distal and proximal parts of a nerve have suggested that in some instances of axonal neuropathy, the degeneration appears to begin distally and to progress centrally. It has been postulated that under these circumstances, the primary site of the disease is in the neuronal cell bodies, which become unable to maintain the great length of the axon in the periphery—resulting in a "dying back" of the axon from its termination toward the parent neuron, but this formulation still remains hypothetical.

Axonal degeneration is described in a wide variety of chronic slowly progressive and symmetric toxic and metabolic polyneuropathies. The gradual evolution of the pathologic process to involve progressively more proximal portions of the peripheral nervous system appears to be the basis for the clinical manifestations. The pathogenesis is not certain, but dysfunction of the metabolism of the neuron rendering it incapable of supporting the axon and a direct effect on axoplasmic flow within the axon are common hypotheses.

In summary, the neuropathologic features of chronic axonal degeneration include (Fig. 12.8) (1) involvement of the most distal portions of the longest nerves, (2) initial increase in neurofilaments followed by (3) decrease of axonal organelles, (4) retraction of the axon from the myelin sheath, (5) disintegration of the axon and myelin sheath, and (6) Schwann-cell proliferation in distal portions of axons.

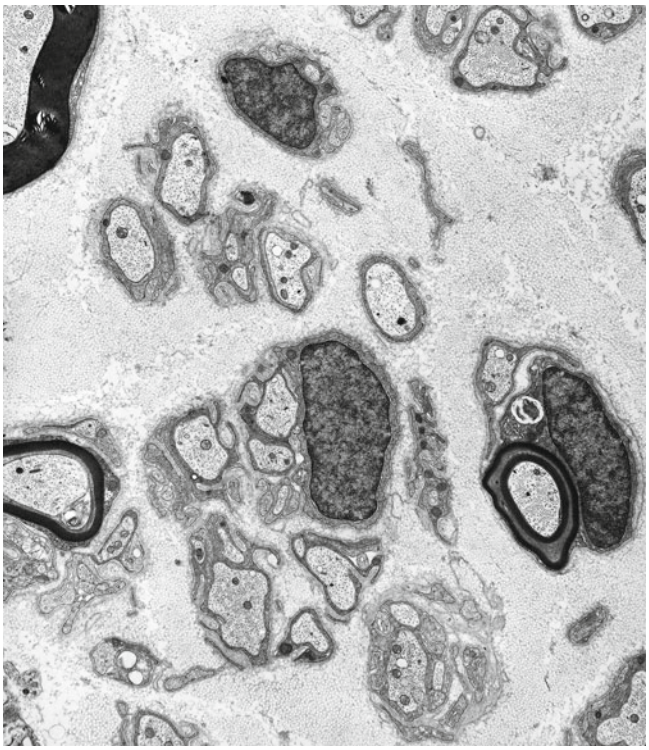

Fig. 12.8 Chronic axonal loss. Electron micrograph showing diminished population of myelinated fibers and increased endoneurial collagen

Axonal Regeneration ("Sprouting")

Axonal regeneration is observed in both acute and chronic axonal neuropathies. Following Wallerian degeneration, the central stumps of the severed nerve, still in continuity with the cell bodies of motor, sensory, and autonomic neurons, are the site of regeneration of the axons. From the severed ends of the axons, regenerative sprouts (as visualized by electron microscopy in experiments on dorsal roots in rats) begin to appear within 20 h of the transection. These characteristically are multiple—a single axon can give rise to as many as 25 sprouts. What happens to these axonal sprouts depends on the proximity to the distal stump of the nerve and the extent to which collagenous scar tissue has developed at the site of transection. If the sprouts are closely approximated with little intervening scar, many of the regenerating axons traverse the gap and enter the bands of Büngner, by which they are guided to the periphery. Other sprouts, meeting obstructions, form tangled skeins and aberrant structures that achieve no useful purpose. With wider separation of the cut ends or denser accumulations of scar tissue, the regenerating axons are prevented from reaching the distal stump and thus turn back and form tangled masses, forming neuromas.

If the original ensheathments of the axons and myelin sheaths remain in continuity, as occurs with injuries such as crushing, compression, or ischemia, the pathway for regeneration of axons is relatively intact. Regeneration under these circumstances can be more effective, with more complete functional recovery, than can be achieved following total transection.

As regeneration continues, multiple axonal sprouts enter each of the Büngner bands forming clusters of axons that are surrounded by the basal lamina of the parent Schwann cell. The presence of these clusters gives, in fact, unmistakable evidence that regeneration is occurring. Gradually thereafter, some of the axons enlarge, and a few may nearly reach the diameter of the parent axon. Meanwhile, the Schwann cells in the Büngner bands undergo rearrangement, such that a one-to-one relationship becomes established between Schwann cells and axons. These Schwann cells then remyelinate the axons that have attained a certain critical size. The new myelin sheaths, however, remain disproportionately thin for the size of the axon, and the internodes

remain disproportionately short. In chronic axonal neuropathies, it is common for cross sections of nerve biopsies to show evidence of axon loss (reduced number of myelinated fibers), axon degeneration (profiles of axonal degeneration), and axonal regeneration (axonal clusters). The groups or clusters of thinly myelinated fibers appear to arise as the proximal axonal stump sprouts multiple small neuritic processes, all of which are surrounded within the Schwann tube of the original axon. Such formations are referred to *as regeneration clusters* and are common in cross sections of nerve biopsies taken from patients with toxic or metabolic neuropathies. Soon after nerve crush or transection (24 h in experimental animals), regeneration commences in the axons proximal to the site of injury.

The typical morphologic characteristics of axonal regeneration are (Fig. 12.9) (1) scattered thinly myelinated axons or axons with undetectable myelin in a cluster, (2) clustered axons with similar diameter sizes and myelin thickness, (3) collagen fibrils interspersed among the myelinated and unmyelinated axons, and (4) a basal lamina tube that had previously enclosed a healthy axon, surrounding the complex of clustered axons.

On teased-fiber preparations, the internodal lengths of regenerated axons appear uniformly shorter than normal. (Normal internodal lengths depend on fiber diameter. A typical 10-μm-diameter fiber has an intermodal length of 0.7–0.8 mm).

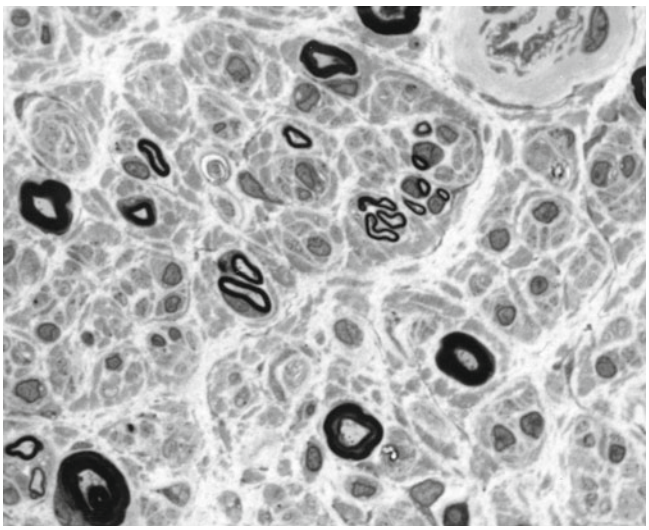

Fig. 12.9 Axonal "sprouting." In addition to axonal loss, there is axonal "sprouting" (*center*), recognized as the presence of small regenerating axons within a cluster

Segmental Demyelination and Remyelination

Demyelination refers to degeneration of the myelin sheath with preservation of the axon. In the peripheral nervous system, this results from an insult that is directed toward the Schwann-cell body or its cytoplasmic process, namely, the myelin sheath. Peripheral nerve segmental demyelination was first described by Gombault in 1880 [39] in experimental lead neuropathy and soon after in human diphtheritic neuropathy by Meyer [40].

The usual tissue preparations that are made from frozen or paraffin-embedded sections of nerve do not satisfactorily demonstrate segmental demyelination. Plastic-embedded semi-thin (1 μm) sections are more useful in showing both axons and myelin sheaths in the same section, and these may at times demonstrate demyelinated axons (in cross section) or a segmental distribution of demyelination (in longitudinal sections). Demyelinated axons can also be clearly shown in electron micrographs, but the fields disclosed by this are ordinarily too small to tell if the demyelination involves individual segments. The best visualization of segmental demyelination is with teased-fiber preparations. With this method, in the acute stages of the process, individual internodes or multiple internodes along the length of a single fiber can be shown to be devoid of myelin thereby leaving a stretch of "naked" axon between two nodes of Ranvier. Almost immediately following demyelination in the peripheral nervous system, remyelination ensues. Some Schwann-cell proliferation occurs, and these Schwann cells produce new myelin sheaths around the denuded axons. The new myelin segments, however, are shorter and thinner than those originally present. These altered myelin segments also are best shown by teased-fiber preparations.

Under some circumstances—both in naturally occurring states of disease and under experimental conditions—repeated episodes of demyelination and remyelination occur. When this happens, increasing numbers of replicating Schwann cells form concentric encirclements around the axon (or sometimes around bundles of collagenous fibers); these events are accompanied by production of large numbers of collagen fibers that become interdigitated among the Schwann cells. Under light and electron microscopy, these intermixed aggregates of Schwann-cell cytoplasm and collagen fibers present the appearance of concentrically laminated structures that resemble the cross section of an onion and thus are regularly referred to as "*onion bulbs*"[41]. Because the reparative process of remyelination begins soon after demyelination, most cases of demyelinating peripheral neuropathies include active remyelination along with demyelination. Segmental demyelination is seen typically in the Guillain–Barré syndrome, chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), some hereditary demyelinating neuropathies, experimental allergic neuritis, and certain toxic neuropathies (such as lead and diphtheria).

In summary, the histologic features characteristic of segmental demyelination and remyelination are (Figs. 12.10a, b and 12.11a, b) as follows:

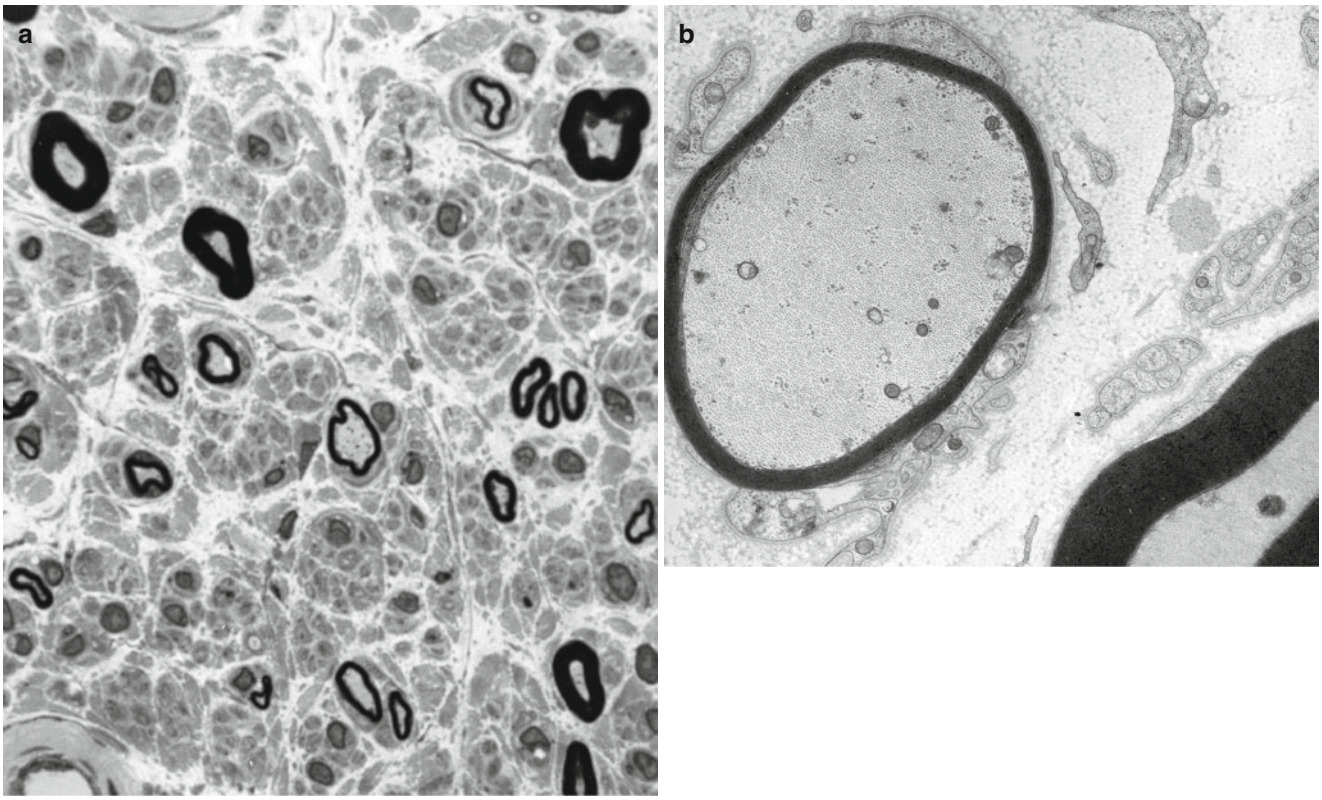

Fig. 12.10 Segmental demyelination and remyelination. (**a**) Demyelination with remyelination is seen as thinly myelinated fibers (Note normal thick myelin sheath of adjacent axons of similar diameter). (**b**) Electron micrograph of thinly myelinated axon

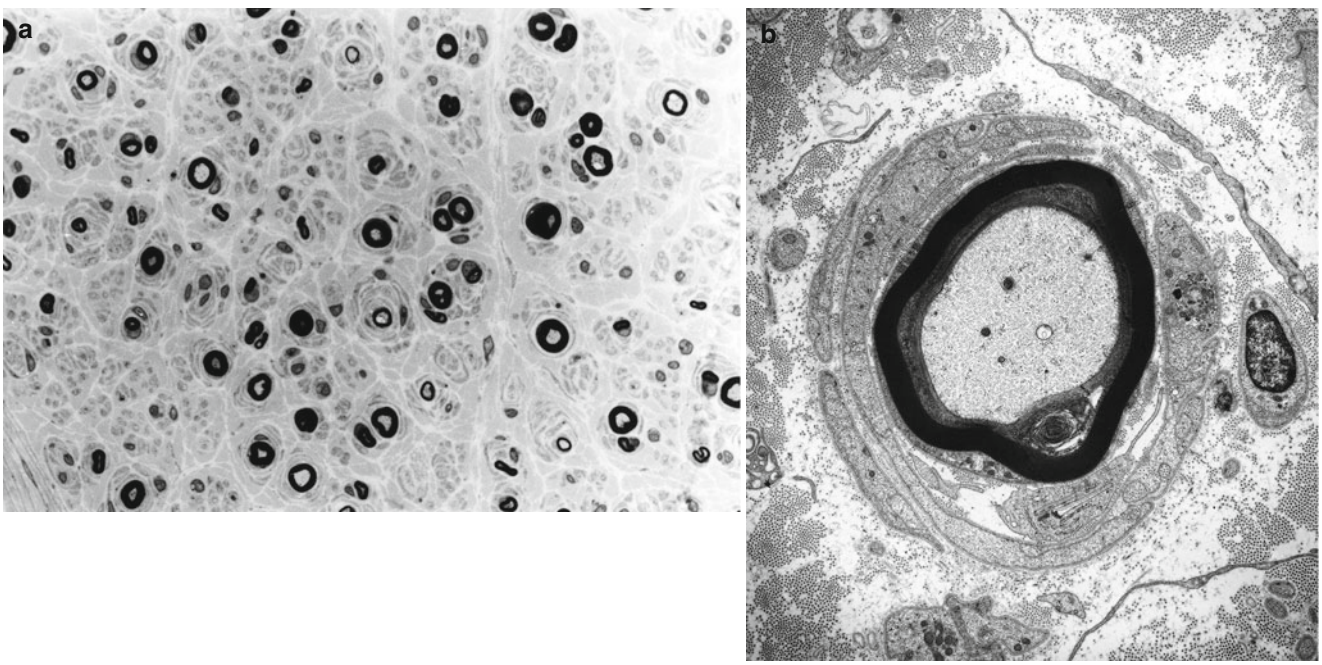

Fig. 12.11 Onion bulbs. (**a**) Light micrograph of onion bulbs, showing axons with prominent concentric layers of Schwann cells. (**b**) Electron micrograph of onion bulb, showing excess Schwann-cell layers around the myelinated axon

Demyelination

1. Early changes in myelin sheaths detected at nodes of Ranvier (paranodal retraction)
2. Insertion of macrophage cell processes between myelin sheath and axon may occur
3. Disintegration of myelin with preservation of the axon

Remyelination

1. Proliferation of Schwann cells at sites of demyelination
2. Remyelination of demyelinated segments, with shorter internodes and thinner myelin sheaths
3. Schwann-cell hyperplasia (redundant Schwann-cell processes around individual axons) as a result of repeated episodes of demyelination and remyelination
4. Progressive onion-bulb formation with multiple concentrically arranged Schwann-cell processes surrounding a thinly myelinated axon

Molecular Basis of Genetically Determined Peripheral Neuropathies

Many peripheral polyneuropathies are hereditary. Due to recent advances in understanding the molecular basis of many of these diseases, most of these diseases are now diagnosed based on genetic testing using blood samples. However, these tests are expensive, and often many genotypes need to be tested. History, family history, physical examination, and electrodiagnostic testing are essential prerequisites to narrowing the differential diagnosis. Despite advances in genetic testing, nerve biopsy may still be necessary if the family history does not suggest a hereditary pattern, genetic testing does not provide a diagnosis, or for other reasons. We will discuss two of the most common categories of hereditary neuropathies: Charcot–Marie–Tooth disease (CMT) and the familial amyloid polyneuropathies (FAPs).

To classify and diagnose CMT (formerly known as hereditary motor and sensory neuropathy or HMSN), which has a broad range of phenotypes and genotypes, an understanding of the classification system is essential. Unfortunately, the classification system is continuously evolving, and different classifications may be found in different references [42–44]. For the purposes of the diagnostician and pathologist, the ultimate goal is to try to determine the genetic cause. We suggest the following rules of thumb for classification.

CMT is categorized based on the inheritance pattern, on whether the disease is primarily axonal or demyelinating, and ultimately by the genotype. Demyelinating polyneuropathies are referred to as CMT1, unless they have an autosomal recessive inheritance pattern, in which case they may be referred to as CMT4. CMT2 refers to axonal polyneuropathies. CMTX refers to X-linked polyneuropathies. The term CMT3 or Dejerine–Sottas disease is less specific and refers to inherited polyneuropathies with an early age of onset. As the ability to classify CMT genetically has developed, these diseases are now often regarded as severe phenotypes of mutations that are better classified in another category. Letters added to the name of each disease to designate the gene identified as the etiology. For example, CMT1B refers to a demyelinating polyneuropathy with autosomal dominant inheritance associated with a mutation in the MPZ gene. A more complete description of these diseases and their classification can be found in Chap. 26. Descriptions of specific pathological findings are not available for all of the varied subtypes of CMT. Below, we describe findings that can be seen in the more common and well-documented subtypes.

CMT1 is the most common hereditary peripheral polyneuropathy. CMT1A results from duplications or point mutations of the PMP22 gene. Nerve section reveals numerous onion-bulb formations characteristic of a demyelinating polyneuropathy. Hypomyelinated axons may be seen. The nerve may be hypertrophic. In severe cases, density of myelinated fibers may be reduced. Using fluorescent in situ hybridization techniques, it is possible to utilize genetic probes to detect PMP22 duplication in CMT1A. A closely related disorder, hereditary neuropathy with liability to pressure palsies (HNPP), is also associated with PMP22, either with different point mutations or with a haploinsufficiency of the gene. Focal hypertrophies of myelin, called tomaculae, can be seen at multiple sites along an axon. This may be best appreciated on teased-fiber analysis. Fluorescent in situ hybridization can also identify HNPP.

CMT1B is associated with a mutation in myelin protein zero (MPZ), an integral membrane protein of Schwann-cell myelin that appears to mediate apposition of membrane layers in compact myelin. On nerve section, hypomyelinated axons are seen, as are onion-bulb formations. Ultrastructurally, abnormal myelin compaction may be seen, with abnormally wide spaces between the dense lines of myelin.

The most common X-linked form of CMT is associated with the gene GJB1 (CMT1X), but other subtypes have been associated with other identified genes. GJB1 encodes the protein connexin 32 (Cx32), a gap junction subunit. Nerve sections of CMT1X may show thinly myelinated nerve fibers in clusters, representing regenerating fibers. Onion bulbs may also be seen.

CMT2A2 represents about 20 % of all axonal CMT cases. It results from a mutation in the gene MFN2, which encodes mitofusin 2, a protein in membranes of mitochondria. Consequently, mitochondrial abnormalities can be visualized on electron microscopy. On light microscopy, nerve fiber density is reduced, and in some cases, onion bulbs may be seen.

The familial amyloid polyneuropathies (FAPs) are a group of autosomal dominant genetic diseases characterized by the deposition of amyloid fibrils in various tissues, including peripheral nerve and muscle. Clinically, this manifests as a

multisystem disease which includes a length-dependent polyneuropathy. Pain, temperature, and autonomic tracts tend to be affected before other modalities [45].

There are three main types of FAP, defined by the protein whose gene carries the causative mutation. They differ clinically and are managed differently. Most forms of FAP are the result of specific mutations of transthyretin (TTR, also known as prealbumin). Over 100 different TTR point mutations have been described, the most common being the Val30Met mutation. FAP may also result from mutations of the gene for apolipoprotein A-I (apoA-I), a protein mediating binding and transport of lipids in serum, or the gene encoding gelsolin (GSN).

In TTR amyloidosis, nerve biopsy may show extracellular amyloid in the endoneurium and around blood vessels. Nerve fiber density may be reduced, and unmyelinated fibers are lost first. Nerve sections stained with Congo red and visualized under polarized light will demonstrate apple-green birefringence of amyloid deposits, if they are present. Electron microscopy may reveal unbranched amyloid fibrils 7–10 nm in diameter. Immunohistochemistry with antibodies against the specific protein (i.e., TTR, apoA-I, or GSN) can determine the specific form of FAP, since in each instance the presence of amyloid is due to the specific protein. Amyloid depositions are multifocal, and the sample biopsied may not contain any amyloid deposits; thus, absence of amyloid on biopsy does not exclude the diagnosis but is thought to have a sensitivity of about 85 %.

Muscle Biopsy

Comprehensive monographs and websites are available on the subject of muscle biopsy techniques and interpretation of findings [46–50]. This overview gives a brief introduction to muscle biopsy techniques and histopathologic interpretation.

General Remarks

The proper evaluation of a muscle biopsy requires joint assessment of the patient's medical history, physical examination, laboratory values, nerve conduction studies (NCS), and needle electromyogram (EMG), together with the morphologic and biochemical data derived from study of the muscle tissue itself. Often, the clinician who decides on a muscle biopsy is not the person who performs the surgical procedure, so communication is essential to ensure that the optimal biopsy site is selected based on clinical assessment, electrodiagnostic results, and radiologic data. Prior notification of the pathology laboratory is also needed so that preparations for the proper handling of the biopsy specimen can be made. The muscle chosen for biopsy is often guided by an EMG. If not done, then the muscle sampled in rapidly evolving muscular disorders should be weak. In chronic muscular disorders, the biopsied muscle should be one that is moderately affected, as clinically uninvolved muscles are less likely to show pathologic changes and severely affected muscle may only demonstrate end-stage disease. Perhaps because most primary myopathies preferentially affect proximal muscles, biopsies of more distal muscles (biceps rather than deltoid, gastrocnemius rather than vastus lateralis) have been associated with slightly lower probabilities of obtaining definitive diagnoses [51]. Sites of previous biopsy, EMG needle implantation, intramuscular injection, or prior trauma should be avoided by the surgeon since the inflammatory and reactive changes that attend these procedures interfere with biopsy interpretation. Collagenous connective tissue, variable cross-sectional diameter of fibers, and internalized nuclei characteristic of muscle tissue at tendinous insertions may also be misinterpreted as pathologic change, so the biopsy should be taken from the belly of the muscle by a surgeon experienced in the muscle biopsy procedure.

Processing Skeletal Muscle Biopsies

Although some questions may be answered with needle biopsy specimens, an open biopsy of muscle is preferred by most laboratories because it affords sufficient tissue for complete study and is more likely to be free of artifact than a needle biopsy. For open biopsies, the individual performing the biopsy should obtain *two* separate specimens: a clamped and an unclamped sample of skeletal muscle. The first specimen (a thin linear segment) is removed in situ on a muscle biopsy clamp to avoid contraction artifacts and is the one destined for light and electron microscopy. Slivers of the surface portions of the muscle are carefully dissected out and immersed in cold glutaraldehyde, preferably within minutes of retrieval; these are later minced, osmicated, and embedded in plastic for light and possibly electron microscopic study. For plastic-embedded specimens, cross and longitudinal sections are first prepared (semi-thin sections 1–2 μm thick), stained with toluidine blue, and examined with the light microscope, and then selected regions are processed for electron microscopic study, if needed. The remainder is washed in buffer, post-fixed in formalin, embedded in paraffin, processed for cross and longitudinal sections, and stained with H&E at several levels to look for interstitial pathology (inflammation, vasculitis, etc.). This portion of the muscle biopsy specimen may also be used for immunohistochemical staining for the presence of specific subtypes of lymphocytes or other immunohistochemical markers. Although many laboratories still use ATPase histochemistry to reveal fiber types, myosin heavy-chain immunostains of

formalin-fixed paraffin-embedded tissue are increasingly being utilized for this purpose.

The second specimen, the unclamped muscle, is retained unfixed and placed in foil or wrapped in saline-moistened gauze (but NOT flooded with saline). One portion of this specimen is snap frozen in isopentane (2-methylbutane) thoroughly precooled by liquid nitrogen (the isopentane should be given time to become partially frozen) and mounted in a suitable embedding medium on a chuck that will allow for cryostat sections. The relatively high specific heat of isopentane compared with liquid nitrogen drops the temperature of the muscle specimen from room temperature to below freezing quickly enough to avoid formation of ice crystals that disrupt the integrity of the fibers and may render the specimen uninterpretable. Frozen sections are then stained with hematoxylin and eosin and may be used for a variety of histochemical reactions and other special stains. The histochemical reactions and stains routinely employed vary somewhat from one laboratory to another. Most investigators run at least an H&E, a modified Gomori trichrome stain, and an oxidative histochemical stain such as nicotinamide adenine dinucleotide-tetrazolium reductase (NADH-TR), succinate dehydrogenase (SDH), or cytochrome oxidase (COx). Many labs also routinely do periodic acid–Schiff (PAS) with and without diastase; oil red O; adenosine triphosphatase (ATPase) performed at pH 4.3, 4.6, and 9.4; and sometimes acid phosphatase and/or amyloid stains. In selected instances, frozen sections can also be stained with antibodies to demonstrate loss of sarcolemmal proteins or other molecular abnormalities [52]. A second portion of the unclamped, unfixed specimen is frozen directly in liquid nitrogen for potential biochemical and molecular studies. Frozen tissues may be stored at −80 °C for extended periods of time and may yield important information as new molecular genetic methods become available.

Normal Muscle Histology

The earliest cell recognized as committed to develop into skeletal muscle is the myoblast, a proliferating cell containing intracytoplasmic myosin and actin filaments [53]. Myoblasts fuse with one another to primary myotubes, multinucleate cells with a roughly cylindrical configuration. As sarcomere structure develops peripherally, the nuclei are initially arranged internally about a myofibril-free zone. By the time the myotube is ready for innervation, the sarcolemma contains abundant, diffuse receptor protein for the neurotransmitter acetylcholine (ACh). When the tip of the nerve fiber comes in contact with the muscle fiber, establishing a motor end plate, the receptor proteins become concentrated at the neuromuscular junction and disappear from the surface of the fiber elsewhere. Once innervated, the nuclei move to the periphery and the interior becomes packed with regular arrays of myofibrils as the myotube becomes a mature myofiber.

It appears that the full complement of muscle fibers is attained by mid-fetal life. At the mid-fetal period, muscle fibers are thin (4–5 μm), their nuclei fill nearly the entire transverse diameter of the fiber, and only a few coarse, striated myofibrils are visible beneath the sarcolemma. Fiber types differentiate in late fetal life, and by the time of birth, the fibers have grown to a width of 8–10 μm.

The functional unit of the neuromuscular system is the *motor unit*. Each motor unit consists of (1) a neuron located in the anterior horn of the spinal cord, or motor nucleus in the brainstem; (2) the axon of that neuron leaving the cord or brainstem, traversing the subarachnoid space, continuing on as the peripheral portion of the spinal or cranial nerve, terminating at the motor end plate; and (3) the muscle fibers being innervated. The number of muscle fibers within a motor unit (those innervated by the axon of a single motor neuron) varies from a few to several hundred. Muscles responsible for highly refined movements, like the extrinsic muscles of the eye, have a high innervation ratio (neuron-to-muscle-fiber ratio, 1:10) while those with relatively coarse movement requirements, like the calf muscles, have a much lower ratio (1:2,000). With increasing voluntary effort, more autonomous units can be called upon to work together.

Light Microscopy

Muscle fibers are arranged in fascicles supported by several connective tissue sheaths. The *epimysium* envelops large groups of muscle fibers. Variable numbers of muscle fibers are grouped in primary and secondary bundles or fasciculi enveloped by *perimysium*, which is contiguous with the epimysium. The *endomysium* consists of a delicate network of connective tissue fibers, blood vessels, lymphatic tissue, and nerves, which surrounds individual muscle fibers (Fig. 12.12a).

Muscle fibers vary considerably in diameter, depending on the function of the muscle and the degree of exercise to which the muscle has been subjected. Cross-sectional muscle diameter is inversely proportional to their degree of involvement in activities demanding precision (e.g., extrinsic eye muscles, 17–20 μm in diameter; gluteus, about 90 μm in diameter). Fiber size is also regulated to some extent by testosterone; males tend to have larger fibers than females. Within each muscle, there may also be some variability in the size of its fibers, closely conforming to a narrow bell-shaped curve in most muscles. In embryos, infants, and children, there is a distinctive bimodal distribution of fibers. Standardized histograms of muscle fiber diameter based on site, age, sex, and preparative techniques are available for many muscles and may be

useful in the analysis of muscle biopsies taken from infants and young children. Myofiber size remains relatively constant in adulthood and then tends to decline with old age ("sarcopenia"). The cross-sectional shape of infant fibers tends to be round, while adult muscle fibers are normally polygonal (Fig. 12.12b). In longitudinal sections, the adult muscle cell (or muscle fiber) is bounded by a plasma membrane (sarcolemma) and basement membrane. Nuclei are positioned at the periphery of the fiber, just beneath the sarcolemma, and are spaced about 10–50 μm apart, depending on the muscle (Fig. 12.12c). The nucleoplasm is fine and evenly distributed, and nucleoli are ordinarily inconspicuous. Nuclei located toward the center of the fiber ("internalized" nuclei) are normally seen in about 3 % of normal adult muscle fibers. The familiar striations of the muscle fiber are imparted by repeating units called *sarcomeres*, composed of interlaced, longitudinally directed thin (actin) filaments anchored to perpendicularly disposed Z disks and thick (myosin) filaments. Myofibrils are composed of serial arrays of sarcomeres that run the length (or at least much of the length) of the muscle fiber. The number of myofibrils in each muscle fiber varies from several hundred to several thousand, depending on the diameter of the fiber. At tendinous insertions, myocytes interdigitate with the basal lamina so that by light microscopy they appear to fuse with the connective tissue. In these areas, nuclei are normally internalized.

Muscle spindles are fusiform structures varying in length from 0.5 to 3.0 mm and oriented parallel to the muscle fibers and attached at the poles to the aponeuroses and connective tissue sheaths surrounding the muscle fasciculi. In cross section, the muscle spindle is a rounded structure with a diameter from 200 to 1,000 μm bounded by a fibrous capsule containing four to six intrafusal muscle fibers, nerve fibers, specialized nerve endings, and blood vessels (Fig. 12.12d). The function of spindles is to respond to muscle stretching and maintain muscle tone.

The junctional complex between nerve and muscle is called the motor end plate or neuromuscular junction (NMJ). In H&E-stained sections, the NMJ appears as an ill-defined aggregate of nuclei and nerve fibers on the surface of the muscle fiber. Special techniques (intravital dyes, metallic impregnation, immunoelectron microscopy) are required to adequately visualize this structure (Fig. 12.13a, b). At the NMJ, the muscle surface is adapted into a series of folds, and the motor axon, covered only by a connective tissue sheath, splays into an elaborate terminal arborization with terminal expansions which make synaptic contact with the muscle. These endings—the axon terminals—contain synaptic vesicles and mitochondria. The synaptic cleft is about 70 nm wide and is filled with fine granular material. Membrane specializations are found on both the axonal and muscular surfaces of the synapse.

Histochemistry

For diagnostic purposes, muscle fibers can be identified as either type I ("slow-twitch") or type II ("fast-twitch") myofibers (Fig. 12.14a). *Type I fibers* are concerned primarily with slow, sustained contractions and are relatively fatigue resistant. These fibers derive most of their energy from aerobic metabolism and breakdown of lipid and are, therefore, mitochondria- and oxidative enzyme-rich and glycogen- and glycolytic enzyme-poor. Human skeletal muscle contains two kinds of type II fibers. *Type IIx* (*formerly known*

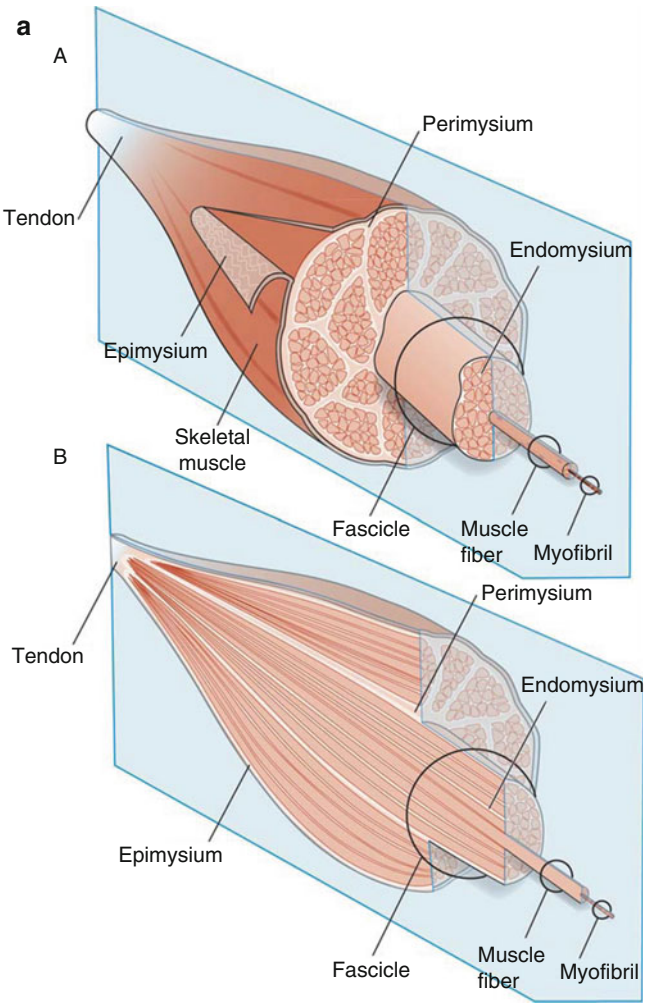

Fig. 12.12 Normal skeletal muscle. (**a**) Diagram A and B (cutaway version of A) showing the relationships between endomysium, perimysium, and epimysium. Awaiting permissions assessment. (**b**) In transverse section, the fibers have a normal polygonal shape, and the nuclei are located in their normal subsarcolemmal location. A small amount of ice crystal artifact is seen within the muscle fibers. The delicate perimysium demarcates individual muscle fascicles, while the thicker epimysium surrounds the entire muscle fiber. (**c**) This plastic-embedded, toluidine blue-stained longitudinal section of muscle fiber enables visualization of cross striations, resulting from the repeated pattern of overlapping thin and thick filaments comprising the muscle sarcomeres. (**d**) Muscle spindle in transverse section. Several irregularly sized muscle fibers are enclosed within the multilayered capsule and are innervated by a peripheral nerve twig

a

MyHC type	Twitch duration	Shortening velocity	Cross–sectional area	Metabolism	Endurance	Energy efficiency
I	Slow	Slow	Small	Oxidative	High	High
IIa						
IIx						
IIb	Fast	Fast	Large	Glycolytic	Low	Low

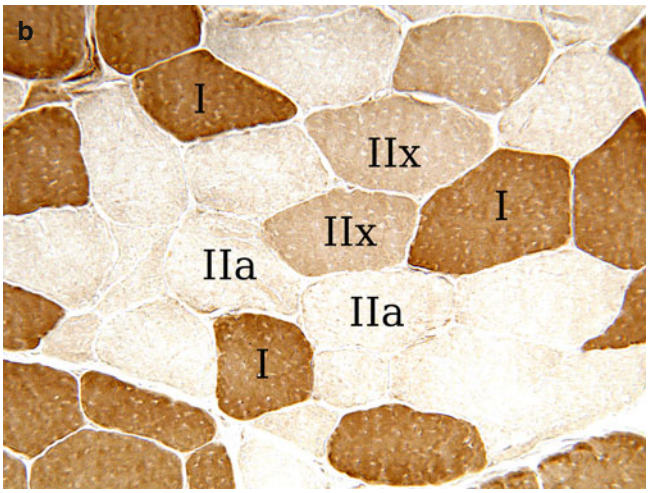

Fig. 12.14 ATPase histochemistry of skeletal muscle. (**a**) awaiting permissions resolution. (**b**) ATPase histochemical staining, performed after preincubation at pH 4.6, allows identification of all three fiber types normally encountered within human skeletal muscles

as type IIb) *fibers* are concerned mainly with quick, strong, short duration contractions, fatigue easily, derive most of their energy from anaerobic glycolysis, and are rich in glycolytic enzymes but poor in oxidative enzymes. *Type IIa fibers* share characteristics with both type I and type IIx fibers. These fast-twitch fibers are also somewhat fatigue resistant and are well endowed with both glycolytic and oxidative enzyme systems. *Type IIc fibers* are undifferentiated and are therefore usually encountered in fetal tissue. In most biopsied human muscles, both oxidative and glycolytic fibers are distributed in a mosaic pattern, with types I, IIa, and IIx fibers each comprising about a third of the total number of muscle fibers. The most widely used histochemical method for fiber typing is the ATPase reaction run at alkaline pH (9.4); in the "reverse ATPase" (r-ATPase) method, sections are preincubated in an acid medium, resulting in a reversal of the checkerboard pattern of dark and light fibers. If the preincubation is at pH 4.3, the reversal is complete, with the type I fibers staining dark and type II fibers light. At pH 4.6, the reversal is partial, allowing visualization of intermediate-staining type IIx fibers (Fig. 12.14b). In oxidative histochemical reactions, type I fibers tend to stain more darkly than type II fibers. Caution is indicated when attempting to assign fiber type on the basis of oxidative reactions, as fibers that are atrophic due to denervation are often excessively dark regardless of fiber type. The distribution of the different fiber types in normal human skeletal muscles varies considerably with anatomic region and age.

Immunohistochemistry

The availability of antibodies specific for myosin heavy-chain subunits has enabled many laboratories to switch to immunohistochemical recognition of fiber types. Advantages of immunohistochemical staining over traditional ATPase staining include (1) the ability to analyze fiber types on formalin-fixed sections, (2) the ability to distinguish markedly atrophic fibers from capillaries, and (3) the ability to automate double immunostaining for fast (MYH2) and slow (MYH7) myosin isoforms (which allows the simultaneous detection of type IIx and IIc fibers) [54]. The detection of acutely denervated and regenerating fibers may also be accomplished on routinely fixed tissues using antibodies to NCAM (CD56) and vimentin [55]. Finally, the detection of intracytoplasmic protein aggregates, critical to the diagnosis of inclusion body myositis and myofibrillar myopathies, may be accomplished using antibodies to CD56/NCAM, ubiquitin, p62/SQSTM1, or TDP-43 [56].

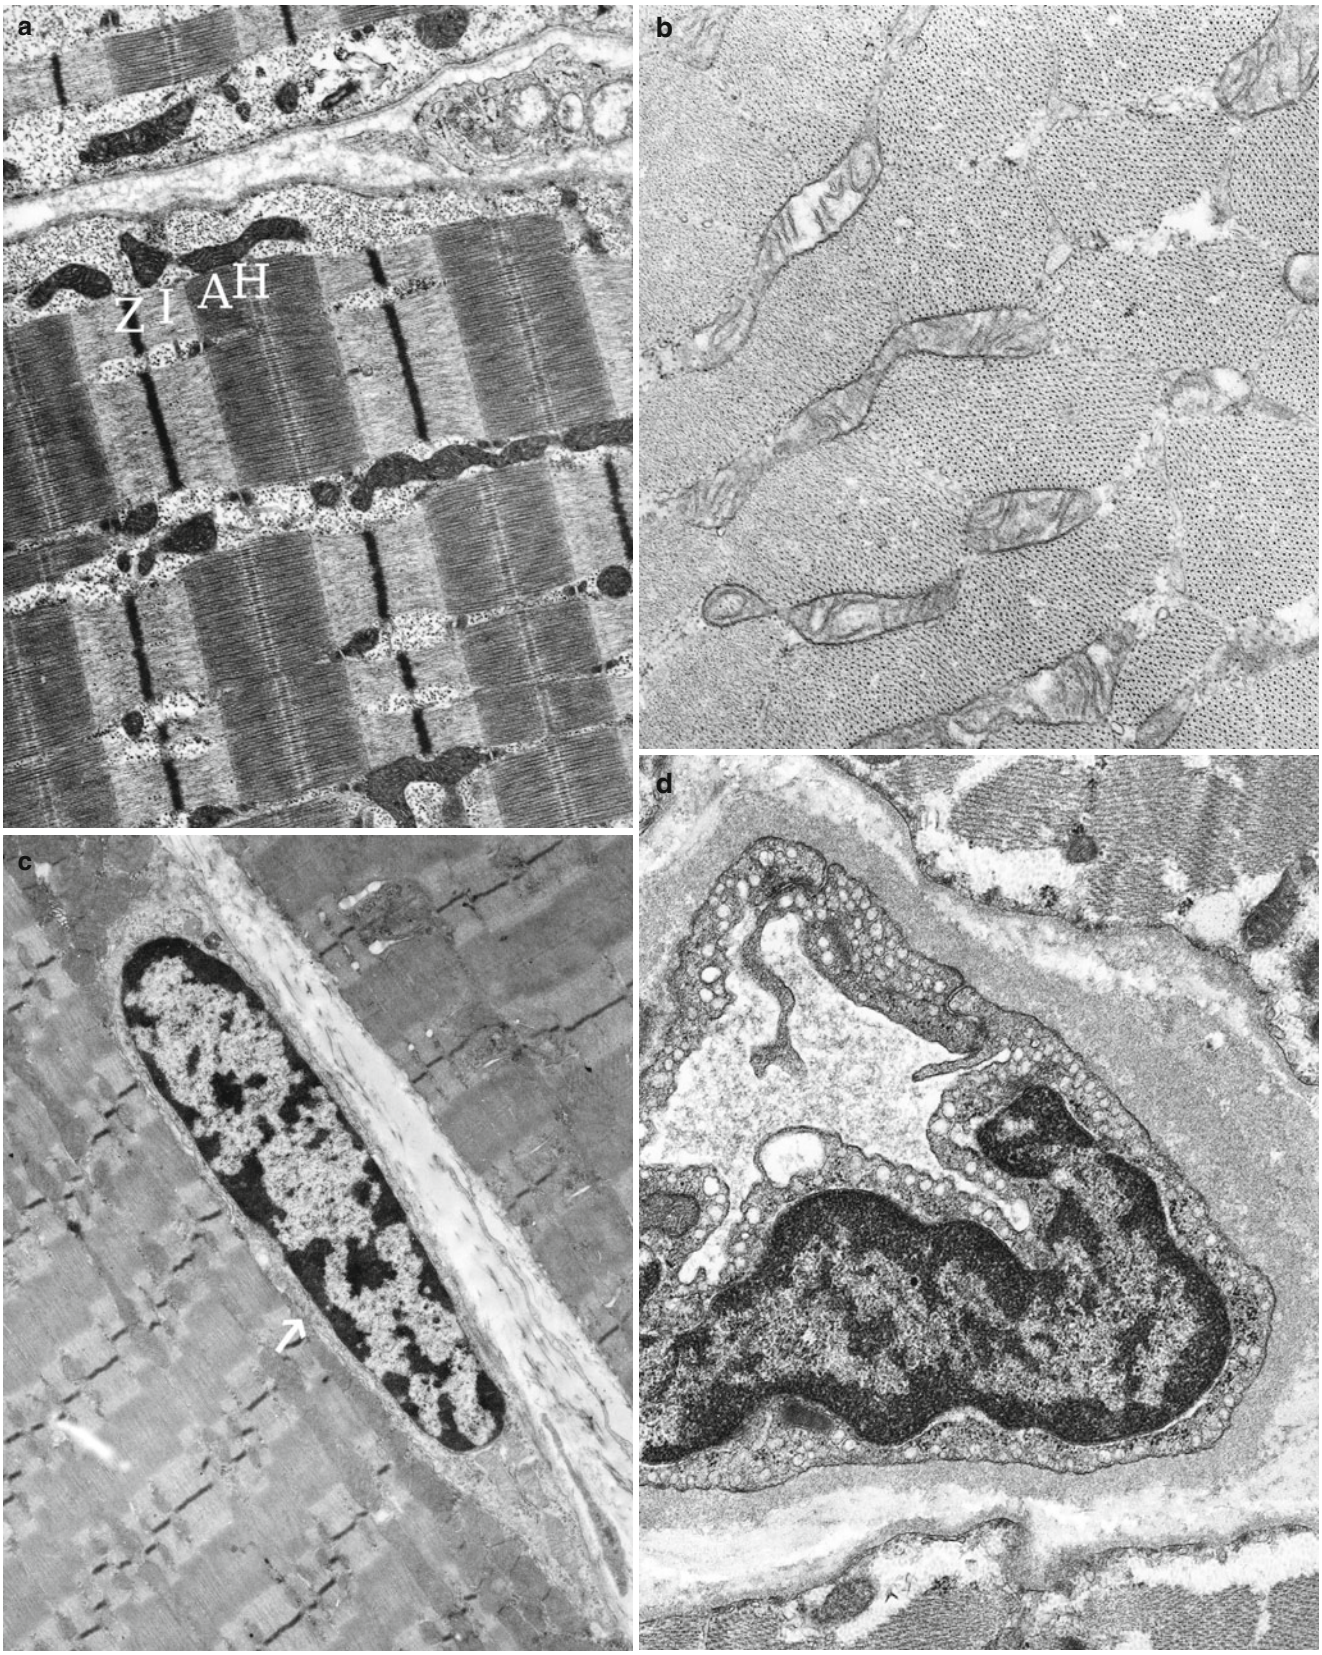

Fig. 12.15 Normal skeletal muscle ultrastructure. (**a**) Longitudinal section showing characteristic banding patterns of sarcomeres. A single sarcomere extends from one Z disk to the next and comprises a symmetric structure centered on the H band. The isotropic (I) band contains thin filaments only, while the anisotropic (A) band contains both thin and thick filaments. (**b**) High magnification of a cross section through several myofibrils showing interdigitation of thick and thin filaments. (**c**) Satellite cell. The interface between the plasma membrane of the satellite cell and the sarcolemma is best seen at the *white arrow*. (**d**) Endomysial capillary. The endothelial cell has prominent pinocytotic vesicles and is completely surrounding its basil lamina, distinct from the lamina of the adjacent myocytes

Electron Microscopy

Muscle fibers are bounded by a cell membrane (sarcolemma) and a basement membrane (basal lamina). The cell membrane is smooth and of even density (300–400 nm). Variability in sarcolemmal thickness, as well as redundancy or reduplication, is commonly seen both normally (e.g., contracted fibers) and in disease. The familiar striations of skeletal muscle are imparted by repeating units of interlaced, longitudinally directed, thin actin filaments and thick, dark myosin filaments (Fig. 12.15a, b). The dark regions are more electron-dense and are referred to as anisotropic, while the light regions are electron-lucent and are referred to as isotropic. The anisotropic region, or A band, is composed of myosin filaments alternating with actin filaments, while the isotropic region, or I band, contains only actin filaments. A narrow dark band, the Z line (or Z disk), bisects the I band. A narrow region of intermediate density, the H zone (composed of myosin filaments only), bisects the A band. A sarcomere is the contractile apparatus between two Z disks; a myofibril is a longitudinally oriented serial array of sarcomeres. Each myofibril is 0.5–1.0 μm thick and is separated from its neighbors by a loop of T tubule, smooth endoplasmic (sarcoplasmic) reticulum, mitochondria, fat globules, and intervening unstructured myoglobin-containing cytoplasm. The T tubular system is composed of invaginations of the sarcolemmal membrane into the interior of the cell and runs parallel to the Z disks. It is accompanied by two cisterns of endoplasmic sarcoplasmic reticulum on either side. The centrally placed T tubule flanked by two cisterns of sarcoplasmic reticulum is called a *triad*.

Satellite cells are located on the surface of the muscle fiber between the cell membrane (sarcolemma) and the basement membrane. They account for 1–2 % of muscle cells at rest but can increase to up to 10 % following muscle activity [57]. Satellite cells are composed of a single nucleus and scant cytoplasm containing many mitochondria and loosely strewn intermediate filaments. Satellite cells function as a reserve population of muscle cells called into action upon muscle injury (Fig. 12.15c). Elevated numbers of satellite nuclei may even represent a form of muscle memory, facilitating retraining [58]

The capillary network surrounding skeletal muscle is extensive. Ultrastructurally, the endothelium of muscle capillaries contains abundant pinocytotic vesicles and fenestrated intercellular junctions. The endothelial cells rest on a single layer of basement membrane; pericytes are visible outside this membrane (Fig. 12.15d).

Basic Skeletal Muscle Pathology

It would not be hyperbolic to call the past 10 years the decade of the skeletal muscle, and much of this newly acquired knowledge is now being applied to the diagnostic evaluation of muscle biopsies [58]. Muscle diseases formerly classified on the basis of morphology alone are increasingly diagnosed and treated based on advances in knowledge with regard to specific abnormalities involving the structure and function of skeletal muscle proteins [59]. For example, the two most prevalent "congenital myopathies" (central core disease and nemaline myopathy) are now known as manifestations of genetic disorders involving excitation–contraction coupling and sarcomeric function, respectively.

Disorders of Excitation–Contraction Coupling

Also referred to as the "muscle channelopathies," this group of disorders generally manifests as episodic or fixed abnormalities in muscle tone. Histopathologically, these disorders express a wide range of seemingly disparate structural abnormalities, most of which are secondary to chronic channel dysfunction. The most prevalent channelopathies affecting skeletal muscle are the myotonic disorders, particularly myotonic dystrophies type 1 and 2. The *myotonic dystrophies* are characterized by prominent central nuclear migration associated with muscle fiber atrophy. In classic myotonic dystrophy, type I muscle fibers are preferentially affected. Type II myotonic dystrophy demonstrates preferential histopathological abnormalities within type II muscle fibers, which are particularly well demonstrated using myosin heavy-chain-specific antibodies (Fig. 12.16a, b). The *periodic paralyses* also derive from mutations involving muscle ion channels. Although many cases demonstrate no specific myopathological alterations, occasional patients may manifest tubular aggregates and/or vacuolar degeneration (Fig. 12.16c). Core myopathies (formerly separated into central core disease and multi-minicore disease) demonstrate a well-known association with malignant hyperthermia. Approximately 50 % of core myopathies result from mutations involving ryanodine receptor 1 or selenoprotein N, leaving a large proportion of these myopathies currently genetically undefined [60].

Sarcomeric Diseases

This group of myopathies derives from mutations involving actin filaments, myosin filaments, Z disk proteins, and a variety of other proteins which are associated with maintaining the normal structure and function of the contractile apparatus. *Nemaline myopathy* has been associated with mutations in seven distinct genes, six of which encode proteins associated with the thin actin filaments [61]. The two most common are recessive mutations in nebulin and de novo dominant mutations in skeletal muscle alpha-actin. Nemaline myopathy derives its name from the Greek word for thread (nema), which describes the purplish red staining rodlike structures seen in Gomori trichrome-stained muscle fibers (Fig. 12.16d). Due to the wide range of muscle disease associated with these abnormal inclusions, it has recently been recommended that the diagnostic appellation "nemaline myopathy" be restricted to the classic presentation of early hypotonia and

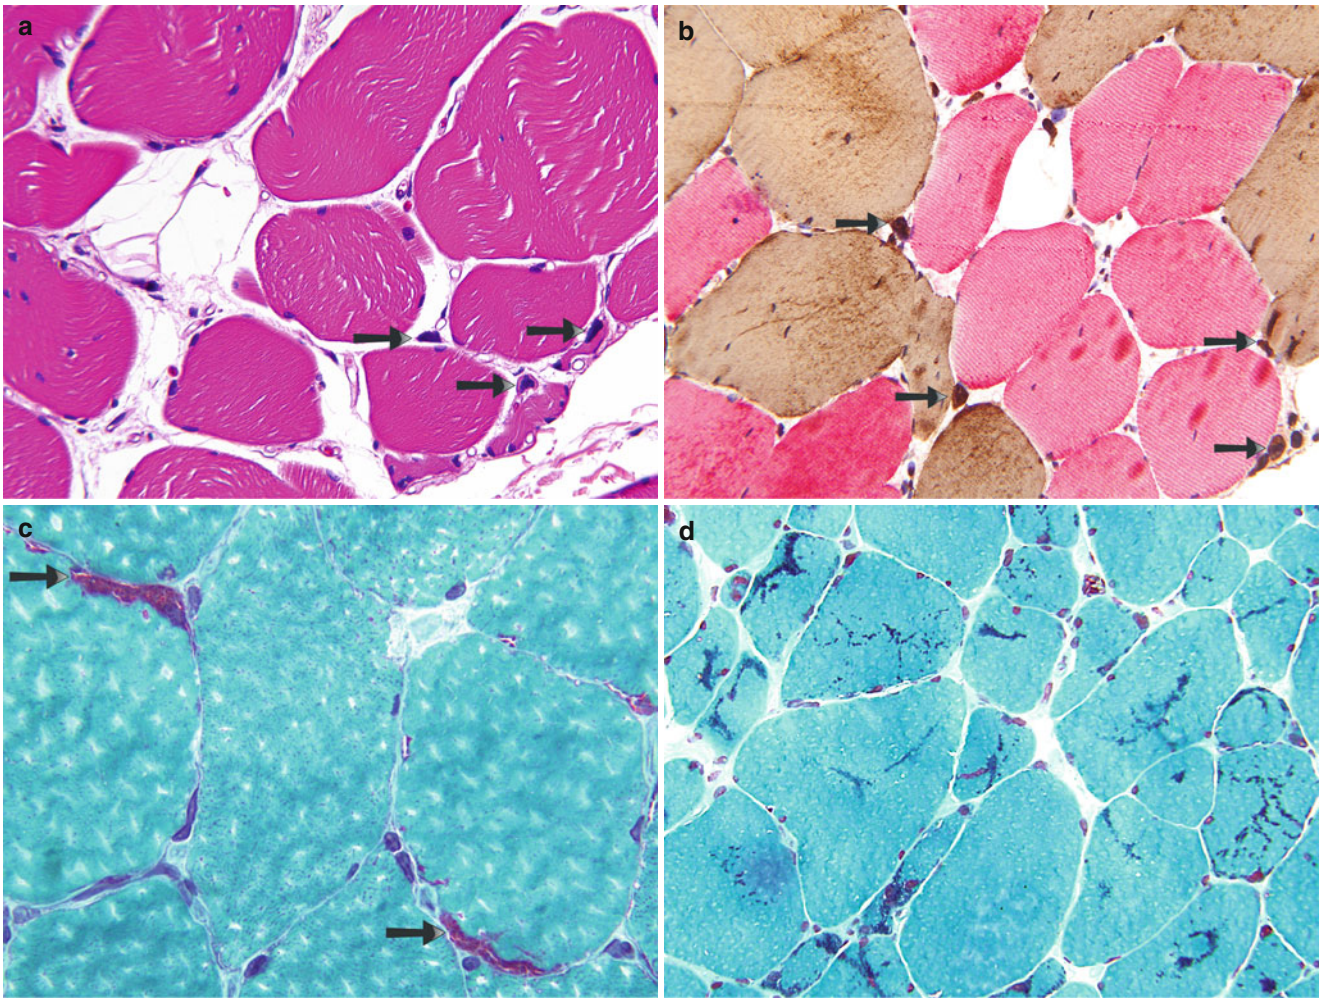

Fig. 12.16 Disorders of excitation–contraction coupling and sarcomeric structure (**a**) Myotonic dystrophy type 2 is characterized by scattered, extremely atrophic muscle fibers (*arrows*) and internalized nuclei within type II muscle fibers. (**b**) Immunohistochemical staining for type I (*red*) and type II (*brown*) myosin heavy-chain isoforms allows identification of both the severely atrophic fibers (*arrows*) and the non-atrophic fibers with internalized nuclei as being type II muscle fibers, characteristic of myotonic dystrophy type 2. (**c**) Tubular aggregates stain *bright red* on Gomori trichrome stain and typically are seen in a subsarcolemmal location (*arrows*). (**d**) As the name implies, nemaline myopathy is characterized by threadlike inclusions within muscle fibers, which are stained *purplish red* by Gomori trichrome

muscle weakness, with adult onset variants referred to more generically as "myopathies with rods." Although congenital myopathies caused by mutations in tropomyosin genes (including congenital fiber type disproportion and cap myopathy) have been described, by far, the most common clinical myopathy secondary to thick filament dysfunction is acquired acute quadriplegic myopathy in critically ill patients, often referred to as "*critical illness myopathy*." In these patients, a combination of circulating inflammatory cytokines, corticosteroids, and neuromuscular blockade eventuates in selective degradation of myosin filaments. Upon removal of the inciting stimuli, eventual reconstitution of sarcomeric structure and function generally supervenes. Finally, a large group of disparate myopathies apparently related only by the presence of myofibrillar degeneration on muscle biopsy have now been related to each other through involvement of muscle proteins responsible for maintaining the structural and functional integrity of the sarcomere [62]. Early-onset forms (often referred to as *desminopathies*) result from mutations either within the desmin gene or in desmin binding proteins, such as alpha beta crystallin. These patients' presentations are often dominated by cardiac dysfunction in addition to muscle weakness. Late-onset myofibrillar myopathies generally result from mutations within Z disk proteins. Late onset in these families is probably due to preservation of proteins with overlapping function, which enable normal sarcomeric function until late in life. As a group, these late-onset myofibrillar myopathies show distinct tendency to present with preferential distal muscle weakness [63].

Mechanical Transduction Disorders

For the muscular dystrophies, a group of genetically determined progressive myopathies, classification schemes are based on the mutated genes and their dysfunctional

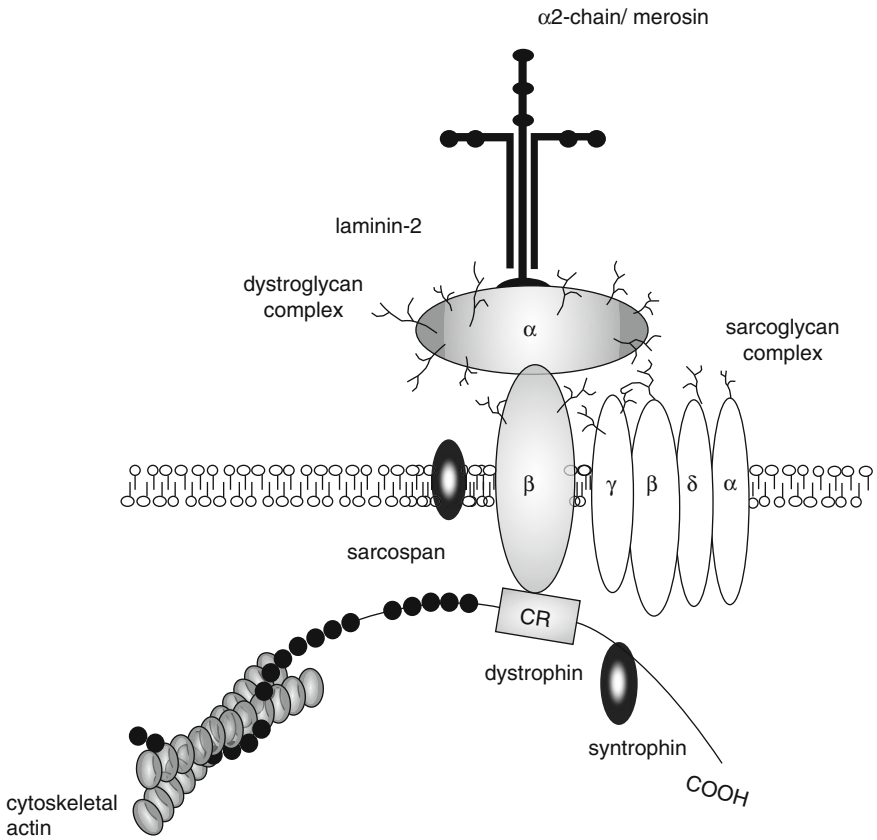

Fig. 12.17 Diagram of the interface between cytoskeletal proteins and the membrane proteins of the sarcolemma. Dystrophin interacts with cytoskeletal actin at its amino terminus and binds the beta subunit of the dystroglycan complex. Four subunits (*alpha, beta, gamma*, and *delta*) comprise the sarcoglycan complex within the cell membrane of the myocyte. The alpha subunit of the dystroglycan complex forms an interface with the laminin proteins of the extracellular matrix (Courtesy of Dr. H. G. W. Lidov)

proteins. Transmembrane protein complexes provide important links between the intracellular cytoskeleton and the extracellular matrix (Fig. 12.17). When various components of this f-actin/dystrophin–dystroglycan/sarcoglycan–laminin axis are absent, the muscle undergoes progressive degeneration with scarring, manifesting as Duchenne/Becker muscular dystrophy, limb girdle muscular dystrophies, or congenital muscular dystrophies [64].

The most common muscular dystrophy, Duchenne muscular dystrophy, is caused by frame-shifting mutations in the gene encoding dystrophin. Immunohistochemistry using commercially available antibodies to dystrophin domains permits the detection of dystrophin in normal muscle biopsies and may be used to demonstrate its absence in Duchenne muscular dystrophy. Becker muscular dystrophy is caused by in-frame mutations in the same gene. Protein epitopes are usually preserved, and western blotting is required to demonstrate a reduction in molecular weight of the dystrophin protein [65].

Limb girdle muscular dystrophies comprise a large heterogeneous group of non-X-linked, noncongenital muscular dystrophies [66]. Mechanistically, limb girdle muscular dystrophies include diseases involving the dystrophin–dystroglycan complex, sarcolemma, sarcomere, nuclear lamina, or cytosolic enzymes. Ninety percent of limb girdle muscular dystrophies (LGMDs) are autosomal recessive (designated LGMD2); 10 % are autosomal dominant (LGMD1). The most common mutations are those involving calpain 3 (LGMD 2A), dysferlin (LGMD 2B), γ-sarcoglycan (LGMD 2C), α-sarcoglycan (LGMD 2D), β-sarcoglycan (LGMD 2E), and δ-sarcoglycan (LGMD 2F). About one-third of limb girdle muscular dystrophy patients are still currently genetically unclassified. In general, western blot analysis of proteins extracted from skeletal muscle is considered to be the gold standard for diagnosis in this group of diseases. Occasionally, immunofluorescent or immunohistochemical assays may be sufficient. Importantly, limb girdle muscular dystrophies may be associated with either lymphocytic or eosinophilic inflammatory infiltrates (Fig. 12.18). Careful clinicopathologic correlation is critical to avoiding the misdiagnosis of primary inflammatory muscle disease in these patients.

The congenital muscular dystrophies (CMD) are a group of muscular dystrophies with onset at or around the time of birth frequently associated with central nervous system pathology [67]. Most result from mutations in a variety of proteins responsible for dystroglycan glycosylation. Although the dystroglycan protein itself is not mutated, these diseases are nevertheless referred to as *dystroglycanopathies*. The various syndromic presentations, including Walker–Warburg syndrome, muscle–eye–brain disease, and Fukuyama muscular dystrophy, are now subsumed under the moniker *muscular dystrophy–dystroglycanopathy* (*MDDG*) and then further subclassified according to the specific syndromic deficits identified.

Artifacts

It has often been said that the mark of an experienced pathologist is the ability to recognize artifacts, and this is nowhere more trenchant than in the interpretation of muscle biopsies. Living muscle fibers are highly irritable, and contraction bands are readily induced by excision (Fig. 12.19a, b). In longitudinal sections, these appear as fusiform widenings with shortening of the sarcomeres. In transverse sections, the contracted fibers are swollen, and the sarcoplasm has a vitreous appearance. Gaps may form in the sarcolemma, and Z lines may be smudged or have a streaming appearance. Sometimes, only the central parts of the fiber contract, giving rise to a central core of streaming Z bands. Extreme degrees of contraction result in irregular bands known as the *Nageotte banding artifact* after the French histologist who first described it [68].

In cryostat preparations, vacuolization may be caused by slow freezing (usually as a result of direct immersion in liquid nitrogen or inadequate precooling of the isopentane) resulting in formation of coarse ice crystals. A dull microtome knife produces cracks and rents.

As mentioned above, it is important to avoid mistaking the small diameters of fibers as they insert into their tendons as evidence of pathological fiber atrophy. Finally, as skeletal muscles are subject to the traumas of daily life, occasional atrophic, degenerating, or regenerating fibers are not at all unusual. In other words, it is generally a mistake to ascribe minor or focal fiber alterations to the presence of intrinsic muscle disease.

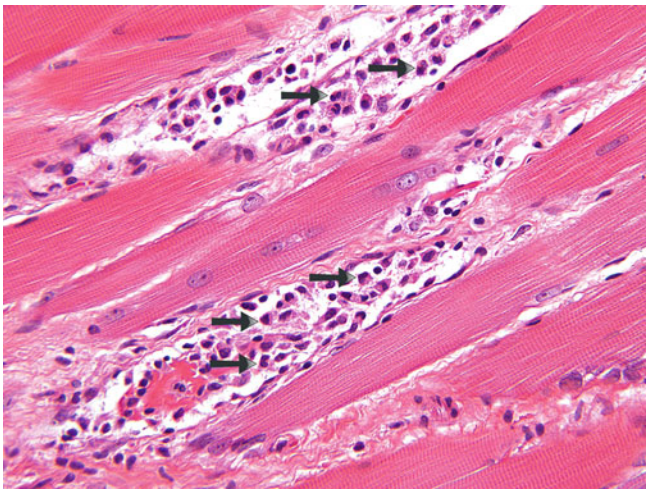

Fig. 12.18 Inflammation may be prominent within limb girdle muscular dystrophies. In this patient with limb girdle muscular dystrophy type 2A (calpainopathy), initial biopsies demonstrated histopathological features indistinguishable from eosinophilic myositis (*arrows*)

Fiber Size Alterations

The increase in the size of a muscle from birth to maturity and in exercise-induced hypertrophy is due to an increase in the number of sarcomeres (and therefore myofibrils) within muscle fibers, not to an increase in the number of muscle fibers. Repeated strong contractions (e.g., resistance training) may augment the girth of muscle fibers by as much as 25 %, and enforced inactivity may reduce it to a similar degree. These volumetric changes are referred to as work hypertrophy and disuse atrophy, respectively. Denny-Brown [69] proved that such alterations in size are a reflection of the number of myofibrils. The number of patent capillaries around the enlarged fibers also increases with exercise and decreases with inactivity. The accommodation of blood supply to fiber size appears to be an essential part of conditioning for increased muscle activity.

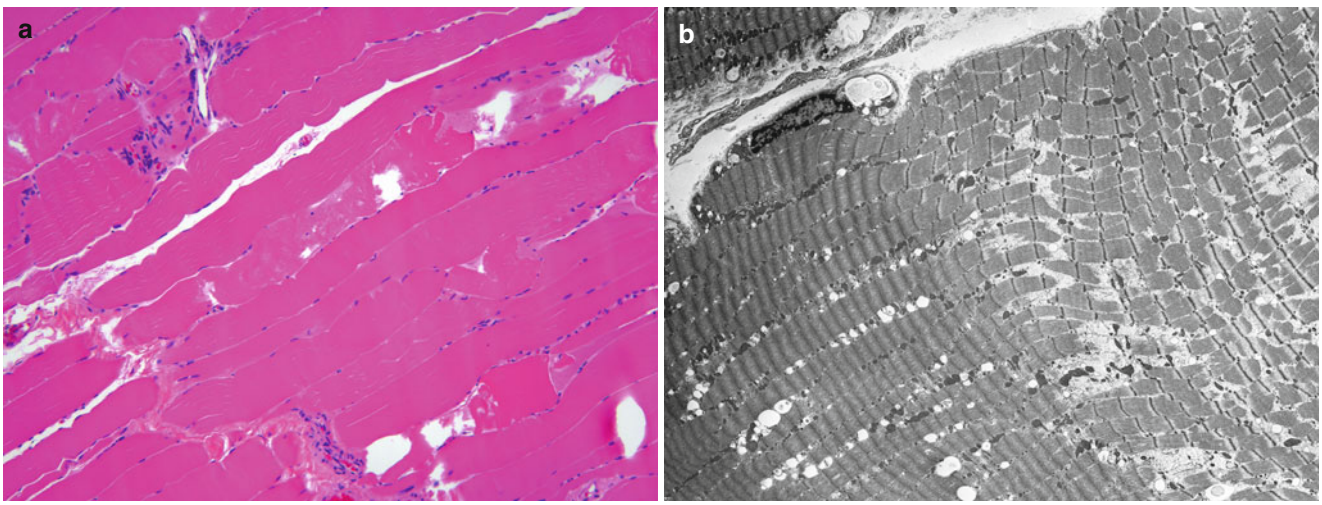

Fig. 12.19 (**a**) Hypercontraction bands may indicate acute muscle necrosis but are also commonly caused by handling of the muscle during processing. The absence of regenerating muscle fibers provides strong evidence in favor of processing artifact in this case. (**b**) Electron micrograph showing hypercontraction band (*left*) and normally contracted sarcomeres (*right*)

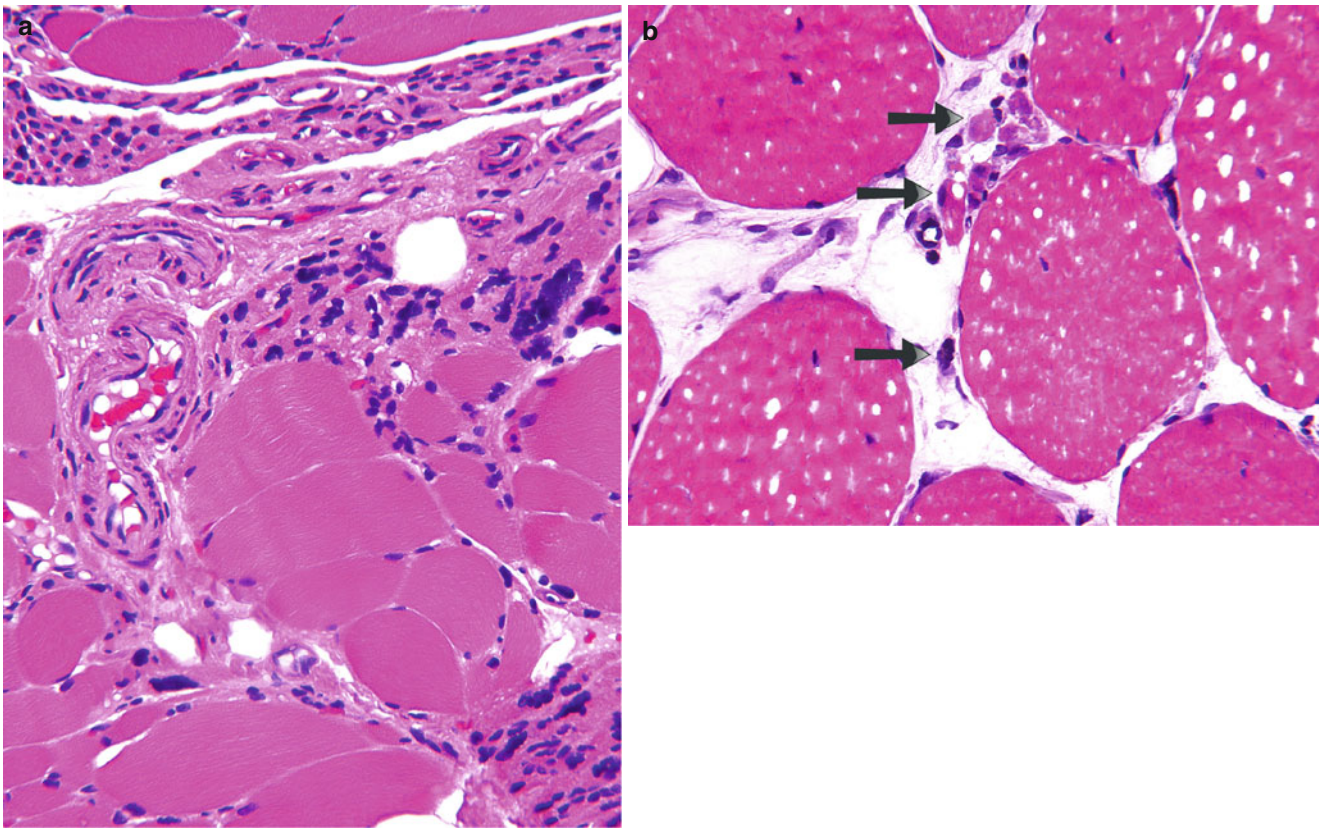

Fig. 12.20 (**a**) At first glance, extremely atrophic muscle fibers may resemble inflammatory infiltrates. (**b**) Careful examination at high power (*arrows*) discloses irregular remnants of eosinophilic cytoplasm, revealing their true myopathic derivation

The term "atrophy" as applied to a muscle fiber refers to a reduction in volume with preservation of sarcolemmal surface area. This may follow loss of innervation (termed neurogenic or denervation atrophy) or may be the consequence of a primary disease of the muscle fiber. Muscle fiber atrophy can also result from immobilization, malnutrition, compression, aging, or vascular insufficiency. Atrophic fibers are smaller than normal because the cytoplasmic contractile proteins are reduced, but the integrity of the cell membrane is preserved. As the cytoplasmic content is diminished, nuclei tend to pile up (transverse sections) or line up in a chain (longitudinal sections). End-stage atrophic fibers appear as "nuclear bags," which on casual inspection may be mistaken for lymphocytic infiltrates. Closer inspection, however, reveals minute amounts of eosinophilic cytoplasm in contradistinction to the discrete amphophilic cytoplasm of lymphocytes (Fig. 12.20a, b)

Due to their dependence on phasic stimulation, type II fibers atrophy more quickly than type I fibers and, therefore, tend to outnumber atrophic type I fibers in neurogenic atrophy. On transverse section, the fibers assume a roughly triangular ("angulated") shape, sometimes partially encircling neighboring normal fibers and conforming to their shape. The process of denervation and reinnervation is best demonstrated with immunocytochemical or histochemical stains that highlight fiber type (Fig. 12.21a–g). Under normal circumstances, type I and type II fibers are distributed so that they appear as alternating fibers, producing a mosaic pattern of staining with the ATPase reaction or myosin heavy-chain immunostaining. In the first phase of denervation, the atrophic fibers of an affected motor unit are distributed in groups throughout the biopsy (small group atrophy). Reinnervation by adjacent axons leads to a clustering of fibers of the same histochemical type in a group (fiber-type grouping). Instead of the usual checkerboard pattern of intermixed fiber types, there is a tendency for both type II fibers and type I fibers to be in large groups, with some fibers entirely surrounded by the same fiber type. Although fiber-type grouping has occasionally been reported in myopathies, it is much more strongly associated with chronic denervation atrophy of muscle, where it is responsible for the enlarged motor unit action potentials elicited on electrodiagnostic testing. Should there then be denervation of the previously reinnervating motor unit, there follows large group atrophy which is type-specific. Electron microscopic examination of atrophic fibers discloses a reduction in the number of myofibrils beginning at the periphery of the fiber. The nuclei of these atrophic fibers appear normal, and sarcotubular profiles and mitochondria increase

in density. The sarcolemma remains intact, but there is duplication and thickening of the basal lamina. In long-standing denervation atrophy, sarcomeric organization is eventually lost, and all that remains are aggregates of haphazardly oriented, poorly organized myofibrils comprising thickened Z lines from which filaments of variable thickness emanate. These, in turn, are interspersed with randomly scattered isolated myofilaments of variable thickness. Muscle fiber atrophy also occurs in myopathic injury secondary to either hereditary or acquired factors; under these circumstances, the atrophic fibers tend to retain either a polygonal or rounded contour (Fig. 12.22a, b).

After long-standing denervation (e.g., in Charcot–Marie–Tooth disease), myocyte cell death with ingrowth of fibroadipose tissue may ensue ("pseudomyopathic changes of chronic denervation"). In cases where the underlying neuropathic disorder has not been previously disclosed or diagnosed, this histological picture is referred to as

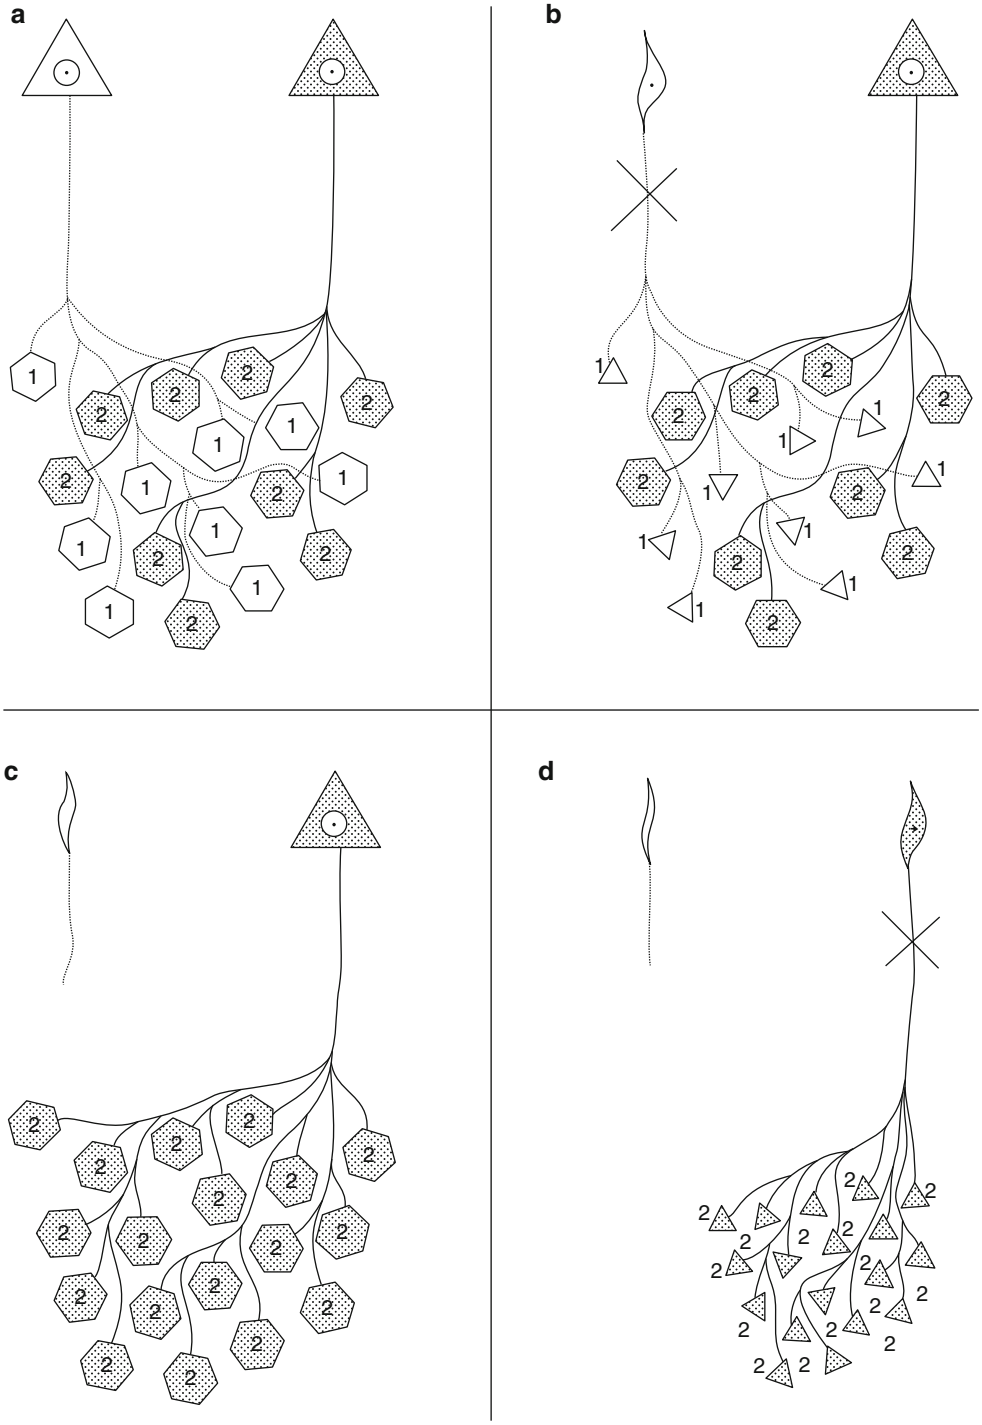

Fig. 12.21 Denervation and reinnervation of skeletal muscle. Diagram of denervation atrophy. (**a**) Normal checkerboard pattern of two motor units (*light* and *dark* anterior horn cells are depicted as triangles). (**b**) *Light* anterior horn cell is damaged, resulting in denervation of muscle fibers of that motor unit (indicated as type 1 fibers). (**c**) Reinnervation accomplished by sprouting of adjacent (*dark*) motor unit axons resulting in type grouping. (**d**) Damage to the axon of the *dark* motor unit results in group atrophy. (**e**) Transverse section showing clusters of angulated atrophic fibers (group atrophy). (**f**) Fiber-type grouping is only evident on the ATPase-stained serial section. (**g**) Electron micrograph showing myofibrillar disarray of an atrophic muscle fiber

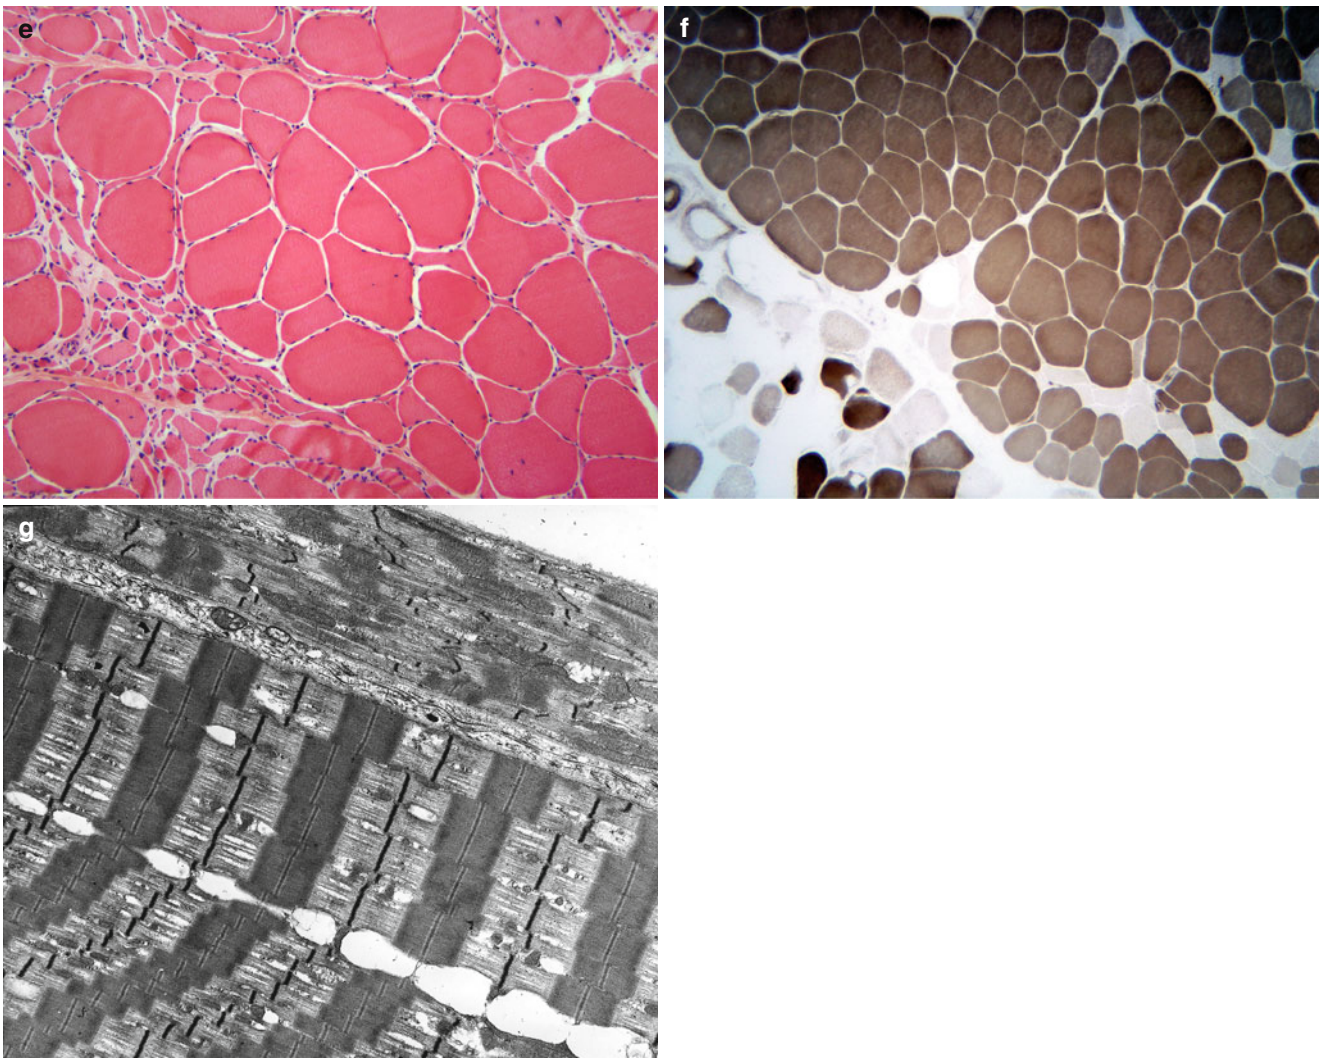

Fig. 12.21 (continued)

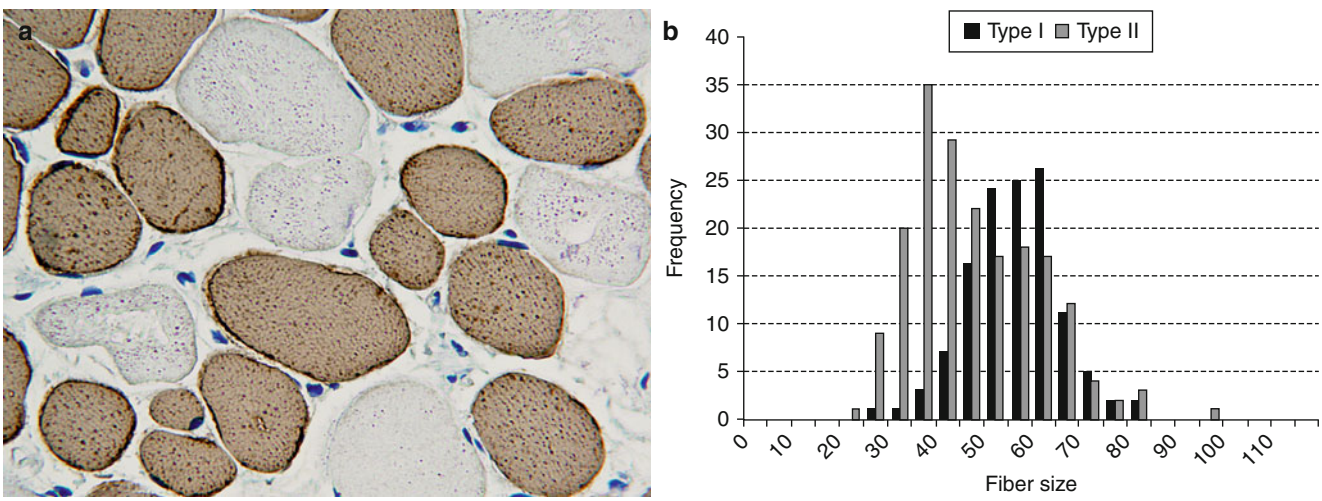

Fig. 12.22 Type 2 atrophy. (**a**) In this muscle biopsy specimen, immunohistochemical staining for fast myosin isoforms showed type II fibers (*stained brown*) to be slightly smaller on average than type I fibers (unstained). (**b**) Morphometric analysis of the muscle biopsy shows a different distribution of the sizes of myocytes of the two fiber types, with a smaller mean diameter of type II fibers

"end-stage" muscle injury, which marks the terminal phase of the muscle disease, be it of neurogenic or myopathic origin (Fig. 12.23).

Hypertrophic fibers are larger than normal, although well proportioned in terms of shape and constituent organelles. These may develop as a consequence of excessive work demands or, rarely, as a consequence of faulty neurogenic signaling. Work hypertrophy of muscle is the basis for increased muscle bulk in resistance training. Muscle fiber injury during training stimulates recruitment of satellite nuclei into injured fibers, eventuating in an increase in the number of myofibrils as the fiber heals.

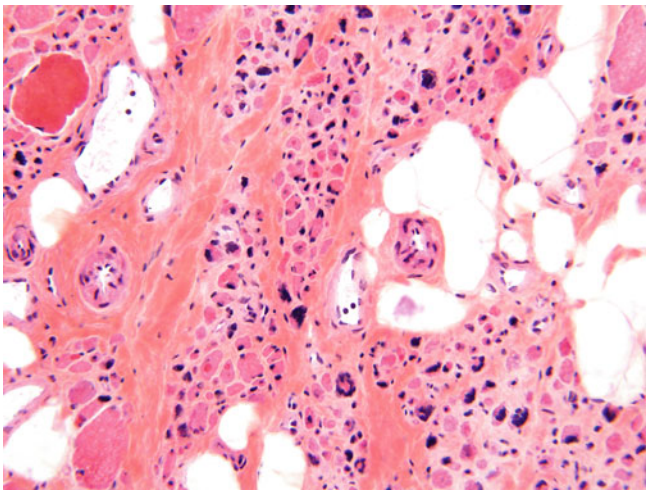

Fig. 12.23 "End-stage" skeletal muscle. Endomysial ingrowth of fibrofatty tissue surrounds clusters of extremely atrophic muscle fibers

Myofiber Degeneration and Regeneration

Segmental necrosis, the degeneration of a longitudinal segment of a muscle fiber, is seen in a large number of myopathies, including those due to vascular immunologic factors. The affected fiber shows focal loss of cross striations replaced by a smudge of hyalinized, somewhat darker-staining degenerated cytoplasm. There may be bulging of the cell at this site or irregular shrinkage of its diameter. The subsarcolemmal myofibrils are damaged preferentially, and the sarcolemma may rupture resulting in extrusion of portions of the sarcoplasm. At the same time, neighboring nuclei become pyknotic or disappear. Eventually, phagocytes are recruited to the necrotic segments, with phagocytic removal of necrotic debris. Simultaneously, satellite nuclei are stimulated and begin regenerating adjacent portions of the muscle fiber (Fig. 12.24a–d). As visualized on H&E, the cytoplasm is purplish blue, and the affected portion of the fiber is somewhat narrower than normal. The cross striations are not apparent, and there is an increase in the size and number of nuclei which also appear larger and vesiculated and contain one or more large nucleoli. Regeneration sometimes produces the appearance of multinucleated giant cells. Fusion between basophilic satellite fibers and the injured fibers is a critical part of the recovery process and may often be visualized during regeneration. Ultrastructurally, regenerating fibers/activated satellite cells can be recognized by the presence of large nuclei and nucleoli occupying an internal position within the fiber. The cell membrane and basal lamina are intact, and the number of organelles is not different from normal, except perhaps for an increased number of free ribosomes. The most striking cellular alterations in regeneration are found

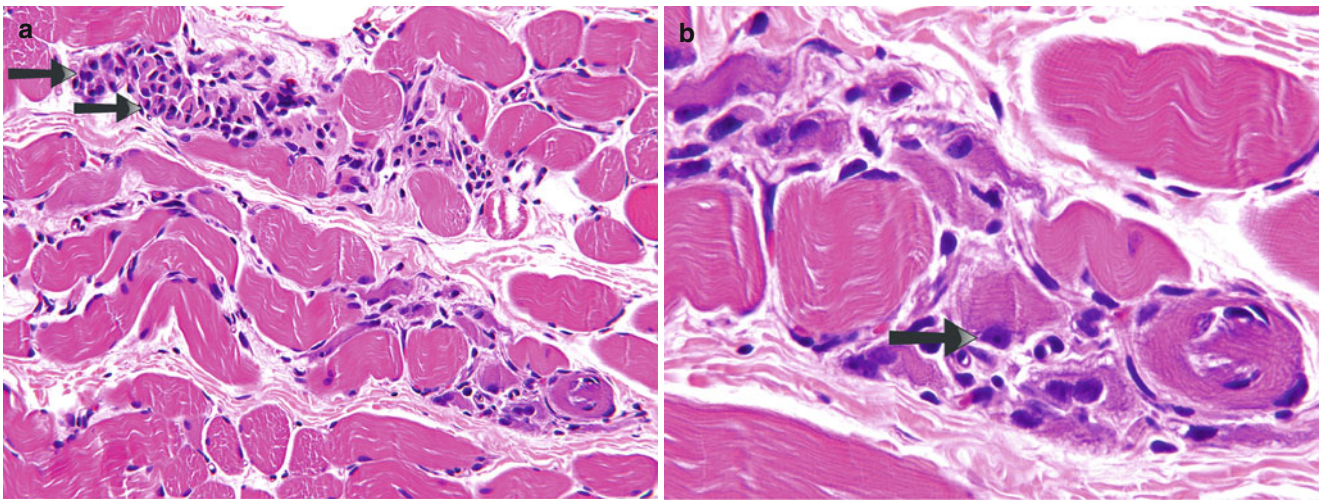

Fig. 12.24 Necrosis and regeneration of skeletal muscle. (**a**) Light microscopy showing a necrotic myocyte being ingested by macrophages (*arrows*), sometimes referred to as myophagocytosis. (**b**) Higher powered view of activated satellite cells characterized by amphophilic cytoplasm, and large nuclei, and prominent nucleoli (*arrow*). (**c**) Electron micrograph showing focal disintegration of a myocyte. (**d**) Electron micrograph showing the prominent nucleus of an activated satellite cells/regenerating myocyte

in the contractile system. There may be large areas of the fiber in which the filaments are poorly organized into myofibrils, although these may be oriented in parallel.

Skin Biopsy

13

Lan Zhou

Introduction

Peripheral nerve fibers are classified according to size, which correlates with the degree of myelination. Small fibers are comprised of myelinated Aδ (delta) fibers and unmyelinated C fibers, which innervate skin (somatic fibers), cardiac muscle (autonomic fibers), and smooth muscles (autonomic fibers) lining gastrointestinal tract, genitourinary tract, blood vessels, glands, and others. They mediate pain and thermal sensation as well as autonomic functions.

Small fiber neuropathy (SFN) results from impairment of small myelinated Aδ (delta) and unmyelinated C fibers. When small somatic nerve fibers are affected, patients present with pain, burning, tingling, or numbness. Examination often shows allodynia, hyperalgesias, or reduced pinprick and thermal sensation in the affected area. Motor strength, proprioception, and tendon reflexes, however, are preserved because these modalities are the functions of large nerve fibers. When autonomic fibers are affected, patients may experience dry eyes, dry mouth, orthostatic dizziness, constipation, bladder incontinence, sexual dysfunction, trouble sweating, or red or white skin discoloration. Examination may show orthostatic hypotension and skin changes. The skin over the affected area may appear atrophic, dry, shiny, discolored, or mildly edematous due to sudomotor and vasomotor abnormalities [1, 2]. The symptoms and signs of SFN are typically length-dependent with a distal-to-proximal gradient. Rare cases of SFN may follow a non-length-dependent distribution in which symptoms and signs may be manifested predominantly in the arms, face, or trunk [3–5].

SFN is a common peripheral nerve disorder. Electrodiagnostic testing – nerve conduction study (NCS) and needle electromyography (EMG) – which is widely used for evaluating peripheral nerve disorders with large fiber involvement, cannot be used to evaluate SFN as the conduction velocities of these small somatic fibers are too slow to allow their conduction responses to be captured during routine NCS. Hence, NCS and needle EMG are typically normal in patients with pure SFN. The lack of objective findings on NCS and EMG may lead many physicians to attribute the SFN symptoms to other disorders such as plantar fasciitis, vascular insufficiency, or degenerative lumbosacral spine disease [2].

Small somatic nerve fibers remained "invisible" until 1990s when the technique of skin biopsy with intraepidermal C fiber density evaluation was developed and utilized for clinical diagnosis of SFN [6–9]. This special test has greatly facilitated the diagnosis and management of SFN [10].

Processing Skin Biopsies

Performing Skin Biopsies

Two methods are used to biopsy skin for evaluating cutaneous innervation, the 3-mm punch biopsy [8] and the blister technique [11]. The blister technique only removes epidermis by placing a suction capsule over the skin without damaging dermal capillaries. Although it is less invasive, painless, and does not cause bleeding, it is not commonly used because it is time-consuming, does not allow evaluation of dermal innervation, and no normative reference value of intraepidermal nerve fiber density (IENFD) is established using this technique [12]. The 3-mm punch biopsy is the standard method for sampling skin. The current technique was initially developed at the Karolinska Institute [9] and later standardized at the University of Minnesota [7] and the Johns Hopkins University [8].

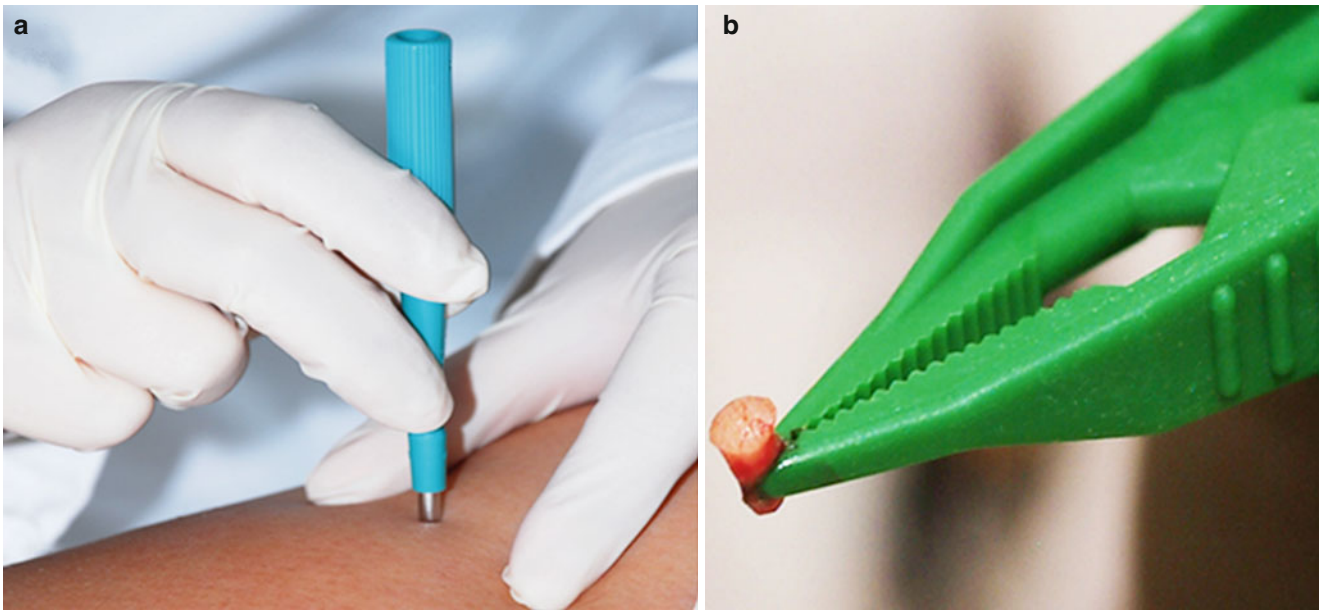

Fig. 13.1 3-mm punch skin biopsy for diagnosing SFN. (**a**) After cleaning the biopsy site, a 3-mm punch is placed on the site perpendicular to the skin surface and twisted down. (**b**). The skin biopsy should be picked up by forceps to pinch the subcutaneous layer but not the top epidermis

The 3-mm punch biopsy is routinely done in one lower limb. The biopsy is taken from distal leg, which is 10 cm above the lateral malleolus. Additional biopsies may be taken from lateral distal thigh (10 cm above the knee) and lateral proximal thigh (10 cm below the greater trochanter) for evaluating the severity and pattern of SFN, length-dependent vs. non-length-dependent [3–5]. Biopsies taken from other sites may be indicated if focal or unilateral small-caliber nerve fiber impairment is suspected [13–15].

The 3-mm punch biopsy is minimally invasive. It is done under local anesthesia using a sterile technique. After a biopsy site is identified, it is cleansed with alcohol swabs and injected with 1 % lidocaine. A 3-mm (diameter) disposable circular punch is then placed on the skin perpendicular to the skin surface and twisted down until the punch is 3–4 mm in. The biopsy is removed with the forceps and surgical blade technique. It is very important that the epidermis should not be pinched because intraepidermal nerve fibers will be evaluated (Fig. 13.1). Bleeding is usually minimum and easily controlled by applying firm pressure to the biopsy site. No sutures are needed, and the biopsy site is usually healed within 7–10 days by granulation which leaves a small scar that gradually resolves.

The 3-mm punch biopsy is well tolerated and is usually completed in about 10 min. The only time patient may feel pain is when lidocaine is injected to numb the biopsy site. It may not be necessary for patients to hold anticoagulants, antiplatelet agents, or nonsteroidal anti-inflammatory agents for the procedure. However, if patients are on these medications, 1 % lidocaine with epinephrine may be used for local anesthesia, because epinephrine has vasoconstrictive effect which can reduce bleeding. The biopsy site may need prolonged pressure, and an absorbable gelatin sponge (gelfoam) may also be applied for hemostasis.

The 3-mm punch biopsy is safe, and no serious adverse effects were reported. The estimated frequency of nonserious side effects, including mild infection and excessive bleeding, is 1.9:1,000 [12]. Mild infection at the biopsy site is usually controlled by topical antibiotics, such as Neosporin® (bacitracin, neomycin, and polymyxin B), and bleeding can usually be controlled by prolonged pressure to the biopsy site without sutures.

Neurologists may perform punch biopsies themselves but only after appropriate training to avoid damage to epidermis. They should send specimens to a cutaneous nerve laboratory, but not a routine reference laboratory, as a special technique, including unique fixative and immunostaining technique, is used to fix and process biopsy specimens. Therefore, it is very important to contact a specialized cutaneous nerve laboratory regarding fixative and processing before planning on a biopsy.

Processing Skin Biopsy Specimens

Immunohistochemical assays are used to detect an antigen expressed by nerve axons to visualize cutaneous nerve fibers to allow morphometric and morphological evaluation of cutaneous innervation. Two methods of immunostaining have been used, the bright-field immunohistochemistry [8] and the immunofluorescence with [7] or without [9] confocal microscopy. Since most diagnostic cutaneous nerve laboratories

use the bright-field immunohistochemistry and normative reference values have been established using this technique, this immunostaining method is briefly reviewed here.

After a skin biopsy is removed, it should be fixed immediately in a cold fixative for approximately 24 h. Two types of fixatives can be used, 2 % paraformaldehyde-lysine-periodate (2 % PLP) and Zamboni (2 % paraformaldehyde and picric acid) fixatives. Formalin, which is commonly used by routine histopathology laboratories, should be avoided because it may cause more fragmented appearance of nerve fibers [16]. The skin specimen is then cryoprotected for at least 6 h using 20 % glycerol in 0.1M Sorensen's phosphate buffer. After freezing, the specimen is sectioned at 50 um. About 45–55 sections can be obtained from each specimen. Four nonadjacent sections from each specimen are then chosen for immunostaining, which is done manually using free-floating skin sections under a dissecting microscope. The wavy nerve fibers can be better viewed in thick 50-um sections than in routine 5-um sections.

The primary antibody used for the immunostaining is the rabbit polyclonal antibody against protein gene product 9.5 (PGP9.5). PGP9.5 is an ubiquitin carboxyl-terminal hydrolase [17], which is a neuronal cytoplasmic marker. It is found in all types of efferent and afferent nerve axons [18, 19], so it is a useful pan-axonal marker to highlight all the nerve fibers. After primary antibody incubation, the sections are incubated with a biotin-conjugated secondary antibody which can bind the primary antibody. This is followed by incubation with avidin-conjugated horseradish peroxidase, and avidin can bind biotin. The immunostaining signal is then developed using the SG kit (blue chromogen/peroxidase substrate) that produces a blue-gray reaction product [8].

Counting IENF and Measuring IENFD

IENF are quantified using a light microscope with 40× objective. A counting rule has been established [20] and recommended to use by EFNS/PNS [12, 21]. Briefly, the nerve fibers that cross the dermal-epidermal junction into the epidermis are counted. The nerve fibers that do not cross the dermal-epidermal junction are not counted. If a nerve fiber branches within epidermis, count as one fiber. If a nerve fiber branches below or within the dermal-epidermal junction, count as two fibers. According to the European Federation of Neurological Societies (EFNS)/Peripheral Nerve Society (PNS) guideline, the nerve fragments within epidermis that do not cross the dermal-epidermal junction are not counted, due to the concern that these fragments may be the extension of adjacent fibers on the same skin section that are visualized to cross the dermal-epidermal junction and counted. Counting these fragments may result in overcounting. However, the original fibers crossing the dermal-epidermal junction may not be shown and counted on the same section due to the wavy nature of nerve fibers, excluding these fragments may thus result in undercounting. Some cutaneous nerve laboratories do count these individual fibers within the epidermis without crossing the dermal-epidermal junction [5, 8, 22–24].

To calculate the linear density of IENF (IENFD), the length of the epidermal surface is measured and a free software available at http://rsb.info.nih.gov/nih-image/index.html may be used [12]. The IENFD is expressed as the number of IENF per length of section (IENF/mm). An alternative "ocular" method has been described and used [25–27], in which special sections are chosen for immunostaining with the assumption that the length of the epidermal surface of these sections is close to 3 mm. So the IENFD is calculated simply by dividing the number of IENF by 3. It has been shown that the IENFD obtained by this method significantly correlated with the IENFD obtained from the conventional quantification by measuring the length of the epidermal surface [25]. However, the EFNS found that further studies are warranted to establish the reliability of the "ocular" method [21].

IENFD measurement is highly reproducible. Reproducibility is highest when four sections from each biopsy specimen are counted [23]. After reviewers are trained to use the same counting rule, the interobserver and intraobserver reliabilities are high [8, 22, 23, 28, 29]. There is no significant difference in IENFD for skin sections stained at different cutaneous laboratories as long as the identical methodology is used by these laboratories to process skin specimens and measure IENFD [23].

Normal Cutaneous Innervation

The skin consists of three layers firmly attached to one another: the outer epidermis, the deeper dermis, and the subcutaneous layer. The cutaneous innervation used to be considered to mainly consist of a plexus of nerve fibers in the reticular dermis and a more superficial plexus of nerve fibers in the papillary dermis parallel to the skin surface. Paul Langerhans first described the penetration of nerve fibers into the epidermis in 1868 by using the gold chloride method [30]. This insensitive staining method, however, made the intraepidermal fibers difficulty to visualize and led people to believe that the epidermal innervation was poor. The intraepidermal fibers were visualized by methylene blue and silver stains in 1950s and 1960s [31, 32]. By using electron microscopy and substance P staining, Kruger demonstrated the penetration of nerve fibers into the stratum spinosum layer of the epidermis in 1985 [33]. Rich innervation of human epidermis was subsequently demonstrated by immunostaining using PGP9.5 antibodies in late 1980s and early 1990s [6, 7, 9]. It was shown that PGP9.5 antibodies labeled more nerve fibers in human skin than

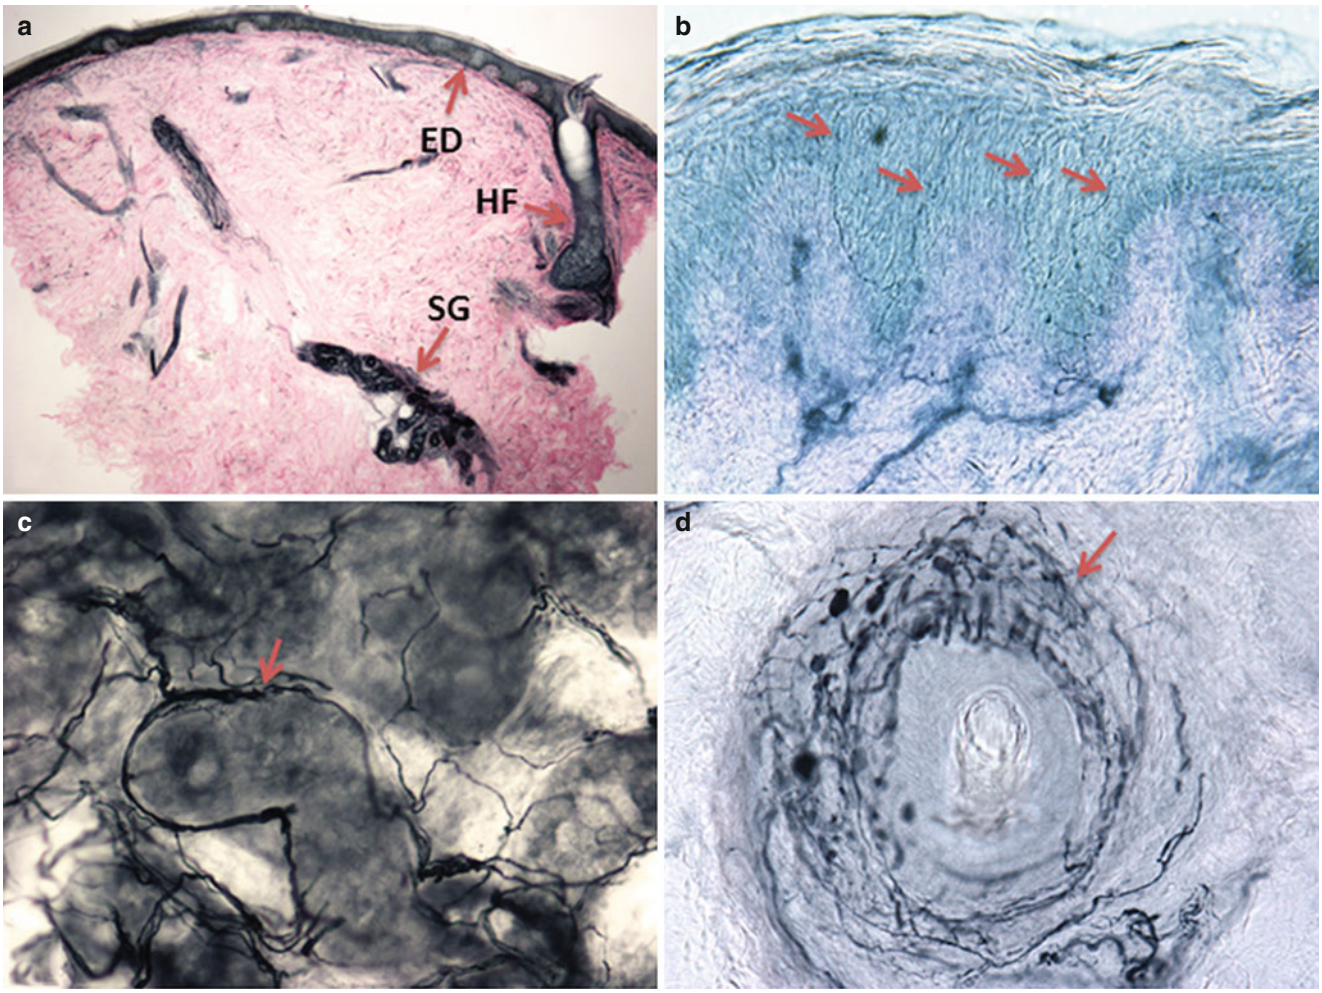

Fig. 13.2 Cutaneous innervation. (**a**) A skin section immunostained with PGP9.5 shows the *top* layer of epidermis (*ED*), hair follicle (*HF*), and sweat glands (*SG*) in the dermis. (**b**) Intraepidermal somatic fibers (*arrows*). (**c**) Dermal sudomotor autonomic fibers surrounding sweat glands (*arrow*). (**d**) Dermal vasomotor autonomic fibers innervating a blood vessel (*arrow*)

neuron-specific enolase, neurofilament, or other peptide marker [34].

The intraepidermal nerve fibers originate from sensory nerves as they express substance P and calcitonin gene-related peptide (CGRP) [35, 36]. In addition, these fibers arise entirely from dorsal root ganglion (DRG) as they disappear from skin after experimental dorsal root ganglionectomy, but not after dorsal rhizotomy, ventral rhizotomy, or sympathectomy [37]. The unmyelinated C fibers are arranged in Remak bundles which also consist of non-myelin-forming Schwann cells. The number of unmyelinated axons in a single Remak bundle varies from 1 to more than 10. Axons exchange among Remak bundles as they pass from DRG to skin [38]. The Remak bundles lose their Schwann cells and the S-100 staining of Schwann cells ends at the dermal-epidermal junction [8]. The unmyelinated axons then ascend vertically through the epidermis between adjacent keratinocytes as free nerve endings [39] (Fig. 13.2). The autonomic C fibers innervate sweat glands (sudomotor fibers), blood vessels (vasomotor fibers), and arrector pilorum muscles (pilomotor fibers) in the dermis.

The technique of 3-mm punch biopsy with intraepidermal nerve fiber density evaluation using PGP9.5 immunostaining was standardized and first utilized to evaluate patients with SFN by the University of Minnesota [7] and the Johns Hopkins University [8]. In 1995, the method of the bright-field PGP9.5 immunostaining and IENFD quantification was published [8]. The majority of diagnostic cutaneous nerve laboratories adopted this method. By using this method, they showed that IENFD at distal leg was lower in patients with HIV-seropositive and HIV-seronegative sensory neuropathy as compared with normal controls. Normative reference range was subsequently developed at distal leg and proximal thigh in 98 normal control subjects with age ranging from 13 to 82 years [22]. This showed no significant age effect except for a significantly higher IENFD in the youngest age decile (10–19 years) [16, 22]. By using the cutoff derived from the fifth percentile of the normative range at distal leg to evaluate 20 patients

with sensory neuropathy, the technique had a sensitivity of 45 %, a specificity of 97 %, a positive predictive value of 75 %, a negative predictive value of 90 %, and a diagnostic efficiency of 88 %. Using fifth percentile cutoff yielded a higher diagnostic efficiency than using tenth percentile cutoff. The high diagnostic efficiency of this technique was also demonstrated by other laboratories [40, 41]. By studying the cutaneous innervation at five sites – distal leg, proximal calf, distal thigh, proximal thigh, and trunk – in ten healthy controls (ages 23–75 years), a normal rostral-to-caudal gradient of IENFD, with a linear relationship to the distance from the spine, was also confirmed [16]. IENFD at a proximal site is higher than that at a distal site. IENFD at proximal thigh was higher than that at distal leg by about 60 % [22].

Several laboratories studied normative reference values at distal leg but did find a decline of IENFD with age [25, 27–29, 42–44]. Recently, a multicenter study was completed to assess the normative values of IENFD at distal leg by involving 550 healthy subjects from eight cutaneous nerve laboratories in Europe, USA, and Asia [45]. The study confirmed the age-related decline of IENFD and also showed no effect of height or weight. Women have higher IENFD than men before 70 years of age. The study developed age- and sex-stratified IENFD normative values for clinical use. However, the sensitivity, specificity, and diagnostic efficiency have not been determined, because no conclusive diagnostic criteria for SFN are available. However, most groups use a similar definition based on clinical symptoms and signs, normal NCS, and abnormal skin biopsy or QST findings [12].

A few reports described the reduction of cutaneous autonomic fiber densities in patients with idiopathic SFN [46] or SFN associated with diabetes [47], leprosy [48], familial dysautonomia [49], and Ross syndrome [50]. Several studies attempted to establish standard and reproducible methods to quantify dermal autonomic fiber densities [51–54] to facilitate clinical evaluation and research of autonomic dysfunction associated with SFN. Gibbons et al. developed and compared three methods of quantifying sudomotor fiber densities [52, 53]. The authors found that the semiquantitative method displayed poor inter- and intra-reviewer reliability and should not be used. The manual method is good but labor intensive. The automated method is superior because it is fast, strongly correlates with the unbiased stereologic technique, and correlates well with examination findings and IENFD. However, whether the sudomotor fiber density measured by this method correlates with the sudomotor function gauged by quantitative sudomotor axon reflex testing (QSART) needs to be determined. Nolano developed a method to quantify pilomotor nerve fiber density (PNFD), and by using this method, they found that the PNFD was significantly reduced in diabetic patients as compared with normal controls. However, PNFD did not correlate with IENF or total neuropathy score [54]. Further morphometric studies of dermal autonomic fiber densities are deemed warranted by EFNS/PNS [12].

Basic Reactions to Injury of Small Nerve Fibers

Small Fiber Degeneration

Small fibers undergo degeneration upon injury. Reduction of IENFD has been shown in neuropathies associated with various medical conditions, including diabetes and prediabetes [46–49], vasculitis [50, 55], systemic lupus erythematosus [56, 57], Sjögren syndrome [58], rheumatoid arthritis [59], HIV infection [8, 24, 60], celiac disease [61], restless leg syndrome [62], Fabry's diseases [63, 64], neurotoxic drug exposure [65], and paraneoplastic sensory ganglionopathy [66].

The diagnosis of SFN is made based on the reduction of IENFD (Fig. 13.3). The majority of SFN is length dependent, in which IENFD at distal leg is more severely reduced (or absent) than distal thigh and proximal thigh due to a "dying back" process affecting small sensory fibers. In some of these cases, IENFD are reduced at proximal sites despite no symptoms or signs developed at these sites [8, 22, 67]. The ability of detecting IENFD reduction in response to small fiber injury at asymptomatic sites demonstrates that skin biopsy with IENFD measurement is a sensitive tool for evaluating SFN. It has been shown that skin biopsy with IENFD analysis is more sensitive than quantitative sensory testing (QST) [40, 60] and more sensitive and less invasive than sural nerve biopsy [43, 68–70]. Patients who underwent both sural nerve biopsy and skin biopsy had reduced IENFD but normal unmyelinated fiber densities in their sural nerve biopsies [68]. Since IENF are more distal to the unmyelinated fibers in the sural nerve, these patients probably had terminal axonopathy with the "dying back" process affecting the terminal unmyelinated small fibers in the skin but not yet affecting the unmyelinated small fibers within the sural nerve trunk.

Non-length-dependent small fiber neuropathy (NLD-SFN) is not as common as length-dependent small fiber sensory neuropathy (LD-SFN). The primary defect in NLD-SFN is most likely at the level of dorsal root ganglia sensory neurons. In a study of 16 patients with sensory ganglionopathy diagnosed by their clinical presentations and NCS abnormalities, 11 had non-length-dependent reduction of IENFD with IENFD more reduced at the proximal thigh than the distal leg, which suggests disease involvement of both large and small dorsal root ganglia sensor neurons [66]. In contrast, all 16 patients with distal axonal neuropathy in the same study showed length-dependent loss of epidermal C fibers. Our recent study showed that in some patients with NLD-SFSN, although SFN symptoms were present in their

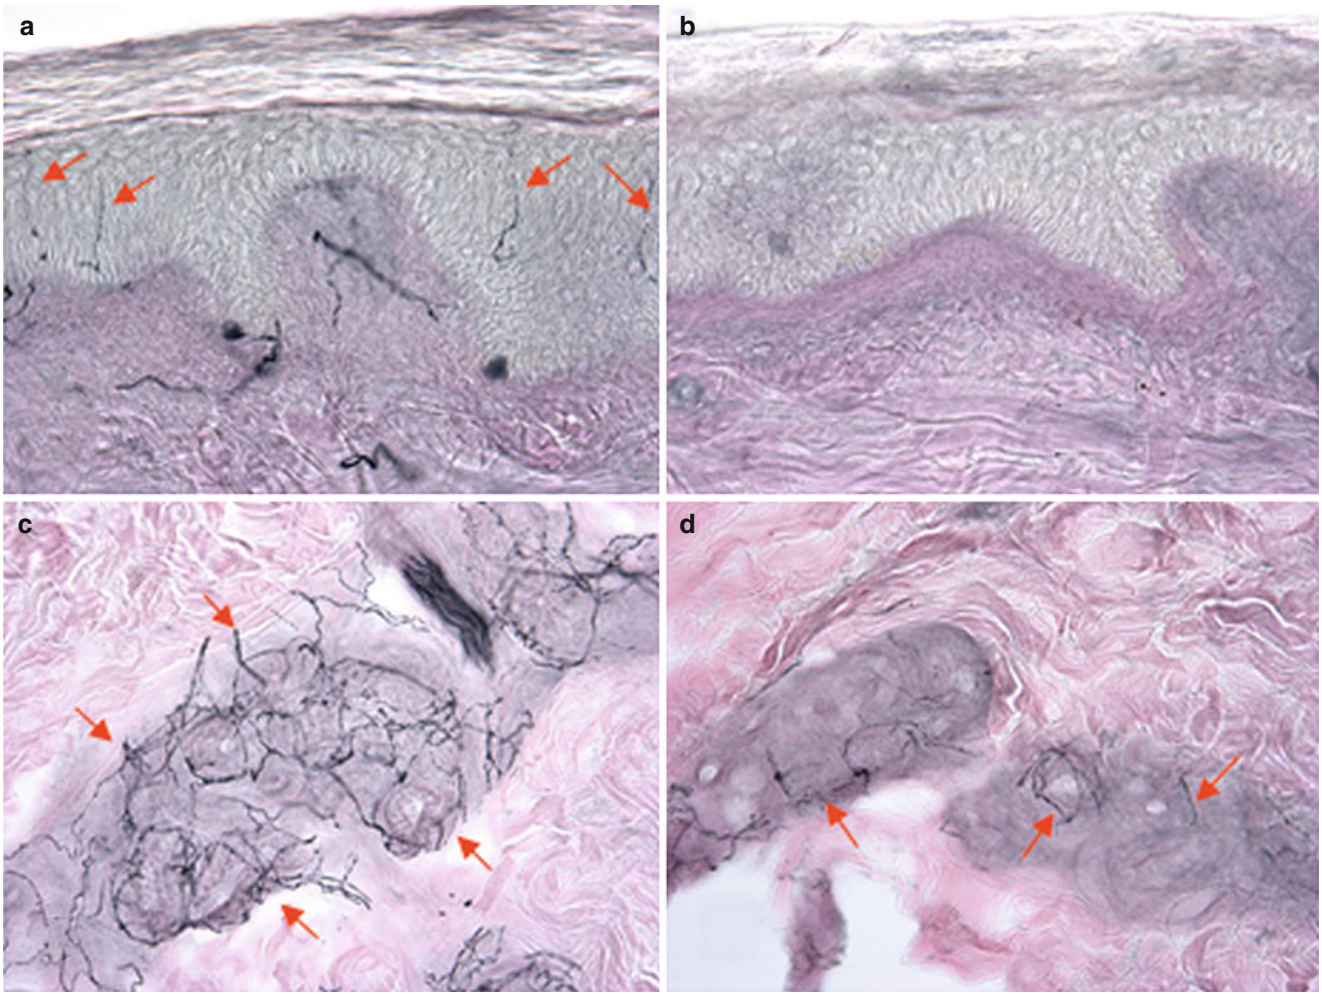

Fig. 13.3 Regional small fiber degeneration. In a patient with complex regional pain syndrome type I affecting the left lower extremity, intraepidermal C fibers were present (*arrows*) at the right foot (**a**) but absent at the left (**b**). Sudomotor autonomic C fibers (*arrows*) also appeared markedly reduced at the left foot (**d**) as compared to the right (**c**) (From Chemali and Zhou [13]. With permission)

face, trunk, and/or upper extremities, but not in their lower extremities, skin biopsies showed non-length-dependent reduction of IENFD in their lower extremities, which is diagnostic for NLD-SFSN [5]. These findings demonstrate that non-length-dependent small fiber degeneration does occur and can be evaluated by routine skin biopsy with IENFD evaluation. Skin biopsy is useful for determining the spatial pattern of SFN.

Small fiber impairment can also be focal, regional, or unilateral. Diabetic truncal neuropathy showed reduced IENFD in the affected dermatomes as compared with asymptomatic truncal areas [14]. We and others also demonstrated small fiber degeneration with reduction of both intraepidermal somatic C fibers and sudomotor autonomic C fibers in patients with complex regional pain syndrome type I [13, 15]. Evaluation of these conditions requires skin biopsy at unconventional sites with no normative values established. In this setting, the contralateral unaffected site should also be biopsied for comparison (Fig. 13.3).

Although skin biopsy with IENFD evaluation is a useful tool for diagnosing SFN, it is not that useful for identifying a specific etiology for SFN. Some cutaneous nerve laboratories perform additional stains on the skin biopsy sections to evaluate vasculitis and amyloidosis, but the diagnostic yield is unknown. Associated conditions have been identified in over 50 % patients with LD-SFN and 40–50 % patients with NLD-SFN, with diabetes/prediabetes being the most common [3–5, 71–73]. Our laboratory and others showed that NLD-SFSN is more commonly seen in women and presents at a younger age as compared with LD-SFSN [3–5]. Diabetes/prediabetes is less prevalent in NLD-SFN than in LD-SFN, while immune-mediated conditions are more commonly seen in NLD-SFN than in LD-SFN [5]. These findings are consistent with the notion that diabetes/prediabetes is more likely to affect distal nerve axons to generate a "dying back" process, while immune-mediated conditions are more likely to generate an immune response to randomly attack sensory neurons/axons.

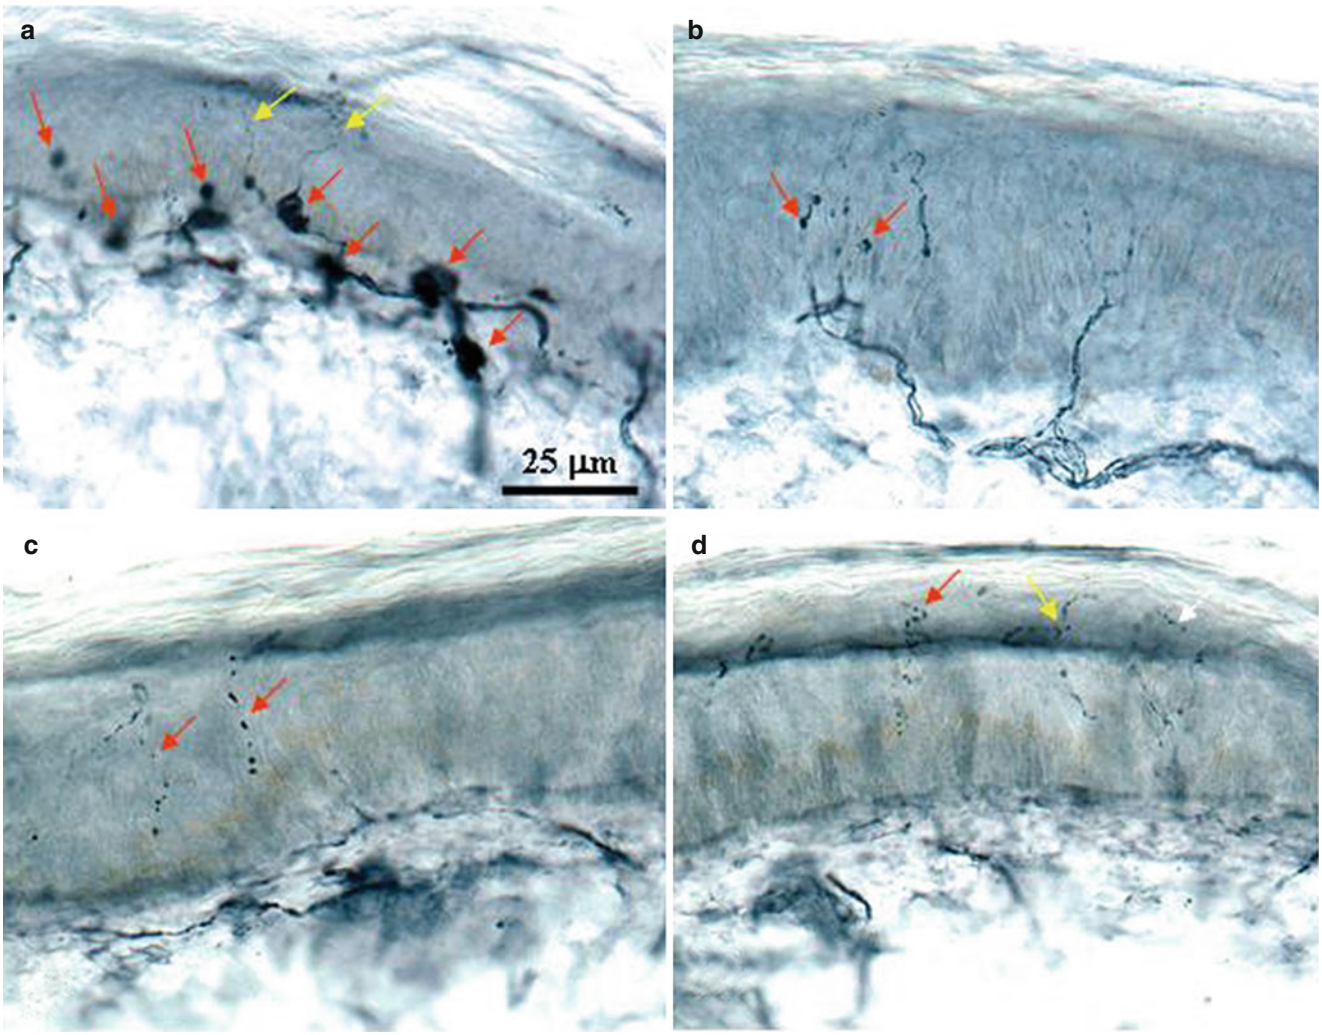

Fig. 13.4 Abnormal morphological changes of IENF. (**a**). Abundant nerve fiber swellings of varying size (*red arrows*) are noted in epidermis, papillary dermis, and dermal-epidermal junction. (**b**) Many small IENF swellings are seen (*red arrows*). (**c**) Intraepidermal fibers are fragmented (*red arrows*) as compared to continuous fibers in (**a**) (*yellow arrows*). (**d**) Tortuous (*red arrow*), branched (*yellow arrow*), and horizontal (*white arrow*) fibers are present (From Zhou et al. [24]. With permission)

Small Fiber Morphological Changes

IENFD can be normal at the early stage of SFN, but in this setting, skin biopsy often shows prominent small fiber morphological changes, including swellings, increased branching and fragmentation, and tortuous intraepidermal C fibers [16, 26, 48, 64, 68, 70, 74] (Fig. 13.4). In severe neuropathies, epidermal denervation was found at progressively more rostral levels, with prominent axonal swellings [70] and increased branching complexities [16] even at sites without neuropathic symptoms. Two studies investigated the diagnostic yield of IENF swellings in SFN [26, 70]. Both found a higher prevalence of swellings at the distal leg in neuropathies, including patients with normal ENFD and persisting painful symptoms in the feet, than in controls. Increased swellings at the distal leg correlated with impaired heat-pain threshold, development of symptomatic neuropathy, and progression of neuropathy. Large swellings of intraepidermal C fibers were found to be able to identify individuals who subsequently developed epidermal denervation, inferring that larger swelling increases the probability for nerve fiber degeneration [74]. Therefore, these abnormal morphological changes, especially large swellings, may represent small fiber pre-degeneration. If these changes are prominent but IENFD are still within normal limits, a follow-up biopsy in 6–12 months may be helpful to detect IENFD reduction and to reach a final diagnosis of SFN.

Small Fiber Regeneration

Small fibers may regenerate after degeneration in response to injury. Three models have been developed and used to study the cutaneous small fiber degeneration and regeneration in

human: (1) the intracutaneous axotomy models [75], (2) the skin blister mechanical denervation model [11], and (3) the capsaicin chemical denervation model [76–78]. The intraepidermal axotomy and skin blister models showed that intraepidermal fiber regeneration started from collateral sprouting from adjacent normal epidermal fibers followed by growing and extension of the transected axons. In the capsaicin model [76], intraepidermal fibers degenerated more rapidly than dermal autonomic fibers, correlating with more rapid decline of sensory function than autonomic function. However, autonomic fibers regenerated more rapidly than intraepidermal sensory fibers. These models demonstrated excellent regenerative capacity of cutaneous small fibers. These models are also useful for the study of molecular mechanisms underlying cutaneous small fiber degeneration and regeneration and for the study of disease-modifying therapies [75, 76].

Several studies showed that IENFD correlated with various clinical and diagnostic SFN severity measurements [24, 28, 47, 79, 80]. Small fiber regeneration correlated with neuropathy symptom improvement. Lauria et al. reported marked reduction of dermal and epidermal denervation in affected dermatomes in one patient with diabetic truncal neuropathy, whose follow-up biopsy 2 years later showed improved dermal and epidermal innervation along with symptom resolution [14]. A few studies [81–84] linked SFN to metabolic syndrome which consists of diabetes/prediabetes, hypertension, dyslipidemia, and central obesity. Smith et al. reported that lifestyle interventions in 32 subjects with prediabetes improved the parameters of metabolic syndrome, which were accompanied by significantly increased IENFD and decreased neuropathic pain [85]. Gibbons et al. also reported substantial improvement of IENFD in diabetic neuropathy patients after 18 months of glycemic control [86]. These findings demonstrate that IENF may regenerate well once the causes of neuropathy are under control. Identifying and treating underlying causes is thus critical to the management of SFN, and it may reverse SFN especially at the early stage of the disease when the damage is limited to the terminal cutaneous small fiber axons. The findings also suggest that serial skin biopsies with cutaneous small fiber density evaluation are potentially useful in future therapy trials to monitor small fiber regeneration and SFN treatment response.

Molecular Diagnosis and Genetic Testing

14

Eric P. Hoffman, Lauren P. Hache, and Rose B. McGee

Introduction

The capability to assay for the status of individual genes or proteins in patient blood or tissues has grown exponentially over the last two decades. Molecular diagnostics has had a particularly important impact on the practice of neurology, both due to the keen interest of the practicing neurologist and the fact that many of the first identified disease genes have been for inherited neurological conditions. With the dramatically expanding knowledge of the primary biochemical defect for hundreds of disorders comes the anticipation that pathophysiological cascades can be slowed or halted, or primary biochemical deficiencies replaced. While this hope has yet to be realized, molecular human genetics has transformed the way in which the inherited and noninherited neurological diseases are researched, and experimental therapeutics are pursued. Finally, molecular diagnostics can provide a definitive diagnosis to a patient (both symptomatic and presymptomatic) while also permitting the genetic counseling of the patient's family.

With the increased knowledge of the underlying genetic abnormality in a patient come ethical and legal hazards which are increasingly recognized by patients, health-care professionals, employers, and legislative oversight committees. These hazards are complicated by the fact that few, if any, molecular diagnostic tests have been approved by the Food and Drug Administration (FDA). The reluctance of most laboratory medicine divisions to provide large-scale molecular diagnostics services is a product of the advanced molecular expertise required for many assays, expensive and nonautomated equipment, and the relatively poor reimbursement from third-party payers. This same testing milieu results in a dispersion of specific genetic tests among hundreds of highly specialized laboratories, and navigating the maze of possible referral sites for each specific gene or protein test is often a daunting task. Fortunately, many Web-based resources are available that make finding an appropriate molecular testing laboratory relatively simple. Getting these tests paid for by Medicare, Medicaid, and private insurance remains more challenging, and this in turn may affect equal access to care.

In this chapter, we give several Web-based resources that assist in diagnosis as it pertains to molecular genetics. Next, we discuss the importance of genetic counseling for patients and families and protection and privacy of health information for molecular diagnostic testing. We provide an overview of molecular diagnostic methods most commonly used for neurological disorders and a review of emerging technologies which promise to greatly change the landscape of molecular diagnostic testing and referral.

Web-Based Resources

There are an estimated 480 neuromuscular disorders caused by a single gene [1], many of which have more than one testing type available with often complex genotype/phenotype correlations and differential clinically based diagnoses. As new information emerges on the variety and character of

B. Katirji et al. (eds.), *Neuromuscular Disorders in Clinical Practice*,
DOI 10.1007/978-1-4614-6567-6_14, © Springer Science+Business Media New York 2014

mutations and as new technology becomes available to test for them, the importance of determining which tests to order and when to order them is magnified. For instance, deletion/duplication testing is indicated first in some disorders, whereas initial gene sequencing is indicated in others. Reviewing testing strategies for each neuromuscular disorder is outside of the scope of this chapter. Fortunately, there are multiple Web-based databases that can facilitate this process, providing pertinent clinical, genetic, and testing information for these diseases.

The need for centralized reference sources for up-to-date information on genotype/phenotype correlations and available testing is well recognized, and a number of impressive efforts have generated Web-based resources that are openly available to the public. The most relevant are a pair of resources funded by the National Institutes of Health's (NIH) National Center for Biotechnology Information (NCBI), called GeneTests and GeneReviews (both available at http://www.ncbi.nlm.nih.gov/sites/GeneTests/). Institutionally sponsored by the University of Washington, the sites provide two types of resources. GeneTests includes a searchable database of clinics and molecular diagnostic tests offered in the USA and internationally, whereas GeneReviews contains reviews of diagnostic categories and specific diseases, with emphasis on genetic testing, genotype/phenotype correlations, and genetic counseling. Online Mendelian Inheritance in Man (OMIM) (http://www.omim.org) contains thousands of gene, protein, and inherited disorder descriptions, with extensive links to publications and databases further describing molecular features. Two such databases are NCBI's Gene (http://www.ncbi.nlm.nih.gov/gene/1756) and Université René Descartes' GenAtlas (http://genatlas.medecine.univ-paris5.fr/) which provide gene structure, function, phenotype, and reference citations for the molecular aspects of disorder-related genes. Europe-based Orphanet (http://www.orpha.net) contains descriptions of rare diseases as well as orphan drug information, diagnostic testing, and clinical sites in Europe. Lastly, there are several excellent websites focused specifically on neuromuscular disorders. Washington University in St. Louis maintains the Neuromuscular Disease Center (http://neuromuscular.wustl.edu/), a comprehensive, outline-format database devoted exclusively to neuromuscular disorders and syndromes. An online version of the annually updated neuromuscular disorders gene table, printed in the *Neuromuscular Disorders* journal, is available at http://www.musclegenetable.org/. The Leiden Muscular Dystrophy mutation database (http://www.dmd.nl/nmdb/) contains collections of DNA variants observed in the muscular dystrophies. In addition, there are Web-based resources devoted to policy, ethical, and confidentiality issues as they pertain to genetic testing. These resources are covered in the *Genetic Counseling and Genetic Confidentiality* section.

GeneTests is particularly useful for finding laboratories that offer specific molecular diagnostic tests. Information in the database is submitted on a voluntary basis by laboratories with a required annual review. This online database provides information on the nature of the testing offered (clinical or research-based), nature of the molecules tested (gene or protein) and types of methods used (e.g., sequencing, mutation detection). This site offers contact information for referring patient samples and links to the websites of the relevant reference laboratories. In addition, the site features a clinical directory with voluntarily submitted information on clinics offering genetic evaluation and counseling services and a section with educational materials for health-care providers. In early 2013, NCBI will begin the process of replacing the laboratory directory component of GeneTests with the Genetic Testing Registry (http://www.ncbi.nlm.nih.gov/gtr). This centralized resource will keep the features of GeneTests while expanding the range of genetic tests listed as well as providing more information and enhanced search capabilities on each test.

GeneReviews features disease-specific reviews that place molecular diagnostics in the context of diagnosis, management, and genetic counseling of inherited disorders. Each review is written by an expert in the field through invitation. Each contribution is then carefully screened for accuracy by two or more expert peer reviewers and substantially text edited by the database curators to ensure consistency and completeness of the contributions. A formal updating process for each review is undertaken every 2–3 years. A major advantage of this resource is that it provides significant guidance regarding the appropriate utilization of genetic and biochemical tests, even among a group of disorders with multiple molecular etiologies. For example, a chapter on congenital muscular dystrophy explains that *LAMA2* genetic testing alone (i.e., without a skin biopsy) can be performed in a patient with medical history and physical and neurological examinations strongly suggesting laminin alpha-2 deficiency. In the case of multiple causative genes, however, a suspected diagnosis of a dystroglycanopathy is better evaluated with an initial muscle biopsy to identify which protein deficiency is present prior to genetic testing. Each review also provides links to patient support organizations and PubMed for cited references. Unlike GeneTests, GeneReviews will not be replaced by the Genetic Testing Registry.

OMIM was the brainchild of Victor McKusick in the 1960s at Johns Hopkins University School of Medicine and was later developed for the Web by NCBI. This resource contains clinical reviews on each known inherited genetic disorder and associated research, with an overall emphasis on relationships between genotype and phenotype. OMIM is constantly updated through searches of the literature by experts at Johns Hopkins Medical School, with each entry organized as a running synopsis of the accumulated literature. As such, it is extensively referenced and usually quite up to date. The "running synopsis" format can sometimes be difficult to follow and they often quote directly from the

abstract or publication within the context of the entry. PubMed links are provided for each reference cited. Another invaluable feature of this site is the Clinical Synopsis search where a list of relevant disorders can be obtained by entering multiple phenotypic features in one search query. The results of this search can also be limited to a specific area (e.g., neurologic).

Orphanet is generated through a joint effort between 40 European countries and serves as an information portal on rare disease for professionals, patients, researchers, and industry. This resource defines a rare disease as occurring 1 in 2,000 or less; most of these are from genetic origin, but the site includes rare infectious and autoimmune diseases. The site offers an abundance of resources, including reference materials, an orphan drug inventory and directories of clinical services, diagnostic testing, and research investigations in Europe. A tool to aid in diagnosis (by entering clinical signs) and guidelines regarding emergency medical and anesthesia are also available.

The Neuromuscular Disease Center offers a comprehensive collection of bulleted lists containing essential clinical and pathological features, genotype/phenotype correlations, and laboratory findings (genetic and biochemical) for each disease. Within each list are links to references and other outlines to explain different concepts or principles. An extensive collection of pictures and illustrations demonstrating clinical, pathological, and even historical aspects of the diseases are included. A differential diagnosis page is also available. The site does not, however, give recommendations on testing strategies and, with the exception of several links, only offers information for their clinical laboratory antibody testing. The online version of the monogenic neuromuscular disorders gene table enables users to explore tables by disease group, name, gene, and gene product. Key references on gene discovery for a disease plus other diseases involving the same gene are included for each item in the table. The Leiden Muscle Dystrophy database features comprehensive collections of user-submitted pathogenic and nonpathogenic variations observed in muscular dystrophy-associated genes. Reference information for phenotypes associated with a variant is provided.

Use of Genetic Information and Genetic Counseling

Use of Genetic Information

Results of genetic testing are potentially volatile and ethically complex pieces of information. Unlike many medical tests, which give a clinical picture relevant to a point in time, genetic tests provide permanent information about the individual tested with implications for both the patient and relatives. Presymptomatic testing for individuals at risk for Huntington disease has been a paradigm for policy development and execution with regard to patient care, standard protocols, genetic counseling, test result confidentiality, and insurance issues, forged through joint efforts between professionals and patient advocacy groups. A core tenet in this paradigm is utilization of genetic counseling sessions prior to ordering the test and, if testing is pursued, after the results become available. From the perspective of the neurologist, such involvement of multiple clinical subdisciplines in what may be considered a relatively straightforward diagnostic test can seem like micromanagement of the neurologist-patient interaction. However, there are unusual aspects of the presymptomatic (and pediatric) patient with regard to genetic testing, with several highly visible media case reports demonstrating the complex issues involved. For example, a Quebec man with a family history of myotonic dystrophy obtained gene testing and was found to be an asymptomatic (preclinical) gene carrier [2]. The patient and his physician were well aware that many myotonic dystrophy patients lead perfectly normal lives due to the variable effects of this mutation. During the process of applying for life insurance, the man was asked if he had a preexisting condition to which he replied in the negative (as he showed no symptoms of the disease). He was subsequently in a car accident and died, but his wife was then denied collection on her husband's life insurance, as the insurance company learned of the myotonic dystrophy result and considered this gene test result evidence of a preexisting health condition. The Quebec Superior Court upheld the insurance company's claim and the wife was unable to collect on the insurance.

Government laws and policies (or lack thereof), as well as insurer and employer policies, regarding the use of genetic information can vary from country to country and state to state. One of the key issues, highlighted by the Quebec story, is whether health and life insurance companies or even employers can base individuals' insurance coverage or employment decisions on genetic information. In most of Europe, where universal health insurance is in place, the focus has been placed on life insurance. Basic life insurance is considered a societal right; therefore, genetic test results must be kept confidential and not be released to the insurance company. However, supplemental life insurance policies are considered differently and life insurance companies have the right to request genetic test results. In the USA, the Genetic Information Nondiscrimination Act (GINA) was passed in 2008 and became fully effective by the end of 2009 [3]. This landmark legislation protects individuals from the use of their genetic information in health insurance eligibility, coverage, premium rate, and underwriting decisions (Title I) and on employment hiring, firing, and promotion decisions (Title II). The law does not apply to life, disability, or long-term care insurances. Under this law, genetic information includes family medical history, genetic tests, and services used by individuals and their family members in

both the clinical and research settings. There are important limitations to recognize in the provisions of GINA. Once a genetic disease has manifested, an individuals' health information can be used in health insurance considerations. For example, a positive genetic test result for Huntington disease in an asymptomatic person cannot be used by health insurance companies as a preexisting condition or to raise premiums. Once the symptoms of the disease become apparent, however, the health information regarding the diagnosis can be used by the insurance company. In addition, a health insurance company can request genetic information (e.g., a documented family history of a genetic disease) if coverage of a service or test for an individual is appropriate only with a known genetic risk.

Patient Confidentiality

Outside of the insurance or employment framework, issues of confidentiality can surface in the context of genetic information within at-risk families. This is a particularly relevant issue in cancer genetic diagnosis, where routine clinical screening of a mutation-carrying presymptomatic patient is clearly able to save lives. In a relatively common scenario, a symptomatic cancer patient's family history reveals multiple members who died with the same cancer diagnosis. Subsequent genetic testing determines that the symptomatic patient is positive for a causative cancer gene mutation. About half of his immediate relatives are at risk for carrying this same mutation and thus are at risk for developing the same cancer. Routine screening could detect the cancer in these relatives at an early stage and lifesaving clinical intervention could be provided. While it might seem that the primary care physician of the original patient should contact the family members, explain the situation, and offer testing, the current practice is that contact initiated by the physician toward the patient's family members is not appropriate and represents a breach of patient confidentiality. Instead, the physician must work through patients, encouraging them to contact family members and ask the family members to contact the physician. In this manner, the testing is requested by the patient, and not the physician, and the breech of patient confidentiality is voluntarily done by the patient's own actions. Unfortunately, there are instances when the patient does not contact the family members, putting them at clear risk of harm. Is the physician then allowed to contact the family members, without the consent of the patient? Generally not, for in spite of the potential risk of disease to family members, the responsibility rests on the tested family member, who remains in charge of their own genetic information and whose family, if told by the proband, has the right to decide if they want testing or not. However, cases have been filed disputing this paradigm and some countries have passed legislation to the contrary, where the physician's obligation to the "general good" or duty-to-warn outweighs their obligation to the single patient. States and countries differ in their opinions and laws in such gray areas and one needs to consult specialists in genetic counseling or medical ethics when faced with such (usually rare) situations.

Consent Forms for Genetic Testing

Another set of issues in genetic testing regards consent forms. In addition to the above-described issues of confidentiality, there are also concerns regarding future commercialization of genetic findings (particularly in research samples), concerns of long-term storage of samples, issues concerning patient access to appropriate genetic counseling when receiving test results, and finally issues regarding future research-based tests which are often done on DNA samples. For all of these reasons, genetic testing requires the use of patient consent forms for diagnostic clinical testing, in addition to needing proper institutional review board (IRB) approvals for research-based testing. The physician's home institution should have an IRB passed for genetic testing of all patients referred to external molecular diagnostic laboratories, in addition to a patient-signed consent form from the testing laboratory. This can be cumbersome, particularly if different IRB protocols and consent forms must be developed for each genetic test available (e.g., carrier testing for Huntington disease and cystic fibrosis has completely different disease-specific issues to be dealt with). As a result, most genetic testing laboratories and referring institutions are content with the use of an external, laboratory-based IRB approval and consent form; however, this practice may be inappropriate. The extent to which the informed consent process is utilized by health-care providers and is covered in laboratory-provided consent forms in the arena of genetic testing varies, complicating matters. The goal of this necessary process is to ensure that the patient fully understands the test and its implications prior to undergoing testing; the responsibility of engaging in this process with the patient rests on the health-care provider offering testing [4]. Ideally, informed consent includes the benefits, risks, and limitations of testing; pretest considerations (e.g., testing of children, potential confidentiality consequences, impact to family members, and possible psychological impact from test results); and posttest considerations (e.g., career plans, reproductive planning, informing family members) [5]. Government standardization of informed consent requirements may simplify the process with universal consent forms in the future.

Clearly, it is imperative for both the physician and the patient to understand the implications of genetic test results on confidentiality, insurance, and lifestyle, before a test is requested. Given the maze of ethical dilemmas and

confidentiality issues that face the communication of gene test results to a patient, it behooves the neurologist to either become intimately familiar with all the issues and appropriate actions or to refer the genetic testing process to appropriate medical specialists such as a genetic counselor or medical geneticist who may be better informed to act appropriately. There is an important World Wide Web resource that provides easy access to genetic policies and regulations, both nationally and internationally. HumGen International (http://www.humgen.org/int/), maintained by McGill University's Centre of Genomics and Policy with support of foundations, pharmaceutical companies, and public funding, has a searchable database of laws, policy statements, and selected literature from governments and professional organizations on social, ethical, and legal aspects of genetics. Most search results link to the original Web source at the respective Web pages of each organization or government. In addition, the US National Human Genome Research Institute (NHGRI) sites feature a section called Issues in Genetics (http://www.genome.gov/issues) that includes resources on genetic testing, discrimination, health issues, and informed consent as well as a policy and legislation database. The US Centers for Disease Control and Prevention (CDC) Public Health Genomics site (http://www.cdc.gov/genomics) gives resources on public health genetic policy, research, and practice.

Basic Principles of Human Molecular Genetics

Molecular diagnostics is based on the principle that an underlying primary gene or protein change is responsible for a set of clinical symptoms and can be identified. It is important to point out that a primary genetic abnormality causes the initiating biochemical problem, either by the loss of a specific protein (recessive disease, "loss-of-function" biochemical defect) or by the production of a toxic protein (dominant disease, "gain/change-of-function" biochemical defect). The protein abnormality then often initiates many cascades of events leading to disease, which may manifest in patient symptoms immediately (e.g., hyperammonemia in ornithine transcarbamylase deficiency), or may not be seen for many years (e.g., toxic protein containing an excess of glutamine amino acids in Huntington disease). The downstream changes may themselves create a pattern of patient symptoms which reflects a specific biochemical problem and therefore becomes diagnostic (e.g., the facial features, myotonia, cataracts, conduction defects, and distal weakness indicative of myotonic dystrophy).

In the past 10 years, genetic tests for neuromuscular disorders have become more widespread and many are now available on a commercial basis. For some disorders, like Duchenne muscular dystrophy (DMD), the first line of testing [6] is genetic testing through deletion and duplication testing of the *dystrophin* gene. Muscle biopsy is not suggested in the flow chart for the diagnostic workup of a dystrophinopathy [6] until genetic testing has been completed and no mutations are identified through deletion/duplication testing and testing for point mutations. For many neuromuscular disorders, genetic testing is now a key component of the diagnosis. In some disorders, it may also have implications for disease prognosis as well as therapeutic approach interventions. Emerging technology such as whole genome or whole exome sequencing may also prove critical when nonspecific patient symptoms can reflect tens or hundreds of different underlying disorders (e.g., spastic paraplegia or epilepsy).

If we limit the initial discussion to the testing of a single molecule, defined here as molecular diagnosis, then either proteins or genes can be tested. Overall, a gene mutation is considered more specific than a protein abnormality. Protein defects (usually an abnormal amount of a single protein) can be primary or secondary to a specific genetic defect, and distinguishing between primary and secondary problems is often not trivial. Also, dominantly inherited disorders form the bulk of the disorders seen in the adult neurology or neurogenetic clinics, and dominantly inherited disorders are generally refractory to protein testing. This is because dominant disorders typically involve a gene mutation that results in a toxic protein, in which the toxicity is most often caused by a single amino acid change in the protein. Protein tests are generally not able to distinguish a normal protein from a toxic one with only one amino acid change. Sometimes the toxic protein can cause an obvious pathology (e.g., toxic glial fibrillary acid protein [GFAP] leading to the characteristic Rosenthal fibers in brain biopsies of Alexander's disease patients, or the amyloid due to beta-amyloid mutations in some cases of Alzheimer's). However, the specificity of such pathological findings is usually not good and in some cases requires difficult-to-obtain tissues for study.

Recessively inherited gene defects typically result in the loss of function of a single protein, and this loss of function is typically associated with the lack of detectable protein in patient tissues. In some instances, the protein deficiency is specific enough to be diagnostic, and in rarer instances, the detection of the protein deficiency can be more straightforward than detecting the gene defect. Of course, protein testing relies on having access to tissues in which the protein is normally expressed. One could test for GFAP protein in a brain biopsy from a patient with possible Alexander's disease, but this procedure is clearly more invasive than testing for specific gene mutations in the DNA in a small peripheral blood sample in the relatively small GFAP gene. As of 2012, 12 commercial laboratories in six different countries offer full sequencing of the GFAP gene.

Here, we will focus on methods and practice of mutation detection in a patient's genomic DNA sample (usually from a small peripheral blood sample). As genomic DNA contains all genes, it is not necessary for the gene to be expressed in order to detect the underlying gene mutation. Note that an exception to this is tumor samples, where typically only the tumor DNA contains the causative gene lesions, and the peripheral blood DNA does not.

Types of DNA Mutation and Their Detection

Cytogenetics

A relatively crude, yet often informative, means by which large genetic anomalies can be visualized is through direct visualization of the chromosomes. Nucleated cells in the body contain 46 chromosomes arranged in pairs with 22 autosomal pairs and six sex chromosomes. During the initial stages of mitosis and meiosis, chromosomes are highly condensed and may be visualized under basic light microscope. Several banding techniques exist which allow scientists to identify chromosomal alterations. Clear examples of cytogenetic abnormalities are seen in patients with aneuploidies (too many or too few chromosomes), such as Down syndrome. Aneuploidies involve many scores of genes, and as a result, the abnormal "dosage" of so many genes typically results in multisystemic syndromes, with neurological symptoms being only one of the manifestations of the disorder. The basic nomenclature for karyotype reporting involves the total number of chromosomes seen in the patient's cells, the sex chromosomes (XY or XX), and an indication of which chromosomes are missing, extra, or derived. Examples include 46,XX normal female; 46,XY normal male; 47,XY,+21 Down syndrome; and 45,X Turner syndrome.

Some nonaneuploid or euploid cytogenetic abnormalities can be visualized under the light microscope. For example, patients with cri du chat syndrome show the loss of the tip of chromosome 5 on one of their two number 5 chromosomes. They have the normal number of chromosomes but have a partial monosomy involving just part of one chromosome. Chromosomes with abnormalities visible by the light microscope are still very large in scale, with the resolution of detection limited to changes four to five million base pairs or larger. As the typical gene is about 30,000 bp in size, even a very small cytogenetic abnormality (four to five million base pairs) can contain a hundred or more of genes. Consistent with the polygenic nature of the change, large deletions are typically syndromes (called contiguous gene deletion syndromes), often including mental retardation, dysmorphic features, and cardiac defects as part of the clinical picture.

Another broadly used cytogenetic method called fluorescent in situ hybridization (FISH) can detect the presence or absence of specific DNA sequences. Pieces of cloned and purified human genomic DNA are labeled with biotin using molecular genetics techniques and then hybridized to a cytogenetic spread of patient chromosomes. The biotinylated probe DNA hybridizes to the complementary sequence of the region of interest on each chromosome in each cell. The biotin is then detected using streptavidin linked to a fluorophore and visualized using fluorescence microscopy. Alternatively, probes can be labeled with fluorescent nucleotides and directly visualized with the microscope, thereby reducing steps and giving clearer results. This method can detect deletions (one chromosome will fluoresce instead of two), duplications (one chromosome shows two areas of fluoresce), or rearrangements (incorrect chromosomes fluoresce) of chromosomes that are below the resolution of the light microscope (40 kilobases to 1 megabase, depending on the size of the probe used). For example Charcot-Marie-Tooth (CMT) 1A, which is caused by a duplication of the *PMP22* gene, can be detected using FISH. The one million base pair duplication is visualized by interphase FISH.

Comparative genomic hybridization (CGH) is a newer technology able to scan chromosome regions associated with loss or gain of genetic information. In CGH, DNA fragments are isolated from both a reference library (controls) and the patient's DNA. The DNA fragments are labeled and then pooled together as DNA probes in hybridization experiments. This method is relatively labor intensive and newer methodologies such as microarray-based CGH have been developed. Array-based CGH uses arrays that contain thousands of fragments of DNA adhered to a chip. The probes are labeled in the same fashion as CGH (green for the control or reference DNA and red for the patient's DNA), but the chip is then analyzed in an automated fashion.

Single Gene Defects and Inheritance Patterns

The large majority of monogenic disorders fall into two inheritance patterns: recessive and dominant.

Dominant Inheritance

Dominant disorders are vertically transmitted through a family, with an affected parent having a 50 % risk to pass the genetic mutation to each child. Major variables in dominant disorders are *penetrance* (chance that a family member with the abnormal gene will show any symptoms of the disorder) and *expressivity* (the severity of symptoms). An increasing number of disorders presenting as isolated cases are now recognized as new dominant mutations – that is, a de novo gene mutation in one copy of a gene causes the disease. Thus, although the disease is dominant at the gene and

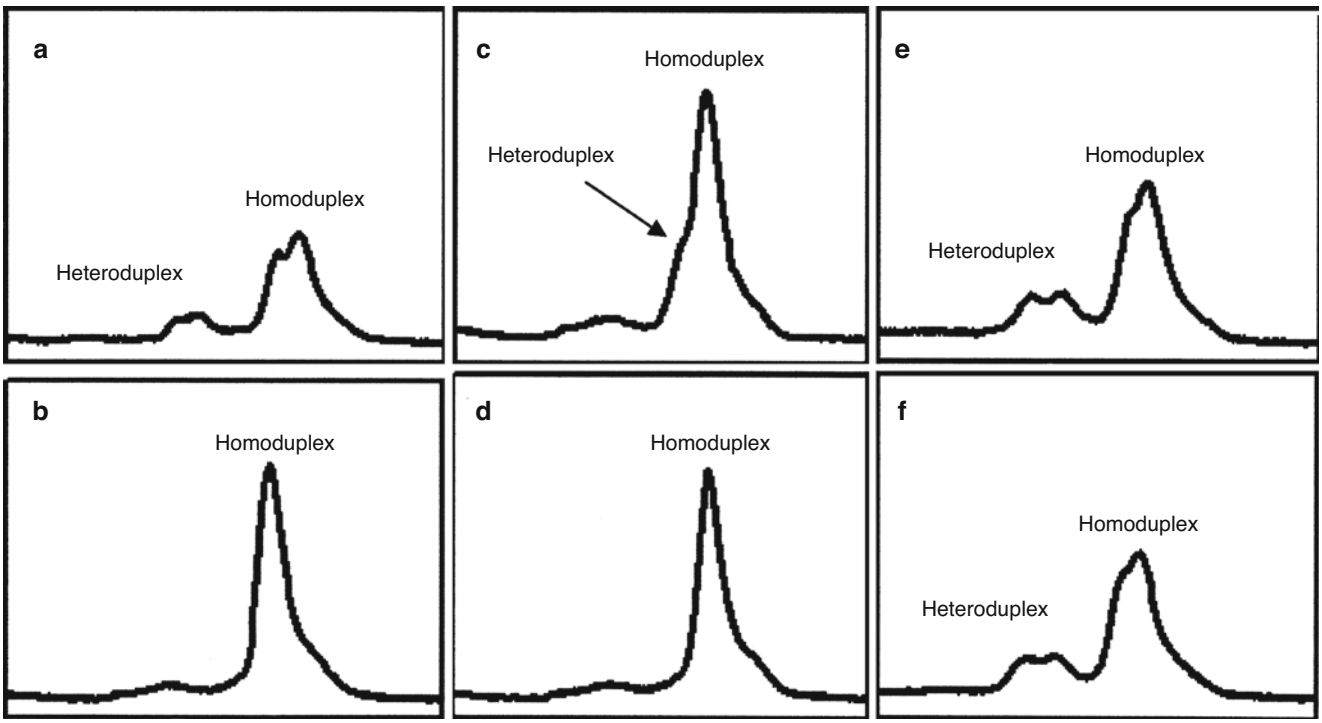

Fig. 14.1 Denaturing high-pressure liquid chromatography (DHPLC) for detection of genetic changes in Rett syndrome. Shown are a number of examples of DHPLC analysis of PCR products corresponding to the MeCP2 gene in Rett syndrome patients (Panels **a**, **c**, **e**, **f**) and controls (Panels **b**, **d**). The PCR product is loaded onto the paired-ion chromatography column and eluted at specific temperatures and denaturant concentrations. Heteroduplexes, which are double-stranded DNA containing both normal and mutant strands of DNA, come off the column at an earlier time, leading to extra leading peaks on the chromatogram. These heteroduplexes are then subjected to automated sequencing to identify the specific mutation (From Hoffbuhr et al. [8])

protein level, a multigenerational family history is not seen, although vertical transmission of the disease will occur if the patient is able to reproduce. Two neurological conditions that are almost always seen as isolated cases are Rett syndrome and Alexander's disease. In both cases, a new mutation of a sperm or egg leads to symptoms in the heterozygous child (a sporadic or isolated case). Rett syndrome patients have normal perinatal development, with a deceleration of head growth and ensuing repetitive hand wringing and apneic episodes. This disease is the result of new heterozygous mutations of the *MECP2* gene (methylated DNA-binding protein) (Fig. 14.1) [7]. The disease is X-linked dominant and could be transmitted to offspring if the women's phenotype is mild enough to permit reproduction. Variation in X-chromosome inactivation patterns protect some females from manifesting Rett symptoms [8]. Similarly, Alexander's disease, which is a severe progressive leukodystrophy showing specific Rosenthal fibers (astrocytic inclusions) on brain biopsy, is due to new dominant mutations of *GFAP* in the heterozygous state [9].

Most dominant disorders result from production of a *toxic protein* by the mutant gene (in contrast to loss of function or lack of protein in recessive inherited disorders, discussed next). The toxic protein is usually the result of a subtle change in the gene, which is compatible with production of the protein at relatively high levels. The most common type of mutation in dominant disorders is a missense mutation, where a single base pair change in the gene leads to a single amino acid change in the encoded protein. These toxic proteins can show altered solubility, with precipitation into aggregates that disrupt cell and tissue function over time (e.g., Parkin mutations in Parkinson's disease, beta-amyloid mutations in Alzheimer's disease). Alternatively, the toxic protein can change its function so that it now has a toxic effect on the physiology of the cell. A particularly illustrative example is with regard to voltage-sensitive sodium channels. The human sodium channel gene family plays a critical role in the central nervous system and peripheral nervous system [10].

Dominant missense mutations in three different tissue-specific sodium channels cause inherited disease. Missense mutations in the muscle sodium channel lead to hyperkalemic periodic paralysis (HYPP) and myotonias in humans and horses [11–13]. Missense mutations in the heart sodium channel lead to long QT syndrome [14], whereas missense mutations in a specific neuronal sodium channel lead to generalized epilepsy with febrile seizures [15]. In each case, the toxic missense mutations lead to failure of rapid inactivation of the respective sodium channel, with persistent inward sodium current in muscle, heart, or nerve leading to the phenotype. It is important to note that although half of the

sodium channels are abnormal (patients are heterozygous), the persistent inward sodium current has a dominant effect on the cell physiology. Such change- or gain-of-function proteins are characteristic of most dominantly inherited neurological disorders.

A second type of toxic protein change is termed *dominant-negative*, where the incorporation of a toxic protein into a chain of proteins destroys the function of the chain ("bad link in a chain" model). Many of these disorders are connective tissue diseases (osteogenesis imperfecta, Marfan's disease, others), which are not typically in the purview of the neurologist. However, some ion channels are multi-subunit and dominant-negative mutations can be observed (e.g., peripheral nerve hyperexcitability due to dominant-negative *KCNQ2* mutations in a multimeric potassium channel).

A third type of toxic protein change can result in poor solubility of the mutant protein often forming progressive aggregates in cells, or alterations in protein traffic through the cell, both of which will have a "dominant toxic" molecular pathophysiology. For example, dominant mutations in the P/Q-type calcium channel result in mutant proteins that alter traffic through the endoplasmic reticulum and a loss of this calcium channel at the cell surface resulting in episodic ataxia. The spinocerebellar ataxias and Huntington disease are caused by too many repeated glutamine residues in the relevant protein, and these cause aggregates that accumulate in specific neuronal subsets, leading to the disease.

Finally, a growing group of dominant disorders represents *haploinsufficiency*, in which "half is not enough." Patients with haploinsufficiency disorders are heterozygotes, with one normal gene and one inactive (loss-of-function) gene. This is functionally the same as the carrier state for autosomal recessive disorders (one normal, one inactive gene, and half the protein product produced). However, carriers of recessive disorders rarely show symptoms, whereas heterozygous patients with haploinsufficiency disorders are symptomatic. Many of the haploinsufficiency disorders involve proteins that play critical roles in pattern formation during development, where the developing organism is exquisitely sensitive to appropriate levels of the protein (e.g., growth factors, growth factor ligands, and transcription factors). As a result, many haploinsufficiency disorders result in dysmorphic features and multiorgan involvement. Examples of these include Waardenburg syndrome (heterozygous loss of function of transcription factor *PAX3*) and campomelic dysplasia (heterozygous loss of function of *SOX9*). Haploinsufficiency disorders tend to be some of the more clinically variable disorders, with the expression of the same gene mutation influenced by the environment, physiology, and genetic background of the individual patient. At a biochemical level, the clinical variability is somewhat intuitive, as biological systems so sensitive to protein levels ("half is not enough") are likely to be similarly sensitive to environmental perturbations of the system and to polymorphic variability between other gene products involved in the system.

Recessive Inheritance

Patients with autosomal recessive disorders typically have parents who are both asymptomatic carriers of the gene defect (heterozygous), whereas the patient is homozygous. With the small family size characteristic of developed countries, a typical autosomal recessive disease is often labeled as an isolated case as no other members of the family present with similar features. In the case of X-linked recessive disease, the mutation can occur during the development of the mother's ovaries, such that one or more eggs carry the mutations, and can then be inherited by a hemizygous male offspring (e.g., DMD). New germ-like mutations increase the recurrence risk for future offspring owing to the possibility that a population of germ cells have the mutation.

As all recessive and haploinsufficiency disorders are caused by a loss of function of the corresponding gene product, there are a plethora of types of gene mutations that can functionally inactivate the gene and encoded protein. Deletions of one or more exons, or the entire gene, are common (e.g., DMD). Single base deletions or insertions that shift the triplet codon reading frame for translation (frameshift mutations) are also seen. Single base pair changes that either introduce a new stop codon or change splicing patterns typically lead to a nonfunctional protein product. Finally, missense mutations are also possible in loss-of-function recessive disorders if the amino acid change interferes with the function of the protein (e.g., active site in an enzyme) or if the amino acid change interferes with the processing of the protein (e.g., failure to transport the protein to the cell surface for correct function).

Complex Genetic

Epigenetic is a term that has been used since the early 1940s. The more recent definition of the word refers to gene modifications that are no due to the DNA sequence itself. These modifications can include DNA methylation, histone modifications, imprinting, X-chromosome inactivation, and gene transcription regulation.

Hypomethylation of chromatin of the D4Z4 repeats are observed in patients with facioscapulohumeral muscular dystrophy (FSHD). Contraction of the D4Z4 repeats to between one and ten repeats is associated with DNA hypomethylation [16]. FSHD has a broad clinical spectrum from asymptomatic to wheelchair bound. There is additionally an infantile onset which is associated with a lower number of D4Z4 repeats and a more severe phenotype.

Imprinted regions of chromosomes show differential expression of genes depending on whether the region is

maternally or paternally inherited. The presence of imprinted regions of the genome was originally detected by cytogenetics and demonstrated the significance of the parental origin of some chromosomal regions. The prototypical examples are Angelman and Prader-Willi syndromes, both due to abnormalities of the same region of chromosome 15. Prader-Willi patients have small stature, hypotonia, small hands and feet, obesity, almond-shaped appearance of palpebral fissures, fair skin and hair, and IQs of 20–80. Angelman patients have ataxia, mental retardation, seizures, puppetlike gait, paroxysmic laughter, and a characteristic facies (microbrachycephaly, maxillary hypoplasia, tongue protrusion, and prognathia). While these disorders are readily distinguishable clinically, both involve the same region of chromosome 15 (15q11-13). Seventy percent to 80 % of Prader-Willi patients show a deletion of 15q11–13 by prometaphase banding cytogenetic studies, while 70 % of Angelman patients have deletions of the same region detectable by FISH. The molecular distinction between these patients is the parental origin of the chromosome upon which the deletion resides: If the chromosome 15 from the father carries the deletion, then Prader-Willi syndrome results; if the maternally derived chromosome carries the deletion, Angelman syndrome is seen.

Genetic testing for the more complex genetic principles such as hypomethylation, X-inactivation, and even imprinting are not as straightforward. These effects are not part of the standard testing on genomic DNA.

Mutation Detection Methods

The specific genetic testing methods utilized to directly detect mutations largely depend on whether or not most patients share one, or a few, specific mutations, or if most patients have their unique or "private" mutation. For example, essentially all patients with oculopharyngeal muscular dystrophy (OPMD) share the same specific mutation (Fig. 14.2). Thus, testing for mutations within the causative poly-A-binding protein 2 (*PABP2*) gene is limited to genotyping for that specific change (the remainder of the gene is not studied, as no patient will show mutations of these other gene regions). To the contrary, each Emery-Dreifuss dystrophy patient has their own gene mutation, so that testing for mutations must be done by screening the entire gene. Intermediate situations exist, where the majority of patients will show a handful of specific mutations, with the remainder showing a wide variety of rare or personal mutation types. For example, approximately 70 % of HYPP patients show one of two missense mutations (methionine to valine change at position 1592 [M1592V], or threonine to methionine [T704M]). So for HYPP patients, the first-tier testing is a targeted mutation analysis which includes these two mutations along with seven other more commonly observed point mutations. When selecting genetic tests, it is also important to note the test's sensitivity; for HYPP the targeted mutation analysis of the nine most common detected mutations is approximately 60 % of patients with symptoms of HYPP. Sequencing of the entire *SCN4A* gene should be considered if no mutations are identified through the targeted mutation analysis.

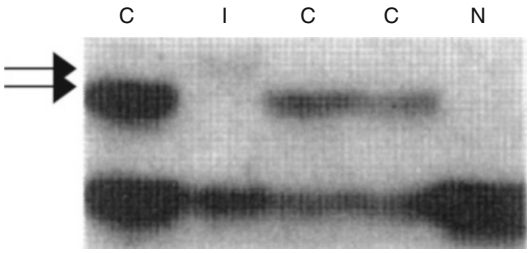

Fig. 14.2 Molecular diagnosis of an oculopharyngeal muscular dystrophy patient by detection of the characteristic small insertion mutation. Shown is detection of a small region of the PAB2 gene (poly-A-binding protein 2 gene) in genomic DNA from patients who may have oculopharyngeal muscular dystrophy (OPMD) based on clinical findings (ptosis, dystrophic biopsy, normal mitochondrial findings, possible dominant inheritance pattern). All OPMD patients studied to date show a small insertion of a few base pairs in the beginning of the PAB2 gene [18], and testing for this disorder is done by simply PCR – amplifying a small region of the PAB2 gene and determining whether the region is the correct size (lane "N"), or if the patients have one normal gene and one abnormally large gene (lanes *C* and *I*; heterozygotes). The patients being tested shows both normal and abnormal bands, indicating that they are affected with OPMD. The patient "I" has a slightly larger increase in the size of the band. Many of these patient's family members are at risk for the disease, due to the dominant inheritance pattern. Care must be taken when counseling presymptomatic family members, as some may wish to know whether they will be affected at a later age, and some may not wish to know. Initial contact with family members should always be done by the patient, as direct contact of family members by health-care workers is generally considered a breach of confidentiality (From Scacheri et al. [20]. with permission)

If many or most patients with a clinically discernible disorder are expected to share the exact same mutation of the exact same gene, then methods are used to detect only this specific mutation. This is termed *genotyping* of the patient, and the test result simply says whether that specific mutation was found or not. There are many dozens of highly sensitive and accurate neurogenetic tests that rely on genotyping for specific mutations. OPMD patients always show an insertion of guanine-cytosine-guanine (GCG) nucleotides in the *PABP2* gene (Fig. 14.2). This insertion mutation can be tested for by simply amplifying over the region of the gene containing this insertion and looking for normal-sized bands (normal) or patients with both normal and abnormally large bands (heterozygous OPMD patients). Similar tests are done for the trinucleotide repeat expansion disorders (e.g., Huntington disease, all spinocerebellar ataxia genes, fragile X, myotonic dystrophy, Friedrich ataxia), as all are caused by insertion of DNA sequence leading to an abnormally large mutant gene.

DNA Mutation Tests

The direct detection of a disease-causing mutation is generally the most specific and accurate form of genetic testing; however, the sensitivity depends on the particular gene under study.

Deletion Testing

Deletion testing is commonly used in the dystrophinopathies (Duchenne and Becker muscular dystrophies) and spinal muscular atrophies (SMA), where the presence or absence of exons in the gene is detected. Deletion testing can be done by polymerase chain reaction (PCR) analysis, or by Southern blotting. PCR testing is more rapid and less expensive; however, Southern blot analysis has a slightly higher sensitivity for deletions and significantly better sensitivity for duplication mutation. A newer approach is multiplex ligation-dependent probe amplification (MLPA®), a proprietary assay from MHC Holland. Primer probes that hybridize to exons of a gene are amplified (in contrast to amplification of DNA in conventional PCR). In one reaction, 40–50 DNA sequences can be detected by using probes unique to each sequence. Each probe has a pair of two oligonucleotides; each oligonucleotide contains a sequence (at the 3′ end of one oligonucleotide and the 5′ end of the other) that will hybridize next to each other on a targeted region of DNA. Each oligonucleotide also has a PCR primer sequence opposite the hybridizing end. When the two oligonucleotides in a probe set hybridize next to each other, a DNA ligase ligates them together and a PCR reaction will amplify the probe via the primer sequence ends. Products for each DNA sequence are distinguished by a stuffer sequence in each probe that gives it a unique size. Thus, the absence of amplified probe product(s) can indicate deletion(s) in a DNA sample. This technique is able to detect multiple and single exon deletions as well as point mutations. For example, an MLPA kit for SMA can detect the causative loss of both exon 7s in *SMN1* or the presence of multiple copies of *SMN2* and *SMN1*, which collectively account for most cases.

Array CGH (aCGH) enables an in-depth investigation for duplicated or deleted regions across the entire genome or in a targeted genomic area. In a targeted approach, a high-resolution aCGH has the benefit of each exon or intron being represented by multiple oligonucleotide probes. This is an advantage over PCR, Southern blot, and MLPA in that losses or gains are detected by more than one probe and therefore are less likely to represent false positives. A targeted aCGH is available for Duchenne and Becker muscular dystrophy that uses thousands of oligonucleotides to scan all 2.2 megabases (Mb) of the *DMD* gene (introns and exons) for deletions and duplications, which represent the cause for most cases of these diseases. In the event that no *DMD* alteration is found with aCGH, small and point mutation techniques may be appropriate since aCGH cannot detect these types of mutations.

Deletion testing is most frequently done in males who are thought to have specific X-linked disorders. This is due to the fact that males have only one X chromosome, so that testing for a deletion is not complicated by the presence of a normal gene on the second chromosome. Testing of female carriers for deletions is also done, although this requires a determination of "dosage" (e.g., whether a female has one or two copies of a specific exon). Large deletion mutations in autosomal conditions are less common, and there is a broad spectrum of mutations in autosomal recessive disease.

Small and Point Mutation Testing

Mutations affecting only one or a few base pairs of the gene are sometimes called *small mutations* or *point mutations* and are usually contained within the exons (coding sequence for the protein) or the exon-intron boundaries (RNA splice sites). If a common mutation exists, then this specific change can be tested for. For example, a single base change in the chloride channel gene (*CLCN1*) leading to the exchange of a glutamic acid (E) for a glycine residue (G) at position amino acid 230 in the protein (G230E mutation) causes about 15 % of cases of myotonia congenita. There are dozens of other mutations of the chloride channel gene that can also cause myotonia, but these are considerably less common. Thus, it is straightforward for the G230E mutation, but if the patient is negative for this change, full sequencing of the *CLCN1* gene should be considered. This can add time and increase costs to identify any other mutations. The interpretation of *CLCN1* sequencing is further complicated by certain mutations having been reported in both autosomal dominant and autosomal recessive myotonia congenital. In another example, about 70 % of cases of hyperkalemic periodic paralysis (HYPP) are caused by one of two missense mutations in the adult skeletal muscle sodium channel gene (either a threonine to methionine T704M or methionine to valine M1592V). If a patient is positive for one of these two changes, then the diagnosis of HYPP is confirmed. If the patient is negative, then they may have a different mutation of the same gene, a mutation of some as yet unidentified gene causing HYPP, or a completely different disorder.

Several methods used to detect point mutations or other small mutations rely on PCR amplification of the exon potentially containing the mutation, then detection of the change using several different techniques: either by detecting the change in restriction enzyme site (so-called *RFLP* [*restriction fragment length polymorphism*] (Fig. 14.3) or *ARMS* [*amplification-refractory mutation system*] (Fig. 14.4)), where primers are designed such that only the normal or mutant copy of the gene is PCR amplified. This assay includes internal controls for amplification efficiency of the sample (Fig. 14.4).

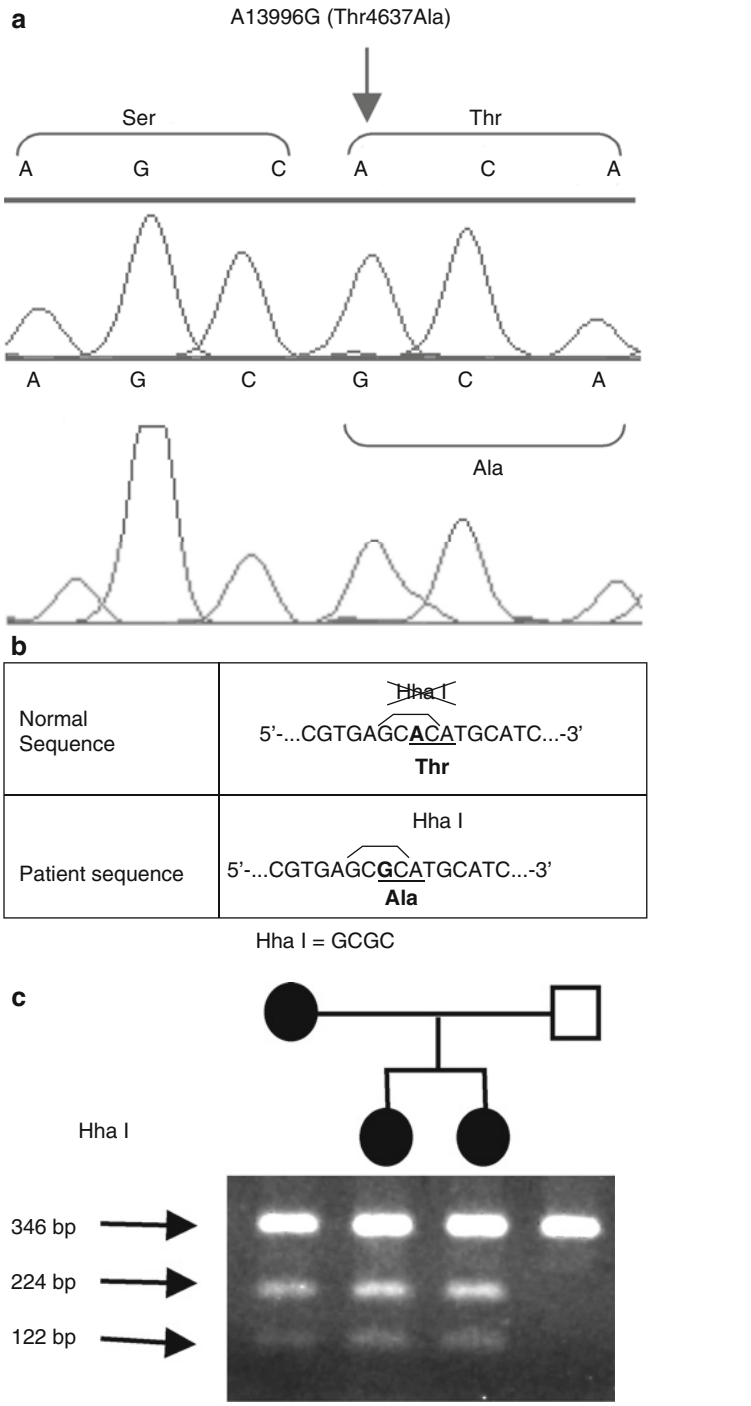

Fig. 14.3 Restriction fragment length polymorphism (RFLP) detection of known gene mutations. Restriction enzyme digestion can be used as a molecular diagnostic test for genetic mutations. In this example, we show the analyses of patients with the same heterozygous point mutation for an autosomal dominant neuromuscular disorder. As shown in the automated sequence data (Panel **a**), the substitution of a guanine (*G*) nucleotide for an adenine (*A*) nucleotide (A13996) changes a threonine amino acid residue to an alanine residue at amino acid position 4637 (*Thr4637Ala*). As shown in Panel **b**, the A→G point mutation creates a Hha I restriction enzyme site not present in normal sequence in unaffected individuals. Shown in Panel **c** is a PCR product from each of the pedigree members shown, digested with Hha I restriction enzyme. The unaffected father of the family shows a full-length PCR product with 346 bp which is *not* digested by Hha I; he has two normal copies of the gene (homozygous). His affected wife and two affected children show three bands after digestion with Hha I. They are each heterozygotes, with one normal gene and one abnormal. The normal gene shows the full-length undigested 346 bp PCR product, while the abnormal gene containing the Thr4637Ala change is cut into two bands by Hha I (224 bp, 122 bp)

Another assay, typically used in a nondiagnostic setting for localization of novel mutations, is *SSCP* analysis (*single-strand conformational polymorphism*) (Fig. 14.5). This assay begins with a double-stranded PCR product of the gene exon potentially containing a DNA mutation. This fragment is then denatured into its constituent single strands and then loaded on a non-denaturing gel (Fig. 14.5). The single-stranded state of a DNA molecule is thermodynamically unstable once it is in the non-denaturing environment of the gel. For this reason, the single molecule finds the lowest free energy of base pairing within the single molecule, forming a very specific "shape" based upon the sequence of the fragment. Any change in the DNA sequence can change the lowest free energy of base pairing within the fragment and hence the shape of the resulting molecule in the gel. Such a shape change, or *conformer*, simply indicates that a sequence change is present in the fragment. This fragment is then subjected to DNA sequencing to determine the precise change

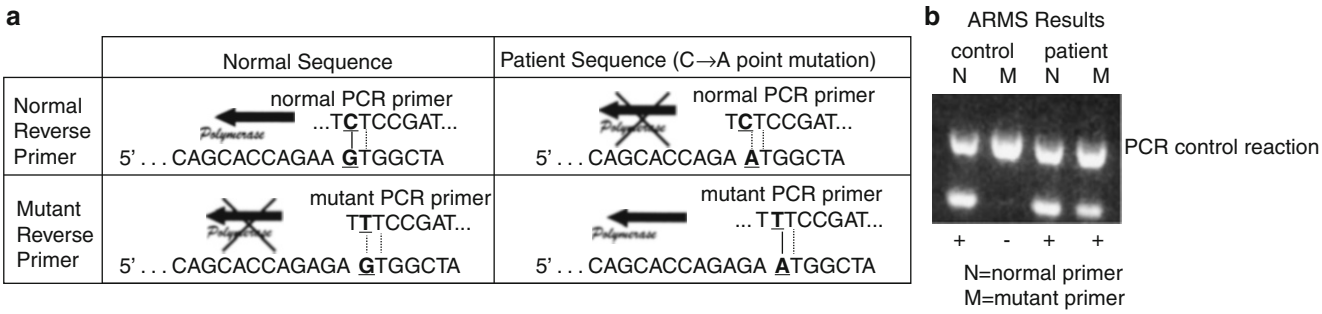

Fig. 14.4 ARMS (amplification-refractory mutation system) analysis of a mutation of the chloride channel gene. The ARMS technique is used to detect known single base changes and exploits the premise that PCR primers must be designed to very closely complement the sequence of interest; otherwise, they will fail to amplify the sequence under study. Two reactions must be run for each sample: one using a primer designed to amplify the normal sequence and one using a primer sequence designed to amplify the mutant sequence (Panel **a**). Intentional mismatches in the primer sequence determine which sequences will amplify with PCR, and a primer with more than one noncomplementary base to the DNA sample will not amplify that segment. Heterozygous positive controls must be run with each sample. An example of utilization of ARMS is shown for the G230E mutation in the CLCN1 chloride channel gene causing myotonia congenita (Panel **b**). The "control" has two normal chloride channel genes and thus amplifies only with the normal (*N*) primer set (in addition to an internal "PCR control reaction") and not with the mutation-specific primer set (*M*). The heterozygous myotonia congenita patient shows amplification with both normal (N) and mutant (M) primer sets, proving that they has the G230E change in the chloride channel. Failure to detect this particular point mutation does not rule out other mutations in this gene

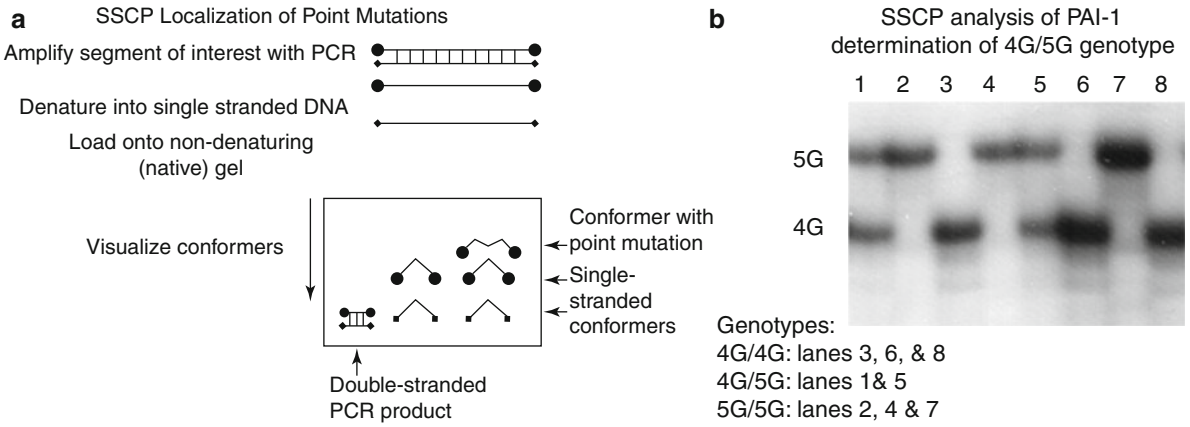

Fig. 14.5 Single-stranded conformational polymorphism (*SSCP*) identification of changes in a PCR product from a candidate gene. Single-stranded conformational polymorphism analysis requires amplification of the region of interest with the polymerase chain reaction (*PCR*). The double-stranded PCR product is heat denatured into single, separate strands which fold onto themselves in a specific conformation, or shape, determined by the DNA sequence (Panel **a**). Single-nucleotide changes affect the conformation of each single-stranded product, thereby altering the DNA migration on a native acrylamide gel (Panel **a**; "conformer with point mutation"). This technique is often used to detect single-nucleotide base changes and other small genetic mutations. Panel **b** shows an application of SSCP to detect changes in the plasminogen activator inhibitor (*PAI-1*). Here the change in the PAI-1 gene is used to test its association with increased risk for myocardial infarction. This example demonstrates the SSCP technique utilized to distinguish the usual DNA sequence in the PAI-1 gene – five consecutive guanine residues – from a polymorphism that predisposes individuals with protein S deficiencies to myocardial infarction. The polymorphism has only four consecutive guanines and is a deletion of one nucleotide

responsible for the mobility shift in the gel. SSCP analyses are not typically used for routine molecular diagnosis, because their sensitivity for detecting changes is only about 70 %, and specific mutations often do not give conformers which are consistent enough for precise molecular diagnostic applications. Nevertheless, this remains a popular technique for researchers attempting to identify novel mutations in cohorts of patients who are thought to possibly have a mutation of a candidate gene.

Highly Parallel Genome-Wide Technologies

The majority of DNA testing technologies described above relies on singling out a single gene or position in the genome (a "locus") and testing it. In such testing paradigms, the gene to be studied is suspected as a candidate due to clinical cues – e.g., a focused study of the dystrophin gene due to high CKs and proximal weakness in a young boy.

Advanced DNA technologies, and decreasing costs of applying these emerging technologies to patient DNA samples, have led to *genome-wide* studies of patient DNA, where the entire genome is put under scrutiny in a single experiment. There are two types of genome-wide approaches: array comparative genomic hybridization (aCGH) (mentioned briefly in the context of the dystrophin gene) and nextgen sequencing.

Array Comparative Genomic Hybridization (aCGH)

This method scans for changes in dosage across the entire genome on a single "chip." It is important to point out that array CGH is excellent for scanning for changes in the *dosage* (copy number) of the patient's DNA, but is not able to see changes in *sequence* (e.g., mutations). A microarray (chip) is utilized that has small oligonucleotides representative of all genes and/or regions of the genome, where each oligonucleotide is printed at a specific address (coordinates) on the microarray. One of the more commonly utilized microarray platforms, Affymetrix, has millions of individual oligonucleotides printed on a 1 cm^2 glass slide (called "features" on the array). The patient DNA is hybridized to the microarray, and the oligonucleotides then query the patient DNA for each region. Deletions are detected by unusually small amounts of the patient DNA hybridizing to a specific feature, and increases in copy number (duplications, amplified regions) are detected as an abnormally large amount of patient DNA binding to the feature.

aCGH is most extensively utilized in two clinical situations: cancer and syndromic (developmental delay, congenital abnormalities) patients. In cancer, the patient's tumor can have multiple chromosomal rearrangements with variable loss or gain of material, and the aCGH pattern across the tumor's genome can be diagnostic of specific cancer subtypes and is increasingly directing appropriate therapy. In intellectual disability, developmental delays, autism, or congenital anomalies, a molecular diagnosis can be provided to about 15–20 % of cases, with a detectable loss or gain of chromosomal material that causes the clinical phenotype observed (Fig. 14.6)[19].

The large majority of patients with single gene defects do not show copy number changes but instead have mutations of the DNA sequence that are not detected by aCGH. Recently, a method to sequence all genes simultaneously has emerged, known as nextgen or highly parallel DNA

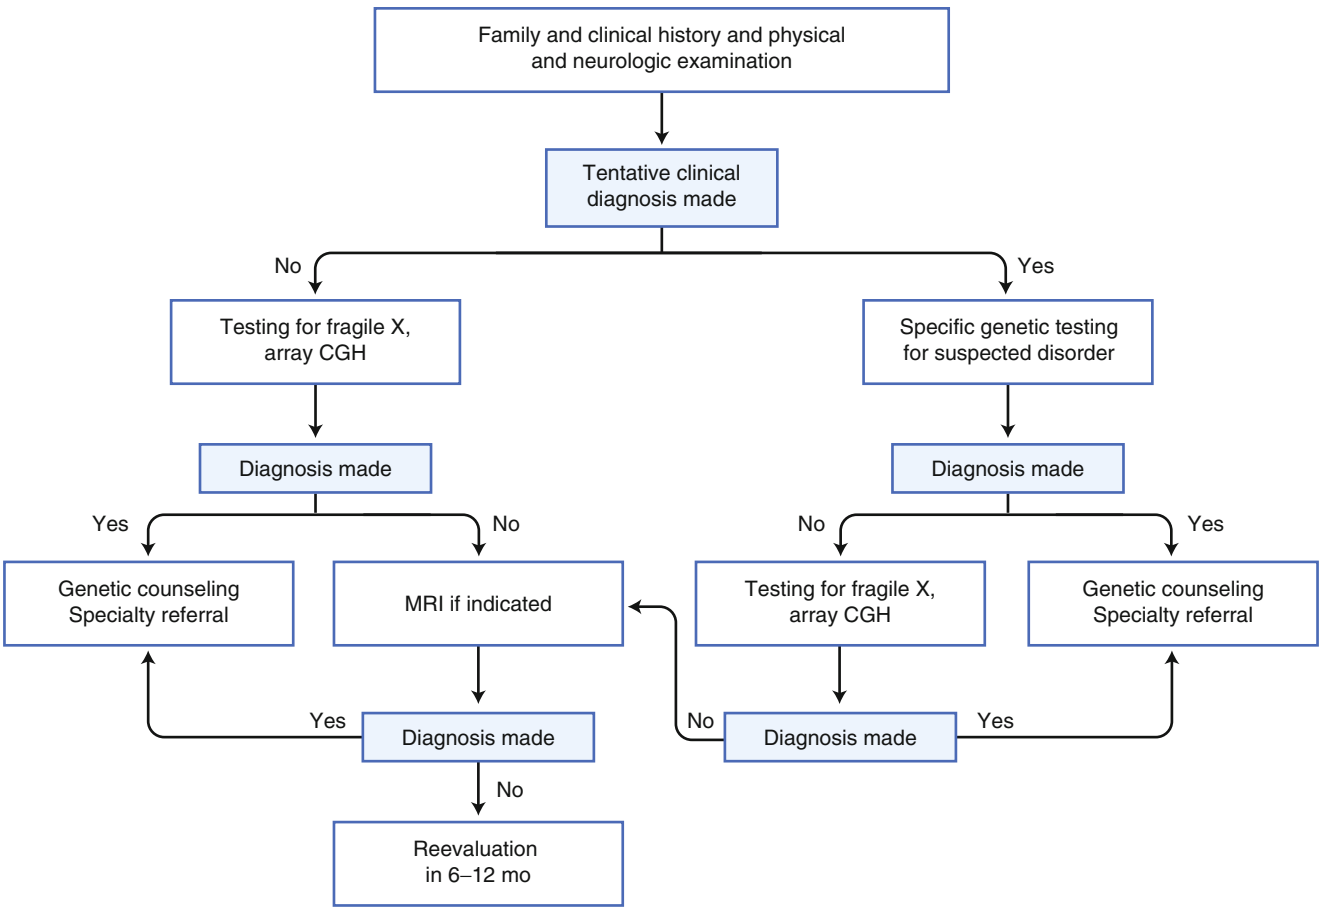

Fig. 14.6 Use of array comparative genomic hybridization (aCGH) in developmental and intellectual delay (From Mefford et al. [19])

sequencing. Nextgen sequencing involves taking patient DNA, fragmenting it into small pieces, then immobilizing individual fragments onto a solid support, where millions or billions of fragments are then sequenced simultaneously. The millions or billions of snippets of DNA sequence from the patient are then "assembled" into gene sequences and then searched for mutations.

A variant of whole genome sequencing (WGS) is exome sequencing. The amount of DNA sequenced in an exome is about 1 % of that sequenced in a whole genome. The difference is that the exome sequence focuses on coding sequences of genes (exons) and does not attempt to sequence all the introns and intervening sequences between genes. Carrying out nextgen sequencing on a patient exome assumes that most or all disease-causing mutations will occur in exons, and thus it is not necessary to sequence the 99 % of DNA that is non-exon. This is likely a generally good assumption, but exceptions almost certainly exist.

Every human contains about six billion bases of DNA: three billion from the mother and three billion from the father. In this three billion, there are about three million polymorphisms where one individual differs from another individual, and this creates the variation we see in the human race. Sequencing the entire genome or exome of a patient yields thousands of sequence differences, and singling out a specific DNA sequence change that is causative of the patient's disorder is not a trivial undertaking. However, as the costs of DNA sequencing continue to go down, speed and accuracy continue to increase, and bioinformatics tools become more powerful, WGS and exome sequencing is expected to become more and more commonplace in the clinical setting.

Part III

Approach to Neuromuscular Diseases: Assessment and Treatment of Neurological Disorders

Outcome Measures and Clinical Assessment Instruments in Neuromuscular Disease

15

Jeffrey Rosenfeld and Carlayne E. Jackson

The number and complexity of clinical trials in neuromuscular disease have escalated steadily over the first part of this century. This increase in clinical trial activity has resulted from both advances in the basic science laboratory and the need for objective data to justify treatment decisions. Presentation of empiric data, without carefully designed and controlled studies, is not generally accepted or published. Managed care and insurance companies have embraced the long-held principles of the scientific process, providing consistent pressure on clinicians to generate justification for treatment decisions with "statistically significant" observations. Considering the large volume of neuromuscular clinical trials in the recent past, there have been relatively few studies which have yielded significant results, causing many treatment decisions being made by consensus rather than evidence. There have been an increasing number of opportunities for neuromuscular physicians to initiate "off-label" therapy and monitor progress by empiric observation. This dichotomy between the need for carefully designed clinical studies and pressures from daily clinical practice to initiate novel therapies has highlighted the importance of appropriate, valid, and reliable disease-specific outcome measures in neuromuscular disease.

Disability resulting from neuromuscular disease includes almost all functions ascribed to the nervous system. Sensation, strength, and coordination are primarily vulnerable depending upon the specific neuromuscular disease implicated. Measurement tools are, however, optimally developed for specific disease states as the implications of the same disability vary depending upon the underlying disease. Weakness resulting from myasthenia gravis, for example, may not have the same impact on a patient's level of function or quality of life compared with similar weakness caused by motor neuron disease. Sensory loss or dysesthesias resulting from neuropathy may require different measurement tools than those needed for measuring sensory pathology resulting from spinal cord or nerve root injury. Often, however, measurement scales are "borrowed" from one disease, for measurement in another. Validation of specific measurement tools is a critical process but is also dependent upon the standard against which a new measure is compared.

The emphasis on careful measurement of clinical efficacy for new neuromuscular therapies is well founded. Multiple reports of consistent and significant laboratory data in animal models have led to large and expensive clinical trials, which did not show the same significant clinical benefit. Examples of this abound in the testing of neurotrophic factors for motor neuron disease. Testing new therapies with great potential has highlighted the importance of selecting specific and sensitive measurement tools. Alternatively, selecting or designing a measure of disease progression that is either too sensitive or too specific can result in errors of data analysis (type I vs. type II) which may result in abandoning potentially beneficial therapy.

This chapter is designed to review issues which result from consideration of the optimal outcome measures, taking into account many of the concerns raised above. By its nature, the process of measurement requires reducing a dynamic process (the patient dealing with their disability) to a "2-dimensional snapshot" (the patient's score at one point in time) that will be used to reflect a patient's condition. Measurement is usually an imperfect process, especially when relatively small treatment effects are expected. Multiple examples of available treatment instruments will be reviewed with an emphasis on their benefits and limitations for future use.

Importance of the Right Scale

The primary objective of any outcome measure is to assess a change specific to the disease under study. The concepts of validity, reliability, sensitivity, and specificity are essential to selection of a suitable outcome measure. Evaluating human disease is often confounded by the reality that disease progression does not usually occur in a single isolated modality suitable for study. Patients who experience pain may interpret it as weakness; patients with weakness may report subjective sensory changes; sensory complaints may be modified by objective weakness or concurrent depression. The primary goal of an ideal outcome measure in neuromuscular disease is to objectively evaluate the outcome relevant to the disease being studied while concurrently acknowledging, or ideally controlling for, the patient's overall disability.

Recently, *quality of life* scales have been recognized as valid and essential outcome measures in testing new treatments and drugs. Ideally, a therapeutic intervention would be desirable if it significantly improves quality of life even without showing similar benefit in more objective assessments of strength or function (gait, speech, breathing). Similarly, if a therapy were to have a significant benefit to strength or function – but failed to show any improvement in a patient's quality of life – it would diminish its value. Specific considerations and pitfalls in the available quality of life scales are considered below.

Selecting the *right outcome measure*, therefore, is the most important task of any researcher wishing to further our understanding and treatment of neuromuscular disease.

The ideal outcome measure should consider [1].

1. Whether it is *appropriate to the function* it is supposed to measure (*i.e.*, *does a test of motor function favor patients with greater preserved strength or will changes in weak patients be detected as well*).
2. Whether the *measure is valid* (*how does it compare with other measures designed to test the same function*).
3. Whether it is a *reliable and reproducible* test (*can the measure be repeated accurately*, *can it be reproduced by others*, *is it simple enough to be repeated without significant additional training*).
4. Whether it is *sensitive* to detect changes in the conditions under study, considering the variability arising from other aspects of the patient's disability.

World Health Organization: Defining Levels of Disease

Standardized classification and terminology has been developed by the World Health Organization for evaluating consequences of disease. The International Classification of Impairments, Disabilities, and Handicaps (ICIDH) was developed as a model for consistency in "reducing" any disease into four defined levels suitable for study:

- *Pathology* is defined as structural damage done to the body, organ, or organ system caused by the disease process.
- *Impairment* is the functional consequence of the underlying pathology (i.e., weakness, shortness of breath, spasticity).
- *Disability* is referred to as the inability to perform specific activities that are determined to be within the range of "normal" for human beings.
- *Handicap* reflects the consequence of an individual's disease on their community and in society. Societal consequences of disease might, by implication, include cultural biases, family attitudes, and economic impact (Table 15.1).

Table 15.1 An application of the ICIDH model to amyotrophic lateral sclerosis

Area of interest	Primary measurement	Available scale
Pathology	Motor neuron loss	Ubiquitin staining
		Abnormal neurofilament staining
		Estimates of motor neuron number by EMG
Impairment	Strength loss	Manual muscle Testing
		Maximal voluntary isometric contraction
		Hand-held dynamometry
	Breathing	Vital capacity (forced, slow)
		Tidal volume
		Maximal inspiratory pressure
		Maximal expiratory pressure
	Spasticity	Ashworth spasticity
	Fine coordination	Ashworth spasticity
Disability	Speech	Speech ALSFRS-R
	Swallowing	Swallowing ALSFRS-R
	Breathing	Breathing ALSFRS-R
	Arm function	Arm ALSFRS-R
		Timed pegboard
		Barthel Index
	Leg function	Leg ALSFRS-R
		Barthel Index
Handicap	Independence loss	Quality of life scales
	Work	Sickness impact profile
	Social integration	Sickness impact profile
	Self-care	Short form 36
	Death	Survival

Adapted from Brooks [2]

The ICIDH is a theoretical construct that is especially helpful in bringing to our awareness the multifactorial dimensions of human disease. It is not clear, and perhaps not appropriate, to ask whether an ideal clinical trial should take into account all aspects from each component of this model. Existing clinical outcome measures most readily assess *impairment*, while newer measures of quality of life and

function assess *disability* and *handicap* [3–6]. By contrast, most basic laboratory studies, which lead to these clinical trials, evaluate *pathology*. The implication from data gathered under a microscope in the laboratory is that preserved or improved anatomy/neurochemistry will directly relate to improvements in a patient's *impairment*, *disability*, *or handicap*; a humbling reality that has not been associated with an abundance of supportive data.

NINDS Outcomes Subgroup

Recently, the NINDS released a consensus statement pertaining to optimal common outcomes in neuromuscular disease trials (http://www.commondataelements.ninds.nih.gov/ALS.aspx#tab=Data_Standards). Domains of functional performance, pulmonary, muscle strength, and quality of life are defined for motor neuron diseases, myopathies, neuropathies, and neuromuscular junction disorders. Ideally, each domain of measurement is defined by a *core* measure central to the pathophysiology of the clinical manifestation. *Supplemental* measures are defined as clinically relevant and validated for use in the population. These measures can be focused on discrete clinical features and may not be as broad in scope as core measures. *Exploratory* measures are not validated, however may have a role in subsequent studies as supplemental or core measures if their use becomes more routine.

Validity

Despite major technologic advances in our ability to diagnose specific neuromuscular diseases, we are often unable to *directly* quantify pathology prior to postmortem study. Assessment techniques and published scales serve as surrogate markers of disease. Validation of these instruments by comparison with a "gold standard" reflecting the actual disease process, *in situ*, is not common. In motor neuron disease, this comparison has been attempted. Our current estimates on the extent of motor neuron loss required prior to the detection of weakness have followed. In other neuromuscular disorders such as neuropathy, myopathy, and disorders of the neuromuscular junction, similar morphometric analyses correlating pathology to loss of function have not been reported.

We are dependent upon the accepted or "validated" scales to use as a benchmark against which to compare newer measures. This process of validation, while necessary, introduces the caveat that a more sensitive or accurate measure might not yield the same results as an older, less sensitive, "validated" measure. This concern is best addressed through the use of multiple measurement tools which may overlap with respect to the measurement endpoints. For example, a newer measure of strength might be devised, and the data generated might correlate significantly with a measure of functional ability and a measure of quality of life. This newer measure might not, however, correlate with available manual or quantitative muscle testing. The newer measure might, therefore, be a better reflection of a patient's strength than the available strength measures against which it is compared.

These considerations are challenging in the process of evaluating and accepting new measures of neuromuscular disease progression. Lessons from the clinical trials summarized below suggest that we should not be complacent with only the accepted, available testing instruments. An ongoing comparison with newer, possibly more sensitive and specific measures should occur with each new clinical trial.

Sensitivity, Specificity, and Reproducibility

The choice of an appropriate measurement tool involves an ideal combination of sensitivity (the probability of detecting a result when it is present) and specificity (the probability of *not* detecting an effect that you do not want to measure). If, for example, a test had a high sensitivity, we would expect many abnormal values to be detected. If that same test had a high specificity index, we would expect that only instances reflecting the desired outcome measure would be detected rather than others that might be abnormal for another reason. When used in clinical trials, sensitivity and specificity have slightly different meanings as we are frequently measuring the *rate of change* in a clinical sign or symptom (i.e., strength, sensation, gait, and quality of life). A test that has a high sensitivity in a polyneuropathy trial, for example, would be a test whose results would change in most cases of polyneuropathy where there is progression or improvement. That same test with a high specificity would not be expected to change unless the improvement or progression was due to the polyneuropathy being tested [7]. Consequently, the related concept of reproducibility is essential, as measuring changes over time requires consistency so that change will not result from measurement error or variability in testing. Assessing the reproducibility of a test can therefore modify any interpretation of sensitivity or specificity.

Type I Versus Type 2 Errors

The most significant consequence in choosing an inappropriate or an insensitive measure when designing a clinical trial is the implication of making an ultimate error in interpreting the results. At the conclusion of a trial found to yield nonstatistically significant results, the possibility of inappropriately rejecting an effective treatment is referred to as *type 1 error*. Conversely, the scenario of wrongly concluding that there is a statistically significant benefit to a new treatment is

referred to as a *type 2 error*. The probability of committing a type 1 versus a type 2 error is dependent upon the outcome measure selected, the sample size, and the desired level of statistical significance or probability on which the analyses are based.

A detailed discussion of statistical considerations for minimizing the probability of a type 1 error, while not inappropriately increasing the possibility of a type 2 error, is beyond the scope of this chapter. Overall, however, minimizing the variability within a measurement (error variance) is the critical consideration. If, for example, a real difference existed between a control and treatment group, but the measurement variable was confounded by random error variance, the difference between groups would be lost in the analysis. Error variance increases with the number of treatment groups and with the complexity of the measurement. Generally, it is therefore ideal to keep the number and complexity of variables low while maximizing the number of observations or patients.

Ordinal Versus Continuous Measures: Parametric Versus Nonparametric Analyses

An appreciation of the difference between ordinal versus continuous data is a critical distinction. Available scales for the assessment of neuromuscular patients exist within both categories with significant implications to the type of data analysis appropriate to each category.

Ordinal data, as the name suggests, implies a rank order to the data, with one score being better or worse than another. An ordinal scale does not permit the user to determine how far apart the points on a scale are but only to hierarchically rank each point. Ordinal data is collected as discrete values. Also called categorical data, values collected are analyzed based upon predetermined categories. The most common ordinal scale in routine medical practice is the use of "severe, moderate, or mild" as a means of classifying the severity of disease. When using ordinal data, the different scores cannot be compared in an absolute way (i.e., a difference between a score of 2 and 3 is not assumed to be the same as a difference between a score of 9 and 10).

Ordinal scales must be analyzed using nonparametric statistics. The allowable statistical comparisons are usually less powerful than parametric statistics as only the relative relationship of one score to the other is taken into account. The magnitude of the differences between scores or the variability of scores is not considered [8]. Comparisons between groups of patients are made using tests such as Mann–Whitney, Wilcoxon, Kruskal-Wallis, or Sign test [9].

Continuous measures are characterized by having uniform tervals between scores. 50 % increment between scores at the low end of the measurement range implies the same relative change as a 50 % increment at the high end of the measurement scale. The use of continuous measures usually implies that the values will be normally distributed (bell shaped or Gaussian) around a mean value. Parametric statistics employ values such as the mean and median and, most importantly, variance to ascribe differences between groups. Analyses of variance and t-tests are examples of common parametric statistics (Table 15.2).

Generally, parametric statistics are more robust at detecting differences compared with nonparametric analyses. Nonparametric values are, however, often easier to gather and are much less prone to error variance.

Motor Scales

Assessment of motor function has been the primary outcome measure for the majority of neuromuscular clinical trials, yet there are relatively few assessment scales available. Most

Table 15.2 Applications of continuous verses ordinal data

	Continuous data	Ordinal data
Sample measurements available	Height, weight, blood pressure, quantitative muscle testing	Manual muscle testing
	Forced vital capacity	ALSFRS-R, Appel ALS Score
	Tidal volume	Quantitative sensory testing
	Maximal inspiratory/expiratory pressure, visual analogue scales	Ashworth spasticity scale
		Quality of life scales
		Neuropathy Disability Scale
		Quantitative Myasthenia Gravis Score
Appropriate statistics	*Parametric* analyses: mean, median, mode, variance, analysis of variance (ANOVA), correlation, regression, T-tests	*Nonparametric* analyses: Spearman rank-order analysis, Mann–Whitney, Wilcoxon, binomial testing, Kruskal-Wallis analysis of variance
Power	More powerful	Less powerful
Advantages	More sensitive to detect a difference	Easier to administer
	Measured differences can be proportional to changes in disease severity	

Table 15.3 Manual muscle testing

Grade	Description
5	Normal strength
4+	Ability to resist against strong pressure throughout range of motion
4	Ability to resist against moderate pressure throughout range of motion
4–	Ability to resist against minimal pressure throughout range of motion
3+	Ability to move through full range of motion against gravity and to resist against minimal pressure through partial range of motion, the contraction breaks abruptly
3	Ability to move through full range of motion against gravity but unable to take any resistance
3–	Ability to move through partial range of motion against gravity
2	Ability to move through full range of motion with gravity eliminated
1	A flicker of movement is seen or felt in the muscle
0	No contraction palpable

typically, manual muscle testing and/or quantitative dynamometry are used to access strength. As noted below, manual testing is simple and widely used as part of the routine neurologic examination. It involves the examiner's subjective determination of the patient's strength using accepted scoring guidelines relative to the patient's ability to resist force (gravity or applied). Quantitative motor assessment is more objective yet may introduce additional sources of variability in measurement. Focal strength determination using dynamometry (grip, pinch, or isokinetic) has also been used in an effort to limit the measurement variability introduced with measurement of multiple muscles. Other composite scales, summarized below, assess a combination of patient's strength and function, usually specific for a disease process.

Manual Muscle Testing

Manual muscle testing (MMT) is the most common method of assessing strength in routine clinical evaluation. Originally developed to assess strength in polio patients [10], the scale is composed of a rating of 0–5 assigned to each muscle group tested [11] (Table 15.3). The scale has been modified and formalized to account for more grades of muscle weakness using a plus or minus designation [12]. A primary distinction in the grading scale is made based on the patient's ability to move against gravity and then against the resistance of the examiner [13].

Advantages: MMT is a quick, simple measure of muscle strength. It requires no specialized equipment and is cost-efficient. The testing can result in highly reproducible data when the protocol is standardized and examiners trained [14, 15].

Disadvantages: MMT data is ordinal and intervals between the various ranks are not equal. There can be significant variation in the force generated by a muscle group graded by the same MMT rank [16]. A decrease in as much as 40 % of a muscle's capacity for contraction could be graded with the same MMT score [13].

Quantitative Dynamometry

Quantitative measurement of force requires a maximal isometric voluntary contraction (MVIC) and the use of a transducer to measure the force. MVIC testing yields continuous data, eliminating the difficulties with MMT due to the limitations of ordinal data collection. When compared with MMT, MVIC has been shown to be more sensitive to early changes in muscle strength, highlighting the relative insensitivity of an ordinal grading of manual muscle strength [17, 18]. A method for standardizing MVIC scores as a deviation from a standard reference from a population of ALS patients (z-score) has been suggested [19]. Z-scores can be averaged in individual muscle groups to yield a "megascore," reflecting strength in a specific extremity [20, 21]. Applications of quantitative dynamometry testing include grip/pinch testing, hand-held dynamometry, and fixed dynamometry.

Advantages: With proper testing conditions, test-retest reliability and sensitivity is better than the alternative, more subjective, measures of muscle strength [22]. Data can be analyzed using more powerful parametric statistics. MVIC testing is more sensitive than MMT and the Appel Score which is dependent upon MMT. Specifically, as noted above, MVIC may be a more sensitive measure for detecting subtle changes in muscle strength, critical for early disease detection and diagnosis.

Disadvantages: Testing requires specialized training and equipment. Reliable data is dependent upon consistent testing conditions including accurate positioning of the patient in the testing apparatus. Comparison of data between different test sites and different examiners must be continually reviewed, due to the many inherent variables affecting the consistency of the testing. While normative data exists from several sources, MVIC testing for clinical trials has been validated primarily in the ALS population [19, 23]. The potential benefit of MVIC in a more slowly progressive neuromuscular disease remains to be established.

Functional Scores

One of the most common methods of assessing outcome of care or treatment in a broader sense is in terms of a patient's ability to perform tasks of daily living. Measurements of function are usually more meaningful to people's lives than objective measures such as grip strength or timed walking.

One of the major problems with a functional scale is that people may react differently to similar levels of impairment depending on their support networks, goals, priorities, and expectations. Functional disability may relate not only to physical factors but also to cognitive, social, economic, or environmental factors. For example, the level of dependency may be a function of the existence of either aids or the availability of assistance from a caregiver. In addition, most disability scales focus narrowly on a range of mobility and self-care tasks and do not always provide assessments of mental functioning, social interactions, or pain.

Measurements of functional status implicate a combination of strength and the consequence(s) of impaired strength or ability (walking, eating, dressing, standing, etc.). There may also be a measure reflecting quality of life within a functional score measure. Such composite functional measures have been most widely used in neuromuscular disease research due to the multisystem impact of that disease. Functional measures can be divided into general (global) measures, applicable to multiple disease states, and disease-specific measures, validated in a specific disease population.

Global Measures of Functional Impairment

Barthel Index

The Barthel Index was initially developed in 1965 to assess the mobility and functional status of musculoskeletal and neuromuscular patients in Maryland's chronic disease hospitals [24]. The Barthel Index assesses the degree of independence a patient demonstrates in various activities of daily living (ADLs) including bowel and bladder function, grooming, toilet use, feeding, transfers, mobility, dressing, climbing stairs, and bathing (Table 15.4). Two versions of the original Barthel Index have been commonly used. Wade and Collin's version [25, 26] contains 10 ADL functions, and the total score ranges from 0 (total dependence) to 20 (total independence) in 1-point increments. Granger's version [27] includes 15 ADL functions, and the total score ranges from 0 (total dependence) to 100 (total independence) in 5-point increments. A score of 60 is the point between independence and some dependence. A score of 20–40 indicates severe dependence, and a score below 20 suggests total dependence in self-care and mobility. In practice, a difference of 4/20 points or more will usually reflect a real difference; smaller differences might arise from errors. The Barthel Index can be self-administered, administered face to face, or over the telephone. In addition, it can be given to a caregiver, nurse, or therapist depending on who can give the most accurate information regarding the patient's actual level of function. Direct observation is not required but may improve the reliability of the index. The Wade and Collin's instrument takes approximately 2–3 min to complete.

Advantages: The Barthel Index has demonstrated high test-retest reliability ($r=0.89$) and inter-rater reliability ($r>0.95$) [27]. It is one of the best known and commonly used ADL instruments [28]. It is best suited for assessing and following patients with paralysis and/or patients with

Table 15.4 The Barthel ADL Index

Bowels
0 = Incontinent (or need to be given enema)
1 = Occasional accident (once/week)
2 = Continent
Bladder
0 = Incontinent
1 = Occasional accident (max. once per 24 h)
2 = Continent (for over 7 days)
Grooming
0 = Needs help with personal care
1 = Independent face/hair/teeth/shaving (implements provided)
Toilet use
0 = Dependent
1 = Needs some help, but can do something alone
2 = Independent
Feeding
0 = Unable
1 = Needs help cutting, spreading butter, etc.
2 = Independent (food provided in reach)
Transfer
0 = Unable – no sitting balance
1 = Major help (one or two people), physical, can sit
2 = Minor help (verbal or physical)
3 = Independent
Mobility
0 = Immobile
1 = Wheelchair independent including corners, >50 yards
2 = Walks with help of one person (verbal or physical)
3 = Independent (but may use any aid, e.g., stick)
Dressing
0 = Dependent
1 = Needs help, but can do about half unaided
2 = Independent (including buttons, zips, laces)
Stairs
0 = Unable
1 = Needs help verbal, physical, carrying aid)
2 = Independent up and down
Bathing
0 = Dependent
1 = Independent (or in shower)
Total = (0–20)

Table 15.5 Rankin scale

Grade	Description
0	No symptoms at all
1	No significant disability, despite symptoms; able to carry out all usual duties and activities
2	Slight disability; unable to carry out all previous activities but able to look after own affairs without assistance
3	Moderate disability, requiring some help, but able to walk without assistance
4	Moderately severe disability; unable to walk without assistance and unable to attend to own bodily needs without assistance
5	Severe disability; bedridden, incontinent, and requiring constant nursing care and attention

continence or mobility problems. It is simple to administer and score, and the score is easily communicated.

Disadvantages: The Barthel Index is an ordinal scale; therefore, changes in points in one function do not reflect equivalent changes in ADL function across different activities. Another criticism is that the maximum range of activities measured does not include the full range of behavioral changes that might occur resulting in a floor and ceiling effect [29]. Some changes may occur outside the range measured and would not be detected by this instrument. Although it is relatively sensitive in detecting functional change over time, small differences may be missed.

It is not recommended for assessing general health status, psychosocial status, or communication skills [27], since it only assesses physical activities and does not include measurement of psychological well-being. It omits tasks of daily living such as shopping and cooking and other tasks essential for living within a community. Therefore, it is mostly suitable for institutionalized patients (for whom it was originally designed) with moderate to severe disability.

Rankin Scale

The Rankin scale was initially developed as the stroke research equivalent of the Glasgow Outcome Scale [30]. The Rankin scale is another ordinal scale of functional outcome which assigns a grade from 0 (no symptoms at all) to 5 (severe disability; bedridden, incontinent, and requiring constant nursing care and attention) (Table 15.5). Most studies divide patients into two groups (0–3, 4–5) or three groups (0, 1–3, 4–5) for the purpose of quantitating the outcome measures.

Advantages: The Rankin scale has been shown to be reliable and simple to administer, making it ideal for use in large multicenter clinical trials [31]. Although it was initially designed to evaluate outcome in stroke patients, it has been used in several neuromuscular trials.

Disadvantages: The Rankin scale has been criticized due to its inherent insensitivity. It mixes objective and subjective items as well as assessments of impairment and disability. In a sense, is not a true measure of handicap since it relies so strongly on mobility.

Purdue Pegboard

The Purdue Pegboard is used to evaluate fine coordination and hand dexterity.

Five subtests comprise the test: right hand (RH), left hand (LH), both hands (BH), RH + LH + BH, and assembly [32]. The test board consists of a board with four cups across the top and two vertical rows of 25 small holes down the center. The two outside cups contain 25 pins each; the cup to the immediate left of center contains 40 washers, and the cup immediate to the right of center contains 20 collars. Performance of the RH and LH subtests requires participants to first use their right hand then left hand to place as many pins as possible down the respective row within 30 s. The score for each of these subtests is the total number of pins placed by each hand in the time allowed. The BH subtest is a bimanual test where the participants use their right and left hand simultaneously to place as many pins as possible down both rows in 30 s. The RH + LH + BH subtest is a mathematical computation of the scores for the RH, LH, and BH subtest. The assembly subtest requires that both hands work simultaneously while performing different tasks for 60 s. The score for this subtest is the total number of pins, washers, and collars placed in 60 s. Each stage of the test is administered three times.

Advantages: Purdue pegboard is one of the best methods that evaluate fine dexterity and coordination of the hand. In the test, memory and learning are important. Remembering the steps of the subtest immediately influences the scores, especially in the assembly subtest.

Disadvantages: It takes 15 min to complete.

Timed Up and Go

The timed "Get-Up and Go" test was initially developed as a clinical measure of balance in elderly people [33, 34]. The test must be performed with the patient wearing regular footwear, using usual walking aid if needed, and sitting back in a chair with arm rest.

On the word "Go," the patient is asked to do the following:

1. Stand up from the arm chair.
2. Walk 3 m (in a line).
3. Turn.
4. Walk back to chair.
5. Sit down.

Observation of the patient for postural stability, steppage, stride length, and sway is recommended in addition to the total time. Normal: completes task in <10 s. Abnormal: completes task in >20 s.

Advantages: Administration time is 5 min or less. The test requires no special equipment or training and is easily included as part of the routine medical examination. Studies

have shown that the time score is reliable, correlates well with log-transformed scores on the Berg Balance Scale, gait speed, and Barthel Index of ADL. It also appears to predict the patient's ability to go outside alone safely.

Disadvantages: This test cannot be used in non-ambulatory patients.

Timed Walk

The 6-min walk test (6MWT) measures the distance an individual is able to walk over a total of 6 min on a hard, flat surface [35–38]. The goal is for the individual to walk as far as possible in 6 min. The individual is allowed to self-pace and rest as needed as they traverse back and forth along a marked walkway. The primary outcome is the distance covered in meters or converted measure (such as feet) over 6 min.

The 10-m walk test assesses walking speed in meters per second over a short duration (10 m). It has been used in various patient populations including stroke, Parkinson's disease, general neurologic movement disorders, and spinal cord injury. The time (seconds) is reported and can also calculate a walking speed m/s. It is performed using a "flying start": the patient walks 14 m and the time is measured for the intermediate 10 m. The individual walks at their preferred walking speed. Individuals can use an assistive device and must wear shoes. Testing can be completed in less than 5 min.

Advantages: The timed walk tests provide a functionally meaningful assessment of walking ability and do not require any specialized equipment or training.

Disadvantages: The assessment cannot be used in non-ambulatory patients. Studies have shown that longer walks (12 min) are more discriminating and highly reproducible, but are more time consuming for the investigator and exhausting for the patient.

Trunk Control Test

The trunk control test was initially developed to assess motor improvement after stroke. It is a simple test of motor function examining only four movements: rolling to a weak side, rolling to a strong side, sitting from a lying position, and balance in the sitting position (Table 15.6) [39, 40]. Tasks are graded on a three-point ordinal scale that has been validated in stroke patients.

Advantages: The simplicity of this test makes it easy to use for routine clinical evaluations. The test appears to be as sensitive and reliable as the more complex Rivermead motor assessment and is much simpler.

Disadvantages: This test of motor function has not, however, been utilized in neuromuscular clinical trials to date. Two of the four tests are defined based upon the identification of a "weak and strong side" which may not be applicable to the majority of neuromuscular disease patients.

Table 15.6 Trunk control test

Tests (*on bed*)	
1.	Rolling to weak side
2.	Rolling to strong side
3.	Sitting up from lying down
4.	Balance in sitting position (on side of bed)
Scoring	
0	Unable to do on own
12	Able to do, but only with non-muscular help – for example, pulling on bed clothes, using arms to steady self when sitting, pulling up on rope or monkey pole
25	Able to complete normally
Trunk score = score (1) + (2) + (3) + (4)	
Trunk control test (guidelines)	
Four movements/functions are tested, with the patient lying on the bed.	
Rolling to weak side	
From lying on back, rolling on to weak side, may push/pull on bed with good arm	
Unable to perform without assistance	0
Requiring assistance	12
Able to perform normally	25
Rolling to strong side	
From lying on back, bringing weak limbs over	
Unable to perform without assistance	0
Requiring assistance	12
Able to perform normally	25
Sitting up from lying down	
From lying on back – may use arm(s) to push or pull	
Unable to perform without assistance	0
Requiring assistance (pulls on pole, rope, sheets, etc.)	12
Able to perform normally	25
Sitting balance	
Sitting on edge of bed, feet off ground – balance for 30 s.	
Unable to perform without assistance	0
Requiring assistance	12
Able to perform normally	25

Motor Club Assessment

The motor club assessment is a specialized test that has been used to measure both impairment and disability following stroke [41–43] and in multiple sclerosis patients [44]. The assessment is easy to administer and grade using fixed categories referring to how easy the various tasks are to complete (Table 15.7). The motor section of the test (measuring impairment) is similar to the grading of manual muscle testing; however, the number of possible categories is more limited (no movement, some movement, normal movement). The functional movement section evaluates motor function common to many activities of daily living (i.e., lying down, sitting up, transferring, kneeling, walking, and climbing stairs).

Advantages: The scale is simple to administer, reducing inter- and intra-observer variability. The nature of the tasks performed has obvious relevance to a patient's ability or level of function.

Table 15.7 Motor club assessment

Motor section	
Scale	
0 = No movement	
1 = Limited range of movement (add-or + for further detail)	
2 = Completed range of movement (compared with other side). Coordination neednot be normal, but range should be full	
Measure of motor impairment	
Positions	
A = Good side lying	
B = Lying	
C = Sitting	
D = Standing	
Movements – arm	**Position/score**
Shoulder shrugging	
Elevation of the shoulder girdle	A___
	B___
	C___
Arm thrusting	
Forward extension of the arm from the flexed position	A___
	B___
	C___
	D___
Arm lifting	
Upward extension of the arm from the flexed position	A___
	B___
	C___
	D___
Forearm supinating	
Supination of the forearm from the prone position (Elbow at right angles in front of the body)	C___
Wrist cocking, forearm supported	
Extended wrists from mid-position	C___
Wrist cocking, with arm raised straight in front	
Extend wrist from mid-position	
Straight arm raised in front	C___
Pinch grip, forearm supported

Movements – leg	
Hip and knee bending	
Bend (flex) hip and knee from straight position; combined movement	A___
	B___
	D___
Knee Flexion	
Isolated knee flexion, thigh immobilized	A___
	B___
	D___
Ankle dorsiflexion; leg straight	
Dorsiflex from the mid-position	B___
	D___
Ankle dorsiflexion; hip and knee bent	
Dorsiflex from the mid-position	C___

Table 15.7 (continued)

Motor club assessment: functional movement activities		
Scoring		
0 = Impossible (no cooperation, help from two or more people)		
1 = Assistance (patient cooperates; help of only one person required)		
2 = Independent with use of aid		
3 = Independent		
X = Not tested (state why)		
Grade	**Activity**	**Notes**
___	Supine to left side sitting	Pulling on edge of bed = aid
___	Supine to right side sitting	Pulling on edge of bed = aid
___	Bridging	Using unaffected leg to help affected/bad leg straighten = aid
___	Sitting balance (60 s)	Use of hands for support = aid
___	Sitting, touch floor and return	Use of hands for support going down or up = aid
___	Sitting to standing	Use of hands to push down on chair for standing = aid
Grade	**Activity**	**Notes**
___	Standing balance (30 s)	Must have both feet on the floor. Use of chair, stick, etc. = aid
___	Standing on left leg (5 s)	Use of chair, stick, etc. = aid
___	Standing on right leg (5 s)	Use of chair, stick, etc. = aid
___	Standing, get down on floor	Use of chair, stick, etc. = aid
___	Kneel standing balance (10 s)	Use of stool, etc. = aid
___	Kneel standing, left (5 s)	Use of stool, etc. = aid
___	Kneel standing, right (5 s)	Use of stool, etc. = aid
___	Get up from floor to standing	Use of stool, etc. = aid
___	Transfer sitting on chair to lying on bed	Use of tripod/stick = aid Support on bed/chair = 1
___	Transfer lying on bed to sitting on chair	Use of tripod/stick = aid Support on bed/chair = 1
___	Walking (15 m)	Also record time and aid used
___	Stairs (up and down 10 steps)	Also record time and aid used
___	Total	

Disadvantages: There have been no formal validity studies, and the scale has not been used frequently. The data are ordinal and the assessment would not likely be sensitive to small changes in muscle strength.

Disease-Specific Functional Assessments

Motor Neuron Disease

Amyotrophic Lateral Sclerosis Functional Rating Scale (ALSFRS-R)

The ALSFRS-R is perhaps the most widely utilized functional rating scale in the motor neuron disease population to date. It was designed to assess the ability of ALS patients to perform activities of daily living in order to determine if there is any functional improvement or decline during a study period [3] (Table 15.8). The ALSFRS-R assesses three bulbar functions, two upper extremity functions (cutting

Table 15.8 ALSFRS-R

1.	*Speech*	
	4	Normal speech processes
	3	Detectable speech disturbance
	2	Intelligible with repeating
	1	Speech combined with nonvocal communication
	0	Loss of useful speech
2.	*Salivation*	
	4	Normal
	3	Slight but definite excess of saliva in mouth; may have nighttime drooling
	2	Moderately excessive saliva; may have minimal drooling
	1	Marked excess of saliva with some drooling
	0	Marked drooling; requires constant tissue or handkerchief
3.	*Swallowing*	
	4	Normal eating habits
	3	Early eating problems – occasional choking
	2	Dietary consistency changes
	1	Needs supplemental tube feeding
	0	NPO (exclusively parenteral or enteral feeding)
4.	*Handwriting*	
	4	Normal
	3	Slow or sloppy: all words are legible
	2	Not all words are legible
	1	Able to grip pen but unable to write
	0	Unable to grip pen
5a.	*Cutting food and handling utensils* (*patients without gastrostomy*)	
	4	Normal
	3	Somewhat slow and clumsy, but no help needed
	2	Can cut most foods, although clumsy and slow; some help needed
	1	Food must be cut by someone, but can still feed slowly
	0	Needs to be fed
5b.	*Cutting food and handling utensils* (*alternate scale for patients with gastrostomy*)	
	4	Normal
	3	Clumsy but able to perform all manipulations independently
	2	Some help needed with closures and fasteners
	1	Provides minimal assistance to caregiver
	D	Unable to perform any aspect of task
6.	*Dressing and hygiene*	
	4	Normal function
	3	Independent and complete self-care with effort or decreased efficiency
	2	Intermittent assistance or substitute methods
	1	Needs attendant for self-care
	0	Total dependence
7.	*Turning in bed and adjusting bed clothes*	
	4	Normal
	3	Somewhat slow and clumsy, but no help needed
	2	Can turn alone or adjust sheets, but with great difficulty
	1	Can initiate, but not turn or adjust sheets alone
	0	Helpless
8.	*Walking*	
	4	Normal.
	3	Early ambulation difficulties.
	2	Walks with assistance.
	1	Non-ambulatory functional movement only.
	0	No purposeful leg movement.
9.	*Climbing stairs*	
	4	Normal
	3	Slow
	2	Mild unsteadiness or fatigue
	1	Needs assistance
	0	Cannot do
10.	*Dyspnea*	
	4	None
	3	Occurs when walking
	2	Occurs with one or more of the following: eating, bathing, dressing (ADL)
	1	Occurs at rest, difficulty breathing when either sitting or lying
	0	Significant difficulty, considering using mechanical respiratory support
11.	*Orthopnea*	
	4	None
	3	Some difficulty sleeping due to shortness of breath, does not routinely use >2 pillows
	2	Needs extra pillows to sleep (>2)
	1	Can only sleep sitting up
	0	Unable to sleep
12.	*Respiratory insufficiency*	
	4	None
	3	Intermittent use of BIPAP
	2	Continuous use of BIPAP at night
	1	Continuous use of BIPAP day and night
	0	Invasive mechanical ventilation by intubation/trach

food and dressing), two lower extremity functions (walking and climbing), two other functions (dressing-hygiene and turning in bed), and three respiratory functions. The score ranges from 48 (normal function) to 0 (unable to attempt the task). The instrument can be administered by a physician, nurse, physical therapist, or trained assistant. The patient's response to how they perform each activity is recorded to the closest approximation from a list of five choices, scored from 0 to 4.

Advantages: The ALSFRS-R is simple, easy to administer, and takes approximately 10 min to complete. It is a sensitive, accurate, and reproducible measure of the clinical course of ALS patients. It has been used extensively in ALS clinical trials and correlates well with quantitative strength testing results. As a result of its widespread use, a large volume of control data are available from prior trials. The expected rate of decline in large populations of motor neuron disease patients adds utility for this measure as a comparison to historical controls.

Table 15.9 Appel ALS scale

Appel ALS Scale

Bulbar Sub-score			6-30
Swallowing Grade	3-15		
Speech Grade	3-15		
Respiratory Sub-score			6-30
Vital Capacity Grade	6-30		
Muscle Strength Sub-score			6-36
Upper Extremity Muscle Strength Grade	2-14		
Lower Extremity Muscle Strength Grade	2-14		
Hand Grip Grade	1-4		
Lateral Pinch Grade	1-4		
Lower Extremity Muscle Function Sub-score			6-35
Stand from Chair Grade	1-5		
Stand from Lying Grade	1-6		
Walk 20 feet	1-5		
Need for Assistive Devices Grade	1-5		
Climb & Descend Four Standard Steps Grade	1-6		
Hips and Legs Grade	1-8		
Upper Extremity Muscle Function Sub-score			6-33
Dress and Feed Self Grade	1-5		
Propel Wheelchair 20 Feet Grade	1-6		TOTAL APPEL ALS SCALE SCORE
Arms and Shoulders Grade	1-6		
Cut Theraplast Grade	1-6		
Pegboard Grade	1-5		
Block Coordination Grade	1-5		30-164

Disadvantages: The ALSFRS-R is an ordinal scale and is likely insensitive to small differences. The scale cannot give information regarding the reason for a decline or disability (i.e., weakness, spasticity, rigidity, etc.).

Appel ALS Scale

The Appel scale was developed as a quantitative estimate of clinical status and disease progression in amyotrophic lateral sclerosis (ALS) patients [45, 46]. The total Appel scale score consists of five domain subscores: bulbar, respiratory, muscle strength, lower extremity function, and upper extremity function (Table 15.9). The scale consists of 16 tests (one pulmonary and 15 extremity tests) and three subjective evaluations. The muscle strength subscore consists of manual muscle testing according to the Medical Research Council grading system [11]. The evaluation yields a total Appel ALS score (starting from 30 for healthy subjects and 164 for maximum impairment) and a subscore for each group of the functions

tested. A retrospective analysis of 1,200 patients, using the Appel scale, has identified important risk factors for disease progression as well as validation with clinical progression on examination [45].

Advantages: The Appel ALS scale has been one of the most widely used composite indices of disease progression among ALS patients, surpassed by the ALSFRS-R score noted above. There is a large volume of data using this scale, reflecting the natural progression of disease, and this can be useful for comparison with smaller samples of patients. The scale is very well suited to a multidisciplinary evaluation of the ALS patient with individual subscales being derived by specialized therapists (occupational, physical, speech, etc.).

Disadvantages: The scale is more time and labor intensive than other composite scores of progressive motor impairment. There is some specialized equipment required, and the evaluations are not all "standard" components of a routine neurologic evaluation in centers not using this measure. Individual subscales have not been validated separately although the tendency to interpret these component subscales as similar markers of linear disease progression can be misleading.

Norris ALS Scale

The Norris scale was also designed as a measure of disease progression in ALS patients [47]. The scale uses a four-point categorical grading of both impairments and disabilities in all levels of the neuraxis (Table 15.10). Motor functions, reflecting both signs and symptoms, are graded as either normal, impaired, minimally present (trace), or not present. Deep tendon reflexes, jaw jerk reflex, Hoffman's sign, and the extent of atrophy with fasciculations are all evaluated in this composite score.

Advantages: The Norris scale is fairly easy to administer, not requiring specialized equipment. It has been used most extensively in evaluating motor neuron disease. Much of the evaluation is done routinely as part of a standard follow-up evaluation for patients with progressive weakness.

Disadvantages: The scale is primarily oriented to patients with progressive motor neuron disease and may not be as appropriate or sensitive to more indolent changes in other disease states. This is an ordinal scale, and the implications of relative changes at both the low and high end of the range cannot be made. The scale includes both measures of functional disability *and* elements of the neurologic examination. This combination assumes a good correlation between disability and clinical pathology, which may not be true. If, for example, hyperreflexia does not correlate with a greater functional disability, the combination of both elements in the same scale may lessen the sensitivity to detecting small changes in either.

Table 15.10 The NORRIS ALS scale [48]

	3 (normal)	2 (impaired)	1 (trace)	0 (no use)
1. Hold up head (test)				
2. Chewing (history)				
3. Swallowing (test)				
4. Speech (test)				
5. Roll over (test)				
6. Sit up (test)				
7. Bowel/bladder pressure (history)				
8. Breathing (test)				
9. Cough (test)				
10. Write (test)				
11. Buttons, zippers (test)				
12. Feeding (history)				
13. Grip/lift self (test)				
14. Grip/lift book, tray (test)				
15. Grip/lift fork, pencil (test)				
16. Change arm position (test)				
17. Climb stairs (test)				
18. Walk (test)				
19. Walk one room (test 15 ft)				
20. Walk assisted (test only if assist required above)				
21. Stand (test)				
22. Change leg position (test)				
23. Biceps, brachioradialis, triceps muscle stretch reflexes (test)				
24. Quadriceps, Achilles, internal hamstring muscle stretch reflexes (test)				
25. Jaw jerk (test)				
26. Plantar response – right (test)				
27. Plantar response – left (test)				
28. Fasciculation (test)				
29. Atrophy – face (test)				
30. Atrophy – arms, shoulders (test)				
31. Atrophy – legs, hips (test)				
32. Labile emotions (history and observation)				
33. Fatigability (test): requiring only two grades: 2 (normal) or 0 (present)				
34. Leg rigidity (test): requiring only two grades: 2 (normal) or 0 (present)				

Point scores range from 0 (maximum impairment) to 100 (healthy)

Table 15.11 CNS-LS

CNS-LS

	Applies never	Applies rarely	Applies occasionally	Applies frequently	Applies most of the time	
	1	2	3	4	5	
Assessment questions						**Answers**
There are times when I feel fine one minute, and then I'll become tearful the next over something small or for no reason at all.						
Others have told me that I seem to become amused very easily, or that I seem to become amused about things that really aren't funny.						
I find myself crying very easily.						
I find that even when I try to control my laughter, I am often unable to do so.						
There are times when I won't be thinking of anything happy or funny at all, but then I'll suddenly be overcome by funny or happy thoughts.						
I find that even when I try to control my crying, I am often unable to do so.						
I find that I am easily overcome by laughter.						

CNS Lability Scale

The Central Nervous System Lability Scale (CNS-LS) is a 7-question validated scale that provides a score which assesses the frequency and severity of episodes of inappropriate laughter and crying (Table 15.11) [49, 50]. A score greater than 11 is considered abnormal and should prompt discussion with the patient regarding possible treatments. The CNS-LS was a secondary endpoint leading to the approval of dextromethorphan/quinidine as the first and only FDA-approved treatment for pseudobulbar affect.

Advantages: The CNS-LS is the only scale which has been validated to measure the severity of pseudobulbar affect in patients with ALS and multiple sclerosis. The scale takes less than a minute to complete.

Disadvantages: The total score may not actually reflect the burden of the PBA symptoms to the patient and caregiver. Patients with scores >11 may not perceive a need for treatment.

SMAFRS

The Spinal Muscular Atrophy Functional Rating Scale (SMAFRS) was adapted from the ALSFRS to assess function in patients with SMA [51, 52]. Patients (or caregivers) are asked to compare how they are today versus how they were before the start of the disease. Patients are graded from 0 to 5 with 5 being no restrictions or normal and 0 being unable to perform. Categories covered are (1) eating, (2) dressing upper body, (3) dressing lower body, (4) bathing, (5) toileting, (6) grooming and oral hygiene, (7) turning in bed and adjusting bed clothes, (8) transfers, (9) walking, and (10) climbing stairs.

Advantages: The SMAFRS is simple, easy to administer, and takes less than 10 min to complete. The instrument was used as a secondary outcome measure in a trial of gabapentin.

Disadvantages: The SMAFRS is insensitive to small differences.

ACTS

The Amyotrophic Lateral Sclerosis Ciliary Neurotrophic Factor Treatment Study ALS Evaluation is a composite measure adapted from multiple independent measurement scales developed earlier [21, 23, 53]. This scale was developed specifically for comprehensive evaluation of ALS patients receiving experimental ciliary neurotrophic factor (CNTF), taking into account impairments *and* disabilities as outlined in the ICIDH guidelines. Impairments are measured by:

- Quantitatively evaluating the rate of speech generated
- Pulmonary function tests

- Purdue pegboard testing
- Timing a 15-ft walk
- Isometric muscle testing in ten muscle groups using computerized dynamometry
- Ordinal scale grading of spasticity, fasciculations, atrophy, and cramping

Standardized scores matching for age and gender are available for comparison [54, 55]. Disability is measured by the ALSFRS scale, described below.

Advantages: The ACTS index has been validated in a large cohort of ALS patients [3]. Consequently, a large volume of data (from patients and normal controls) is available, enhancing the reliability of the test and providing empiric estimates of variability critical to sample size determination. The multidimensional aspect of the test yields a composite index of both functional impairments and physical disabilities important when evaluating a disease with multisystem involvement.

Disadvantages: Specialized equipment and training are required for reliable testing. The testing procedure has been developed for and tested only in ALS patients. The composite ACTS score may be insensitive to heterogeneous changes in muscle strength or functional capability. Differences in strength between proximal (stronger) muscles and distal (weaker) muscles are lost when the overall "percent predicted" value of muscle strength is derived by combining values from the two muscle groups. Similarly, if muscle groups, stronger at the start of a trial, became weaker at a slower rate than those which were weaker at the outset, then this difference could not be detected.

Myopathy

IBMFRS

The Inclusion Body Myositis Functional Rating Scale (IBMFRS) was adapted from the ALSFRS to assess function in patients with IBM [56]. The areas addressed in the questionnaire include swallowing, handwriting, cutting food and handling utensils, fine motor tasks, dressing, hygiene, turning in bed and adjusting covers, sitting to standing, walking, and climbing stairs. Answers to each item are graded on a 0–4 scale, with 4 being normal and 0 being unable to perform. The best possible score is 40.

Advantages: The IBMFRS is the first functional scale developed exclusively for IBM clinical trials. It can be administered in less than 10 min and does not require any expensive, specialized equipment, or personnel training to administer. The IBMFRS was utilized as a secondary outcome measure in a multicenter pilot trial of the clinical safety and tolerability of high-dose beta-interferon-1a. It appeared to correlate well with traditional measures of efficacy (MMT and MVIC) and was the measure most sensitive to change over time.

Disadvantages: Further studies are needed to determine whether the IBMFRS can also be self-administered or given over the phone.

Myositis Intention to Treat Activities Index (MITAX)

The MITAX assesses specific manifestations in seven organs/systems, including constitutional, cutaneous, skeletal, gastrointestinal, pulmonary, cardiac, and muscular [57, 58]. Each question is answered as 0 = not present, 1 = improving, 2 = the same, 3 = worse, or 4 = new. This score is then converted by a scoring schema to a final score ranging from A to E for each system, where A indicates very active disease requiring treatment with high-dose daily corticosteroids or a significant immunosuppressive therapy, B indicates a need for modest doses of corticosteroids and/or ongoing immunosuppression, C indicates a need for low-dose steroids or symptomatic drugs only, D indicates the system is no longer active, and E indicates that the system was never active. Each organ system receives only a single A–E score (which can be numerically converted to A = 9, B = 3, C = 1, and D/E = 0 to obtain a global score) based on the score of the most severe item in that organ system. The organ system scores are summed to obtain a total MITAX score with a range of 0–63 or 0–54 when the muscular system is excluded.

Advantages: The MITAX is accepted by the Pediatric Rheumatology International Trials Organization as a core set measure to assess the core set domain of global disease activity tool. The MITAX has excellent content validity, good inter-rater reliability, and excellent responsiveness. The criterion validity of the MITAX score supports use in the clinical setting. The time to administer the tool would not be much greater than a routine clinical assessment.

Disadvantages: For a patient with a complex condition, it can take up to 15–20 min to complete.

Myositis Disease Activity Assessment (MYOACT)

The MYOACT is a tool that assesses disease activity of extramuscular organ systems and muscle to assess patients with adult and juvenile dermatomyositis (DM), polymyositis (PM), and inclusion body myositis (IBM) (57, Rider, 2011 #6792). The MYOACT is a series of physician's assessment of disease activity in various organ systems based on history and examination, using a VAS to assess the severity of activity. Each organ system is scored from 0 to 10 cm, and the 6 extramuscular organ systems can be summed to obtain an extramuscular score of 0–60 cm or a total score that includes the muscle system that ranges from 0 to 70 cm.

Advantages: The MYOACT is accepted by the Pediatric Rheumatology International Trials Organization as a core set measure to assess the core set domain of global disease activity tool. The MYOACT has excellent content validity, with a large amount of input in their development from myositis researchers. It has good inter-rater reliability, moderate construct validity, and excellent responsiveness in adult and

Table 15.12 Quantitative Myasthenia Gravis Scale

Test items weakness	None	Mild	Moderate	Severe	Score
Grade	0	1	2	3	
Double vision (lateral gaze) sec.	60	11–59	1–10	Spontaneous	
Ptosis (upward gaze) sec.	60	11–59	1–10	Spontaneous	
Facial muscles	Normal lid closure	Complete, weak, some resistance	Complete, without resistance	Incomplete	
Swallowing 4 oz. water (1/2 cup)	Normal	Minimal coughing or throat clearing	Severe coughing, choking, or nasal regurgitation	Cannot swallow (test not attempted)	
Speech following counting aloud from 1 to 50 (onset of dysarthria)	None at #50	Dysarthria at #30–49	Dysarthria at #10–29	Dysarthria at #9	
Right arm outstretched (90°, sitting) sec.	240	90–239	10–89	0–9	
Left arm outstretched (90°, sitting) sec.	240	90–239	10–89	0–9	
Forced vital capacity	>80 %	65–79 %	50–64 %	<50 %	
Rt handgrip: male	>45	15–44	5–14	0–4	
(Kg): female	>30	10–29	5–9	0–4	
Left handgrip: male	>35	15–34	5–14	0–4	
(Kg): female	>25	10–24	5–9	0–4	
Head, lifted (45 %, supine) sec.	120	30–119	1–29	0	
Right leg outstretched (45–50 %, supine) sec.	100	31–99	1–30	0	
Left leg outstretched (45–50 %, supine) sec.	100	31–99	1–30	0	

juvenile PM/DM patients. To assess a patient in remission or close to remission takes less than 5 min.

Disadvantages: For a patient with a complex condition, it can take up to 15–20 min to complete. The VAS may be subjective and somewhat dependent on the experience of the rater.

Myasthenia Gravis

Quantitative Myasthenia Gravis (MG) (QMG) Score

The QMG was initially developed by Besinger and Toyka in 1981 and later modified by Tindall et al. [4] and Barohn et al. [5]. The QMG consists of 13 independent assessments including:

- The time to develop diplopia with prolonged lateral gaze
- The time to develop ptosis with prolonged upgaze
- Facial strength
- Ability to swallow 1/2 cup of water
- Speech following counting aloud from 1 to 50
- The time the patient can outstretch either arm
- Vital capacity
- Right and left grip strength
- The time the patient can lift head 45° in a supine position
- The time the patient can outstretch either leg

Each item is graded from 0 (normal) to 3 (severe weakness) with a total score ranging from 0 to 39 (Table 15.12).

This measure has been widely used in many MG trials and has been recommended as a primary outcome measure. It is frequently compared with the MG Composite score (see below) by the MG task force. This easy to use scale has been validated and has high reliability in accessing relevant clinical changes. There is also a measurement of fatigability within the measure, and this has been especially relevant to measurement of outcome in MG [4, 5, 59, 60].

Advantages: Inter-examiner reliability has been demonstrated for the QMG, and it has been used in several MG therapeutic trials (mycophenolate, IVIG) as an outcome measure.

Disadvantages: A patient can have an improved total score but be incapacitated by poor strength in one or two areas; therefore, it does not necessarily reflect the patient's functional status. In addition, for similar reasons, it cannot be used to compare severity between patients. Completion of the QMG is time consuming, and some investigators have proposed only testing one arm and leg.

MG Composite Score

This score assesses a quantitative evaluation of signs and symptoms in ten functional domains. It is validated and reliable, and currently, the 2011–2012 MG task force is recommending this as the preferred primary outcome measure for clinical trials in MG (Table 15.13). It can be completed more quickly than the Quantitative MG Score [59, 61, 62].

Advantages: This scale is currently recommended by the MGFA task force as the preferred measure for subsequent trials in myasthenia gravis. It has been shown to be validated and reliable. A 3-point change in the scale is thought to be clinically meaningful and correlates with a myasthenia gravis quality of life scale.

Disadvantages: The scale involves reporting from both physician and patient. Ceiling and floor effects have not been addressed as possible confounds.

Table 15.13 MG composite scale

Ptosis, upward gaze (physician examination)	>45 s = 0	11–45 s = 1	1–10 s = 2	Immediate = 3
Double vision on lateral gaze, left or right (physician examination)	>45 s = 0	11–45 s = 1	1–10 s = 3	Immediate = 4
Eye closure (physician examination)	Normal = 0	Mild weakness (Can be forced open with effort) = 0	Moderate weakness (Can be forced open easily) = 1	Severe weakness (Unable to keep eyes closed) = 2
Talking (patient history)	Normal = 0	Intermittent slurring or nasal speech = 2	Constant slurring or nasal but can be understood = 4	Difficult to understand speech = 6
Chewing (patient history)	Normal = 0	Fatigue with solid food = 2	Fatigue with soft food = 4	Gastric tube = 6
Swallowing (patient history)	Normal = 0	Rare episode of choking or trouble swallowing = 2	Frequent trouble swallowing, for example, necessitating changes in diet = 5	Gastric tube = 6
Breathing (thought to be caused by MG)	Normal = 0	Shortness of breath with exertion = 2	Shortness of breath at rest = 4	Ventilator dependence = 9
Neck flexion or extension (weakest) (physician examination)	Normal = 0	Mild weakness = 1	Moderate weakness (i.e., ~50 % weak, ± 15 %) = 3	Severe weakness = 4
Shoulder abduction (physician examination)	Normal = 0	Mild weakness = 2	Moderate weakness (i.e., ~50 % weak, ± 15 %) = 4	Severe weakness = 5
Hip flexion (physician examination)	Normal = 0	Mild weakness = 2	Moderate weakness (i.e., ~50 % weak, ± 15 %) = 4	Severe weakness = 5

Myasthenic Muscular Score (MMS)

The MMS consists of nine assessments ranging from timed tasks (maintaining upper limbs horizontally and maintaining lower limbs above bed plane while supine) in which patients are assigned points based upon how long they can perform the test to functional activities (raising head above gravity, sitting up from a lying position, ocular muscle function, eyelid occlusion, chewing, swallowing, and speech) (Table 15.14). The timed tasks are scored from 0 to 15, and the functional assessments are scored from 0 to 10. The total score can range from 0 (most severely affected) to 100 (complete remission).

Advantages: The MMS has been used in two multicenter randomized trials. It can be administered in 5–10 min and does require any specialized training.

Disadvantages: The reproducibility of the MMS has not been assessed. In both trials in which this score was used as a primary endpoint, no difference was identified between the treatment groups (intravenous gamma globulin versus plasma exchange and prednisone versus azathioprine), suggesting that the instrument may not be sensitive in detecting small changes in clinical outcome.

Myasthenia Gravis Severity Scale (MSS)

The MSS was developed for use in a trial comparing intravenous gamma globulin and plasma exchange in the treatment of myasthenic crisis [63]. The scale rates ability to cough, ocular function, bulbar function, and extremity strength on a scale from 1 (most severely affected) to 3 (normal) and rates dyspnea on a scale from 1 (intubated) to 4 (asymptomatic). The total score, therefore, ranges from 5 to 16 (Table 15.15).

Table 15.14 Myasthenic Muscular Score

Maintain upper limbs horizontally outstretched	
1 point per 10 s	Maximum 15
	Minimum 0
Maintain lower limbs above bed plane, while lying on back	
1 point per 5 s	Maximum 15
	Minimum 0
Raise head above bed plane, while lying on back	
Against resistance	10
Without resistance	5
Impossible	0
Sit up from lying position	
Without help of hands	10
Impossible	0
Extrinsic ocular musculature	
Normal	10
Ptosis	5
Double vision	0
Eyelid occlusion	
Complete	10
Incomplete with corneal covering	5
Incomplete without corneal covering	0
Chewing	
Normal	10
Weak	5
Impossible	0
Swallowing	
Normal	10
Impaired without aspiration	5
Impaired with aspiration	0
Speech	
Normal	10
Nasal	5
Slurred	0

Advantages: The MSS was designed to functionally evaluate critically ill myasthenia gravis patients and, therefore, is heavily weighted to the assessment of respiratory function. It can be administered easily and quickly.

Disadvantages: The MSS is an insensitive measure in myasthenia gravis patients with mild to moderate disease.

Myasthenic Functional Score (MFS)

The MFS was used along with the Myasthenic Muscular Score in a trial comparing azathioprine to prednisone [64]. It is a five-grade functional scale, defined as 1: complete remission; 2: minor symptoms allowing normal activity, except for exertional activity; 3: moderate symptoms allowing occupational or partial daily activity; 4: major disability requiring discontinuation of occupational activity or major reduction of daily activity; and 5: major disability requiring continuous help by others or mechanical ventilation.

Advantages: The MFS can be performed quickly with no specialized training required.

Disadvantages: The MFS is a very crude assessment of function and is insensitive in detecting small changes in function.

Table 15.15 Myasthenia gravis severity scale

Dyspnea
1 = Intubated
2 = Dyspnea at rest
3 = Dyspnea on exertion
4 = None
Cough
1 = Intubated
2 = Weak
3 = Normal
Ocular
1 = Weakness at rest
2 = Weakness on fatigue
3 = None
Bulbar
1 = Weakness at rest
2 = Weakness on fatigue
3 = None
Extremities
1 = Worst affected muscle 3/5 or less
2 = Worst affected muscle 4/5 motor strength or weakness on fatigue
3 = No detectable weakness

Myasthenia Gravis Activities of Daily Living Score (MG ADL Score)

The MG ADL Score is an example of a disease-specific functional status measurement score. It consists of eight functional tasks which are scored on a scale from 0 (normal) to 3 (severe impairment): talking, chewing, swallowing, breathing, impairment of ability to brush teeth or comb hair, impairment of ability to arise from a chair or toilet, double vision, and eyelid droop (Table 15.16). The total score ranges between 0 and 24.

Advantages: The MG ADL Score is a disease-specific functional scale for MG which has been adopted in several MG clinical trials. It is simple and economical to administer and does not require an extensive amount of time to complete.

Disadvantages: The responses are largely subjective and based upon the patient's response rather than objective assessment of function.

Peripheral Neuropathy

Neuropathy Disability Scale

This functional scale was initially developed for use in a controlled trial of prednisone in acute polyneuropathy [65]. Patient function is ranked as: 0 (healthy), 1 (minor symptoms

Table 15.16 MG activities of daily living (ADL) scale

Grade	0	1	2	3	Score
Talking	Normal	Intermittent Slurring or nasal speech	Constant slurring or nasal, but can be understood	Difficult to understand speech	
Chewing	Normal	Fatigue with solid food	Fatigue with soft food	Gastric tube	
Swallowing	Normal	Rare episode of choking	Frequent choking necessitating changes in diet	Gastric tube	
Breathing	Normal	Shortness of breath with exertion	Shortness of breath at rest	Ventilator dependence	
Impairment of ability to brush teeth or comb hair	None	Extra effort, but no rest periods needed	Rest periods needed	Cannot do one of these functions	
Impairment of ability to arise from a chair or toilet	None	Mild, sometimes uses arms	Moderate, always uses arms	Severe, require assistance	
Double vision	None	Occurs, but not daily	Daily, but not constant	Constant	
Eyelid droop	None	Occurs, but not daily	Daily, but not constant	Constant	
			Total MG ADL Score ___		

Table 15.17 INCAT disability scale

Arm disability
0 = No upper limb problems
1 = Symptoms, in one or both arms, not affecting the ability to perform any of the following functions: doing all zips *and* buttons, washing *or* brushing hair, using a knife and fork together, and handling small coins
2 = Symptoms, in one arm or both arms, affecting but not preventing any of the above-mentioned functions
3 = Symptoms, in one arm or both arms, preventing one or two of the above-mentioned functions
4 = Symptoms, in one arm or both arms, preventing three or all of the functions listed, but some purposeful movements still possible
5 = Inability to use either arm for any purposeful movement
Leg disability
0 = Walking not affected
1 = Walking affected, but walks independently outdoors
2 = Usually uses unilateral support (stick, single crutch, one arm) to walk outdoors
3 = Usually uses bilateral support (sticks, crutches, frame, two arms) to walk outdoors
4 = Usually uses wheelchair to travel outdoors, but able to stand and walk a few steps with help
5 = Restricted to wheelchair, unable to stand and walk a few steps with help
Overall disability = Sum of arm and leg disability

or signs, able to run), 2 (able to walk >5 m without assistance but unable to run), 3 (able to walk >5 m with assistance), 4 (bed or chair bound), 5 (requiring assisted ventilation for at least part of the day), and 6 (dead). This scale can be self-administered, administered face to face, or administered over the telephone.

Advantages: The Neuropathy Disability Scale is simple, reliable, and can be administered quickly.

Disadvantages: The Neuropathy Disability Scale is unable to distinguish between the potentially wide ranges of functional disability within particular grades and has not been systematically validated. The difference between grade 2 and grade 1 is at times difficult to determine, particularly in older individuals who are not in the habit of running [66]. It has also not been compared to other universally accepted functional outcome scales.

INCAT Disability Scale

The INCAT Disability Scale was initially used as the primary outcome measurement in a trial comparing intravenous immunoglobulin versus oral prednisone in chronic inflammatory demyelinating polyneuropathy (CIDP) (Table 15.17) [67]. It was subsequently used in a randomized, response-conditional crossover trial of immunoglobulin versus placebo. Participants whose INCAT score did not improve by > 1 point received alternate treatment in a 24-week crossover period.

Advantages: The scale is simple to perform and has been established as the primary endpoint in two pivotal trials in CIDP. A very similar scale has been validated as reproducible and responsive to change [68]

Disadvantages: The scale may not be sensitive to small changes in strength or function and does not assess the function of sensory nerves.

CMT Neuropathy Scale

The CMT Neuropathy Score (CMTNS) was modified from the earlier total neuropathy score, a composite measure of disability in length-dependent axonal neuropathies (Table 15.18). The CMTNS provides a single measure of function and disability in patients with Charcot-Marie-Tooth Disease [69].

Advantages: The CMTNS is validated measure of length-dependent axonal and demyelinating CMT disability and has been used as an end point for longitudinal studies and clinical trials of CMT. The test is short and can usually be administered in several minutes. The CMTNS has also can be used for demyelinating and/or axonal length-dependent neuropathies.

Disadvantages: Within the CMTNS, some measurements (such as the sensory nerve amplitude, vibration) may be expected to decrease with the patient's age and therefore could artificially affect the score. The authors of the test emphasize the importance of age-matched controls. There have also been concerns for both floor and ceiling effects with the use of the CMTNS.

Overall Neuropathy Limitations Scale (ONLS)

The ONLS is a measure of disability in patients with peripheral neuropathies (Table 15.19). The scale focuses on common activities of daily living. It is composed of one section with measurements relative to the lower limb and mobility and another for the upper limb [70].

There are 14 total items and 2 domains (arm scale, 7 items; leg scale, 7 items) with a final score between 0 and 12. Higher scores indicate greater limitations.

ONLS can be administered as an interview or as an observation in patients with communication or cognitive difficulties.

Advantages: This is a short, easily administered, validated test in patients with peripheral neuropathy. The scale surveys both functional limitations (turning a key, use of utensils, etc.) as well as an objective/subjective grade of motor strength and disability. It can be used in patients with communication or cognitive impairment.

Disadvantages: Due to the broad spectrum of disability that can be associated with neuropathy, the ONLS may not be especially sensitive to more selective or focal deficits as seen in sensory predominant neuropathy, multifocal neuropathy, or mononeuropathy.

This may be of use to people with communication or cognitive difficulties. If it is to be based upon an observed score, the following equipment is required: a key and lock, hair brush, knife and fork (or other eating implements, e.g., chopsticks), and a shirt with buttons and zips.

Table 15.18 CMT Neuropathy Score

	Score				
Parameter	0	1	2	3	4
Sensory symptoms	None	Limited to toes	Extend up to and may include ankle	Extend up to and may include knee	Extends above knees
Motor symptoms					
Legs	None	Trips, catches toes, slaps feet	AFO on at least 1 leg or ankle support	Cane, walker, ankle surgery	Wheelchair most of the time
Arms	None	Difficulty with buttons/ zippers	Unable to do buttons or zippers but can write	Cannot write or use keyboard	Proximal arms
Pin sensibility	Normal	Reduced in fingers/toes	Reduced up to and may include wrist/ankle	Reduced up to and may include elbow/knee	Reduced above elbow/knee
Vibration	Normal	Reduced at fingers/toes	Reduced at wrist/ankle	Reduced at elbow/knee	Reduced above elbow/knee
Strength					
Legs	Normal	4+, 4, or 4– on foot dorsiflexion	≤3 ft dorsiflexion	≤3 dorsiflexion and plantar flexion	Proximal weakness
Arms	Normal	4+, 4, or 4– on intrinsics or finger extensors	≤3 intrinsics or finger extensors	<5 wrist extensors	Weak above elbow
Ulnar CMAP (median)	>6 mV (>4 mV)	4.0–5.9 mV (2.8–3.9)	2.0–3.9 mV (1.2–2.7)	0.1–1.9 mV (0.1–1.1)	Absent (absent)
Ulnar SNAP (median)	>9 μV (>22 μV)	6.0–8.9 μV (14.0–21.9)	3.0–5.9 μV (7.0–13.9)	0.1–2.9 μV (0.1–6.9)	Absent (absent)
Total (max. 36)					

AFO ankle-foot orthosis, *CMAP* compound muscle potential, *SNAP* sensory nerve action potential

Sensory Scales

Perceptions of sensory stimuli are among the most challenging to quantitate. By definition, sensation is dependent upon the patient's perception and report of the testing stimuli. Consequently, a patient's prior experience and current emotional state confound clinical detection of sensory pathology by physical examination.

Quantitative sensory testing (QST) is based on methods that define not only the stimulus (type, characteristics, quantity, presentation, testing format, and environment) but also the response (form and analysis) [71]. Using available computer technology, it is possible to deliver precisely defined stimuli, which can be quantified and graded over a broad range of intensities. Graded intensities of pressure, temperature, vibration, and light touch can be consistently delivered via a commercially available apparatus.

The main application for QST is in quantifying modality-specific detection thresholds [72]. These methods can standardize an important, but historically, variable aspect of the neurologic examination.

Computer Aided Sensory Evaluator System IV (CASE IV)

The CASE IV system has been utilized in several clinical trials evaluating peripheral neuropathy patients [73–75]. This automated, commercially available device allows for reliable assessment of several sensory modalities including temperature, pain, vibration, and pressure. These stimuli directly activate sensory receptors. Computerized sensory testing allows the stimulus intensity to be varied in a fixed pattern. Patients are asked to report which changes in intensity are detectable.

Available software for QST allows for a *forced-choice algorithm* where subjects are told that a stimulus will be delivered in one of two intervals. Subjects are forced to choose in which interval the stimulus was delivered. If the correct interval is chosen, the intensity is reduced in the next presentation. The interval in which the stimulus is presented is randomly varied. Through repeat testing and varying the stimulus intensity, the threshold below which the subject has a predetermined chance (50 or 75 %) of guessing correctly can be determined. Approximately 10–15 min may be required to administer a single forced-choice QST. If multiple modalities are tested in multiple nerves, several hours may be required to complete an entire testing session.

An alternative algorithm, referred to as the *4-2-1 stepping algorithm*, is more time efficient. Using a single stimulus interval, a mid-intensity stimulus is delivered. If it is perceived, intensity is reduced by 4 threshold differences (referred to as just-noticeable differences, which are standardized) until the stimuli are no longer detectable. The intensity is then increased by 2 *just-noticeable differences* until it is again perceived. This protocol requires only 3 min per modality and, therefore, is considerably more time efficient [76].

Advantages: Ideally, this level of stimulus control results in a testing procedure which yields more unified sensory responses to selected stimuli. Data from QST can also be correlated with the amplitude of a sensory nerve action potential and eventually with the number and sizes of nerve fibers. In detecting patterns of sensory abnormality, QST can

Table 15.19 The overall neuropathy limitations scale [70]

ARM SCALE

Does the patient have any symptoms in their hands or arms, eg tingling, numbness or weakness?
Yes ☐ **No** ☐ (if "no", please go to "legs" section)

Is the patient affected in their ability to:	Not affected	Affected, but not prevented	Prevented
Wash and brush their hair	☐	☐	☐
Turn a key in a lock	☐	☐	☐
Use a knife and fork together (or spoon, if knife and fork not used)	☐	☐	☐
Do or undo button or zips	☐	☐	☐
Dress the upper part of their body excluding buttons or zips	☐	☐	☐

If all these functions are prevented can the patient make purposeful movements with their bands or arms? Yes ☐ No ☐ Not applicable ☐

Arm Grade
0 = Normal
1 = Minor symptoms in one or both arms but not affecting any of the functions listed **SCORE = ____**
2 = Disability in one or both arms affecting but not preventing any of the functions listed
3 = Disability in one or both arms preventing at least one but not all functions listed
4 = Disability in both arms preventing all functions listed but purposeful movement still possible
5 = Disability in both arms preventing all purposeful movements

LEG SCALE

	Yes	No	Not applicable
Does the patient have difficulty running or climbing stairs?	☐	☐	☐
Does the patient have difficulty with walking?	☐	☐	☐
Does their gait look abnormal?	☐	☐	☐
How do they mobilize for about 10 meters (i.e. 33 feet)?			
Without aid	☐	☐	☐
With one stick or crutch or holding someone's arm	☐	☐	☐
With two sticks or crutches or one stick or crutch holding onto someone's arm or frame	☐	☐	☐
With a wheelchair	☐	☐	☐
If they use a wheelchair, can they stand and walk 1 meter with the help of one person?	☐	☐	☐
If they cannot walk as above are they able to make some purposeful movements of their legs, eg reposition legs in bed?	☐	☐	☐

Does the patient use **ankle foot orthoses/braces?** (please circle) ☐ ☐ **If yes:** (please circle) **right/left**

Leg Grade
0 = Walking/climbing stairs/running not affected
1 = Walking/climbing stairs/running is affected, but gait does not look abnormal SCORE = ____
2 = Walks independently but gait looks abnormal
3 = Requires unilateral support to walk 10 meters (stick, single crutch, one arm)
4 = Requires bilateral support to walk 10 meters (sticks, crutches, crutch and arm, frame)
5= Requires wheelchair to travel 10 meters but able to stand and walk 1 meter with the help of one person
6 = Restricted to wheelchair, unable to stand and walk 1 meter with the help of one person, but able to make some purposeful leg movements
7 = Restricted to wheelchair or bed most of the day, unable to make any purposeful movements of the legs

Overall Neuropathy Limitation Scale = arm scale (range 0 to 5) + leg scale (range 0 to 7):
|range 0 (no disability) to 12 (maximum disability)| TOTAL SCORE: ____

Is there any disorder, other than peripheral neuropathy, which affects the above functions? **Yes** ☐ **No** ☐
If **yes**, please describe:

Fig. 15.1 Arrangement to perform the quantitative sudomotor axon reflex test

also suggest the presence of specific diseases and be used to follow the course of the sensory loss [71].

Quantifying and monitoring sensory pathology can involve the use of summated or averaged sensory nerve action potential amplitudes. These data can be correlated with vibratory detection thresholds which are sensitive, specific, and highly reproducible for the assessment of large myelinated sensory fibers. Quantitative evaluation of cooling and warming detection thresholds yields an estimate of pathology in small myelinated sensory fibers. Although less well validated for longitudinal trials, a visual analogue scale scoring of heat pain provides an additional assessment of unmyelinated sensory fibers. Heart rate variation to deep breathing, Valsalva, or standing is useful to assess cardiac autonomic function [7].

Disadvantages: Despite the consistency of the stimuli presented, accurate testing still requires significant patient cooperation and attention. The data are not entirely objective; as with any sensory testing, the patient's subjective perception is the primary endpoint. Equipment is commercially available but expensive. The time involved in testing sessions can be long, further increasing the expense of acquiring these data.

QSART

The quantitative sudomotor axon reflex test (QSART) is designed to look at small nerve fibers which innervate sweat glands [77, 78].

The test includes measures of resting skin temperature, resting sweat output, and stimulated sweat output. Upper and lower extremities are sampled. A plastic collection cup is placed on the skin. Temperature and sweat production under the skin can be measured. Sweat production is stimulated via iontophoretic application of acetylcholine delivered through the skin.

Advantages: Evaluation of sudomotor function is a technical and logistic challenge. The QSART is a commercially available apparatus that can standardize sudomotor function within the context of a clinical trial or laboratory.

Disadvantages: Specialized equipment must be purchased along with the availability of a trained technician. The test usually takes approximately 45 min to complete and may invoke mild burning discomfort to the patient (Fig. 15.1 [79]).

Nerve Conduction Studies

Nerve conduction studies have been used as markers of disease progression in clinical trials of polyneuropathy [72]. A decrease in conduction velocity is a fairly specific index for loss of large myelinated axons [80, 81]. If sensory conduction is unchanged, a reduction in the amplitude of the motor response is very specific for a loss of motor axons at the level of the motor root or anterior horn cell, by contrast to the generalized changes expected in a polyneuropathy [7]. Late responses (F-wave and H-reflex) can also be useful in measuring conduction over long segments, avoiding the errors incurred in distance measurements. In trials which include patients with severe polyneuropathy (significant loss of fibers), concurrent study of less affected upper extremities is important to insure that normal responses are detectable. In trials targeting more mild neuropathy, nerve conduction studies limited to the lower extremities may be sufficient due to the length-dependent pathology [7]. Careful consideration must be given to studying the *rate of change* rather than the actual value of amplitude or velocity in trials using nerve conduction data. Physiologic variability contributed by a patient's age, limb temperature, and body habitus can confound electrophysiologic data collection.

Advantages: Techniques for testing sensory nerve conduction are standardized. Electrophysiologic equipment is readily available and used in routine practice.

Table 15.20 Modified Ashworth scale for grading spasticity

Grade	Description
0	No increase in muscle tone
1	Slight increase in muscle tone, manifested by a catch and release or by minimal resistance at the end of the range of motion when the affected part(s) is moved in flexion or extension
2	More marked increase in muscle tone through most of ROM, but affected part(s) easily moved
3	Considerable increase in muscle tone, passive movement difficult
4	Affected part(s) rigid in flexion or extension

Disadvantages: Nerve conduction studies are generally insensitive to small fiber loss which is common in many neuropathies. Variables such as temperature, measurement, and the patient's age and height can add significant sources of measurement error.

Spasticity Scales

Validation of spasticity scales as an outcome measure in neuromuscular disease and especially ALS clinical trials is limited. Whether increased muscle tone correlates with impairment and, therefore, whether or not it is a valid indicator of clinical improvement or deterioration will ultimately require further study.

Modified Ashworth Scale

The Ashworth scale was originally developed for use in a trial of carisoprodol in multiple sclerosis patients to assess spasticity in the upper and lower extremities [82]. It is the only clinical measurement of abnormal muscle tone which has been formally evaluated [83]. The modified Ashworth scale consists of an ordinal scale which grades spasticity on a scale from 0 (no increase in tone) to 4 (Table 15.20). The grading was modified to be opposite to that which was originally reported by Ashworth where normal tone was given a grade of 4. Spasticity is assessed by passive range of motion on flexion and extension of the forearm at the elbow and on flexion and extension movement about the knee.

Advantages: The Ashworth scale has been shown to be a valid measurement of spasticity, and reliability has been proven at the elbow. It is a simple scale which can be taught with minimal training. The scale has been used in several ALS multicenter clinical trials.

Disadvantages: Although this scale is felt to be valid, the importance of disturbance in muscle tone as a specific impairment requires further study. Studies suggest that disability is more closely related to weakness than to spasticity [83].

Respiratory Scales

Progressive respiratory impairment is the primary cause of death in many neuromuscular diseases. Measurements of respiratory muscle strength, therefore, are being used more commonly as secondary outcome measures in clinical trials. The use of pulmonary function studies to assess the efficacy of a particular treatment or clinical intervention is best reserved for those disorders associated with more rapid and predictable declines in respiratory function such as ALS.

Forced Vital Capacity

The forced vital capacity (FVC) is the maximal amount of air that can be forcibly exhaled after a maximal inspiration. FVC is often reported as a percentage of a predicted vital capacity based on the patient's gender, height, and age. The FVC measurement should be performed with a nose clip with the patient in either a seated or supine position. The maneuver involves two steps: a full inspiration to total lung capacity, followed by a rapid, forceful maximal expiration (to residual volume) into a spirometer. Some authors have suggested that supine FVC may be a more sensitive measurement of diaphragmatic weakness [84]. In patients who have difficulty obtaining a tight lip seal on the mouth tube, it may be necessary to use a mouthpiece or mask. Three trials of the FVC are commonly compared, and variability is acceptable when less than 5 %.

Advantages: The deterioration in FVC has been used as a surrogate measure for survival in patients with motor neuron disease [85]. Schiffman et al. [86] reported that a reduction in FVC% was the factor most related to a patient's respiratory symptoms. This is a standard measure of pulmonary function which all respiratory therapists are trained to perform. In addition, measurement of FVC assesses the strength of both inspiratory and expiratory muscles in a single test.

Disadvantages: The accuracy of FVC measurements decreases with progressive bulbar spasticity and lower facial weakness [87]. In addition, the administration of noninvasive ventilation (NIV) can alter the results of this test over time since NIV has been shown to slow down the rate of FVC deterioration [88]. A decline in FVC may also be influenced by factors such as emphysema, congestive heart failure, and asthma as well as by muscular weakness. As a primary measure of respiratory impairment, FVC may not be sensitive to early or small changes in underlying motor neuron loss or muscle weakness. Due to compensatory mechanisms ensuring adequate respiratory function, a significant number of

motor neurons are likely to be lost prior to the onset of decline in FVC.

Slow Vital Capacity

The slow vital capacity (SVC) is the maximal volume of air that can be exhaled over a period of at least 30 s [89]. The values generated for SVC and FVC, in the same patient, should be quantitatively similar unless airway obstruction is present. SVC, however, may be an easier and more reliable measure to obtain, requiring less coordinated effort.

Advantages: This study attempts to accommodate patients who have significant spasticity and difficulty forcibly exhaling with a single coordinated effort. With a proper spirometer, SVC may be less variable as it is not confounded by an inconsistent (spastic) expiratory effort.

Disadvantages: Experience with using SVC as a primary or secondary endpoint in neuromuscular trials is limited. Computerized spirometers require specialized programming to accommodate the measure. Measurement via manual spirometry (Wright's spirometer) requires specialized training and awareness by the examiner.

Tidal Volume

Measurement of tidal volume requires patients to breathe normally without further instruction or demand. The volume of each individual breath is recorded and averaged over 1 min.

Advantages: Measurement of TV is less dependent on patient cooperation, coordination, and lower facial strength. In patients with lower facial weakness, tidal volume appears to be a better, more accurate predictor of respiratory function compared with FVC [87].

Disadvantages: TV measurements have not been used in any major clinical trial, although preliminary data suggests that it significantly correlates with changes in FVC in ALS patients ($r = 0.625$) [87].

Maximal Inspiratory/Expiratory Pressures

Measurement of maximal static respiratory pressures is particularly important in evaluating respiratory muscle weakness in patients with neuromuscular disease, and it has been performed as an outcome measure in several clinical trials [90–92]. In order to determine maximal expiratory pressure, the patient is urged to inspire fully to total lung capacity and then to exhale as forcefully as possible into a pressure gauge. The highest pressure attained and held for at least 1 s is the maximal expiratory pressure (MEP). The lower limit of normal for males is 71 cm H_2O and for females is 39 cm H_2O [93]. The maximal inspiratory pressure (MIP) is determined by having the patient inspire maximally from the pressure gauge after having expired completely to residual volume. The value recorded is the lowest pressure attained and held for at least 1 s. The lower limit of normal for males is 111 cm H_2O and for females is 88 cm H_2O [93]. Low peak inspiratory or expiratory pressures may be the result of any of a number of factors including suboptimal effort, fatigue, weakness of the respiratory muscles, deformity of the chest wall, or intrinsic diseases of the lungs or chest wall. Although the first three factors characteristically reduce both the MIP and MEP, disease of the lungs or chest wall often reduces, selectively, either the MIP or MEP. For example, diseases that reduce lung volume, such as interstitial fibrosis, shorten the length of the expiratory muscles at the end – inspiratory position and generally reduce the MEP. Alternatively, diseases such as obstructive airway disease that increase lung volume by decreasing the inspiratory muscle length at end-expiration, generally reduce the MIP.

Advantages: Patients with no respiratory symptoms may demonstrate significant reductions in MIP and MEP and still have normal spirometry [94] since maximal pressures are not required to achieve maximal expiratory flow rates. This suggests, therefore, that measurements of MIP and MEP are probably more sensitive in detecting early respiratory insufficiency in comparison to FVC measurements [95]. Determination of the MIP and MEP may also be helpful in suggesting the mechanism of reduced airflow during spirometry. Poorly reproducible peak flows that are consistently subnormal raise the question of poor patient effort. Conversely, consistently low values that occur despite maximal effort may signal an underlying neuromuscular disease.

Disadvantages: Experience with using maximal respiratory pressures as an outcome measure is limited.

Quality of Life Scales

Quality of life (QOL) is an extremely important issue particularly to patients who suffer from chronic, debilitating, and, many times, terminal diseases. A medication or intervention that merely prolongs life without improving quality of life may not be considered an effective therapy. For this reason, quality of life assessment is currently incorporated into most clinical trials as a secondary outcome measure. Unfortunately, the most commonly used instruments are actually a measure of health status (an objective description of a person's ability to perform certain roles) rather than of health-related quality of life (the personal valuation of these different disabilities). In addition, the majority of QOL instruments are heavily weighted to physical function. As a result, they show a decline with disease progression even if the patient's perception of QOL does not necessarily worsen. Psychological, existential, and spiritual factors presumably play an essential role in perceived QOL, and yet these areas are poorly evaluated using standardized scales. QOL may change at different stages of a disease

despite the intervention or medication being tested. While one instrument may be adequate early in disease, it may not be suitable to assess palliative care. Traditional questionnaires impose an external value system in which weighting of the component parts is standardized and is usually derived from grouped data. These measures may be reliable, but may not be relevant to an individual's present life situation. Similar impairments and functional disabilities do not have the same relevance or importance for all individuals. Furthermore, the importance of particular functions does not necessarily remain the same for a given individual over the course of a chronic illness.

Individualized Neuromuscular Quality of Life Questionnaire (INQoL)

The Individualized Neuromuscular Quality of Life Questionnaire is a neuromuscular disease-specific quality of life measure for adults [96, 97].

There are 12 domains: daily activities, leisure, employment, relationship with partner, relationships with family, relationships with friends, general social interaction, psychological impact on emotions, perception of the future, identity/self-image, independence, and coping strategies. For each domain, patients are asked the extent to which their neuromuscular disease affected this domain (on a five-point Likert scale from "not at all" affected to "very much" affected) and the importance that they attached to this impact (on a five-point Likert scale, ranging from "not at all important" to "extremely important").

Advantages: INQOL is one of few QOL measurements that were specifically designed for patients with neuromuscular disease.

Disadvantages: The INQOL takes approximately 20 min to complete. It has only been used in a single trial of dermatomyositis.

Short Form-36 (SF-36)

The 36-item short form (SF-36) is a multidimensional health questionnaire which was designed to survey the health status of the general population in the Medical Outcomes Study (Table 15.21) [98, 99]. The Medical Outcomes Study is an observational study examining practice styles and outcome measures in different clinical disease states [100]. The SF-36 measures both functional status and emotional well-being by utilizing eight health subscales: (1) physical functioning, (2) social functioning, (3) role limitations because of physical health problems, (4) role limitations because of emotional problems, (5) mental health status (psychological distress and psychological well-being), (6) bodily pain, (7) vitality (energy/fatigue), and (8) general health perceptions. The SF-36 contains 36 questions, 35 of which pertain to the 8 subscales and one item which relates to the perceived change in health over the past year. For each subscale, items are coded, totaled, and transformed to a 0–100 scale, with 100 indicating the best health state and 0 representing the worst health state. Each subscale employs its own response format which varies from "yes/no" responses to a six-point scale of "none" to "very severe." Two versions are available varying in the time of recall to current health status questions; respondents are asked about their health over the past 4 weeks (the most commonly used form) or over the past 1 week (used in evaluating acute conditions).

Advantages: The SF-36 can be reliably completed either over the phone or face to face and can also be self-administered in approximately 10 min. It is a comprehensive assessment and is applicable across many demographic and social groups. Test-retest reliability has been shown to range from $r=0.60$ (social functioning) to $r=0.81$ (physical functioning) [101].

Disadvantages: The SF-36 appears to be less comprehensive and not as suitable to an elderly population in comparison to the Sickness Impact Profile (SIP) [102]. This is due to the fact that the items pertaining to vigorous activities and work are not generally applicable to an elderly population. In addition, areas such as sleep disturbance, pain, emotional well-being, and mobility are not comprehensively addressed. On the other hand, when studying a more active population, the SF-36 appears to be a more sensitive mobility measure than the SIP [103]. The SF-36 also tends to have a floor or ceiling effect due to the limited range of responses [28]. In addition, the SF-36 is not able to assess change in health status over a short period of time due to the time frame in which questions are asked [104]. Finally, the SF-36 is a generic questionnaire, and although it is sensitive enough to detect changes in health state in a general population, this instrument should probably be combined with a disease-specific questionnaire when assessing a specific population of patients.

Short Form-12 (SF-12)

In an attempt to shorten the SF-36, a SF-12 version has also been used and validated in several clinical trials [99]. The 12 items are all contained in each version of the SF-36 (Table 15.22). The 12 items include self-assessment of health, physical functioning, physical role limitation, mental role limitation, social functioning, mental health items, and pain. Both 4-week and 1-week recall versions are available. The 12 items in this instrument yield the same eight scale profiles of the SF-36.

Advantages: The main advantage of the SF-12 in comparison to the SF-36 is its simplicity and ease of administra-

Table 15.21 SF-36 health survey (standard)

SF-36 HEALTH SURVEY (STANDARD)

INSTRUCTIONS: This questionnaire asks for your views about your health. This information will help keep track of how you feel and how well you are able to do your usual activities.

Please answer every question by marking one box. If you are unsure about how to answer, please give the best answer that you can.

1. *In general, would you say your health is:*

☐ Excellent ☐ Very good ☐ Good ☐ Fair ☐ Poor

2. Compared to one year ago, how would you rate your health in general now? (Check one box)

☐ Much better now than one year ago
☐ Somewhat better now than one year ago
☐ About the same as one year ago
☐ Somewhat worse now than one year ago
☐ Much worse now than one year ago

3. The following items are about activities you might do during a typical day. Does your health now limit you in these activities? If so, how much?

		Yes, Limited A lot	Yes, Limited A Little	No, Not Limited At All
3.	**Vigorous activities**, such as running, lifting heavy objects, participating in strenuous sports	☐	☐	☐
3.1	**Moderate activities**, such as moving a table, pushing a vacuum cleaner, bowling or playing golf	☐	☐	☐
3.2	Lifting or carrying groceries	☐	☐	☐
3.3	Climbing several flights of stairs	☐	☐	☐
3.4	Climbing one flight of stairs	☐	☐	☐
3.5	Bending, kneeling, or stooping	☐	☐	☐
3.6	Walking more than a kilometre or 2/3 of a mile	☐	☐	☐
3.7	Walking several blocks	☐	☐	☐
3.8	Walking one block	☐	☐	☐
3.9	Bathing or dressing yourself	☐	☐	☐

4. During the past 4weeks, have you had any of the following problems with your work or other regular daily activities as a result of your physical health?

		YES	NO
4.1	Cut down on the **amount of time** you spent on work or other activities	☐	☐
4.2	**Accomplished less** than you would like	☐	☐
4.3	Were limited in the **kind** of work or other activities	☐	☐
4.4	Had difficulty performing the work or other activities (for example, it took extra effort)	☐	☐

Table 15.21 (continued)

5. During the past 4 weeks, have you had any of the following problems with your work or other regular daily activities as a result of any emotional problems (such as feeling depressed or anxious)?

		YES	NO
5.1	Cut down the **amount of time** you spend on work or other activities	☐	☐
5.2	**Accomplished less** than you would like	☐	☐
5.3	Didn't do work or other activities as carefully as usual	☐	☐

6. During the 4 past weeks, to what extent has your physical health or emotional problems interfered with your normal social activities with family, friends, neighbors, or groups? (Check the box which applies)

☐ Not at all
☐ Slightly
☐ Moderately
☐ Quite a bit
☐ Extremely

7. How much bodily pain have you had during the past 4 weeks (check the box which applies)

☐ None
☐ Very mild
☐ Mild
☐ Moderate
☐ Severe
☐ Very severe

8. During the past 4weeks, how much did pain interfere with your normal work (including both work outside the home and housework)? (Check the box which applies)

☐ Not at all
☐ Very mild
☐ Mild
☐ Quite a bit
☐ Extremely

9. These questions are about how you feel and how things have been with you during the past 4 weeks. For each question, please give the one answer that comes closest to the way you have been feeling. How much of the time during the past 4 weeks.

		All of the Time	Most of the Time	A good Bit of the Time	Some of the Time	A Little of the Time	None of the Time
9.1	Did you feel full of pep?	☐	☐	☐	☐	☐	☐
9.2	Have you been a very nervous person?	☐	☐	☐	☐	☐	☐
9.3	Have you felt so down in the dumps that nothing could cheer you up?	☐	☐	☐	☐	☐	☐
9.4	Have you felt calm and peaceful	☐	☐	☐	☐	☐	☐
9.5	Did you have a lot of energy?	☐	☐	☐	☐	☐	☐
9.6	Have you felt downhearted and blue?	☐	☐	☐	☐	☐	☐
9.7	Did you feel worn out?	☐	☐	☐	☐	☐	☐
9.8	Have you been a happy person?	☐	☐	☐	☐	☐	☐
9.9	Did you feel tired?	☐	☐	☐	☐	☐	☐

Table 15.21 (continued)

9.5	Did you have a lot of energy?	☐	☐	☐	☐	☐	☐
9.6	Have you felt downhearted and blue?	☐	☐	☐	☐	☐	☐
9.7	Did you feel worn out?	☐	☐	☐	☐	☐	☐
9.8	Have you been a happy person?	☐	☐	☐	☐	☐	☐
9.9	Did you feel tired?	☐	☐	☐	☐	☐	☐

10. During the past 4 weeks, how much of the time has your physical health or emotional problems interfered with your social activities (like visiting with friends, relatives, etc.)?

All of the Time	Most of the Time	Some of the Time	A little of the Time	None of the Time
☐	☐	☐	☐	☐

11. How TRUE or FALSE is each of the following statements for you? (Check the box which applies on each line)

		Definitely True	Mostly True	Don't Know	Mostly False	Definitely False
11.1	I seem to get sick a little easier than other people	☐	☐	☐	☐	☐
11.2	I am as healthy as anybody I know	☐	☐	☐	☐	☐
11.3	I expect my health to get worse	☐	☐	☐	☐	☐
11.4	My health is excellent	☐	☐	☐	☐	☐

Table 15.22 SF-12 health survey (standard)

All of the Time	Most of the Time	Some of the Time	A little of the Time	None of the time

tion. Ware et al. [105] reported that the 12 selected items were able to reproduce at least 90 % of the variance in the physical and mental subscales of the SF-36 and therefore suggested that the population norms for the SF-36 can also be used as norms for the SF-12.

Disadvantages: The eight scale profiles provided by the SF-12 have fewer levels and provide less precise scores than the SF-36 since some subscales have just one or two items.

Sickness Impact Profile (SIP)

The SIP is a popular generic health status questionnaire that was initially developed in 1976 as a measure of perceived health [106]. The SIP contains 136 behavioral items covering 12 areas of behavior or performance: work, recreation, emotion, affect, home life, sleep, rest, eating, ambulation, mobility, communication, and social interaction. The questionnaire asks respondents to mark the statements that relate

to them on the day of administration. The wording of items and instructions focuses on performance rather than capacity. The SIP can be self-administered and requires 20–30 min to complete. The total score on the SIP ranges from 100 (poor health) to 0 (better health). The SIP can be scored by item, by broad domains (psychosocial health or physical), or by the 12 subscales [107]. A normal, healthy population will typically score a 2 or 3 on this instrument, whereas a stroke patient or terminally ill cancer patient may score in the mid-30s [108]. The developers of the SIP have designated a change of 5 % points as clinically meaningful. In a study of ALS patients [109], the patients gained between 7 and 8 % points on the SIP per year.

Advantages: The SIP has demonstrated high test-retest reliability ($r = 0.88–0.92$) [106]. The SIP can be applied to a large number of different patient populations since it is a comprehensive, global measure of health status. It has been widely used in the United States as an outcome measure. Since the questions have to be answered yes or no, it can be administered even to severely speech-impaired patients. It has been shown to correlate strongly with muscle strength measurements [109].

Disadvantages: The major disadvantage of the SIP is the time required for its completion. This is particularly relevant when the SIP is being used as a supplement to a more detailed disease-specific measure. The SIP19 ("mini-SIP") has also been validated and was used in the National ALS Care Database. It contains 19 of the 33 items within the Body Care and Movement and Home Management categories. These items were shown to correlate as well as with the MVIC megascore as the entire SIP score [110].

Another criticism of the SIP is its failure to detect changes over time in the same individuals [111]. This limitation is especially critical when considering use of this instrument in clinical trials in which quality of life is a secondary endpoint in evaluating the efficacy of a specific intervention or medication. Patients are continuously reminded of all the activities they can no longer perform, which can result in depressive symptoms and reluctance to complete subsequent SIP questionnaires. Most of the questionnaire examines what the patient can or cannot do, while only a very small portion actually assesses the patient's subjective state of well-being. Finally, when analyzing the responses, there is no way of knowing whether the columns left blank represent "no" replies or whether the respondent/interviewer omitted them deliberately or in error.

Short Form Individual Quality of Life Measure (SEIQoL)

The SEIQoL was developed to assess quality of life from the individual's perspective [112]. It is an interview-based instrument derived from a technique known as judgment analysis. An abbreviated form of the measure, the SEIQoL-direct weighting (SEIQoL-DW) [113], replaces the more cumbersome and time-consuming judgment analysis technique with a procedure for measuring the relative importance or weight to the respondent of selected life areas. The direct weighting apparatus consists of five interlocking, colored circular laminated disks that can be rotated around a central point to form a type of pie chart. The laminated disks are mounted on a larger disk, which displays a scale from 0 to 100, and from which the size of each colored segment can be read. Each colored segment is labeled with a life area selected by the respondent as being important to his or her quality of life. The respondent adjusts the disks until the size of each colored segment corresponds to the relative importance of the life area represented by that segment.

As with the full measure, the SEIQoL-DW is administered in a standardized semi-structured interview and takes 5–10 min to administer. Individuals are initially asked to name the five areas of life (cues) which are most important to the overall quality of their life. The respondent then rates their current status against a vertical visual analogue scale from "as good as could possibly be" to "as bad as could possibly be." The possible score range for each cue level is 0–100. The final step involves quantifying the relative contribution of each cue to the judgment of overall quality of life using the direct weighting instrument described above. The total value of all five weights sums to 100.

For making group comparisons, a global quality of life score can be calculated by multiplying the individual's current self-rating on each cue by the corresponding cue weight and summing the products across the five cues. The global quality of life score can range from 0 to 100. The score is a continuous measure which can be subjected to parametric statistical analyses.

Advantages: Administration of the SEIQoL-DW is relatively simple and requires minimal training [113]. The SEIQoL-DW was developed and validated against the full version of the SEIQoL and found to be a valid and reliable measure of explicit weighting policies for quality of life domains. Studies in healthy subjects have indicated that the measure is reproducible and has high criterion validity. This instrument has the capacity to evaluate an individual's quality of life on the basis of the areas of life that he or she considers to be important, quantifies current functioning in each of these personally nominated life areas, and weights their relative importance for that individual at that particular time in the course of their illness.

Disadvantages: While the weights derived from the direct weighting and the full judgment analysis are similar, some differences exist suggesting that the SEIQoL-DW may be measuring explicit weights about which the respon-

dent is consciously aware, whereas the full measure may include elements of judgment about which the respondent is unaware but which may have a bearing on their actual quality of life [113].

McGill Quality of Life Scale (MQoL)

The MQoL is a 20-item scale developed to measure quality of life in patients with severe, life-threatening illness. It has had specific applicability in patients at the end of life. The scale has been revised in several versions [114, 115].

The scale measures quality of life in four domains: physical, psychological, outlook on life, and meaningful existence. Of all the available subscores, meaningful existence (existential life) has been suggested as most valid due to the correlation with previously validated Spitzer Quality of Life Index.

Advantages: This is a simple, accepted, and reliable measure of quality of life, measured in a palliative care setting. Some cross-cultural validity has also been reported.

Disadvantages: The measure was validated in patients identified in palliative or "terminal" care settings. Evaluation of quality of life in chronically ill patients receiving aggressive symptomatic or adjunctive therapy may identify different issues than those captured in the population identified as receiving "end-of-life care."

Prior Clinical Applications in Neuromuscular Disease

The use of outcome measures in neuromuscular disease has varied widely. There has been significant variability in the use of available outcome measures, even within the confines of clinical trials testing patients with the same disease (Tables 15.23, 15.24, 15.25, and 15.26). Most clinical trials, testing potentially therapeutic agents in neuromuscular disease, have yielded negative results, despite laboratory data suggesting significant beneficial effects in animal models. The continued use of different outcome measures, in new combinations, for new trials, may be justified considering the lack of a "gold standard" against which significant clinical efficacy has been determined. We regularly validate new scales with established scales that appear to be sensitive to changes in a disease process, often despite the absence of data showing efficacy when those scales were originally established.

There is a clear need for newer, more sensitive outcome measures to detect small changes in disease progression. This has been highlighted by the importance of early diagnosis as a therapeutic advantage as well as the modest benefit of currently available therapeutic agents. In neuromuscular diseases such as ALS, the heterogeneity of disease presentation and progression also confounds the ability to select optimal outcome measures and favors new trials which are stratified based on more selective clinical criteria.

Table 15.23 Selected trials in amyotrophic lateral sclerosis

Name	Duration	Motor scale	Functional scale	Other
Creatine monohydrate in ALS: effects on strength, fatigue, respiratory status and ALSFRS [116]	9 months	MVIC fatigue	ALSFRS	Survival FVC SEI
Efficacy of minocycline in patients with amyotrophic lateral sclerosis: a phase III randomised trial [117]	4 month lead-in 9 month treatment	MMT	ALSFRS	FVC QoL Survival
A randomized, placebo-controlled trial of topiramate in amyotrophic lateral sclerosis [118]	12 months	MVIC	ALSFRS	FVC Grip strength Survival
Trial of celecoxib in amyotrophic lateral sclerosis [119]	12 months	MVIC	ALSFRS	Survival FVC CSF prostaglandin
Recombinant-methionyl human brain-derived neurotrophic factor (BDNF) given by intrathecal infusion to subjects with amyotrophic lateral sclerosis (phase III) [120]	Randomized 18 months	MMT	ALSFRS	Survival SIP Profile of mood states (POMS-Bi) Health resource utilization questionnaire
A controlled trial of recombinant methionyl human BDNF in ALS: the BDNF study group (phase III) [121]	Randomized 12 months		ALSFRS Schwab and England scale	Survival SF-36
Efficacy and safety of xaliproden in amyotrophic lateral sclerosis: results of two phase III trials [122]	Randomized 18 months Stratified	MMT	ALSFRS	Survival SIP Slow VC Ashworth spasticity scale Clinical global impression scale Symptom visual analog scales
Intracerebroventricular recombinant methionyl human glial cell line derived neurotrophic factor (r-metHuGDNF) for the treatment of patients with amyotrophic lateral sclerosis (unpublished)	Randomized 9 months Safety study	MVIC	ALSFRS 15′ walk PATA repetition	Survival FVC Ashworth spasticity scale
A controlled trial of recombinant-methionyl human BDNF (r-met HuBDNF) in ALS: Phase III [120]	Randomized trial 9 months		ALSFRS Walking speed PATA repetition	FVC Survival SIP
Placebo-controlled trial of gabapentin in patients with amyotrophic lateral sclerosis [123]	Randomized trial 9 months	MVIC (slope of arm megascore)	ALSFRS Walking speed	FVC SF-12 Ashworth Spasticity Scale
Effect of recombinant human insulin-like growth factor I (rhIGF-1) on progression of amyotrophic lateral sclerosis: a placebo-controlled study [124]	Randomized trial 9 months	Appel ALS rating scale (slope)		SIP FVC

Name	Duration	Motor scale	Functional scale	Other
Insulin-like growth factor I in the treatment of amyotrophic lateral sclerosis: results of the European multicenter, double-blind, placebo-controlled trial [125]	Randomized trial 9 months	Appel ALS rating scale (change in score)		SIP FVC Clinical global impression scale
A placebo-controlled trial of recombinant human ciliary neurotrophic factor in amyotrophic lateral sclerosis [126]	Randomized trial 6 months	MVIC (combination megascore, arm and leg megascores)		SIP FVC
A double-blind placebo-controlled clinical trial of subcutaneous recombinant human ciliary neurotrophic factor (rhCNTF) in amyotrophic lateral sclerosis [90]	Randomized trial 9 months	MVIC	ALSFRS Schwab and England scale	FVC NIF Ashworth spasticity scale
Randomized, double-blind controlled trial of acetylcysteine in amyotrophic lateral sclerosis [127]	Randomized trial 12 months	MMT	Barthel Index	FVC Survival
Dose-ranging study of riluzole in amyotrophic lateral sclerosis [128]	Randomized trial 18 months	MMT Norris ALS scale		Survival FVC Clinical global impression scale
A controlled trial of riluzole in amyotrophic lateral sclerosis [129]	Randomized trial 573 days (median duration of placebo-controlled period)	MMT	"Functional status"	Survival FVC Clinical global impression scale
Selegiline is ineffective in a collaborative, double-blind, placebo-controlled trial for treatment of amyotrophic lateral sclerosis [130]	Randomized trial 6 months	Appel ALS rating scale (rate of change)		Survival
A clinical trial of verapamil in amyotrophic lateral sclerosis [131]	Randomized trial 9 months	MVIC (arm and leg megascores)		FVC (pulmonary megascore)
Controlled trial of nimodipine in amyotrophic lateral sclerosis [132]	Randomized trial 7 months	MVIC	"Timed upper and lower extremity functions"	FVC
Intravenous thyrotropin-releasing hormone in patients with ALS dose response and randomized concurrent placebo-controlled pilot studies [133]	Randomized 4 weeks	MVIC	Timed rise from seat Timed step onto footstool Timed walk	FVC MVV Exercise capacity tests Oxygen consumption at maximal exercise
Levamisole is ineffective in the treatment of ALS [134]	Crossover trial 12 months	Norris ALS Scale		
A double-blind controlled trial of bovine brain gangliosides in ALS [135]	Randomized trial 6 months	MVIC	Timed syllable repetition Timed swallow Arm and leg ADL scale Timed motor activities	FVC MVV Forced cough EMG NCS

Trial of immunosuppression in amyotrophic lateral sclerosis using total lymphoid irradiation [136]	Randomized trial 2 years	MVIC MMT	Timed swallow Timed gait Timed rise from seat Modified Kurtzke disability scale	FVC Survival
Branched-chain amino acids and amyotrophic lateral sclerosis [137]	Randomized 12 months	Appel ALS rating scale MMT Norris ALS scale		
Comparative efficacy and safety of intravenous and oral administration of a TRH analogue (Rx 77368) in motor neuron disease [138]	3–5 weeks	MMT Norris scale	Timed tongue protrusion Timed jaw movements Timed word repetition Timed swallowing	FVC MIP/MEP

Table 15.24 Selected trials in myopathy

Name	Duration	Motor scale	Functional scale	Other	Comments
Deflazacort in Duchenne dystrophy: study of long-term effect [139]	24 months	MMT	Timed gower Timed chair Timed stairs Timed gait		
Randomized, double-blind 6-month trial of prednisone in Duchenne's muscular dystrophy [91]	6 months	MMT	Timed stand from lying position Timed walk 30 ft Time to climb 4 stairs	MEP FVC MVV Lifting weights	Disability precluded determination of measurements
Pilot trial of albuterol in facioscapulohumeral muscular dystrophy [140]	3 months	MMT MVIC			MVIC detected difference;
Treatment of inclusion body myositis with IVIG [141]	6 months	MMT MVIC		Swallowing function	
Inclusion body myositis: treatment with intravenous immunoglobulin [142]	4 months	MMT	"Disability Score" based upon ability to ambulate	Creatine kinase	
The treatment of inclusion body myositis: a retrospective review and a randomized, prospective trial of immunosuppressive therapy [143]	6 months	MMT	ADL scale (adapted from Convery Assessment scale)	Creatine kinase	
Azathioprine with prednisone for polymyositis [144]	3 months	MMT		Creatine kinase Muscle biopsy (inflammatory score)	
A clinical trial of the safety and activity of recombinant human insulin-like growth factor 1/ recombinant human insulin-like growth factor binding protein 2 in myotonic dystrophy type 1 [145]	24 weeks	MMT MVIC Handgrip	Timed walk 30 ft Purdue pegboard 6-min walk	FVC) DEXA (lean body mass SIP	
a randomized, pilot trial of etanercept in dermatomyositis [146]	24 weeks	MMT MVIC	MITAX MYOACT	VAS (patient self-assessment and pruritus) SF-36 INQoL PFTs DEXA	

Table 15.25 Selected trials in neuropathy

Name	Duration	Motor scale	Functional scale	Other
Treatment of chronic inflammatory demyelinating polyneuropathy with intravenous immunoglobulin [147]	Retrospective review of 15 patients	MMT		Nerve conduction studies
Treatment of chronic inflammatory demyelinating polyneuropathy with interferon - 2a [148]	Open-label prospective study 6 weeks	MMT Grip dynamometry	Rankin disability	Nerve conduction studies Sensory score
A randomized trial comparing intravenous immune globulin and plasma exchange in Guillain-Barre syndrome [149]	Randomized trail 6 months	MMT	Neuropathy disability scale	
Randomized trial of plasma exchange, intravenous immunoglobulin, and combined treatments in Guillain-Barre syndrome [150]	Randomized trial 48 weeks		Neuropathy Disability Scale Arm grade	FVC
Plasma exchange in polyneuropathy associated with monoclonal gammopathy of undetermined significance [151]	Randomized trial		Neuropathy disability scale	Nerve conduction studies Vibratory detection threshold
The Rochester diabetic neuropathy study [152]	Cross-sectional survey		Neuropathy Disability Score	Neuropathy symptom score Neuropathy symptom profile Nerve conduction studies Quantitative sensory exam Quantitative autonomic exam
Plasma exchange in chronic inflammatory demyelinating polyradiculoneuropathy [92]	6 weeks	Handgrip dynamometry Maximal finger pinch		Neurologic disability score MIP MEP Touch and vibratory thresholds Nerve conduction studies
Chronic inflammatory demyelinating polyneuropathy: clinical features and response to treatment in 67 consecutive patients with and without a monoclonal gammopathy [153]	Retrospective review of 67 patients	MMT	Rankin disability scale	Nerve conduction studies Sensory exam
Cyclosporin A in resistant chronic inflammatory demyelinating/ polyradiculoneuropathy [154]	Retrospective review of 17 patients		Disability scale (similar to Rankin)	Nerve conduction studies
Intravenous immune globulin (10 % caprylate-chromatography purified) for the treatment of chronic inflammatory demyelinating polyradiculoneuropathy (ICE study): a randomized placebo-controlled trial [155]	Randomized, double-blind, response-conditional crossover trial of 117 patients 48 weeks		INCAT disability score Rotterdam handicap scale	SF-36

Table 15.26 Selected trials in myasthenia gravis

Name	Duration	Motor scale	Functional scale	Other
Clinical trial of plasma exchange and high-dose intravenous immunoglobulin myasthenia gravis [64]	Randomized trial 15 days		Myasthenic Muscular Score	Acetylcholine receptor antibody titer
A randomized clinical trial comparing prednisone and azathioprine in myasthenia gravis. Results of the second interim analysis [156]	Randomized trial 60 months		Myasthenic Muscular Score Myasthenic Functional Score	
A clinical therapeutic trial of cyclosporine in myasthenia gravis [60]	Randomized, placebo-controlled		Quantitative Myasthenia Gravis Score	Acetylcholine receptor antibody titer Dosage of medications
Plasma exchange versus intravenous immunoglobulin treatment in myasthenic crisis [63]	Retrospective chart review		Myasthenia Gravis Severity Scale Functional Outcome	Ventilatory status
Randomized, controlled trial of intravenous immunoglobulin in myasthenia gravis [157]	Randomized, placebo-controlled double-blind trial 42 days		Myasthenia Gravis activity of daily living scale Quantitative Myasthenia Gravis Score	Repetitive stimulation Single fiber electromyography Acetylcholine receptor antibody titer Dosage of medications
A trial of mycophenolate mofetil with prednisone as initial immunotherapy in myasthenia gravis [158]	Randomized, placebo-controlled double-blind 12 weeks	MMT	Quantitative Myasthenia Gravis Score MG ADL Score	SF-36 Acetylcholine receptor antibody titer FVC
Comparison of IVIG and PLEX in patients with myasthenia gravis [159]	Randomized trial for 60 days		Quantitative Myasthenia Gravis Score	VAS (patient assessment of benefit) MGFA classification MG quality of life SFEMG Jitter %Decrement on RNS Acetylcholine receptor antibody titer

Physical Management of Patients with Neuromuscular Diseases

16

John R. Bach and Priya Bolikal

Interventions to Optimize Habilitation

Prevention of Joint Contractures

The physical/orthopedic treatment goals for neuromuscular diseases (NMD) are to maintain the balance of strength at each joint, prevent contractures, prolong the ability to walk safely with minimal or no bracing, and maximize arm function. There is often an imbalance of strength at major joints. When this imbalance is severe, shortening of skin, muscle, tendon, and ligament occurs which, over time, results in joint contractures.

Lower Extremities

Stretching

Loss of the ability to walk results from muscle weakness and from loss of articular range-of-motion (ROM). ROM is largely lost due to an imbalance of strength at the weight bearing articulations. One approach to preventing and managing lower extremity contractures is to perform ROM and joint stretching. ROM is performed to the point of maximal stretch or a few degrees past the point of discomfort for several minutes a few times per day on joints with or prone to contractures.

The most important muscle groups to stretch for most NMD patients are the ankle plantarflexors, the hamstrings, and the hip flexors. Occupational and physical therapists often provide education and guidance for individualized home therapy programs. There is indirect evidence that the regular use of stretching has prolonged the ability to walk for many children with NMD. Today, children with DMD appear to be able to walk longer than children managed in the 1950s before there was as much emphasis on ROM and stretching [1]. Although patients with most NMDs can benefit from daily ROM throughout life, no amount of ROM can entirely prevent contractures when muscle strength imbalance is severe.

Late Surgery

Once a contracture decreases limb function, the only way to restore full or functional ROM is to surgically stretch or "release" the joint's tightened soft tissues. The most commonly used surgical protocol to reverse lower limb contractures in NMD is one that was described for an 11-year-old "Duchenne" patient in 1845 and was redescribed in 1959 [2]. It includes the surgical release of tight flexor muscles at the hips, knees, and ankles (the Achilles tendon) and the release of the iliotibial bands at the knees at the point when the patient begins falling frequently. Following surgery, long leg bracing is required. It can also be helpful to transfer the tibialis posterior to insert into the dorsum of the foot (Fig. 16.1). This converts a plantarflexor into a dorsiflexor. This not only increases the ROM of the ankle but also balances the strength at the ankles [1].

In the 1970s, up to 40 % of MDA clinics [3] used late surgical interventions as patients "were about to lose their independent walking". Besides requiring long leg braces, this late surgical approach necessitates extensive postoperative physical therapy. Ambulation is not always prolonged in this manner; however, at times it can be prolonged for up to 5 years. Because it is not possible to predict who will benefit, and because bracing and postoperative therapy are very expensive and cumbersome, the use of this approach has fallen off over the years and is now very uncommon in the USA.

DOI 10.1007/978-1-4614-6567-6_16,

Early Surgery

Lower limb musculotendinous releases have been performed as prophylactic rather than corrective measures for Becker, Emery-Dreifuss, DMD, and other myopathies and in SMA types 3 and 4. Patients with these conditions often have a similar pattern of muscle weakness and contractures. Early surgery can eliminate the need for ongoing physical therapy and splinting and help preserve the strength of the weaker muscles by eliminating the overdominance of their antagonists [4]. Early surgical intervention is also safer and better tolerated than late approaches. It is performed when contractures begin to appear and patients have increasing difficulty (take longer) in rising from a seated position on the floor. Iliotibial band contractures are measured by the angle that the legs take with respect to the sagittal plane with the patient supine and the legs dangling. Tibialis posterior muscle strength is examined by applying pressure laterally against inversion of the externally rotated plantar flexed foot. The interventions include wide resection of the fascia lata and iliotibial bands as well as release of muscle tendons at the hips, lateral thighs, knees, and heel cords (Fig. 16.2). People with greater hip and knee strength and minor hip or knee contractures may require only Achilles tendon lengthening and possibly tibialis posterior transfers without tendon releases at the hips and knees. Early surgical intervention can decrease a vicious cycle of weakness, muscle tightness, contracture, and abstinence from walking that leads to deconditioning and further weakness. With early intervention, free walking is permitted by the second post-op day in ankle casts, and only brief outpatient or home physiotherapy is required. Continued ambulation is free of bracing and is prolonged by a mean of 1.25 years for DMD patients and longer for patients with less rapidly progressive conditions [5].

Fig. 16.1 Examining passive ankle dorsiflexion range-of-motion

Upper Extremity

Arm and hand contractures begin to develop early in pediatric NMD. Finger deformities begin by age 8 for children with DMD; they begin earlier in children with SMA or other early onset disorders. They also occur in adults with slowly progressive conditions. Ultimately, when shoulder and elbow contractures become greater than 25°, most people perceive them as hampering function, detracting from appearance, and being associated with pain and discomfort [6].

Fig. 16.2 Child with Duchenne muscular dystrophy exhibiting characteristic hip, knee, and ankle musculotendinous contractures before and their relief with surgical correction

Although an early vigorous upper extremity ROM program has been advocated, there has been no attempt at studying the effects of ROM, stretching, positioning, bracing, or surgery on the development of arm and hand contractures. At this time it may be most appropriate to recommend arm and hand ROM and stretching several times a day in an effort to prevent soft tissue contractures. The fact that a multidisciplinary approach of physical therapy, splinting, and surgery can be effective in ameliorating lower limb contractures [1] implies that effective treatment strategies may be possible for upper limb contractures as well.

Splinting and Casting

Splinting can be used to maximize joint function and hamper contracture development. Resting splints for the lower limbs and the ankles are commonly used during sleep and when the patient is confined to a wheelchair. Resting hand splints can also be used at night to impede finger and wrist contractures and during the daytime for patients without functional active movements. Resting splints provide a sustained stretch to the joint while holding it in a neutral position. They are also used after surgical releases of soft tissue contractures.

"Foot drop" is an almost ubiquitous complication of NMD. Ankle foot orthoses (AFOs) can be used to stabilize the ankle. Since it is difficult to stand from a chair with an AFO that holds the ankle in a fixed position (as it limits knee bending), dynamic components can be used. Dynamic splints permit increased movement and provide force to the movable body parts, allowing more functional use of the extremity. Static AFO's are used for individuals with flaccid ankles and little ambulation, whereas spring-loaded devices can be employed to assist ankle dorsiflexion without restricting plantarflexion.

Patients often resist using splints during sleep. Splints can be expensive and unattractive, can hamper bed mobility and sleep comfort, and may not prevent the progression of contractures. When used by growing children, fabrication of full-length lower limb splints also needs to be repeated about every 6 months.

Casting can provide a sustained stretching of the joint at the maximal angle tolerated. Casts can be reapplied every few days to increase the angle and progressively stretch the joint. This procedure is known as serial casting. Without continuous casting, however, contractures will still progress.

Standers can give support to the trunk, hips, knees, and ankles to both stretch lower extremity contractures and provide weight bearing to impede osteoporosis. These can be especially useful for children who are unable to operate standing motorized wheelchairs.

Prevention of Severe Spinal Deformity

Weak paraspinal muscles result in collapse of the spinal column and deformity of the chest. This results in scoliosis and kyphosis. For children with NMDs, spinal deformities progress rapidly once muscle weakness prevents a child from walking, and progression continues throughout life. Left untreated or braced, the spine can collapse to curves of over 100° (Fig. 16.3). Although its prevention usually yields no benefits on lung function and may even decrease vital capacity (VC) by fixing the rib cage [7], severe scoliosis can restrict heart functioning, cause intolerable unilateral back, buttock, and leg pressure, cause painful lumbar radiculopathy, necessitate expensive custom seating systems that are never very satisfactory, and can render ineffective, otherwise practical ventilatory aids like the intermittent abdominal pressure ventilator (IAPV).

Some physicians do not consider surgical options because they mistakenly think that the child has little hope of long-term survival. Surgeons often use interim bracing while applying the 40° criterion used for surgically managing idiopathic scoliosis. For children with DMD, by the time the curve reaches 40°, the VC may be below 23 % [8] and most surgeons would be reluctant to operate without prophylactic tracheotomy. This is usually refused, and because results of surgical correction are rarely curative, 75 % of scoliotic DMD patients and others with NMDs never undergo vital scoliosis correction surgery [3, 8].

The greater the degree of curvature, the less likely it is correctible. Thus, early surgery can provide a full correction and minimize cardiopulmonary risks. Late surgery, before patients have lost the ability to sit, however, can still be done safely even for patients with little or no measurable VC when using the respiratory principles noted in this chapter [7]. For people with normal muscle strength, a brace can decrease the rate of development of scoliosis because it acts as a reminder to use the paraspinal muscles to straighten the spine. Bracing does not slow scoliosis development in people with NMD because these patients cannot move away from the braces' pressure points. Although bracing does not impede curve development in children with infantile SMA and others whose scoliosis begins in early childhood, it may help maintain more curve flexibility for better surgical correction. Therefore, bracing is reasonable, at least until age 6, to allow for growth of the spine, at which point, spinal instrumentation with fusion is first justified [9–11].

There are now a variety of spinal instrumentation approaches leading to spinal fusion for correction of scoliosis. Following surgical intervention the patient is usually discharged within 4 or 5 days. To prevent respiratory complications, patients are taught noninvasive ventilation and mechanically assisted coughing (MAC) before surgery. By using these aids in conjunction with oximetry feedback

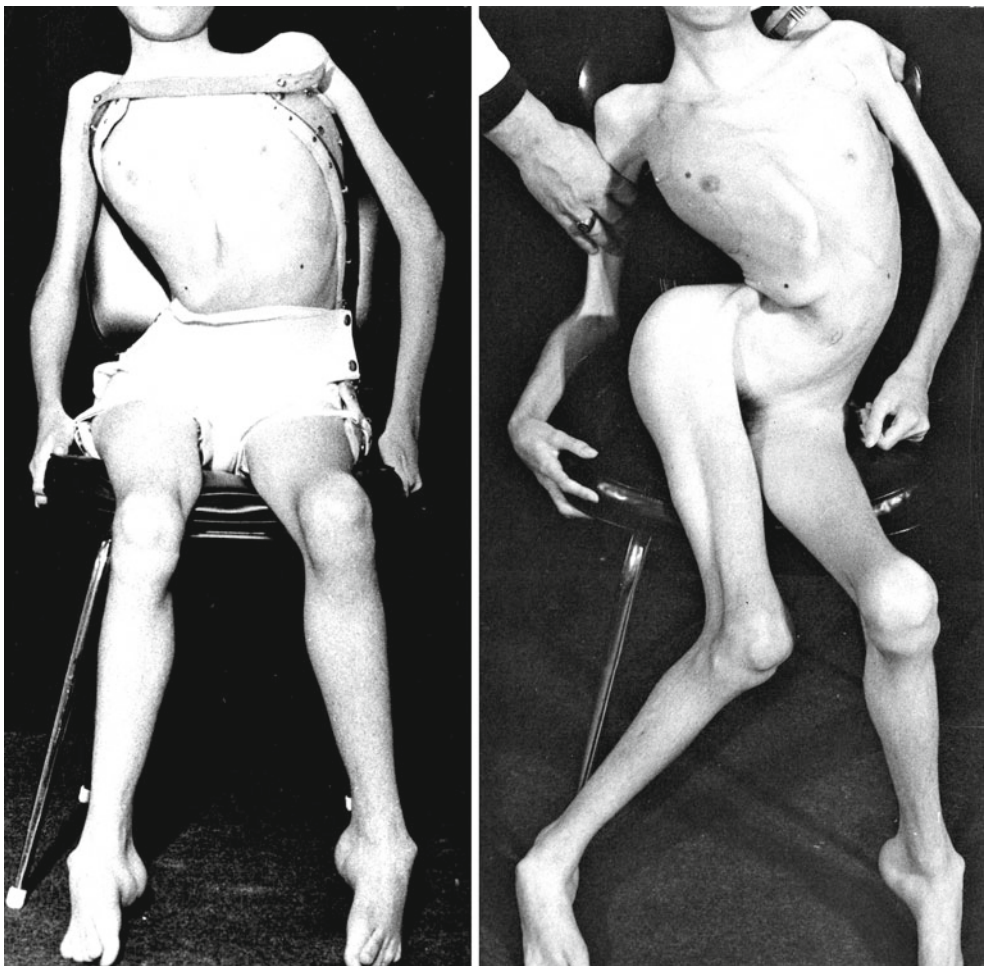

Fig. 16.3 Thoracolumbar bracing has no effect on preventing scoliosis for people with Duchenne muscular dystrophy (Republished with appreciation from Rideau et al. [4])

(to be described), they can be extubated as soon as narcotics can be discontinued, regardless of whether or not they are able to breathe.

Extremity Exercise

The muscle groups with greater than antigravity strength can be strengthened by resistance exercise training. Even with strengthening, however, their subsequent rate of strength loss, with or without continued exercise, may be even greater than without exercise. Muscles with less than antigravity strength cannot be strengthened with exercise and tend to be the muscles that lose function. Strengthening exercise does not appear to be warranted, therefore, for these muscles [12]. Nevertheless, although no harm has been demonstrated as a result of activity and exercise, patients should not be forced to exercise by overzealous parents, for example. Vignos advised patients to undertake 2–3 h/day of standing, walking, or swimming as long as they were capable and felt rested after a night's sleep [13]. This ancient recommendation is still appropriate today. All patients should be encouraged to keep as active as possible with activities they enjoy while avoiding muscle strain.

The use of nocturnal noninvasive intermittent positive pressure ventilation (NIV) while exercising has been shown to increase exercise tolerance and slow motor decline in post-poliomyelitis survivors and ALS patients with severe respiratory muscle dysfunction [14].

Respiratory Muscle Exercise

There is evidence that the use of inspiratory muscle resistive exercises can improve inspiratory muscle endurance for patients with respiratory muscle impairment. Endurance is considered to be improved when patients can breathe at 30–90 % of maximum voluntary ventilation or against greater pressures for longer periods of time. This can only occur, however, if the patient's VC is greater than 30 % of predicted normal when beginning the exercises [15]. A study of post-polio nocturnal ventilator users in which nine out of ten had VCs greater than 30 % of normal demonstrated improved endurance and generally claimed improved functioning

despite lack of better total body endurance [16]. Despite this, there is no evidence that inspiratory resistive exercise can improve VC, delay the need for ventilator use, or decrease the risk of respiratory failure during intercurrent chest infections. Indeed, patients often begin to require inspiratory muscle aids (NIV) once their VCs diminish below 30 % [17]. The failure to demonstrate respiratory benefits is in large part because episodes of respiratory failure in these patients are primarily due to expiratory (cough) muscle weakness rather than inspiratory dysfunction [18], for which there has been little attention. Therefore, it is unclear how inspiratory muscle strengthening might translate into improved clinical outcomes since respiratory failure is usually caused by ineffective coughing [18].

Respiratory Muscle Aids to Avert Tracheostomy and Prolong Survival

Pathophysiology

Respiratory function plateaus at age 19–20 then decreases by 1–1.2 %/year. Patients with neuromuscular conditions have VCs that often plateau earlier and can come to require continuous ventilatory support.

Ventilatory insufficiency is defined by hypercapnia in the presence of a normal arterial-alveolar (A-a) gradient. This hypercapnia is not caused by intrinsic lung disease or irreversible upper or lower airway obstruction, as in COPD. These patients can have airway obstruction from bronchial mucous plugging that causes an elevated A-a gradient. However, the mucous plugging is reversible by using expiratory (cough) aids. Symptomatic hypercapnic patients benefit from the use of noninvasive ventilation for at least part of the day and, more often, overnight. With progressive inspiratory muscle weakness, ventilator-free breathing ability is eventually lost.

Ventilatory muscle failure is defined by the inability of the inspiratory and expiratory muscles to sustain one's respiration without resorting to ventilator use. Ventilatory insufficiency leading to failure can be nocturnal only resulting from diaphragm dysfunction with the patient unable to breathe when supine or can result from a lack of central ventilatory drive or from severe generalized respiratory muscle dysfunction. Many patients with ventilatory insufficiency survive for years without ventilator use at the cost of orthopnea and increasing hypercapnia, associated symptoms and dangers, and a compensatory metabolic alkalosis that depresses central ventilatory drive. The alkalosis allows the brain to accommodate to hypercapnia without overt symptoms of acute ventilatory failure. Hypercapnic patients not using NIV, and especially those receiving supplemental oxygen, develop increasingly severe hypercapnia that eventually results in coma from carbon dioxide narcosis and ventilatory arrest. When symptomatic hypercapnic patients are treated with NIV, blood gasses normalize and the alkalosis resolves as the kidneys excrete excess bicarbonate ions. Because of the need to take deeper breaths to maintain normal $PaCO_2$ and blood pH levels, a nocturnal-only ventilator user can become dyspneic when discontinuing ventilator use in the morning and may require gradually decreasing NIV. Such patients eventually require NIV for increasing periods during the day until continuously NIV dependent. Some patients with ventilatory muscle failure and no measurable VC with their respiratory muscles use only a nocturnal aid and rely on glossopharyngeal breathing (GPB) to ventilate their lungs during daytime hours.

For patients with primarily ventilatory impairment, respiratory morbidity and mortality are a direct result of respiratory muscle dysfunction and can be avoided by assisting respiratory muscles. This is possible only if bulbar muscle dysfunction is not so severe that continuous aspiration of saliva causes the SpO_2 to remain below 95 %. Such patients develop essentially irreversible upper-airway obstruction and require tracheostomy tubes to protect the airway. In general, this scenario occurs for bulbar amyotrophic lateral sclerosis (ALS) patients who have lost the ability to speak and for a few other patients with NMD.

Epidemiology

Surveys in the USA, Western Europe, and Japan indicate that the use of home mechanical ventilation is increasing rapidly [19]. Most people who appear to require more than nocturnal ventilator use, however, and those who have difficulty weaning when intubated during chest infections generally undergo tracheotomy. This usually occurs because of lack of awareness of how to introduce physical medicine aids. Likewise, 90 % of episodes of acute respiratory failure for young patients with NMD occur as a result of inability to generate effective cough peak flows during otherwise benign upper respiratory infections [18]. These episodes are usually avoidable [20]. Respiratory muscle dysfunction amenable to treatment by respiratory muscle aids occurs in many people with the diagnoses listed in Table 16.1.

What Are Physical Medicine Respiratory Muscle Aids?

Inspiratory and expiratory muscle aids are devices and techniques that involve the manual or mechanical application of forces to the body or intermittent pressure changes to the airway, to assist inspiratory or expiratory muscle function. The devices that act on the body include body ventilators that create pressure changes around the thorax and abdomen.

Table 16.1 Conditions with chronic alveolar hypoventilation manageable with respiratory muscle aids

Myopathies:
Congenital, metabolic, inflammatory, and mitochondrial myopathies, myopathies of systemic disease such as carcinomatous myopathy, cachexia/anorexia nervosa, medication and ICU-associated, muscular dystrophies such as Duchenne and Becker, limb-girdle, Emery-Dreifuss, facioscapulohumeral, congenital, and myotonic
Endocrine related as with hypothyroidism, acromegaly
Mixed connective tissue disease and arthrogryposis
Anterior horn cell disorders:
Spinal muscular atrophies, motor neuron diseases, poliomyelitis
Neuropathies:
Hereditary sensory motor neuropathies
Familial hypertrophic interstitial polyneuropathy
Phrenic neuropathies
Guillain-Barre syndrome

Negative pressure applied to the airway during expiration assists coughing, just as positive pressure applied to the airway during inhalation (NIV) assists the inspiratory muscles. Continuous positive airway pressure (CPAP) does not assist ventilation and is not useful for patients with primarily ventilatory impairment.

Patient Evaluation

Patients with diminished ventilatory reserve who are able to walk commonly complain of exertional dyspnea. Eventually, morning headaches, fatigue, sleep disturbances, and hypersomnolence develop [17]. For wheelchair users, symptoms may be minimal, except during intercurrent respiratory infections when anxiety, inability to fall asleep, and dyspnea become problems.

The patient is observed for increased respiratory rate, decreased depth, or irregularity of breathing. Paradoxical breathing or asymmetric movement of the abdomen or thorax is often present. Hypophonia, nasal alae flaring, use of auxiliary respiratory musculature, peribuccal or generalized cyanosis, flushing or pallor, hypertension, difficulty controlling airway secretions, dysphagia, regurgitation of fluids through the nose, nasality of speech, cor pulmonale, confusion, and fluid retention may all be signs of ventilatory insufficiency.

Maximum inspiratory and expiratory pressures generated at the mouth correlate best with inspiratory and expiratory muscle strength. Maximum voluntary ventilation gauges respiratory muscle endurance. The VC gives an indication of both of these parameters and is simple, easy to measure, objective, and very reproducible. Because hypoventilation is often worse during sleep, the supine VC is a better indicator of ventilatory dysfunction than the sitting VC. Spirometry is also useful for monitoring progress with GPB and air stacking. A patient's maximum insufflation capacity (MIC) is determined by giving the patient the largest volume of air that can be held with a closed glottis from a manual resuscitator or a portable ventilator that is volume cycled. The patient then expels the air into the spirometer. Patients who learn GPB can often air stack consecutive GPB gulps to or beyond the MIC [21]. A nasal interface or lip seal can be used for air stacking when the lips are too weak for effective air stacking via the mouth (Fig. 16.4).

Fig. 16.4 Patient with Duchenne muscular dystrophy, continuously ventilator dependent for 7 years, air stacking via nasal interface

Cough peak flows (CPF) are measured using a peak flow meter (Access Peak Flow Meter, Healthscan Products Inc., Cedar Grove, NJ). CPF, assisted or unassisted, of 160 L/m are the minimum needed to cough effectively [22], and this is the best indicator for tracheostomy tube removal irrespective of remaining pulmonary function (Fig. 16.5) [23]. Indeed, about 40 % of patients with ALS can survive despite continuous ventilator dependence using NIV [24]. Patients with VCs less than 1,500 mL have assisted CPF measured from a maximally stacked volume of air and with an abdominal thrust delivered simultaneously with glottic opening.

For the stable patient without intrinsic pulmonary disease, arterial blood gas sampling is unnecessary. Besides the discomfort, 25 % of patients hyperventilate as a result of anxiety or pain during the procedure [22]. Noninvasive continuous blood gas monitoring, including capnography and oximetry, yields more useful information, particularly during sleep.

Nocturnal noninvasive blood gas monitoring can be performed for patients with diminished supine VC, especially for those with rapidly evolving conditions and symptoms suggestive of hypoventilation. The oximeter and the capnograph, which measures end-tidal pCO_2, must be capable of

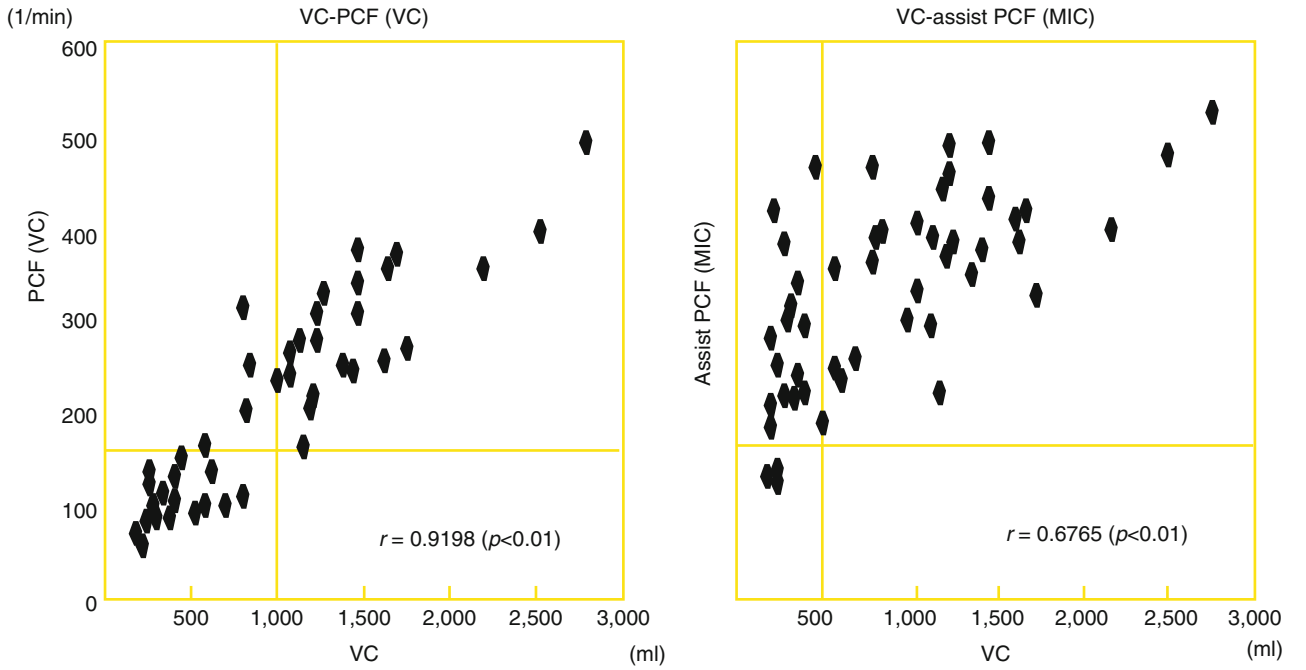

Fig. 16.5 Peak cough flows increase from ineffective levels (below 160 L/m) to effective levels by maximally insufflating the patient and then providing an abdominal thrust (With permission and appreciation to Dr. Yuka Ishikawa, Department of Pediatrics Yakumo Byoin National Sanatorium, Yakumo-cho Hikkarclo)

summarizing and printing out the data [17]. These studies are most conveniently performed in the home. When symptoms are obvious, a trial of nocturnal NIV rather than nocturnal end-tidal CO_2 and oximetry monitoring is appropriate. Any symptomatic patient with decreased VC, multiple nocturnal oxyhemoglobin desaturations below 95 %, and elevated nocturnal $PaCO_2$ requires treatment for nocturnal hypoventilation.

For symptomatic patients with normal VC, an unclear pattern of oxyhemoglobin desaturation, and no apparent carbon dioxide retention, sleep disordered breathing is suspected. This is particularly true when loud high-pitched snoring, interrupted breathing, and hypersomnolence dominate the picture [25]. These patients undergo polysomnography and are considered for CPAP therapy.

The Intervention Objectives

The intervention goals are to maintain lung and chest-wall compliance, to promote normal lung and chest-wall growth for children, to maintain normal alveolar ventilation around the clock, and to maximize CPF. The long-term goals are to avert episodes of acute respiratory failure during intercurrent chest infections, avoid hospitalizations, and prolong survival without resorting to tracheotomy. All goals can be attained by evaluating, training, and equipping patients in the outpatient setting and at home.

Goal One: Maintain Pulmonary Compliance, Lung Growth, and Chest-Wall Mobility

Pulmonary compliance is lost because the ability to expand the lungs to the predicted inspiratory capacity is lost as the VC decreases. As the VC decreases, the largest breath that one can take can only expand a small portion of the lungs. Like limb articulations and other soft tissues, regular range-of-motion (ROM) is required to prevent chest-wall contractures and lung restriction [26]. This can only be achieved by providing deep insufflations, air stacking, or nocturnal NIV. The extent to which the MIC is greater than the VC predicts the capacity of the patient to be maintained by noninvasive rather than tracheostomy ventilatory support [22]. This is because the MIC-VC difference, like assisted CPF, is a function of bulbar muscle integrity. Patients who cannot close the glottis and, therefore, cannot air stack must be passively insufflated using a Cough Assist™ (Philips-Respironics International Inc., Murrysville, Pa) or pressure-cycling ventilator at pressures of 40–70 cm H_2O. The maximum passive insufflation volume can be termed the "Lung Insufflation Capacity" or LIC [27].

The primary objectives in using air stacking or maximum insufflations for lung and chest-wall ROM are to increase the VC and MIC, to maximize CPF (see Fig. 16.5), to maintain or improve pulmonary compliance, to prevent or eliminate atelectasis, and to master NIV. In 282 spirometry evaluations of NMD patients for VC, MIC, and LIC, the authors found

mean values of 1,131 ± 744 mL, 1,712 ± 926 mL, and 2,069 ± 867 mL, respectively [27]. With the higher lung volumes by air stacking, assisted CPF were 4.3 ± 1.7 L/s by comparison with 2.5 ± 2.0 L/s unassisted. The deeper lung volumes by air stacking also permitted patients to raise voice volume as desired.

Because any patient who can air stack is also able to use NIV, if such a patient is intubated for respiratory failure, he or she can be extubated directly to continuous NIV regardless of whether the patient has regained any breathing tolerance. Before patients' VCs decrease to 70 % of predicted normal, they are instructed to air stack 10–15 times at least two or three times daily. Thus, the first respiratory equipment that is prescribed for patients with ventilatory impairment is often a manual resuscitator. In general, because of the importance of air stacking, NIV is provided via portable ventilators volume cycling on assist/control mode rather than by pressure-limiting devices.

Infants cannot air stack or cooperate to receive maximal insufflations. All babies with SMA type 1, infants with SMA type 2, and others with infantile NMD who have paradoxical chest-wall movement require nocturnal NIV to prevent pectus excavatum and promote lung growth as well as for ventilatory assistance [28]. In addition to nocturnal aid, deep insufflations can be provided via oral-nasal interfaces and manual resuscitators by timing the delivery of air to the child's breathing phases. Children can become cooperative with deep insufflation therapy by 14–30 months of age.

Goal Two: Continuously Maintain Normal Alveolar Ventilation by Assisting Inspiratory Muscles as Needed

1. The Nocturnal Inspiratory Muscle Aids
   (a) Negative Pressure Body Ventilators (NPBVs)

   The most common NPBV used today is the chest-shell ventilator. However, it is only practical for use during sleep and, like all negative pressure body ventilators and phrenic/diaphragm pacing, causes severe obstructive sleep apneas. The latter can necessitate continuous positive airway pressure or a tracheostomy, so there are few, if any, indications for the use of negative pressure body ventilators today. These devices also become less effective with aging and decreasing pulmonary compliance [29].

   (b) Noninvasive Intermittent Positive Pressure Ventilation (NIV)

   For the great majority of patients, NIV can be introduced in the clinic or home setting. It can be noninvasively delivered via mouthpieces, nasal and oral-nasal interfaces for nocturnal ventilatory support. Mouthpiece and nasal IPPV are open systems that require the user to rely on central nervous system reflexes to prevent excessive insufflation leakage during sleep; thus, it is critical to avoid supplemental oxygen and sedative medications [17, 30].

   There are numerous commercially available nasal interfaces (CPAP masks). Each interface design applies pressure differently to the paranasal area. One cannot predict which model will be most effective and preferred by any particular patient. Nasal bridge pressure and insufflation leakage into the eyes are common symptoms with several of these generic models. Such difficulties can be avoided by using nasal prong systems or custom designs [17, 31, 32]. No patient should be offered and expected to use only one nasal interface.

   Excessive insufflation leakage can be avoided by switching to the use of lip seal-nasal prong or nasal prong-oral systems that provide an essentially closed system of NIV support. Such interfaces deliver air via mouth and nose during sleep with less strap pressure than is required for oro-nasal (anesthesia) masks. This optimizes skin comfort and minimizes air (insufflation) leakage.

2. The Daytime Inspiratory Muscle Aids
   (a) Body Ventilators

   The intermittent abdominal pressure ventilator (IAPV) involves the intermittent inflation of an elastic air sac that is contained in a corset or belt worn beneath the patient's outer clothing (Fig. 16.6) (Exsufflation Belt™, Respironics Inc., Murrysville, PA). The sac is cyclically inflated by a positive pressure ventilator. Bladder inflation moves the diaphragm upward to assist in expiration. During bladder deflation, gravity causes the abdominal contents and diaphragm to return to the resting position, and inspiration occurs passively. A trunk angle of 30° or more from the horizontal is necessary for it to be effective.

Fig. 16.6 A post-polio survivor with no measurable vital capacity since 1952 using an intermittent abdominal pressure ventilator (Exsufflation Belt™, Respironics International Inc., Murrysville, PA) during daytime hours and lip seal IPPV nightly since 1956. The air bladder inside the girdle is connected to the ventilator circuit (seen here), then the girdle is placed under the clothes and over the patient's abdomen

Fig. 16.7 Forty-eight-year-old man with Duchenne muscular dystrophy who has used 24-h mouthpiece IPPV for 25 years, now with no measurable vital capacity. The mouthpiece is fixed adjacent to the mouth by a flexible metal support arm (microphone holder)

If the patient has any inspiratory capacity or is capable of GPB, he or she can add volumes of air autonomously to that taken in mechanically. The IAPV generally augments tidal volumes by about 300 mL, but volumes as high as 1,200 mL have been reported [30]. Patients with less than 1 h of breathing tolerance usually prefer to use the IAPV rather than use noninvasive IPPV during daytime hours.

(b) Mouthpiece NIV

Mouthpiece NIV is the most important method of daytime ventilatory support. Some patients keep the 15-mm angled mouthpiece between their teeth all day. Most patients prefer to have the mouthpiece held near the mouth. A metal clamp attached to a wheelchair can be used for this purpose (Fig. 16.7), or the mouthpiece can be fixed onto motorized wheelchair controls—most often, sip and puff, chin, or tongue controls. The ventilator is set for large tidal volumes, often 1,000–2,000 mL. The patient grabs the mouthpiece with his mouth and supplements or substitutes for inadequate autonomous breath volumes. The patient varies the volume of air taken from ventilator cycle to ventilator cycle and breath to breath to vary speech volume and cough flows as well as to air stack to fully expand the lungs.

To use mouthpiece IPPV effectively and conveniently, adequate neck rotation and oral motor function are necessary to grab the mouthpiece and receive IPPV without insufflation leakage. To prevent the latter, the soft palate must move posteriorly and caudally to seal off the nasopharynx. In addition, the patient must open the glottis and vocal cords, dilate the hypopharynx, and maintain airway patency to receive the air. These normally reflexive movements may require a few minutes to relearn for patients who have been receiving ventilation via a tracheostomy tube.

(c) Nasal Intermittent NIV

Because patients prefer to use mouthpiece NIV or the IAPV for daytime use [33, 34], nasal NIV is most practical for nocturnal use. Daytime nasal NIV is indicated for infants and for those who cannot grab or retain a mouthpiece because of oral muscle weakness, inadequate jaw opening, or insufficient neck movement. Nevertheless, 24-h nasal NIV can be a viable and desirable alternative to tracheostomy, even for some patients with severe lip and oropharyngeal muscle weakness [17]. Nasal NIV users learn to close their mouths or seal off the oropharynx with their soft palates and tongues to prevent oral insufflation leakage.

Complications of Noninvasive Intermittent Positive Pressure Ventilation

Besides orthodontic deformities and skin pressure from the interface, other potential complications include very infrequent allergy to the interface, dry mouth, eye irritation from air leakage, nasal congestion, sinusitis, nose bleeding, gum discomfort and receding from nasal interface, maxillary flattening in small children, aerophagia [35], and, as for invasive ventilation, possible barotraumas although this is rare in NMD patients. Two cases of pneumothorax in over 1,000 ventilator users and over 5,000 patient-ventilator use years have been reported [36]. In addition, occasional patients experience claustrophobia. Proper interface selection eliminates or minimizes these difficulties.

Abdominal distention tends to occur sporadically in NIV users. The air usually passes as flatus once the patient gets up or is placed into a wheelchair in the morning. When severe, it can cause increased ventilator dependence. A gastrostomy may be needed to "burp" out the air.

Goal Three: Maximize Cough Flows

1. Why Are Expiratory Muscle Aids Needed?

Bulbar, inspiratory, and expiratory muscles are needed for effective coughing. The latter are predominantly the

abdominal and intercostal muscles. Clearing airway secretions and airway mucus can be a continual problem for patients who cannot swallow saliva or food without aspiration. For patients with respiratory muscle dysfunction and functional bulbar musculature, it becomes a problem during chest infections, following general anesthesia, and during any other periods of bronchial hypersecretion.

2. Manually Assisted Coughing

Assisted CPF can be greatly increased in patients receiving maximal insufflations followed by manual abdominal thrusts for assisted coughing [37]. In 364 evaluations of NMD patients able to air stack, the mean VC in the sitting position was 996.9 mL, the mean MIC was 1647.6 mL, and although CPFs were 2.3 L/s (less than 2.7 L/s or the minimum needed to eliminate airway secretions) mean-assisted CPF were 3.9 L/s. An epigastric thrust with one hand, while applying counterpressure across the chest to avoid paradoxical chest expansion, further increases assisted CPF for 20 % of patients [38]. Manually assisted coughing is usually less effective in the presence of severe scoliosis because of a combination of restricted lung capacity and the inability to effect diaphragm movement by abdominal thrusting because of severe rib cage and diaphragm deformity. When inadequate, and especially when inadequacy is due to difficulty air stacking, the most effective alternative for increasing CPF and clearing airway secretions is the use of MAC.

The inability to generate more than 2.7 L/s or 160 L/m of assisted CPF despite having a VC or MIC greater than 1 L usually indicates fixed upper-airway obstruction or severe bulbar muscle weakness and hypopharyngeal collapse during coughing attempts. Vocal cord adhesions or paralysis may have resulted from a previous translaryngeal intubation or tracheostomy [39]. Because some lesions, especially obstructive granulation tissue, can be corrected surgically, laryngoscopic examination is warranted.

3. Mechanical Insufflation-Exsufflation

(a) Introduction of Mechanical Insufflation-Exsufflation

MI-Es (Cough Assist™, J. H. Emerson Co., Cambridge, MA) deliver deep insufflations followed immediately by deep exsufflations. The insufflation and exsufflation pressures and delivery times are independently adjustable. Insufflation to exsufflation pressures of +40 to −40 cm H2O are usually the most effective and preferred by most patients. Onset of insufflation generates an insufflation flow peak and a lung insufflation of more than 2 L. Mechanical exsufflation generates two exsufflation flow notches. One occurs when the insufflation pressure stops and is due to the elastic recoil of the lung. The second one, a bit greater, is caused by the exsufflation pressure itself. Except after a meal, an abdominal thrust is applied in conjunction with the exsufflation (MAC, or mechanically assisted coughing). MI-E can be provided via an oral-nasal mask, a simple mouthpiece, or via a translaryngeal or tracheostomy tube. When delivered via a tracheostomy tube, the cuff, when present, should be inflated. The Cough Assist™ can be manually or automatically cycled. Manual cycling facilitates caregiver-patient coordination of inspiration and expiration with insufflation and exsufflation, but it requires hands to deliver an abdominal thrust, to hold the mask on the patient, and to cycle the machine.

One treatment consists of about five cycles of MAC followed by a short period of normal breathing or ventilator use to avoid hyperventilation. Insufflation and exsufflation pressures are almost always from +35 to +60 cm H_2O to −35 to −60 cm H_2O. Most patients use pressures of 40 cm H_2O for insufflations and exsufflations, as it has been shown to be most effective in animal models [40]. Insufflation and exsufflation times are adjusted to provide maximum chest expansion and rapid lung emptying. In general, 2–4 s are required. Multiple treatments are given in one sitting until no further secretions are expulsed and any secretion or mucus-induced oxyhemoglobin desaturations are reversed. Use can be required as frequently as every few minutes around the clock during chest infections.

The use of MAC via the upper airway can be effective for children as young as 11 months of age. Patients this young can become accustomed to it and permit its effective use by not crying or closing their glottises. Between 2.5 and 5 years of age, most children become able to cooperate and cough on queue with mechanical in-exsufflation. Exsufflation-timed abdominal thrusts are also used for infants.

Whether via the upper airway or via indwelling airway tubes, routine airway suctioning misses the left main stem bronchus about 90 % of the time [41]. MAC, on the other hand, provides the same exsufflation flows in both left and right airways without the discomfort or airway trauma of tracheal suctioning. Patients prefer MAC to suctioning for comfort and effectiveness, and they find it less tiring [42]. Deep suctioning, whether via airway tube or via the upper airway, can be discontinued for most patients.

(b) Efficacy of MAC

The efficacy of MAC has been demonstrated both clinically and on animal models [43]. Flow generation is adequate in both proximal and distal airways to eliminate respiratory tract debris [44, 45]. VC, pulmonary flow rates, and SpO_2 when abnormal improve immediately with clearing of airway secretions and mucus by MAC [46, 47]. An increase in VC of 15–42 % was noted immediately following treatment in 67 patients with “obstructive dyspnea,” and a 55 % increase in VC was noted following MAC in patients with neuromuscular conditions

[48]. More recently, an increase in VC of 15–400 % (200–800 mL) and normalization of SpO_2 has been observed as MAC eliminates airway mucus for ventilator-assisted NMD patients with chest infections [38].

(c) Indications for MAC

Of the three muscle groups required for effective coughing, MAC can only take the place of the inspiratory and expiratory muscles. Thus, it cannot be used to avert tracheotomy very long if bulbar function is inadequate to prevent airway collapse, as is often the case in advanced bulbar ALS, or aspiration of saliva is continuous. On the other hand, patients with completely intact bulbar muscle function, such as most ventilator users with traumatic tetraplegia, can usually air stack to volumes of 3 L or more, and, unless very scoliotic or obese, a properly delivered abdominal thrust can often result in assisted CPF of 6–9 L/s. These flows should be more than adequate to clear the airways and prevent pneumonia and respiratory failure without need for MAC. Thus, the patients who need MAC the most are those whose bulbar muscle function can maintain adequate airway patency but is insufficient to permit optimal air stacking for assisted CPF more than 250–300 L/m. This is typical of most non-bulbar ALS, NMD patients. The most typical example of patients who can consistently avoid hospitalization and respiratory failure by using MI-E during intercurrent chest infections is DMD patients [47]. Patients with respiratory muscle weakness complicated by scoliosis and inability to capture the asymmetric diaphragm by abdominal thrusting also greatly benefit from MAC.

Glossopharyngeal Breathing

Both inspiratory and, indirectly, expiratory muscle function can be assisted by GPB [21]. GPB can provide an individual with weak inspiratory muscles and no VC or breathing tolerance with normal alveolar ventilation when not using a ventilator or in the event of sudden ventilator failure day or night [21, 48]. The technique involves the use of the glottis to add to an inspiratory effort by projecting (gulping) boluses of air into the lungs. The glottis closes with each "gulp." One breath usually consists of 6–9 gulps of 40–200 mL each (Fig. 16.8). During the training period, the efficiency of GPB can be monitored by spirometrically measuring the milliliters of air per gulp, gulps per breath, and breaths per minute (Fig. 16.9). A training manual [49] and numerous videos are available [50], the best of which was produced in 1999 [51].

Although severe oropharyngeal muscle weakness can limit the usefulness of GPB, in one center 13 DMD ventilator users had no breathing tolerance other than by GPB [52]. Approximately 60 % of ventilator users with no autonomous ability to breathe and good bulbar muscle function can use

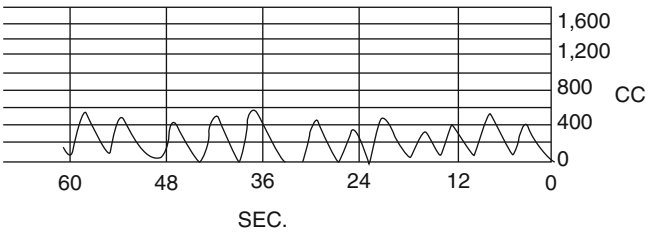

Fig. 16.8 Normal minute ventilation (60–90 mL/gulp, 6–8 gulps per breath, 12 breaths per minute for 48 mL/gulp) for 4,760 mL/min of alveolar ventilation throughout daytime hours by glossopharyngeal breathing (GPB) for an individual with no measurable vital capacity otherwise. Maximum glossopharyngeal single breath capacities can exceed 3,000 mL for such individuals

GPB and discontinue ventilator use for minutes to up to all day [48, 53]. GPB is also rarely useful in the presence of an indwelling tracheostomy tube. It cannot be used when the tube is uncapped as it is during tracheostomy IPPV, and even when capped, the gulped air tends to leak around the outer walls of the tube and out the stoma as airway volumes and pressures increase during the GPB air-stacking process. The safety and versatility afforded by GPB are additional reasons to eliminate tracheostomy in favor of noninvasive aids. Some patients with no measurable VC have awoken at night, breathing glossopharyngeally, to find that their ventilators had failed, a scenario not possible for tracheostomy ventilation users.

Oximetry Monitoring and Feedback Protocol

For a patient with chronic alveolar hypoventilation who has not been using ventilatory support or the patient being weaned from tracheostomy ventilation, introduction to and use of mouthpiece or nasal IPPV is facilitated by oximetry feedback. An SpO_2 alarm may be set to 94 %. The patient sees that by taking slightly deeper breaths, SpO_2 will exceed 95 % within seconds. He or she is instructed to maintain SpO_2 above 94 % all day [47]. This can be achieved by unassisted breathing for a period of time and, once tired, by mouthpiece or nasal NIV. With time, the patient requires increasing periods of NIV to maintain adequate ventilation (SpO_2 greater than 94 %). In this manner, an oximeter may also help to reset central ventilatory drive.

Oximetry feedback is especially important during the management of respiratory tract infections. The cough of infants and small children who can never sit is inadequate to prevent chest cold-triggered pneumonia and respiratory failure. Children who can sit are usually protected from this until after 2 years of age. Older children and adults whose assisted CPF decreases below 300 L/m are also at high risk for chest cold-triggered acute respiratory failure. Such patients require continuous SpO_2 monitoring and are taught

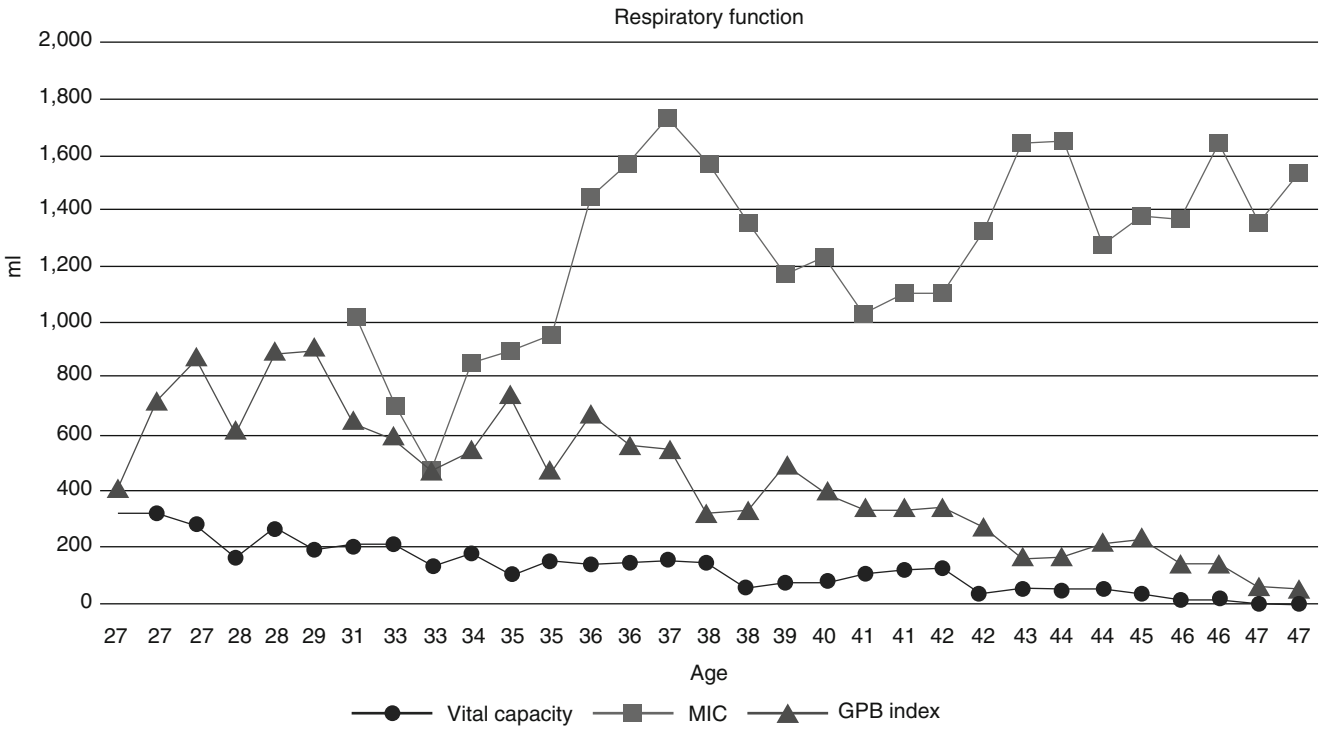

Fig. 16.9 Vital capacity, maximum insufflations capacity (*MIC*), and glossopharyngeal breathing maximum single breath capacity (GPmaxSBC) over time for 48-year old with Duchenne muscular dystrophy demonstrating relative preservation of MIC by comparison to GPmax SBC

that any dip in SpO_2 below 95 % is due either to underventilation or bronchial mucous plugging and if these two causes are not quickly addressed, may lead to atelectasis or pneumonia. They are instructed to use NIV to maintain normal ventilation and MAC to reverse mucous plug associated oxyhemoglobin desaturations. In this way, most episodes that would otherwise cause acute respiratory failure are successfully managed at home. For adults with infrequent chest colds, rapid access to this equipment may be all that is necessary.

Invasive Ventilatory Support

The use of noninvasive aids can be contraindicated by the presence of any of the following: depressed cognitive function, orthopedic conditions interfering with the application of NIV interfaces and exsufflation techniques, pulmonary disease necessitating high FiO_2, uncontrolled seizures, or substance abuse [54, 55]. Also, the presence of a nasogastric tube can hamper the fitting of a nasal interface or mouthpiece interface for NIV by interfering with both soft palate closure of the pharynx and seal at the nose. Although tracheostomy ventilation can also extend survival for these patients [56], morbidity and mortality outcomes are not as favorable as by noninvasive approaches [18, 57]. Tracheotomy is indicated for severe bulbar ALS patients [22], rarely if ever for DMD and SMA patients [20, 57], other than for an occasional patient with SMA type 1 who aspirates too much saliva to maintain normal SpO_2 [28, 58]. Patients with DMD, even those who are continuously NIV dependent, can avoid hospitalizations and pulmonary morbidity and mortality for decades and tracheotomy indefinitely when properly managed by using respiratory muscle aids [20].

Although widely thought to be fatal before age 2, SMA1, when managed according to a recently described noninvasive respiratory aid protocol, has thus far allowed many of these patients to survive into adolescence without a tracheostomy. In a recent study, 95 patients with typical, severe SMA type 1A and 7 patients with SMA type 1B who received ventilator assistance were studied. Sixty-eight of the patients without tracheostomy tubes were dependent on NIV continuously with 19 having no ventilator-free breathing capability. Sixty of the 68 individuals could communicate verbally. Twenty-seven of the patients had tracheostomy tubes; 14 of which had their tubes placed prior to referral to the clinic. Of these 27 patients, 6 were verbal prior to placement of the tubes and retained some verbalization afterward. Of the 21 individuals who had not developed speech prior to tracheostomy, none developed it after [58].

When tracheostomy ventilation is used despite the fact that oropharyngeal muscles are sufficient for swallowing, speaking, and permitting decannulation to NIV, either cuffless tubes or tracheostomy cuff deflation should be used

Fig. 16.10 Thirty-four-year old with Duchenne muscular dystrophy ventilated by intermittent abdominal pressure ventilator, using a robot arm for activities of daily living

up to 24 h a day [59]. Delivered air volumes are increased to compensate leak and support speech and one-way valves used to further facilitate verbal communication [60].

Quality of Life

Poor quality of life is usually given as the reason for withholding ventilator use [61]. However, no quality-of-life criteria, particularly those established by physically intact individuals, can be appropriately applied to all individuals. Life satisfaction depends, rather, on personal preferences [62] and on subjective satisfaction in physical, mental, and social situations, even though these may be deficient in some manner. Thus, not quality of life but potential satisfaction with life should be considered. It is particularly appropriate that the life satisfaction of individuals who are living the consequences of having chosen to use ventilators be considered when deciding about such ethically and financially complex matters as ventilator use for others. Interestingly, data indicate that severely disabled, long-term post-poliomyelitis, DMD, and SCI ventilator users [61] generally have very positive views of their lives and life satisfaction. These individuals find quality of life in interpersonal activities, and they are very significantly more satisfied with life than health-care professional estimates suggest [62]. Crucial for this is often the availability of personal attendant-care services and assistive equipment (Fig. 16.10). Thus, in the face of calls to limit entitlement spending, it should be noted that a society willing to provide free room, board, health care, legal and educational services, vocational training, and cable television for felons at exorbitant cost has the ethical responsibility to provide attendant-care services to those in need, some of whom are crime victims themselves.

17 Immunotherapy in the Treatment of Autoimmune Neuromuscular Diseases

Vibhav K. Bansal and Matthew N. Meriggioli

General Principles of Immunotherapy

An increasing number of immunotherapies have been used in recent years to treat the group of neuromuscular diseases believed to have an autoimmune pathogenesis. A number of general principles should be applied when considering immunotherapy in any given patient. First, the diagnosis of an immune-mediated neuromuscular disease must be firmly established and confirmed, usually by some combination of serological and electrophysiologic testing. Once the diagnosis is established, a risk-benefit assessment for the drug under consideration must be done. This should take into account the severity of the disease manifestations, patient comorbidities and concomitant treatments, and the safety profile as well as cost of the immunotherapeutic agent. The treating neurologist should also be very familiar with the drug, its side effects, and the required toxicity monitoring. The side effects of immunosuppressive therapy can at times be worse than the disease, especially when the drugs are used for a long time, or without proper collateral measures to prevent adverse reactions. In women, pregnancy planning is critical as many immunosuppressant drugs are teratogenic. Patients must also be informed that in addition to specific short-term side effects (see below), long-term immunosuppression may increase the risk for development of infections and certain neoplasms.

The overall goal of immune-directed therapy is to induce remission or substantial improvement of symptoms in as timely a manner as possible (Table 17.1). With the exception of Guillain-Barré syndrome (GBS) – an acute, monophasic disorder – and its variants, maintenance of remission (or improvement) is then accomplished by slow and gradual tapering of medications over many months until the minimum dose of medication required to maintain disease control is identified.

The range of available immune-directed treatments is summarized in Table 17.2. Standard dosing, common side effects, basic recommendations for toxicity monitoring, and indications for use are also listed. Not all treatments have demonstrated clinical efficacy by randomized controlled clinical trials, and many of the indications are based on cohort, case control studies, or case reports.

Treatment Considerations

Assessment of Efficacy

For neuromuscular disorders, monitoring of clinical efficacy of treatment is mainly assessed by measurement of strength and sensory and/or autonomic function with appropriate

Table 17.1 General principles of immunotherapy

Initiation of therapy
Confirm diagnosis
Disease severity, likelihood of response, risk-benefit ratio
Patient features: age, concomitant diseases/medications
Drug side effects and cost
Drug dosing
Initial: use high dose to bring disease into remission
Follow-up: taper medications
Slowly
Determine minimum dose required to maintain remission
Monitor side effects
Use objective measures of drug efficacy
Quantitative strength testing
Functional testing
Activities of daily living

Table 17.2 Immune therapies for autoimmune neuromuscular disease

Treatment	Major indications	Initial dosing/frequency	Side effects	Monitor
Plasma exchange (PE)	GBS, CIDP, PPN, MG	4–6 exchanges on alternate days	Rapid fluid and electrolyte shifts	BP, CBC, PT/PTT/INR
IVIg	GBS, CIDP, MMN, MG, LEMS, DM	1–2 g/kg (over 2–5 days)	Hypersensitivity reactions	Renal function
Prednisone	CIDP, PPN, MG, DM, PM, VN	(a) 0.75–1.5 mg/kg/day (b) 60–100 mg on alternate days	Weight gain, diabetes, osteoporosis, hypertension, cataracts	Weight, blood glucose, BP, electrolytes, DEXA scan, ocular exam
Azathioprine (AZA)	MG, CIDP, DM, PM,	2–3 mg/kg/day	Flu-like reaction (20–30 %) pancytopenia, liver toxicity, pancreatitis	TMPT (pretreatment), chronic: CBC, liver function
Mycophenolate mofetil (MMF)	MG,CIDP	2–2.5 g/day in divided twice daily doses	Leukopenia, liver toxicity, infections	CBC, liver function
Cyclosporine	MG, CIDP	4–6 mg/kg/day in divided twice daily doses	Renal insufficiency, pancytopenia	Renal function, CBC
Tacrolimus	MG	3–5 mg/day	Renal insufficiency, hyperglycemia	Renal function, CBC, blood glucose
Cyclophosphamide	CIDP, MG, VN	(a) 500 mg/m^2 (b) 50 mg/kg × 4	Pancytopenia, hemorrhagic cystitis, malignancy (total dose >75 g)	CBC, platelets, liver function, UA
Rituximab	MG, CIDP, PPN, DM	4 × 375 mg/m^2 weekly 1,000 mg IV × 2 doses (separated by 2 weeks)	Hypersensitivity, hypotension, infection (PML)	CBC, CD19 counts, JC virus Abs
Methotrexate	DM, PM, MG	7.5 mg/week in divided doses (increase to 20–25 mg weekly)	Stomatitis, hepatitis, liver and lung interstitial fibrosis	CBC, liver/renal function, CXR

GBS Guillain-Barre syndrome, *CIDP* chronic inflammatory demyelinating polyneuropathy, *MG* myasthenia gravis, *MMN* multifocal motor neuropathy, *PPN* paraproteinemic neuropathy, *DM* dermatomyositis, *PM* polymyositis, *LEMS* Lambert-Eaton Myasthenia Syndrome, *VN* vasculitic neuropathy, *CBC* complete blood count, *UA* urinalysis

clinical testing and established quantitative scores. These clinical assessments may also be supplemented by surrogate markers, such as electrophysiologic testing, antibody titers, and creatine kinase (CK) levels. Documenting improvement in muscle strength using objective measures can be a difficult problem, since the standard, commonly used assessment, the Medical Research Council (MRC) scale, is somewhat limited for the sensitive detection of mild or even moderate changes in muscle strength. Specifically, in the range of 4–5, the determinations are inconsistent, subjective, and variable among examiners. Therefore, it is desirable for the clinician to supplement the MRC scale with simple functional tests of performance. For example, using a stopwatch to time certain basic motor tasks, such as getting up from a chair, taking off a sweater, or walking across the room, and describing how a patient performs a task (e.g., the ease of movement or need for additional aids) can be very informative. Further, recording simple movements, such as how far the patient can raise each leg off the bed, elevate both hands above the ears when standing or sitting, arise from a chair with arms crossed on the chest, or step onto a stool, may often times give a more accurate picture of the disability than a vague 4, 4–, or 4+ rating on the MRC scale.

While a careful and detailed history may be extremely helpful in assessing treatment response, some patients underreport changes in strength, and others are easily persuaded that they are better or over-interpret the feeling of well-being associated with corticosteroids as an "improvement." It is more informative to ask specific questions about the performance of certain tasks at home or at work or about any change in the activities of daily living. Has there been improvement in the ability to get out of a bath, chair, or the back seat of a car? Has there been a perceptible change in shoulder girdle weakness as manifested by combing/washing hair and removing heavy objects from high shelving? For distal upper limb weakness, inquiring about problems with opening door handles and in using a key in a tight lock (patients with "grade 4" weakness may be functionally locked out of their homes), as well as button and zipper manipulation, are quite useful. It is helpful to get the patient to describe lost skills or abilities at baseline; these can give an index of the rate of evolution and in treatable disorders, regaining a lost function is a good indicator of response to treatment. Historical assessment of symptoms of weakness depends on lifestyle as much as on the pattern and severity of weakness. A bricklayer or athlete will note more subtle changes in symptoms sooner than a sedentary individual.

Without a concomitant change in the activities of daily living and objective measurement of muscle strength, there is no practical value in gauging improvement on the basis of a change in a laboratory test value, such as the creatine kinase (CK) level in inflammatory myopathy, of the nerve conduction study in neuropathy, or the titers of acetylcholine receptor antibodies in myasthenia gravis and myelin-associated

glycoprotein (MAG) antibodies in demyelinating polyneuropathies. When a patient improves, most of the laboratory test values also improve, but the opposite is not true because immunotherapy may reverse many laboratory values without clinical improvement. For example, the CK level, the acetylcholine receptor antibody titer, or the titer of MAG antibodies always drop with plasma exchange because of removal of proteins and immunoglobulins, irrespective of whether the patient improves or not. In contrast, in chronic inflammatory demyelinating polyneuropathy (CIDP), the patient often improves, but the nerve conduction velocities or the amplitudes of the evoked responses may not substantially change [1]. The main rule, therefore, is not to "chase" a laboratory value in order to establish improvement but to use these tests as supportive measures of clinical change and to understand the underlying mechanism of the disease.

Starting and Stopping Therapy

Treatment should be initiated when the diagnosis is established and all the necessary diagnostic procedures are performed. However, the start of therapy should be tailored to the needs of the individual patient. When the disease causes significant weakness and other symptoms that interfere with the patient's activities of daily living, treatment should be started as soon as possible. When the disease is mild with little functional limitations, however, the decision is more complex. It may be preferable in such cases to explain to the patient the merits of therapy with respect to anticipated outcome and adverse effects. Treatment decisions should be influenced not only by the severity of the disease but also by the patient's lifestyle, profession, finances, and family or community support. The patient needs to understand the goals of treatment and the associated risks and must agree to comply with the necessary toxicity monitoring (clinic visits and laboratory tests).

In general, therapy is usually initiated at a high dose to bring the disease into remission quickly (Table 17.1). One exception to this is the case of prednisone in myasthenia gravis (MG) where high steroid doses may precipitate a disease worsening – in these patients, either a gradual dose escalation paradigm or pretreatment with plasma exchange or intravenous immune globulin is necessary (see below). Time-to-response should also be taken into consideration since the onset of benefit may be quite delayed for some of the drugs, and the patient should be made aware of this. Sufficient time must be given for treatment to take effect, or the agent may be withdrawn after an inadequately short period of time with the patient considered "resistant" to the drug.

In a patient who responds to immune therapy, the ultimate goal is to find the lowest dose of the safest drug that controls the disease with the least adverse effects. For example, corticosteroid therapies may require the addition of a steroid-sparing drug, such as azathioprine, if there is a need to reduce or reverse adverse effects and lower the amount of steroids without breakthrough of the disease. After a favorable therapeutic response, the tapering schedule will vary depending upon the immunotherapeutic agent(s) involved. In general, stepwise reductions in the dose of prednisone may be accomplished as frequently as every 2–6 weeks, while tapering of chronic immunosuppressant drugs requires longer periods of observation since the effects of dose reduction (like the therapeutic effects) may be delayed. In certain situations (e.g., rituximab in myasthenia gravis), continued treatment after a therapeutic response may not be necessary, and careful clinical observation for disease relapse will determine the need for continued therapy.

A minority of patients will fail to improve despite appropriate and adequate standard treatments. In this situation, the patient and family may become discouraged, lose confidence, and start doubting the physician's competence and expertise. Reacting by adding another drug or therapeutic procedure, which may be of no benefit and have more adverse effects, perpetuates the vicious cycle of uncertainty and confusion. In addition, the practice of continuing an immunosuppressive agent that has not worked, with the hope that it may slow down the progression of the disease, is potentially more detrimental than beneficial. Therefore, immune drugs that are judged to be ineffective after an adequate trial should be discontinued. If the disease has improved and remains stable with only mild deficit, the patient should be reassured that overtreatment will not be of greater benefit and that a certain amount of neurologic dysfunction that does not interfere with the patient's lifestyle is not uncommon in certain autoimmune neurological diseases. Although physicians are often influenced by patients and their families to "do something," it is preferable, if the diagnosis is correct but nothing seems to work, to provide only supportive care rather than expose the patient to the dangers of prolonged immunotherapy. On the other hand, when a patient has a rapidly progressive disease and there is evidence that intense immunotherapy could make a difference, another trial of immunosuppressive or immunomodulating therapy may be considered. The lack of response to one drug does not necessarily mean the patient will not respond to others, and sequential trials with different drugs may be necessary until an effective mode of therapy is found. Clinical judgment should always prevail.

Treatment of Acute Disease or Relapses

As noted, the primary goal of treatment of a new onset or newly diagnosed autoimmune neuromuscular condition is to induce a disease remission, which is accomplished by suppressing the inflammatory immune attack or by removing pathogenic circulating antibodies or other immune factors.

The primary agents used for this purpose are corticosteroids, intravenous immune globulin (IVIg) and plasma exchange (PE). Chronic immunosuppressive drugs that have a relatively quick onset of response (e.g., cyclosporine, tacrolimus) may also be considered, typically in combination with steroids, IVIg, or PE.

Corticosteroids

Corticosteroids exert broad effects on the immune system, suppressing inflammation and innate and adaptive immune responses [2]. Corticosteroids produce a rapid depletion of circulating T cells due to a combination of effects, including the inhibition of interleukin (IL)-2 signaling and induction of T cell apoptosis [3]. Other relevant mechanism may include the inhibition of the recruitment and migration of lymphocytes to areas of inflammation and interference with the production of lymphokines [2, 4, 5]. Prednisone is the most commonly prescribed oral corticosteroid and is the most frequently used drug in the treatment of immune-mediated neuromuscular disorders, having a therapeutic role in all except Guillain-Barre syndrome and multifocal motor neuropathy.

The treatment response will often determine the need for stronger immunosuppressive drugs. An aggressive approach with high-dose prednisone (0.75–1 mg/kg/day or 60–80 mg/day as a single daily morning dose for an initial period of 3–4 weeks) beginning early in the disease course is preferred. Prednisone is then tapered over a 10–12 week period to 60–80 mg as a single daily, alternate-day dose by gradually reducing the alternate, "off-day" dose by 5–10 mg/week. This could be done faster if necessitated by side effects, though this carries a greater risk of disease relapse. If there is evidence of efficacy and there are no serious adverse effects, the dosage is reduced gradually by 5–10 mg every 3–4 weeks until the lowest possible dose that controls the disease is reached. In a patient responding to prednisone, a "maintenance" dose of 10–25 mg every other day may be needed to secure persistent improvement and stability. On the other hand, if by the time the dosage has been reduced to 60–80 mg every other day, there is no objective benefit (defined as increased muscle strength and function), the patient may be considered unresponsive to prednisone, and tapering is accelerated while the next immunosuppressive drug in the line of preference is started.

The single-dose, alternate-day program minimizes adverse effects while adequately controlling the underlying disease. We generally do not start therapy with alternate-day prednisone, without a preceding daily high-dose daily schedule, because the response may be delayed or inadequate. Furthermore, it is more difficult to induce a remission with an alternate-day program, but it is easier to maintain once achieved with a high daily dosage. It is also preferable to give prednisone as a single dose in the morning, because the higher morning concentration of natural cortisol results in a competitive decrease in metabolism of the administered prednisone, decreased clearance of the unbound (active) prednisolone, and, theoretically, a greater beneficial effect [5]. The morning dose of exogenous prednisone is also less likely to suppress the evening secretion of adrenocorticotropic hormone (ACTH), and, consequently, the endogenous cortisol secretion is anticipated to be normal the next morning.

Table 17.3 Corticosteroid side effects and prevention strategies

Side effect	Prevention strategies
Edema (sodium/fluid retention)	Sodium-restricted diet
Obesity	Low-calorie, low-fat diet; exercise
Potassium loss	Supplement (up to 40 mEq/day)
Hypertension	Monthly checks, treatment
Impaired glucose tolerance	Monitor fasting blood glucose, treat if necessary; recommend "low glycemic index" diet
Osteoporosis	Ca + (1,000 mg/day)/vitamin D (50,000 units/week), DEXA scan yearly, bisphosphonates, female hormone replacement
Steroid myopathy	Exercise, high-protein diet
Cataracts/glaucoma	At least yearly ophthalmologic examination
Growth suppression (children)	Use minimum effective dose
Peptic ulcer disease	H2 inhibitors; proton pump inhibitors
Psychosis/anxiety	Use minimum effective steroid dose; anxiolytics, antidepressants if necessary
Insomnia	Sleep hygiene, zolpidem (5–10 mg), wean off/discontinue as steroid dose is tapered

Adverse Effects of Corticosteroids

The most common adverse effects of chronic corticosteroid therapy are summarized in Table 17.3 and include the following [5, 6]: (1) abnormality of fat distribution with generalized obesity, hence the need for strict caloric restriction; (2) lipolytic action resulting in hyperlipidemia, which can rarely cause fat emboli in the femoral head and aseptic necrosis of the hip. Epidural lipomatosis resulting in spinal cord compression is rare but should be suspected if a patient on long-term steroid therapy is developing back pain and signs of myelopathy. Fatty liver, documented by ultrasound, is also common and may be responsible for increase in levels of liver enzymes; (3) glucose intolerance, hence the need for low carbohydrate diet; (4) retarded growth in children, which can be minimized with the alternate-day program; (5) menstrual irregularities; (6) edema and hypertension, hence the need for low-salt diet from the beginning of therapy; (7) osteoporosis especially in postmenopausal women, hence

the suggestion for coadministration of vitamin D, calcium supplements, or bisphosphonates; (8) gastrointestinal complaints (but rarely bleeding), which can be avoided by taking prednisone after meals and may be minimized with antacids or histamine blockers, as described earlier; (9) skin changes, including acne, ecchymosis, facial hirsutism, and stria; (10) posterior subcapsular cataracts and, rarely, glaucoma, necessitating frequent eye examinations; (11) central nervous system complications, such as insomnia, irritability, and exacerbation of the physiologic action tremor in the hands; and (12) proximal muscle weakness often referred to as "steroid myopathy" (see below). Most side effects improve with dose reduction and become minimal at less than 20 mg every other day.

Steroid Myopathy

The long-term use of prednisone may cause muscle weakness associated with a normal or unchanged CK level, referred to as "steroid myopathy" [7]. This may present a particular diagnostic/therapeutic challenge in patients with inflammatory myopathy, in whom it may be difficult to distinguish between steroid-induced myopathy and increased weakness related to disease activity. The decision to adjust the prednisone dosage in a patient with myositis who has previously responded to treatment may be aided by review of the past 2 months of strength alterations, mobility, serum CK, medication changes, and associated medical conditions. For example, a patient who recently has had increased CK levels, no new overt signs of steroid toxicity with reduced or unchanged dosage of steroids, and no evidence of a systemic illness or infection, increasing muscle weakness is most likely due to exacerbation of the disease, which may require an increase in prednisone or development of a steroid-resistant state. A useful clinical sign is worsening of the strength of neck flexor muscles with exacerbation of myositis, while these muscles remain unchanged with steroid-induced muscle weakness. Also, electromyography (EMG) may help by showing abundance of spontaneous activity when the weakness is related to myositis, while these abnormalities are absent with steroid myopathy. Steroid myopathy associated with the use of prednisone in MG is uncommon in our experience.

Intravenous Steroid Therapy

In certain autoimmune neuromuscular conditions, high doses of steroids (methylprednisolone, solumedrol) are given by intravenous pulse therapy to enhance potency and onset of benefit [8]. Typically, a dose of 500–1,000 mg methylprednisolone IV is given daily for 3–5 days. Subsequently, doses of 500–1,000 mg weekly, then every 2 weeks are administered, followed by gradual tapering, maintenance therapy, or switch to oral corticosteroid therapy. Pulsed dose intravenous steroids are typically used in the treatment of CIDP [8] and in paraproteinemic [9] and vasculitic neuropathies [10]. Similar to prednisone, IV pulsed steroids have no role in GBS or MMN and should generally be avoided in the treatment of MG because of a likely enhanced risk of steroid-associated exacerbation.

Plasma Exchange

Plasma exchange (PE) is a well-established procedure in the treatment of autoimmune neuromuscular disorders. PE temporarily reduces the levels of circulating antibodies and other circulating factors (complement, immune complexes, cytokines) and often produces clinical improvement in a matter of days [11]. It is generally used for short-term, urgent treatment of severe disease when a rapid response is needed (e.g., severe bulbar and/or respiratory muscle weakness) or in patients who do not respond to other therapies. A typical course of PE consists of 5–6 exchanges administered on an every other day schedule, during which 2–3 l of plasma are removed. Decisions regarding the total number of exchanges depend upon clinical response and tolerability, but more than six exchanges may be required in some patients.

Other immunosuppressants (see corticosteroids and below) are typically required to maintain the effects of PE in the long term, as the benefits typically wear off after 3–4 weeks although they may persist for as long as 3 months. Repeated exchanges probably do not have a cumulative benefit, and the use of PE as chronic maintenance therapy is not recommended, unless other treatments fail or are contraindicated.

Side effects during PE include paresthesias from citrate-induced hypocalcemia, symptomatic hypotension, transitory cardiac arrhythmias, nausea, lightheadedness, chills, and pedal edema. The major complications relate to the use of large-bore venous access. The risks of subclavian lines, arteriovenous shunts, or grafts for venous access include thromboses, thrombophlebitis, subacute bacterial endocarditis, and pneumothorax. Specific removal of circulating immune pathogenic factors may also be accomplished using immunoadsorption columns, some of which use immobilized antigenic proteins to remove autoantibodies from patients' serum. Further development of this technique may provide a more specific, efficient, and safer alternative to PE.

PE is a therapeutic option in severely affected patients as a short-term, temporary measure in MG, chronic inflammatory demyelinating polyneuropathy, and Guillain-Barré syndrome [11–13]. There is less experience with its use in other autoimmune neuromuscular disorders but may be effective presumably by removing autoantibodies and/or cytokines. It is not effective in multifocal motor neuropathy or in the myositides.

Intravenous Immunoglobulin (IVIg) and Subcutaneous Immunoglobulin

IVIg has emerged as a major immunotherapeutic modality in neurology [14–16] and in autoimmune neuromuscular disorders in particular. IVIg has multiple potential mechanisms of actions, including inhibition of cytokines, competition with autoantibodies, inhibition of complement deposition, effect on superantigens, interference with Fc receptor binding on macrophages or the immunoglobulins on B cells, blocking the Fc receptors on target antigens, and interference with antigen recognition by sensitized T cells via the soluble MHC class I, MHC class II, CD8, and CD4 molecules present in the IVIg preparation [17–19]. More than one of these actions are likely operant in diseases for which IVIg has shown efficacy.

The therapeutic dose of IVIg is empirically set at 2 g/kg. Although earlier practice divided the total dose for infusion into five daily doses of 400 mg/kg each, the preference now is to divide the total dose into two daily doses of 1 g/kg each especially in younger patients who have normal renal and cardiovascular function. In our experience, the 2-day infusion is not associated with more adverse reactions than the 5-day infusion as long as the rate of infusion does not exceed 200 ml/h or 0.08 ml/kg/min. Considering the drug's rapid diffusion to the extravascular space, achieving a high concentration of IVIg within 2 days may also enhance its efficacy. The half-life of IVIg is estimated at 18–32 days [19], so maintenance protocols usually call for 0.5–1 g/kg every 3–4 weeks, as dictated by the patients' clinical responses.

In general, adverse reactions to IVIg therapy are usually minor and occur in less than 10 % of patients [20]. Mild to moderate headache, chills, myalgia, or chest discomfort may develop in the first hour of the infusion and usually respond to stopping the infusion for 30 min and resuming it at a slower rate. Post-infusion fatigue, fever, or nausea may occur and last for up to 24 h. A slow rate of infusion is advisable in patients with a compromised cardiovascular system or congestive heart failure to avoid fluid overload. IVIg therapy may cause an increase in serum viscosity, which may predispose to the development of thromboembolic events, particularly in patients with high-normal or slightly elevated serum viscosity, such as those with cryoglobulinemia, hypercholesterolemia, or hypergammaglobulinemia. Rare cases of stroke, pulmonary embolism, or myocardial infarction after IVIg treatment have been reported [21–23]. Whether low-dose heparin or anti-platelet agents can prevent thromboembolic events in such patients is unknown. In patients with a history of migraine, IVIg therapy may trigger a migrainous attack, which may be prevented by pretreatment with propranolol [24]. Aseptic meningitis may rarely develop in some patients treated with IVIg, particularly those with a history of migraine [25, 26]. The symptoms respond to strong analgesia and subside in 24–48 h. Additional diagnostic testing is rarely necessary, and prophylaxis with intravenous steroids prior to subsequent infusions can be variably effective in our experience.

Acute renal tubular necrosis, mostly reversible, occurs rarely with IVIg therapy in patients who have preexisting kidney disease and volume depletion, particularly the elderly and those with diabetes or poor hydration [27, 28]. Skin reactions (urticaria, lichenoid cutaneous lesions, pruritus, and petechiae [29]) to IVIg therapy, although rare, may develop 2–5 days after the infusions and may last up to 30 days. A severe anaphylactic reaction may occur in patients with an absence or severe deficiency of IgA. Selective IgA deficiency is common (prevalence about 1:1,000) and asymptomatic. The reaction is rare, occurs mostly in patients with common variable immunodeficiency [30], and may be associated with the presence of serum IgG anti-IgA antibodies [31]. We do not routinely determine the serum IgA level before starting therapy but recommend that initial infusions be done in a hospital or outpatient setting where urgent care for an anaphylactic reaction is readily available. Finally, the IVIg preparations available in the United States are now safe with respect to the transmission of known viruses or infections. Despite this, clinicians should be watchful to ensure the early detection of any unforeseen or unexpected infectious agents (e.g., prion proteins) associated with its long-term use.

In controlled trials, IVIg was effective in Guillain-Barré syndrome [32–34], CIDP [35–40], multifocal motor neuropathy [41–45], dermatomyositis [46], Lambert-Eaton myasthenic syndrome [47], and MG [48–50]. IVIG was effective only in a small numbers of patients with IgM paraproteinemias [51, 52], and it was ineffective in inclusion-body myositis [53]. In uncontrolled studies, IVIg has been reported to be effective in some patients with polymyositis [54, 55].

Recent studies suggest that subcutaneous delivery of an immunoglobulin preparation (SCIg) may be effective and may represent an alternative to IVIg in patients with difficult venous access [56–59]. A randomized trial suggests that SCIg is safe and therapeutically equivalent to IVIg [59]. The most important limitation is the relatively small volumes that can be administered subcutaneously at a single injection site. Notably, patients commonly experience subcutaneous swelling and have found the procedure too difficult for self-administration [57, 58].

Long-Term Maintenance (Nonsteroidal) Immunotherapies

Although most patients with MG, polymyositis, dermatomyositis, and CIDP respond to steroids to some degree and for some period of time, a number of them fail to improve,

become steroid resistant, or are unable to successfully taper the steroid to an acceptable maintenance dose (≤20–25 mg every other day). The decision to start an immunosuppressive drug in these patients is based on the following factors: (a) "steroid-sparing" effect is needed since, in spite of steroid responsiveness, the patient has developed significant complications; (b) attempts to lower a high steroid dosage have repeatedly resulted in a new relapse; (c) adequate doses of prednisone for at least a 2–3 month period have been ineffective; and (d) the disease is rapidly progressive, with evolving severe limb and/or bulbar weakness or respiratory failure. The preference, however, for selecting an immunosuppressive drug is empirical. The choice is usually based on individual prejudices, experience, and assessment of the relative efficacy/safety ratio with each drug.

Azathioprine (AZA)

Azathioprine (AZA) is a purine antimetabolite that interferes with T and B cell proliferation. It is safe and inexpensive and has been used successfully in several autoimmune disorders. AZA therapy is initiated at 50 mg/day. In the absence of systemic side effects, the dose is then gradually titrated upward by 50 mg/week to a dose of 2–3 mg/kg/day. An idiosyncratic reaction, with "flu-like" symptoms, occurs within 10–14 days after starting AZA in 15–20 % of patients. This reaction requires stopping the drug. Hepatotoxicity and leukopenia are also important adverse effects [60] but are reversible if detected early, and the dose of AZA is reduced or discontinued. Blood counts and liver function tests should be followed periodically. An elevation of liver enzymes, if slight, needs only observation. Elevation of liver enzymes may be related to a "fatty liver" from long-term steroid use rather than from AZA. Patients with thiopurine methyl transferase deficiency cannot completely metabolize AZA so that a normal dose may lead to dangerous leukopenia [61]. Measurement of thiopurine methyl transferase levels is recommended by some prior to initiating AZA therapy, but is certainly advisable with early or marked AZA-associated leukopenia. Long-term use of AZA may increase the risk of developing certain malignancies [62], and the risk is likely dose and duration dependent, so the minimum effective maintenance dose of AZA should be used. Because it is usually effective after 6 months or at times longer of treatment, patience is required before it is concluded that the drug is ineffective. AZA is used in the treatment of myasthenia gravis [63], CIDP [64, 65], and the inflammatory myopathies [66, 67], mainly as a steroid-sparing drug, although with the exception of myasthenia gravis, evidence of efficacy consists mainly of uncontrolled case series.

Mycophenolate Mofetil (MMF)

Mycophenolate mofetil (MMF) selectively blocks purine synthesis, thereby suppressing both T and B cell proliferation. This drug is well tolerated, has few adverse effects, and appears to be effective for long-term therapy especially in myasthenia gravis [68]. It is a therapeutic option as a steroid-sparing agent or as a long-term immunosuppressant. Because it is less toxic than other immunosuppressant drugs (AZA, cyclosporine, cyclophosphamide), it has gained some favor as a first-line steroid-sparing agent. The typical MMF dose is 1,000 mg twice daily, but doses up to 3,000 mg a day have been used. It has a relatively slow onset of action (>3 months) and is very expensive. The main side effects are hyperglycemia, hypercholesterolemia, gastrointestinal symptoms, and electrolyte disorders [68]. Regular monitoring of the complete blood count and basic chemistries is required. Progressive multifocal leukoencephalopathy (PML) has been reported in patients treated with MMF [69], but a causal relationship is uncertain.

MMF is mainly used in the treatment of MG, based on pilot studies, and retrospective series indicating efficacy [70, 71]. Notably, two randomized, controlled trials failed to show additional benefit of MMF over 20 mg daily prednisone as initial immunotherapy of MG [72] and did not show a significant steroid-sparing effect of MMF in patients on prednisone [73], but a number of study-related issues have called these negative results into question, including the generally mild disease status of the patients, the better-than expected response to relatively low-dose prednisone, and the short duration of the studies. MMF has also been used in CIDP, MMN, and refractory PM and DM [74].

Methotrexate

Methotrexate is a folate inhibitor with a relatively safe side-effect profile that has been successfully used in rheumatoid arthritis and other autoimmune disorders [75]. Several doses and regimens have been used, but the most common is oral administration starting at 7.5 mg weekly for the first 3 weeks (given in a total of 3 doses, 2.5 mg every 12 h), increasing it gradually by 2.5 mg/week up to a total of 20–25 mg weekly [76]. When using methotrexate chronically, folic acid supplementation (1 mg daily, by mouth) is recommended. A relevant side effect is methotrexate pneumonitis, which can be difficult to distinguish from the interstitial lung disease seen in some patients with inflammatory myopathies. Other adverse effects include stomatitis, gastrointestinal symptoms, leukopenia, thrombocytopenia, renal toxicity, hepatotoxicity, and malignancies. Leucovorin rescue, in which the drug is given 24 h after administration of intravenous methotrexate, at doses of 50 mg/m^2 orally every 6 h for a total of 4

doses, may be considered to counteract the side effects of methotrexate. Methotrexate is most commonly used as a steroid-sparing drug in the inflammatory myopathies [76]. Its use in the inflammatory neuropathies or MG has been very limited, although a controlled clinical trial of methotrexate in MG is ongoing. Because it acts faster than AZA, it may be considered in appropriate clinical situations when a quicker therapeutic response is desirable.

Cyclophosphamide

Cyclophosphamide is an alkylating antineoplastic agent that is among the strongest immunosuppressive drugs. It can be given intravenously or orally at doses that vary depending upon the disease and route of administration. The intravenous route is preferred and pulsed dosing is believed to mitigate against the potentially severe side effects (0.5–1 mg/m^2 monthly × 6). Adequate hydration the day before, and antiemetics are helpful. It can be also given orally at 2.0–2.5 mg/kg (50 mg T.I.D), but it is safer intravenously. A switch to AZA or MMF is desirable once remission or substantial improvement is achieved. Adverse reactions include nausea, vomiting, alopecia, hemorrhagic cystitis, pulmonary fibrosis, bone marrow suppression, secondary malignancies, and sterility. Contraceptives are recommended for women and concomitant testosterone in men. It is critical to monitor the neutrophil count (no less than 1,500–2,000) and the lymphocyte count (no less than 1,000) at 7, 10, 14, and 21 days after intravenous infusion and perform frequent urinalysis even for several months after the drug is stopped. Cyclophosphamide has been helpful in some patients with multifocal motor neuropathy [77], CIDP [78], and vasculitic neuropathy [79] and in a subset of patients with inflammatory myopathies who also have interstitial lung disease [80].

Cyclosporine

Cyclosporine inhibits T cell proliferation via disruption of calcineurin signaling, which blocks the synthesis of IL-2 and other proteins essential to the function of T cells. It is used mainly in patients in whom AZA is either ineffective or not tolerated. The recommended initial dose of cyclosporine is 4–6 mg/kg/day in two divided doses, but maintenance doses of 3–4 mg/kg/day or less are often adequate to maintain the effect. Side effects are common and include hirsutism, tremor, gum hyperplasia, and anemia, but hypertension and nephrotoxicity are the main treatment-limiting adverse reactions [81]. CNS neurotoxicity includes tremor, convulsions, hallucinations, and a reversible leukoencephalopathy. Renal function should be also closely monitored and nonsteroidal anti-inflammatory drugs are contraindicated. When creatinine increases more than 30 %, the drug should be discontinued. There are many potential drug interactions given the fact that cyclosporine is metabolized via the P450 pathway. Cyclosporine is helpful in myasthenia gravis [82]. Uncontrolled studies have suggested benefit in dermatomyositis [80] and CIDP [83], but its use was associated with severe side effects and often led to drug discontinuation. The advantage of cyclosporine compared to azathioprine is that it acts faster, but it may be more toxic, if not monitored closely.

Tacrolimus

Tacrolimus (FK506) has a similar mechanism of action as cyclosporine, and a potential benefit in MG has been suggested by several reports [84–86], including a randomized, but unblinded, study in 36 new onset MG patients [86]. Sustained benefit has been reported in anti-ryanodine receptor-positive patients, which has been hypothesized to be due to enhancement of ryanodine receptor-related sarcoplasmic calcium release [87]. Doses of 3–5 mg/day have been used in different series, with a side effect profile suggesting that it is somewhat less nephrotoxic than cyclosporine. Despite this, potential nephrotoxicity and neurotoxicity remain the main severe side effects that limit more widespread use. Like cyclosporine, tacrolimus is metabolized via the cytochrome P450 pathway, giving rise to many potential drug interactions. Grapefruit may increase the serum tacrolimus (or cyclosporine) concentration. In addition to its use in MG, tacrolimus has also been used in small numbers of patients with refractory CIDP [88] and myositis with interstitial lung disease [80].

Biological Agents

Rituximab

Rituximab (RTX) is a human/murine chimeric monoclonal antibody (mAb) that specifically targets the B cell surface marker CD20 of B cells [89]. The binding of RTX to CD20 leads to significant depletion of peripheral B cells [89]. Based on its potential for targeting of autoreactive B cell clones, it is under investigation for its potential therapeutic role in antibody-mediated autoimmunity and has been increasingly used in the treatment of several autoimmune diseases [90, 91]. Multiple mechanisms have been proposed to for rituximab-mediated B cell depletion [89]. The main mechanism involved may be complement mediated B cell depletion, since the primary cause for resistance of malignant B cells to rituximab's effects is reported to be through enhanced expression of complement regulatory proteins [92].

There are two FDA-approved uses for RTX (B cell lymphoma and rheumatoid arthritis). Each uses a different protocol. Treatment of lymphoma patients involves four infusions of RTX at a dose of 375 mg/m^2, given on four consecutive weeks. The protocol for rheumatoid arthritis is two infusions at a dose of 1,000 mg of RTX, given 2 weeks apart. Both protocols have been used in the treatment of autoimmune neuromuscular disease, although the majority of patients in have received the lymphoma protocol. In many cases, RTX has been used in refractory disease so that concomitant therapies, usually involving corticosteroids and immunosuppressive agents, were also coadministered.

The most commonly encountered side effects are constitutional/systemic symptoms during the initial infusion. A 2005 report on the safety of RTX in patients with cancer and RA concluded that serious adverse reactions occur only in a small minority of patients but overall RTX therapy is safe [93]. Eighty-four percent of patients experience infusion related reactions including nausea, headache, fatigue, rash, and flu-like symptoms after RTX administration. The incidence of these symptoms is highest after the first infusion and decreases with subsequent infusions. These observations correlate well with the RTX use in autoimmune disease. The use of paracetamol, antihistamines, and corticosteroids is recommended as pretreatment to help control infusion related reactions.

Progressive multifocal leukoencephalopathy (PML) has been associated with the use of a number of monoclonal antibodies, including rituximab [94]. The incidence of PML occurring in patients treated with rituximab is estimated at 1:25,000 [94]. Until 2010, only patients previously treated with other immunosuppressive agents were thought to be at risk; however, at least one case of PML has been diagnosed in the absence of concomitant or prior immunosuppressive therapy [95]. The occurrence of PML in the context of B cell depletion suggests that humoral immunity may play a role in the control of JC virus replication. Despite the low risk, the associated mortality and morbidity of PML justifies a cautious approach in considering rituximab in the treatment of an autoimmune neuromuscular disease. In addition, the concomitant use of other therapeutic agents that may also enhance the risk for PML (e.g., mycophenolate mofetil, other monoclonals) should be avoided.

Rituximab has been used in the treatment of IgM paraproteinemic neuropathy [96] and in treatment-resistant CIDP [97] and MG; [98] the results of a controlled study of its use in polymyositis is pending.

Alemtuzumab

Alemtuzumab is a humanized monoclonal antibody against the CD52 antigen, present in mature lymphocytes. Alemtuzumab potently depletes T lymphocytes, resulting in severe lymphopenia with a consequent increased risk of opportunistic infections. It was reported to have some efficacy in the treatment of IBM [99] and may be potentially useful in the treatment of refractory CIDP. Some data suggest that treated patients may be at and enhanced risk to develop other autoimmune disorders, particularly some B cell-mediated diseases, such as thyroid autoimmune disease or thrombotic thrombocytopenic purpura [100].

TNF-Alpha Antagonists (Etanercept, Infliximab)

Few reports suggest that the TNF-alpha antagonist etanercept or infliximab may be potentially useful in the treatment of the inflammatory myopathies and MG [101, 102]. Etanercept acts as a decoy receptor, binding soluble TNF and, thus, reducing TNF levels. TNF-α is upregulated in muscles of patients with inflammatory myopathies and in the nerves of patients with CIDP and is toxic to the myotubes and Schwann cells in vitro, perhaps revealing relevant mechanisms for potential benefit in inflammatory neuropathies and myopathies. The main side effects include respiratory infections, injection-site reactions, enhanced risk for infections, and headache. Tuberculosis screening must be performed prior to treatment.

Immunomodulating Procedures and Other Immunosuppressive Agents

Thymectomy

The use of thymectomy in MG was initially based on empiric observations that MG patients improved after removal of the thymus. The presumed role of the thymus in MG has provided theoretical justification for the procedure, but its precise mode of action is unclear. Acetylcholine receptor proteins are expressed in the thymus in the presence of maturing lymphocytes. Thus removal of the thymus gland may eliminate the source of autoantigen and continuous autosensitization. Thymectomy has been used as a treatment for MG for nearly 70 years. There have been no randomized controlled trials establishing efficacy in either patients with or without thymoma, and conclusions from retrospective, non-randomized studies are confounded by baseline differences between surgical and nonsurgical groups, among other things. A comprehensive meta-analysis concluded that there was probably some benefit from thymectomy in non-thymomatous MG patients and that it should be considered as a treatment option in selected MG patients [103]. Most experts consider thymectomy a therapeutic option in anti-AChR-positive, generalized MG with disease onset before

the age of 50, and some would also recommend it in patients who lack anti-AChR antibodies. An international prospective, single-blinded randomized trial of thymectomy in non-thymomatous MG is currently ongoing and will hopefully clarify this issue. At this time, the only absolute indication for thymectomy is the presence of thymoma. The role of thymectomy in anti-MuSK MG is not clear.

Hematopoietic Stem Cell Transplantation

Autologous hematopoietic stem cell transplantation has been used in the treatment of autoimmune diseases refractory to standard therapies since 1996 [104]. This procedure induces marked immunosuppression and is associated with considerable risk. Nevertheless, case series suggest effectiveness in refractory myasthenia gravis and chronic inflammatory demyelinating polyneuropathy [105, 106]. Caution should be exercised in light of the potential for serious adverse effects.

Complement Inhibitors (Eculizumab)

Complement activation is also thought to be a crucial step in the pathogenesis of MG, CIDP, and all variants of GBS and therefore represents an appealing candidate for selective immunotherapy. Eculizumab is an anti-complement agent that works by inhibiting the complement protein C5, which acts at a relatively late stage in the complement cascade. Results of a recently completed study examining the safety and efficacy of eculizumab in patients with refractory MG are pending.

Sirolimus (Rapamycin)

This drug is a macrolide antibiotic like tacrolimus that inhibits the proliferation of both T and B cells and the production of cytokines, especially IL-2. In contrast to tacrolimus that inhibits transcription of IL-2, sirolimus acts to prevent the translation of mRNA for key cytokines including IL-2 and has an effect on T cells even after their activation. There is anecdotal evidence that sirolimus was effective in some difficult cases of polymyositis.

Drug Interactions

Certain drugs can interact with the immunosuppressive drugs or immunomodulating agents and counteract or interfere with their action. Some of the more common interactions include:

(a) Anticonvulsants such as phenobarbital, carbamazepine, and phenytoin, all inducers of the hepatic microsomal enzyme system, may accelerate the elimination of prednisone. When patients are taking these drugs, a somewhat higher than anticipated steroid dose may be required to achieve a therapeutic response.
(b) Because azathioprine is metabolized by xanthine oxidase, its concurrent administration with allopurinol may be potentiated liver toxicity and myelosuppression. The combination of these drugs should be avoided.
(c) Cyclosporine, in combination with a lipid-lowering drug belonging the statin class of medications, can be myotoxic or cause myoglobinuria. If cyclosporine or tacrolimus is combined with a nonsteroidal anti-inflammatory agent, amphotericin B, or certain antibiotics, such as the macrolides, its nephrotoxicity may be enhanced. Hyperkalemia may result if cyclosporine is given together with potassium-retaining antibiotics or potassium supplements. Plasma cyclosporine level may be increased with the coadministration of cimetidine, steroids, warfarin, ketoconazole, and macrolide antibiotics (such as erythromycin and mithramycin). Its level is decreased with the coadministration of hepatic microsomal enzyme inducers, such as phenobarbital, phenytoin, carbamazepine, or the sulfonamides. Also note that St. John's wort, grapefruit, and grapefruit juice may increase cyclosporine levels.
(d) Concurrent administration of trimethoprim and methotrexate may increase risk of myelosuppression.

Specific Treatment of Autoimmune Neuromuscular Diseases

The neuromuscular disorders treated with immunosuppressive or immunomodulating agents comprise a heterogenous group of disorders that may be classified into three main groups: (1) the inflammatory neuropathies, (2) neuromuscular junction disorders, and (3) the inflammatory myopathies.

The Inflammatory Neuropathies

Guillain-Barre Syndrome (GBS)

GBS is an acute, immune-mediated polyneuropathy with a reported incidence of 1–2 per 100,000 population [107]. The main features of GBS are rapidly progressive, relatively symmetric weakness of the limbs usually accompanied by areflexia, with or without involvement of respiratory muscles or cranial nerve-innervated muscles. By definition, maximum weakness is reached within 4 weeks, but most patients reach their maximum weakness within 2 weeks. Thus, immune-directed treatment is focused on short-term therapy of acute disease, and chronic immunosuppression is not indicated. The current established treatments of GBS are plasma exchange (PE) and intravenous immunoglobulin (IVIg) [107].

PE is beneficial when given within the first 4 weeks of disease onset in GBS, but the largest effect is seen when started early (within the first 2 weeks) [108–110]. The usual regimen is PE five times every other day over 10 days to 2 weeks, with a total exchange of about five plasma volumes. Patients treated with PE have been shown to have a significantly reduced disability at 1 month using the Guillain-Barre Syndrome Disability Scale, and treated patients ambulate independently in less time than untreated patients [110].

The first randomized controlled clinical trial on the use of IVIg in GBS was published in 1992 and showed that IVIg was as effective as PE [34]. In subsequent studies, no difference was found between IVIg and PE with respect to the improvement in disability grade after 4 weeks, the duration of mechanical ventilation, mortality, or residual disability [111]. The combination of PE followed by IVIg has been found not to be significantly better than PE or IVIg alone [33]. However, because of its greater ease of administration and better tolerability, IVIg (2 g/kg divided over 2–5 days) has replaced PE as the preferred treatment in many centers.

Oral or intravenous steroids are not beneficial in GBS [112, 113], and the combination of IVIg and intravenous methylprednisolone is not more effective than IVIg alone [113]. Despite treatment (IVIG or PE), GBS continues to have a mortality of up to 9 % and severe disability of 17 % [107]. Both treatments are associated with potential complications (see above), and clinical trials have shown that not all patients are able to complete the full course of therapy.

The easy access of IVIg and its administration without need for a central venous access has made IVIg the treatment of choice in children with GBS, even though its effectiveness in this population is based on uncontrolled trials or small series of patients.

Treatment Guidelines

Most published clinical trials have included only patients who are treated within the first 2 weeks from onset of weakness and who are unable to walk without assistance. If these criteria are met, there is no doubt that patients with GBS should be treated with IVIg or PE. If no contraindication exists for either, IVIg is the preferred therapy as it is associated with fewer complications and is cheaper overall. Patients with rapidly progressive limb weakness, impaired pulmonary function, severe swallowing difficulties, or autonomic dysfunction should also be treated with IVIg. Treatment outside of 2 weeks from symptom onset is also indicated for patients in these groups, particularly if symptoms are progressive at the time of treatment, but it is likely that outcomes are worse. IVIg is also preferable in small children or patients who have poor venous access, sepsis, or unstable hemodynamics. PE may be preferred in patients with known anaphylaxis to IVIg or vaccinations and for those who have history of hypercoagulable or hyperviscosity states. No randomized trials have assessed the effect of PE or IVIg in mildly affected patients with GBS, "mildly affected" arbitrarily defined as being able to walk (with or without assistance). A retrospective study showed that these patients may have residual disabilities, perhaps justifying therapy [114].

Some patients with GBS continue to deteriorate after PE or a standard course of IVIg [115]. Whether these patients need PE after they have been treated with IVIg has not been investigated. As noted, there is evidence that the combination of PE followed by IVIg is no better than PE or IVIg alone. PE after IVIg is also not advised, because PE would likely wash out the previously administered IVIg. A second course of IVIg in unresponsive patients with GBS may be effective and is the recommended strategy [116, 117]. Similarly, about 5–10 % of patients with GBS deteriorate after initial improvement or stabilization following IVIg treatment. In this situation, it is common practice to give a second IVIg course (2 g/kg in 2–5 days), because these patients are likely to improve after reinitiating this treatment. Some patients with GBS might even have several episodes of deterioration. This often raises the question of whether these patients might have chronic inflammatory demyelinating polyneuropathy with acute onset (see next section).

Chronic Inflammatory Demyelinating Polyneuropathy (CIDP)

CIDP is characterized by symmetric weakness and distal sensory loss with areflexia. It develops in either a relapsing-remitting or chronic progressive course. The goal of therapy is to promote recovery of strength, improve gait and balance, and lessen sensory loss and paresthesias. Data from controlled clinical trials indicate that corticosteroids, IVIg, and PE result in short- or long-term clinical improvement in about two-thirds of patients [118]. Long-term maintenance therapy is needed in most patients.

Corticosteroids

CIDP is historically described as a "steroid-responsive" polyneuropathy. While corticosteroids have been widely used for CIDP treatment, only one randomized, unblinded trial showed effectiveness at 12 weeks [119]. Additional case series and extensive experience suggests that steroids are effective in CIDP treatment. Therapy is usually started with high-dose (60–100 mg) daily therapy, and the dose is then slowly tapered to a low-dose daily or alternate-day regimen. Onset of response is as early as 2 weeks but requires as long as 2 months. Studies have suggested similar effectiveness and lower side effects when using pulsed intravenous dexamethasone or methylprednisolone, compared to standard oral steroid regimens [8, 120], but there is no convincing data that this is any safer than chronic oral therapy. A recent study has shown that cure or long-term remission can be achieved in about one-quarter of patients with CIDP after 1 or 2

courses of pulsed dexamethasone or 8-month daily prednisolone [121]. A subset of patients with CIDP, particularly those with pure motor forms of CIDP, may worsen with steroids, and this should be taken into account in patients experiencing an acute treatment-related deterioration.

Plasma Exchange

PE has shown efficacy in the treatment of CIDP in controlled trials [122, 123]. Typically, a standard treatment course consists of 5–6 exchanges administered every other day. Maintenance therapy of at least one exchange every 6–8 weeks in combination with steroids or other immunosuppressant drugs may be considered. The need for large-bore venous access limits the feasibility of PE as a maintenance therapy. Because of this, IVIg is generally the preferred therapy.

IVIg

A number of controlled studies support the use of IVIg in CIDP [35–39]. Most recently, a large randomized controlled study confirmed the efficacy of IVIg in the treatment of CIDP and also demonstrated that maintenance IVIg doses of 1 g/kg administered every 3 weeks can sustain improvement and prevent further axonal degeneration [40]. These results argue for the use of IVIg as a first-line therapy. Although controlled studies have not been done, IVIg is also efficacious in childhood CIDP [60]. Multiple courses of IVIg appear to secure continuous efficacy. We have found that a combined alternate-day prednisone regimen combined with IVIg therapy in difficult cases has considerable success and minimal toxicity.

A number of patients who respond to IVIg may show a less consistent response in subsequent infusions, and others may not respond fully at the onset of therapy. In some of these patients, we have found that the combination of IVIg with prednisone (or intravenous steroids) may be effective. In general, CIDP may be more difficult to treat if axonal changes are extensive, regardless of the regimen used. On the other hand, patients with less severe axonal changes improve much better, hence the need to initiate therapy early.

In practice, the choice of initiating therapy with prednisone, IVIg, or PE (all effective in controlled trials) is determined on the basis of cost, long-term side effects, patient age, venous access, disease severity, and concurrent illnesses. While IVIg has become the treatment of choice for CIDP because of its demonstrated efficacy and safety profile, some patients may not respond. Patients may respond only to IVIg, others respond only to prednisone, and a third group benefit from combination therapy. Only after conducting a controlled comparative trial can it be determined which of these drugs (or combinations) is superior. The question is also important considering the disparities in the cost of steroids compared to IVIG or PE.

Other Immunosuppressant or Immunomodulating Agents

Up to one-third of CIDP patients will not respond adequately to steroids, IVIg, or PE [118]. Azathioprine, cyclosporine, and mycophenolate mofetil have all been used in CIDP mainly as steroid- or IVIg-sparing agents, although there are no controlled studies supporting their use. Nevertheless, these agents should be considered in patients who are intolerant or have an inadequate response to standard therapies. A trial of methotrexate in CIDP showed no difference in the treatment vs. placebo group in the ability to lower IVIG or steroid doses by more than 20 % [124]. In small uncontrolled studies, rituximab has shown favorable results in CIDP, with up to 50 % of treated patients improving after 2–12 months [125]. In selected cases, particularly when CIDP co-occurs with hematologic diseases, it may be considered as an early option.

Treatment Guidelines

After a diagnosis of CIDP is confirmed, if symptoms are mild and not significantly functionally limiting, no treatment is given. If significant symptoms or disability are present, a course of IVIg (2 g/kg) is administered. If this is effective, the patient is followed to observe the evolution of the CIDP, and, at the first sign of symptom recurrence, another course of IVIg is given, and then, serial IVIg treatments at a set frequency (1 g/kg every 3–6 weeks) are initiated. If IVIg infusions are required frequently, a second drug is started, usually prednisone at 1 mg/kg daily for a month, which is then tapered and maintained at low doses (below 25 mg every other day). We then start reducing IVIg frequency and/or dose to the minimum required. PE is best reserved for patients in whom IVIg therapy is ineffective. We use other immunosuppressant drugs, usually cyclosporine, mycophenolate mofetil, or azathioprine as steroid-sparing agents or in those patients in whom either steroids are contraindicated or an unacceptably high dose of steroids is required to maintain disease control. If there is no response IVIg, steroids, or PE, we try rituximab (2 g 15 days apart or 375 mg/m^2 in 4 weekly infusions) or cyclophosphamide (1 g/m^2 monthly) taking into consideration patient age and degree of disability.

Multifocal Motor Neuropathy (MMN)

MMN is a purely motor neuropathy characterized by slowly progressive, asymmetric, predominantly distal weakness of the limbs. It is characterized electrophysiologically by the presence of multifocal motor conduction block and immunologically by the detection of anti-GM1 antibodies in the serum of approximately 50 % of patients [126]. IVIg is the treatment of choice in light of four double-blind placebo-controlled trials confirming its efficacy and safety [41–44]. Approximately 70–90 % of patients improve with this therapy [127, 128]. It appears that more recently affected nerves

respond better to IVIg treatments, possibly because there is less axonal loss. The majority of patients require multiple regularly scheduled treatments [45]. Clinical parameters including muscle strength measures and patient perceptions have shown consistent improvement in response to IVIg treatment [45], and reinnervation and remyelination with reversal of conduction block has been demonstrated [129].

Prednisone and PE are ineffective in most patients with MMN and may even exacerbate symptoms [130, 131]. Cyclophosphamide was the first drug used to treat MMN and is reported to be effective in case series [77], but the substantial risk for severe adverse reactions restricts its use. Uncontrolled studies have suggested benefit with the use of cyclosporine, methotrexate, azathioprine, and mycophenolate mofetil [126]. In a randomized controlled trial, mycophenolate mofetil failed to demonstrate any additional benefit as an adjunct to IVIG [132]. Treatment with eculizumab, a monoclonal antibody directed against complement factor C5, did not allow dose reduction of IVIg in most patients, although some improvements in objective motor performance measures were observed after treatment in an open-label study of 13 patients [133]. The effectiveness of rituximab in small patient series has been inconsistent [126].

Treatment Guidelines

The initial IVIg course is usually given at 2 g/kg over 2–5 consecutive days. Only 20–30 % of patients treated with a single IVIg achieve full remission [126], and the beneficial effects of IVIg only last a few weeks, so repeated infusions are necessary. Nevertheless, after IVIg-induced improvement, patients are typically followed carefully, and a subsequent deterioration is treated with second course of IVIg (2 g/kg), and plans for serial therapy are made. As is the case for CIDP, the optimal dose and interval for IVIg maintenance therapy has not been established, but must be determined based on the patient's response and careful monitoring of muscle strength testing and self-evaluation of disability and quality of life. Typically, 0.4–1.0 g/kg once every 4 weeks is required. Regular reevaluation of the maintenance regimen is recommended as many patients require an increase in the IVIg dose over time [45]. If there is no response to IVIg, the diagnosis should be reconsidered, and if the disease process is still believed to be most consistent with MMN, an additional IVIg course should be given, followed by consideration of treatment with cyclophosphamide or rituximab

It is important to note that there is no correlation between anti-GM1 levels and treatment efficacy. However, patients with high serum titers of this antibody may be more likely to respond to IVIG therapy [134]. Anecdotal evidence from observations of our own and others suggests that the efficacy of IVIg in MMN (and also in CIDP) might be restored in occasional patients if a short course of PE precedes the next IVIg infusion.

Paraproteinemic Immune Polyneuropathies

Coexistence of an immune polyneuropathy and a monoclonal gammopathy represents a heterogeneous group of disorders. The paraprotein may be a monoclonal gammopathy of uncertain significance (MGUS), or it may occur in the context of a malignancy such as multiple myeloma or Waldenstrom's macroglobulinemia. In the case of an established hematologic malignancy, this should take precedence over treatment of the polyneuropathy. In some of the IgM MGUS-associated neuropathies, the IgM paraproteins bind to myelin-associated glycoprotein (MAG) in peripheral nerve, thereby establishing a direct link between the paraprotein and the neuropathy. Patients with IgM MGUS-associated neuropathies and anti-MAG antibodies typically have a predominantly distal usually very slowly progressive demyelinating neuropathy with prominence of sensory symptoms and sensory ataxia [135]. They are often poorly responsive to therapies, so it is important to recognize this particular clinical phenotype and tailor treatment accordingly.

In IgM MGUS neuropathies with anti-MAG antibodies, there is some evidence that both PE and steroids may be effective mainly in combination with other immunosuppressants (chlorambucil) [136]. A small randomized controlled trial of IVIg in IgM MGUS neuropathy showed only a modest benefit in no more than 18 % of patients but included patients without anti-MAG activity [51]. A randomized controlled trial of rituximab in IgM anti-MAG neuropathy showed evidence for mild efficacy both clinically and on anti-MAG antibody levels [137]. The most improved patients were those with high anti-MAG titers and most severe sensory deficits at baseline. It is also important to remember that a number of patients with anti-MAG IgM MGUS have mild or chronic disease with prolonged periods of stability that may not require treatment.

Patients with IgM- (without anti-MAG antibodies), IgA-, or IgG MGUS-associated neuropathies may resemble idiopathic CIDP clinically, and treatment in these cases should be based on recommendations for CIDP (see above). However, because elevated serum levels of monoclonal proteins may cause high serum viscosity (which can be further increased with IVIg), caution is required when IVIg is infused in such patients to avoid precipitating thromboembolic events. Patients with IgM-, IgG-, and IgA MGUS-associated axonal neuropathies often have distal sensorimotor dysfunction with slow progression, not requiring treatment. Monoclonal gammopathy associated with cryoglobulinemia is often associated with hepatitis C infection and manifests as a multifocal axonal neuropathy. Management usually involves treatment of the underlying hepatitis C infection, although PE may be helpful in severe cases [138]. The coexistence of MGUS with an axonal neuropathy should indicate the possibility of amyloidosis, particularly when there is coexistent pain, weight loss, organomegaly, or

cardiomyopathy. Prognosis in these cases is usually not good, and patients with confirmed amyloidosis require a tertiary care referral for appropriate management, including possibly peripheral stem cell transplant.

Vasculitic Neuropathy (VN)

The classic presentation of vasculitic neuropathy is acutely evolving motor and sensory dysfunction in the distribution of multiple peripheral nerves, but it may also present as overlapping mononeuropathies or rarely as a distal symmetric polyneuropathy. The vasculitis may be part of a systemic inflammatory disease affecting the peripheral nerves or may be nonsystemic affecting the peripheral nerves without associated systemic features [9]. Once the diagnosis is made, most patients require prompt treatment. In general, the primary initial consideration is whether the patient requires monotherapy with corticosteroids alone vs. combination therapy with a cytotoxic agent [9, 139]. The presence of rapidly progressive weakness and/or multiorgan involvement in systemic vasculitis should lead to consideration of combination therapy – prednisone 1–1.5 mg/kg/day or methylprednisolone plus cyclophosphamide usually administered as intravenous pulsed doses. A typical protocol for cyclophosphamide administration is 0.6 g/m^2 every 2 weeks × 3, followed by 0.7 g/m^2 every 3 weeks × 3–6. The dose may be decreased in the elderly or in patients with renal insufficiency. Combination therapy is also advised for rapidly progressive nonsystemic vasculitic neuropathy and for patients who progress on corticosteroid monotherapy [139]. Patients are switched from cyclophosphamide to a less toxic immunosuppressive drug after induction therapy (typically after 6 months). First-line immunosuppressive options for maintenance therapy include methotrexate AZA, cyclosporine, and MMF.

Neuromuscular Junction Disorders

Myasthenia Gravis (MG)

Patients with MG respond fairly well to the available immunotherapies, such as thymectomy, corticosteroids, azathioprine, cyclosporine, tacrolimus, plasmapheresis, and IVIg [140]. Patients with mild or purely ocular MG may be initially treated symptomatically with anticholinesterase drugs. Corticosteroids are generally the first line of immunotherapy and are used when symptoms of MG are not adequately controlled by anticholinesterase drugs alone. In four large retrospective series of steroid treatment for generalized MG, administered at various doses, more than 73 % of the 422 patients treated achieved either "marked improvement" or remission [141–144]. Prednisone is the primary steroid drug used and may be administered at high doses (0.75–1.0 mg/kg/day) initially and then gradually tapered off or continued at low doses for many years. Approximately one-third of patients have a temporary exacerbation after starting prednisone; this usually begins within the first 7–10 days with high prednisone doses and lasts for several days [140, 141]. In mild cases, cholinesterase inhibitors may manage this worsening. In patients with oropharyngeal or respiratory involvement, PE or IVIg may be given before beginning prednisone to prevent or reduce the severity of corticosteroid-induced exacerbations.

Nonsteroidal Immunosuppressant Drugs

Nonsteroidal immunosuppressant medications are typically used in combination with prednisone as either steroid-sparing agents or as add-on drugs to enhance treatment response in those patients with a partial or minimal response to prednisone. Retrospective studies indicate that AZA is effective in 70–90 % of MG patients, but the onset of benefit may be delayed for as long as 12 months [63, 145]. The efficacy of mycophenolate mofetil (MMF) in MG has been suggested by retrospective analyses [70, 71]. The standard MMF dose used in MG is 1,000 mg twice daily, but doses up to 3,000 mg a day may be used. Two recently completed controlled trials of MMF in MG failed to show additional benefit of MMF over 20 mg daily prednisone given as initial immunotherapy [72] or a significant steroid-sparing effect of MMF in patients on prednisone [73]. A number of factors have been cited to explain these negative results, including the generally mild disease status of the patients, the better-than expected response to relatively low-dose prednisone, and the short duration of the studies. While the clinical efficacy of MMF in MG remains an open question, it continues to be widely utilized in the treatment of MG.

The efficacy of cyclosporine in MG has been suggested by a small, randomized, placebo-controlled clinical trial [82], and retrospective studies have supported its use as a steroid-sparing agent [81]. Cyclosporine is used mainly in patients in whom AZA is either ineffective or not tolerated. Tacrolimus (FK506) has a similar mechanism of action as cyclosporine, and potential benefit in MG has been suggested by several reports [84–86], including a randomized, but unblinded, study in 36 de novo MG patients [86]. Sustained benefit has been reported in anti-ryanodine receptor-positive patients, which has been hypothesized to be due to enhancement of ryanodine receptor-related sarcoplasmic calcium release [87].

A percentage of MG patients are refractory or develop intolerable side effects to treatment with corticosteroids in combination with one or more of the immunosuppressive

agents described above. Agents that may be considered in these refractory patients include cyclophosphamide and rituximab. Pulsed doses of intravenous cyclophosphamide (500 mg/m^2) given to patients with refractory MG improved muscle strength and lowered steroid requirement [146]. Remarkable therapeutic responses have also been reported in refractory MG patients receiving a one-time, high-dose (50 mg/kg) intravenous course of cyclophosphamide for 4 days followed by rescue therapy, with benefit persisting for several years without relapse [147]. As previously noted, side effects of cyclophosphamide are common and potentially serious, including myelosuppression, hemorrhagic cystitis, and an increased risk for infection and malignancy.

Rituximab is a chimeric monoclonal antibody directed against the B cell surface marker CD20. It effectively reduces circulating B cell counts and based on its potential for targeting of autoreactive B cell clones, may have a therapeutic role in antibody-mediated autoimmune diseases. Case reports have suggested benefit in refractory MG patients, particularly in MuSK MG [148, 149]. Further investigation is needed to determine its role in MG therapy, but it appears to be a less toxic alternative to cyclophosphamide in refractory cases and may be appropriate to consider early in the course of anti-MuSK patients since there is some evidence of induction of long-lasting therapeutic benefit without need for serial treatment in some patients.

PE and IVIg are used for short-term treatment of MG exacerbations and when it is desirable to achieve a rapid clinical response. PE temporarily reduces the levels of circulating antibodies and produces improvement in a matter of days in the most patients with acquired MG [140]. Typically one exchange, removing one to two plasma volumes, is performed every other day, up to a total of four to six times. IVIg is widely used for exacerbating MG. Support for its use comes from RCTs that show efficacy comparable to PE [48, 50] and a double-blind, placebo-controlled trial in MG patients with worsening weakness [49]. A number of issues regarding IVIg in the treatment of MG remain unanswered. First, we do not know if IVIg has a synergistic effect with the other drugs; second, it is unclear if IVIg has a role as a steroid-sparing agent, especially in children or the elderly; third, it is uncertain whether it works as fast as PE or affects the acetylcholine receptor antibody titers; and fourth, we are not clear if it is as effective as plasmapheresis in myasthenic crisis.

Thymectomy

The use of thymectomy in MG is based on empiric observations that MG patients improve after removal of the thymus. The presumed role of the thymus in MG has provided theoretical justification for the procedure, and thymectomy has been used as a treatment for non-thymomatous MG for nearly 70 years. There have been no randomized controlled trials, and conclusions from retrospective, non-randomized studies are confounded by baseline differences between surgical and nonsurgical groups, among other things. A comprehensive meta-analysis concluded that there was probably some benefit from thymectomy and that it should be considered as a treatment option in selected MG patients [103]. Most experts consider thymectomy a therapeutic option in anti-AChR-positive, generalized MG with disease onset before the age of 50, and some would also recommend it in patients who lack anti-AChR antibodies. An international prospective, single-blinded randomized trial of thymectomy in non-thymomatous MG is currently ongoing and will hopefully clarify this issue. At this time, the only absolute indication for thymectomy is the presence of thymoma. The role of thymectomy in anti-MuSK MG is not clear.

Treatment Guidelines

The treatment of patients with MG must be individualized according to the clinical presentation and requires a comprehensive assessment of the patient's functional impairment and its effect on daily life. The therapeutic goal is to return the patient to normal function as rapidly as possible while minimizing the side effects of therapy. Cholinesterase inhibitors may be sufficient in a minority of patients with restricted ocular or mild generalized disease (with or without prior thymectomy). In those not adequately treated with cholinesterase inhibitors alone, immunotherapy should be initiated promptly, starting with prednisone and adding the other immunomodulating drugs discussed above as needed (first-line agents include MMF and AZA). In a patient with relatively mild disease and a complete or near complete remission with prednisone, the addition of MMF or AZA can be considered if the prednisone cannot be tapered to an acceptable level. In patients with more severe disease or an incomplete response to prednisone, the addition of MMF or AZA should occur early in the therapeutic course. It is important to recognize that the effects of MMF and AZA can be quite delayed, so tapering of the prednisone dose should be done cautiously during the first 4–6 months. In patients treated with immunotherapies, the lowest effective dose should always be determined in regular follow-up clinic evaluations. In patients refractory to prednisone and MMF/AZA, treatment with tacrolimus or rituximab (particularly if anti-MuSK positive MG) should be considered.

Many case series report short-term benefit from PE and IVIg in myasthenic crisis. We recommend PE in the treatment

of crisis except when there is hemodynamic instability, sepsis, or coagulopathy or during the first trimester of pregnancy.

Thymectomy is indicated in patients with imaging evidence of a thymoma and should be considered in non-thymomatous MG patients with generalized, anti-AChR-positive disease and onset prior to age 50. Thymectomy is never an urgent procedure, and MG symptoms should be adequately controlled with immunomodulating agents (including PE or IVIg) prior to thymectomy or any surgical procedure.

Lambert-Eaton Myasthenic Syndrome (LEMS)

Once the diagnosis of LEMS is established, an extensive search for underlying malignancy, especially small cell lung cancer, is mandatory. Chronic smokers should undergo bronchoscopy and/or PET scan if chest-imaging studies are normal. Weakness may improve after effective cancer therapy, and some patients require no further treatment. Therefore, in "paraneoplastic LEMS," the target of initial treatment is the underlying malignancy. Patients with LEMS may have a gratifying symptomatic response to 3,4 diaminopyridine (3,4 DAP) [150–152], and although this is not an immunotherapy, it is generally considered the first-line treatment. Immunotherapy should be considered in LEMS patients who remain significantly symptomatic despite 3,4 DAP and should be tailored to the individual, based on the severity of weakness, underlying (malignant) disease, life expectancy, and response to previous treatment. Treatments, such as PE, corticosteroids, and immunosuppressive agents, including rituximab [153], may be of benefit in some patients but have not been tested in controlled trials. Both PE and IVIg provide short-term improvement in some patients with LEMS [154]. If these treatments are not effective, it must be determined if weakness is sufficiently severe to warrant immunotherapy with prednisone, AZA, cyclosporine, or rituximab. In patients with severe weakness, it may be advisable to give IVIg or PE first before considering adding prednisone or other immunosuppressant drugs. Maintaining improvement may require repeated courses of treatment.

Along these lines, a controlled study comparing IVIg to placebo showed a statistically significant increase in muscle strength compared to placebo, which peaked at 2–4 weeks and declined by 8 weeks. The effectiveness of IVIg was associated with a statistically significant reduction of antibodies against voltage-gated calcium channels [47]. On the basis of this controlled study alone, along with anecdotal case reports, it seems that IVIg is useful in treatment-resistant cases of LEMS, perhaps in lieu of steroids, and as an alternative to chronic immunosuppression.

The Inflammatory Myopathies

The inflammatory myopathies are a group of disorders characterized by immune-mediated muscle injury. The three most commonly mentioned subtypes are dermatomyositis (DM), polymyositis (PM), and inclusion-body myositis (IBM).

Dermatomyositis (DM)

DM is a multisystem disease predominantly affecting skeletal muscle (myopathy) and skin (skin rash – dermatitis) that can affect both adults and children. DM may be associated with interstitial lung disease or malignancy, so the appropriate work-up to evaluate for these conditions should be performed prior to instituting immunotherapy. Well-designed randomized controlled clinical trials in DM have been limited. DM is typically treated with high-dose oral prednisone, usually starting at a dose of 1 mg/kg/day [155]. Steroid therapy may also be initiated using intravenous methylprednisolone 500–1,000 mg IV per day for 3–5 days followed by oral prednisone. Oral prednisone is continued until the patient's weakness resolves, plateaus, or side effects are intolerable, usually 1–3 months. Steroid tapering is then initiated slowly with careful monitoring for any relapse or worsening. In general, the taper should proceed no faster than a decrease of 5–10 mg/day every 6 weeks, continuing until there is breakthrough of symptoms which indicates the minimal effective dosage for maintenance of remission.

While prednisone is effective in most patients with inflammatory myopathies, relapses are common when it is tapered, limiting its long-term use as a stand-alone drug. Steroid-sparing or second-line agents for the immunotherapy of DM include IVIg, AZA, methotrexate, and rituximab. Methotrexate is commonly used for its steroid-sparing effects in DM [155]. It is given once weekly in divided doses. A commonly used regimen initiates therapy with 7.5 mg weekly (2.5 mg every 12 h × 3), and the dose is increased by 2.5 mg/week to as much as 20 mg/week. Folate (1 mg four times daily) is coadministered [76]. The efficacy of AZA has been suggested in open-label studies and case series in the treatment of refractory DM [76, 155]. Approximately 75 % of patients treated with AZA appear to demonstrate improvements in strength [156]. Doses of 1.5–2 mg/kg are commonly used, but it is preferable to use doses up to 3 mg/kg for more effective immunosuppression. Because AZA is usually effective after 6 months of treatment, patience is required before concluding that the drug is ineffective.

In patients with severe weakness, myositis with interstitial lung disease (ILD), or concomitant osteopenia or

osteoporosis, methotrexate or AZA is typically started concomitantly with prednisone. Because methotrexate can cause pulmonary fibrosis, it is best avoided in patients who already have ILD. In these patients, MMF may be an alternative to AZA. In very weak patients, sometimes a short course of intravenous methylprednisolone is helpful prior to initiating prednisone or other immunosuppressant therapies.

In a double-blind study of IVIg therapy in 15 patients with refractory DM, strength improved in the IVIg randomized patients [43]. IVIg therapy may be used as an initial treatment (in combination with steroids) in severely affected patients with a goal of more rapid improvement. As a chronic or maintenance treatment, it may be considered in steroid-resistant patients or as an add-on therapy in patients who are not adequately controlled with combination of steroids and methotrexate or AZA, with a goal of reducing long-term steroid exposure. In some patients, IVIg infusions can lower the prednisone dose required for maintenance, demonstrating the most effective (although most expensive) steroid-sparing effect [7].

The IVIg-induced improvement in strength does not last more than 4–8 weeks, and repeated infusions are required periodically to maintain it. Patients who initially benefit from IVIg continue to respond to it in conjunction with low-dose steroids. They may need periodic infusions to maintain a reasonably good response or show less impressive improvement, possibly due to further progression of the disease. Overall, however, low-dose prednisone appears to enhance the benefit of IVIg. It has also been observed that some patients with DM who had become unresponsive to steroids may respond again to prednisone after a few IVIg infusions [7].

The efficacy of rituximab has also been suggested in the treatment of refractory DM. Case series have suggested significant improvements in muscle strength and functionality with concomitant reductions in serum CK and LDH [157, 158]. These effects have been sustained for more than 2 years in some patients [158]. An ongoing double-blinded placebo-controlled trial is underway to evaluate the benefit of rituximab in refractory DM.

Polymyositis

The diagnosis of PM encompasses a range of different disease associated with "inflammatory changes" on muscle biopsy. Patients present with subacute progressive proximal weakness without a skin rash. As with DM, there may be an association with interstitial lung disease, although there is no established association with malignancy. Treatment is essentially as described for DM above.

Inclusion-Body Myositis (IBM)

There is no treatment that has been shown to be effective in IBM, and most experts choose not to treat with immunosuppressant drugs because of this and the associated risks of adverse effects. IVIg is not effective [159]. In a small study, alemtuzumab infusions were shown to slow disease progression in IBM patients by up to 6 months and improved the strength of some patients and reduced endomysial inflammation on repeat muscle biopsy [99]. These encouraging results remain to be confirmed.

Immune-Mediated Necrotizing Myopathy

Immune-mediated necrotizing myopathy refers to a subset of inflammatory myopathies characterized by rapid onset and severe proximal weakness which tends to be refractory to immunotherapy [160]. While previously considered a form of polymyositis, pathological evaluation of muscle specimens revealed significant necrotic, degenerating, and regenerating muscle fibers with scant inflammatory cells. Many of these patients may have antibodies to the signal recognition particle complex (anti-SRP) [161]. In general, these patients should be treated aggressively with a combination of intravenous corticosteroids and IVIg or PE at disease onset. Steroid-sparing agents should be used as for DM and PM; refractory patients may respond to rituximab although there is little experience. A distinct form of autoimmune necrotizing myopathy has been reported in association with the use of statin drugs, with patients commonly relapsing when immunotherapy is tapered even with discontinuation of the statin agent [162]. An autoantibody targeting 3-hydroxy-3-methylglutaryl-conenyzme A reductase (anti-HMGCR), the target for statin therapy, has also been found in patients with this disorder [163]. This may represent an example of an environmental trigger for sustained autoimmunity, meriting further study.

A Step-by-Step Approach to Therapy

A "recipe" for treating each disease may be attractive but is not universally applicable because many of the treatment modalities are based on uncontrolled trials, and in some cases the immunosuppressive drugs are used empirically. Consequently, formulation of a step-by-step method of treatment may be considered an oversimplified approach. Nonetheless, it is useful to offer practical guidelines, drawn from our experience and that of others, for a step-by step approach to the use of immunotherapies (Table 17.4). These are not meant to be firm prescriptions, and modifications should be made according to the patient's needs or disease status or in response to new developments as appropriate.

Table 17.4 General treatment recommendations for immune-mediated neuromuscular disorders

Guillain-Barré syndrome
Step 1. IVIg or PE
Note: Both of these modalities are equally effective. IVIg is easier to administer, available worldwide, and may be initiated with minimal delays. Steroids are of no benefit and should not be used
Step 2. If early relapse occurs, repeat the treatment
Chronic inflammatory demyelinating polyneuropathy
Step 1. IVIg or prednisone
Step 2. IVIg and prednisone (if one treatment alone is not adequate)
Also may consider IV methylprednisolone 500–1,000 mg given with each IVIg
Step 3. PE (if two agents are ineffective)
If the need for a "steroid-sparing" agent arises with the use of prednisone, try MMF, cyclosporine, or cyclophosphamide
Step 4. Rituximab (particularly if associated IgM paraprotein – see below)
Multifocal motor neuropathy
Step 1. IVIg
Step 2. Adjust dose/frequency of IVIg (if effect of IVIg lessens)
Step 3. Cyclophosphamide (if IVIg is ineffective or loses its effect)
IgM paraproteinemic neuropathies with anti-MAG antibodies
Step 1. No treatment (if mild or pure sensory)
Step 2. Prednisone + chlorambucil for at least 3 months
Step 3. IVIg or PE alone or combined with prednisone and chlorambucil (if Step 2 ineffective) but the results are overall disappointing
Step 4. Rituximab
Demyelinating MGUS polyneuropathies
Step 1. Prednisone
Step 2. PE (if prednisone is ineffective or loses its effect)
Step 3. IVIg (if PE is ineffective)
If the neuropathy is axonal, it usually does not respond to therapy, but a trial of the therapies outlined is justified
Myasthenia gravis
Step 1. Pyridostigmine
Step 2. Prednisone (if pyridostigmine does not adequately control weakness)
Step 3. MMF or AZA (if prednisone does not control weakness or as steroid-sparing agent)
Step 4. Thymectomy for patients 12–50 years
Step 5. Tacrolimus or cyclosporine (if prednisone does not control weakness or as steroid-sparing agent, when azathioprine, mycophenolate ineffective)
Step 6. Rituximab (for refractory disease, particularly anti-MuSK MG)
Step 7. PE or IVIg. Both offer short-term benefit and may be used intermittently between steps 1 and 6 until the other therapies become effective. PE preferred for myasthenic crisis
Lambert-Eaton myasthenic syndrome
Step 1. 3,4-Diaminopyridine (available in compounding pharmacies and via compassionate use protocols in US)
Step 2. IVIg (patients with moderate to severe symptomatic weakness)
Step 3. Prednisone (patients with symptomatic weakness); combine with IVIg
Step 4. Azathioprine (if prednisone and IVIg do not control weakness or as steroid-sparing agent)
Step 5. PE or rituximab (if not controlled by Steps 2–4 and if weakness is severe)
Dermatomyositis and polymyositis
Step 1. Prednisone
Step 2. Methotrexate (if prednisone does not control weakness or as steroid-sparer)
Step 3. IVIg (to induce rapid improvement in severe disease and as a steroid-sparer)
Step 4. Cyclophosphamide (if refractory with interstitial lung disease)
Step 5. Other immunomodulators (azathioprine, mycophenolate mofetil, rituximab) (if steps 1–3 do not control weakness or as steroid-sparer)
Inclusion-body myositis
No pharmacologic treatment. Patients may benefit from a graded resistance exercise program (mild/early disease). A trial with IVIg may be considered if there is acute worsening, life-threatening dysphagia, or very prominent inflammatory endomysial infiltrates on muscle biopsy

Table 17.4 (continued)

Immune necrotizing myopathy
Step 1. High-dose steroids (IV or oral) + PE or IVIg
If statin-associated, stop statin drugs
Step 2. Methotrexate, azathioprine, or mycophenolate mofetil (steroid-sparing)
Step 3. Rituximab (for refractory disease)
Vasculitis of the peripheral nervous system
Step 1. Treat underlying tumor, infection, inflammatory disorder if present
Step 2. Prednisone or methylprednisolone (for more rapidly progressing disease)
Step 3. Steroids plus cyclophosphamide (when weakness moderate to severe and evidence for multiorgan involvement)

Critical and Respiratory Care in Neuromuscular Disorders

18

Osama O. Zaidat, Rana Hejal, and Jose I. Suarez

Introduction

The specialty of critical care medicine arose largely from the practical need to develop mechanisms of ventilatory support for patients with neuromuscular disorders (NMD), particularly poliomyelitis, and advances in respiratory care and the introduction of mechanical ventilation, as we know it today, dramatically decreased mortality in patients with NMD. In recent years, the implementation of critical care concepts and accessibility to specialized intensive care units have further improved morbidity and outcome [1, 2].

Knowledge of basic critical care principles and changes in pulmonary function are vital for providing optimal medical care. Managing NMD patients extends beyond the simple identification of various cardiorespiratory abnormalities and available treatment modalities in the intensive care unit (ICU). It involves prompt recognition and management of the natural progression of a disease, side effects of treatments, and comorbid illnesses that commonly occur in the ICU setting. Thus, all intensivists and physicians caring for patients with NMD should be familiar with the pathophysiologic changes associated with these disorders. The most common primary and secondary neuromuscular disorders seen in the ICU are shown in Table 18.1.

Pulmonary Function in Neuromuscular Disorders

Patients with respiratory muscle weakness have a restrictive pattern on pulmonary function testing, based on static and dynamic lung volume indices [3, 4]. The vital capacity (VC), total lung capacity (TLC), and functional residual capacity (FRC) tend to be lower than predicted values, while the residual volume (RV) and the ratio of forced expiratory volume in 1 s to forced vital capacity (FEV_1/FVC) are normal. The diffusion capacity in NMD patients is preserved, which helps distinguish them from patients with restrictive defects related to parenchymal lung disease.

One expects significant loss of muscle strength to cause reductions in the VC, based on the normal pressure-volume curve of the respiratory system [5]. However, the VC is frequently reduced because of the concomitant reduction in respiratory apparatus compliance. This reduction in static lung compliance, which is usually about 30 % and improves with deep breathing, is due to increased alveolar surface tension as a result of breathing at low lung volumes [6]. The exact mechanism is unknown, but it is likely multifactorial in nature. Chest wall compliance and lung elasticity are altered [7, 8]. The low level of stress on the elastic tissue, due to chronic small tidal volumes and alveolar collapse, may be a factor in this process. Atelectasis and microatelectasis have unclear roles in the pathogenesis, since patients may have low compliance and elasticity without evidence of complete or partial collapse. Also, chest computerized tomography fails to show an association between microatelectasis and reduced lung compliance in patients with generalized NMD or traumatic tetraplegia [9]. Although daily use of intermittent positive-pressure ventilation (IPPV) is an effective method for improving lung compliance and preventing atelectasis formation, a true cause and effect relationship has not been established [10].

Respiratory muscle strength and reserve are indirectly measured by (1) negative inspiratory force (NIF) (synonymous with maximum inspiratory pressure, MIP),

Table 18.2 Useful respiratory physiologic variables in the respiratory management of patients with neuromuscular disease

Variable	Normal values	Consider ICU admission (or noninvasive measures in chronic NMD)	Consider intubation and assisted ventilation	Consider weaning off ventilator
Vital capacity (VC)	50–70 ml/kg	25–30 ml/kg	10–15 ml/kg	>15 ml/kg
Negative inspiratory force (NIF)[a]	>60 cm H_2O	−30 to −40 cm H_2O	<20 cm H_2O	>25 cm H_2O
Maximum expiratory pressure (MEP)	>100 cm H_2O	<50 cm H_2O	<40 cm H_2O	>40 cm H_2O

[a]Also called maximum inspiratory pressure (MIP)

which reflects inspiratory muscle and diaphragm strength and is usually less than −60 cm H_2O; (2) maximum expiratory pressure (MEP), which measures expiratory muscle strength and is usually greater than 100 cm H_2O; and (3) forced vital capacity (FVC), with a usual normal value of 50–70 ml/kg (Table 18.2). Monitoring these physiologic parameters helps identify patients with impending respiratory failure. Inability to cough and clear secretions occurs when MEP is less than 40 cm H_2O and FVC is less than 30 ml/kg, while ventilatory failure develops when NIF is less than 20 cm H_2O and FVC is less than 10 ml/kg [11]. NIF measurement correlates well with diaphragmatic fatigue and has the highest predictive value for initiation and weaning from mechanical ventilation [12, 13]. Other parameters of diaphragmatic function such as maximum transdiaphragmatic pressures and tidal volume (Vt) are severely diminished in the acute and recovery phases of primary NMD such as Guillain-Barre syndrome (GBS) and myasthenia gravis (MG). Although these variables improve during recovery, they do remain abnormally low [12, 13].

Abnormalities in the thoracoabdominal pattern of breathing include decreased contribution of thoracic and abdominal compartments to Vt, due to paradoxical rib cage and abdominal movements [14, 15]. Perez et al. quantitatively studied the effect of IPPV and an abdominal binder on Vt, the thoracic contribution to Vt, the phase angle changes between thoracic and abdominal volumes, and the labored breathing index in 31 patients with spinal muscular atrophy (SMA) and myopathy [15]. In SMA, a motor neuron disease, the paresis mainly involves the intercostal muscles sparing the diaphragm, while in myopathies, the diaphragm is partially paralyzed sparing the intercostal muscles. Thus, in myopathies, the intercostal muscles contribute mainly to thoracic cage movement during inspiration leading to the paradoxical inward abdominal movement and asynchrony between the thoracic and abdominal motion. On the other hand, motor neuron disease involvement of the intercostal muscles hinders expansion of the thoracic cage during inspiration, leading to smaller thoracic contribution to the Vt when compared to myopathies [14, 15]. This may explain

Table 18.3 Respiratory abnormalities associated with neuromuscular disorders

Physiologic abnormalities
Reduced chest wall compliance
Reduced static and dynamic lung volumes
Decreased ability to sigh and yawn
Reduced ability to clear secretions
Hypercapnia when muscle strength drops below 30 % of its predicted value
Clinical consequences
Atelectasis and microatelectasis
Aspiration pneumonia
Difficulty weaning from mechanical ventilation
Abnormal thoracoabdominal breathing pattern
Obstructive sleep apnea
Hypersomnolence

the more frequently abnormal thoracoabdominal breathing pattern and labored breathing seen in patients with motor neuron disease. These abnormal breathing patterns improve with institution of IPPV of 25–30 cm H_2O, particularly in patients with SMA [15], and reappear after its discontinuation [10]. Abdominal binding also increases thoracic contribution to the Vt. This is more noticeable in motor neuron disease than in myopathies [14, 15]. Observing a paradoxical pattern of thoracoabdominal breathing that is more pronounced in the supine position or measuring FVC in supine and sitting positions may alert the examiner to diaphragmatic dysfunction. However, this technique is rather insensitive and should not be solely relied upon in clinical practice.

Other findings in patients with NMD include inability to clear secretions and absent sighs and yawns, which are believed to help distribute surfactant evenly and, thereby, prevent alveolar collapse. Furthermore, NMD increase both the resistive and elastic loads on respiratory muscles, leading to an increase in work of breathing. The latter cannot be adequately accomplished by the weakened respiratory apparatus, causing fatigue and, ultimately, failure. In NMD with bulbar muscle involvement, the detection of abnormalities on pulmonary function tests, particularly abnormal contour of the flow-volume loop, may be apparent before any clinical evidence of bulbar muscle weakness [16–18]. This may signify involvement of the upper airway musculature and suggests an increased risk for developing respiratory complications related to the upper airway. In addition, patients with NMD have blunted responses to carbon dioxide and variable degrees of hypoxia [12, 19, 20]. Both of these changes account for the increased incidence of sleep-disordered breathing in this patient population. A summary of impairment of respiratory function and mechanics in NMD patients is outlined in Table 18.3.

Basic Critical Care Approach in NMD

As with all critically ill patients, the basic assessment and management of patients with neuromuscular disease require particular attention to airway, breathing, and circulation. Respiratory musculature weakness in patients with NMD renders them more vulnerable to respiratory compromise that may progress to failure. Those with bulbar involvement are at risk for upper airway obstruction and aspiration, whereas those with generalized weakness are prone to developing atelectasis, lobar or lung collapse. These phenomena are due to inability to protect the upper airway, cough, sigh, or clear secretions. All these considerations are important when a patient with a primary NMD presents, not only with an exacerbation, but also with any acute stressor. Both situations require prompt institution of incentive spirometry, chest physical therapy, and nasotracheal suction. Once a clinical assessment is made, the patient's ability to maintain adequate ventilation should be determined and monitored closely [21–23]. Standard respiratory parameters including FVC, MEP, and NIF measurements are inexpensive and easily performed at bedside and correlate well with respiratory derangement, as described above.

Evaluation and management of confounding systemic abnormalities is paramount to decreasing morbidity and mortality in patients with NMD. For example, electrolyte imbalances that may induce muscle weakness have devastating consequences in patients with primary muscle or neuromuscular junction disorder. Infections, local or systemic, may lead to neuropathies, muscle necrosis, and weakness. Concurrent illnesses, such as pulmonary embolism, ischemic heart disease, thyroid dysfunction, and renal dysfunction and hypovolemic states, may precipitate acute decompensation. In disorders that affect the autonomic nervous system (Table 18.4), cardiac and hemodynamic monitoring should be instituted at the onset of any sign of dysfunction or instability, since fluctuations in blood pressure and arrhythmias may be fatal. Prophylaxis against gastrointestinal stress ulcers, reflux, dysmotility syndromes, and venous thromboembolic disease should be introduced early in the course of the illness in all critically ill patients. Nutritional support, preferably enteral feeding, should be started as soon as possible to prevent cachexia and secondary weakness. In addition, medications known to induce myopathies and weakness must be avoided whenever possible.

Pain control is a vital adjunct to the overall care of these patients. Since most ICU patients are unable to communicate or express themselves verbally, objective parameters, such as abrupt rise in systolic blood pressure, tachycardia, and diaphoresis, are useful measures to gauge distress. Steroids, nonsteroidal anti-inflammatory drugs, or codeine is usually a good choice for pain management. Other common

Inherited myopathies: Duchenne's, myotonic dystrophies, glycogen storage diseases (Pompe's, McArdle's, and Tauri's), nemaline myopathy, mitochondrial, periodic paralysis
Porphyria
Vasculitic neuromuscular diseases

conditions that occur in ICU patients include sleep deprivation, delirium, and frank psychosis. After excluding an organic cause of altered mental status, these processes may be remedied by restoring patients' sleep-wake cycle and increasing adequate external environmental stimuli such as radio, television, family visitations, and rooms with windows that permit daylight. In addition, rehabilitation is usually started in the ICU as soon as the clinical situation allows. Devices to prevent contractures may be applied, and range of motion exercises started at bedside and advanced as tolerated.

Last, but equally important, are the ethical dilemmas that patients and their families face. The majority of patients are unfamiliar with their disease, its potential complications, and short- and long-term management issues at hand. Devoting adequate time for individual and group counseling through family meetings in order to answer questions and concerns is invaluable and must be a priority for the treating physicians. Maintaining a constant line of communication between the treating team, patient, and family helps patients cope with the stress of an intensive care environment. It is important to discuss a patient's and family's values and expectations, and when appropriate, palliative care should be introduced, and the palliative care team consulted.

Acute Ventilatory Management

Respiratory failure in NMD is the leading indication for admission to the ICU (Table 18.5). Disorders with an acute onset have a relatively predictable course. Many patients, who appear to be stable, lapse into respiratory failure within hours. Others, who are discharged prematurely from the ICU, are readmitted with ventilatory failure. Since the primary goals are to prevent, detect, and manage respiratory failure, close monitoring of simple respiratory indices is warranted in order to institute elective ventilatory support as dictated by the clinical setting [21–24]. The clinician must decide when to admit a patient to the ICU, establish an artificial airway, mechanically ventilate, and begin weaning and discontinue ventilatory support (Fig. 18.1) [24–32].

The maintenance of a patent, well-protected airway is the most important initial task for an intensivist in any clinical scenario. Upper airway compromise is clinically suspected if there is excessive drooling, difficulty swallowing oral secretions, use of accessory muscles, or stridor. In less severe cases, subtle changes on the flow-volume curve during spirometry may suggest airway compromise. Hence, an artificial airway should be established, regardless of gas-exchange abnormalities, with any sign of upper airway compromise.

Patients with acute or chronic NMD who present with an upper respiratory illness, even without obvious ventilatory failure, need frequent repeated measurements of respiratory parameters (FVC, NIF, and MEP) to guide therapy. The first step is to prevent any further pulmonary function compromise by immediately instituting chest physical therapy accompanied by nasotracheal suctioning, incentive spirometry, and IPPB. Management of the underlying disease affects outcome and, therefore, immediate initiation of therapy to arrest the disease process and, hopefully, halt further deterioration in respiratory function should be instituted. Equally important, aggressive correction of other factors that may compromise neuromuscular function, such as electrolyte imbalance, medications, fever, infection, and dehydration, should be carried out. Medications should be reviewed for any possible toxic effect on nerve, muscle, and neuromuscular junction. Keeping patients in a partially upright sitting

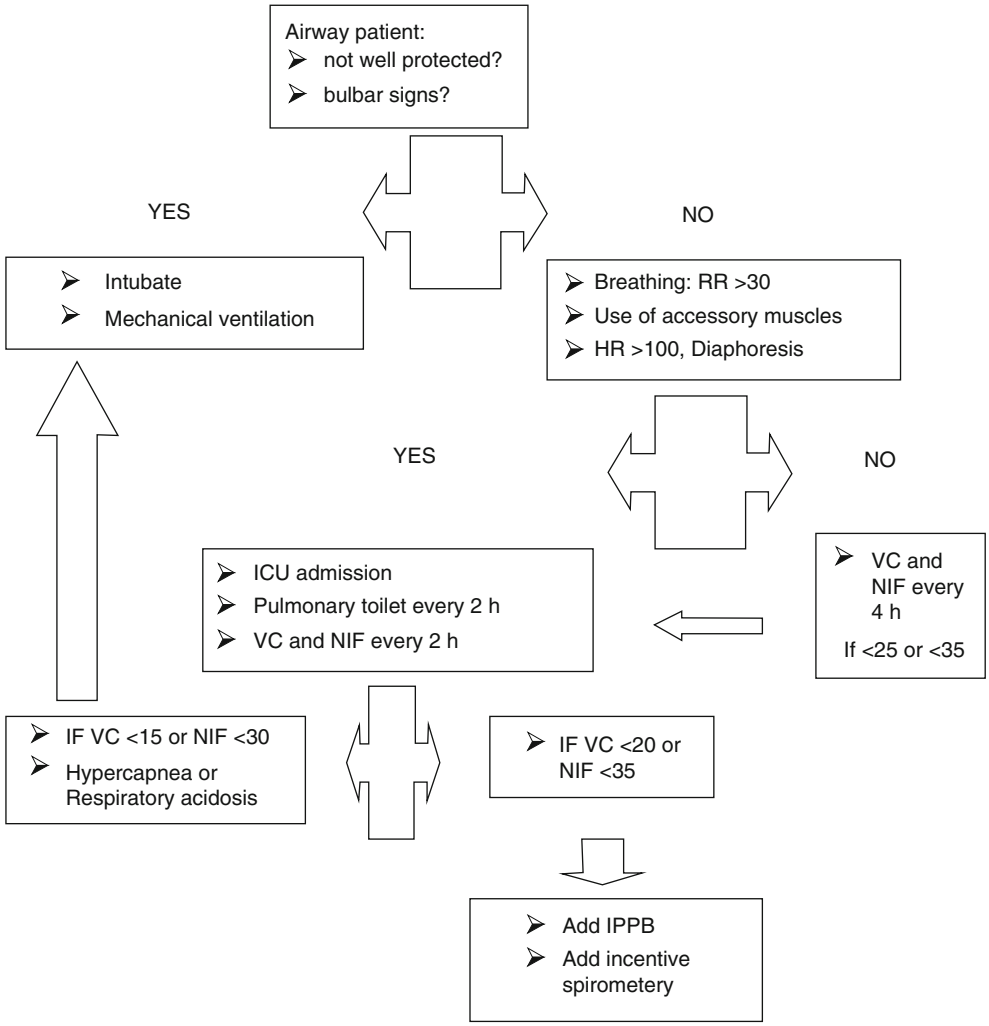

Fig. 18.1 Neuromuscular disease: acute presentation. Management algorithm (*RR* respiratory rate, *HR* heart rate, *ICU* intensive care unit, *VC* vital capacity, *NIF* negative inspiratory force, *IPPB* intermittent positive pressure breathing)

position at a 30° angle can help optimize diaphragm position and therefore its function.

The next step is to decide when to transfer a patient to the ICU. There are several suggested criteria for ICU admission [24–32]: (1) clinically ominous signs such as bulbar involvement with stridor, use of accessory muscles, a paradoxical respiratory pattern, diaphoresis, and autonomic instability; (2) any patient with NMD presenting with acute respiratory symptoms and weak proximal muscles; and (3) reduction in physiologic measures, namely, FVC of 25–30 ml/kg, NIF of 30–40 cm H_2O, and MEP <50 cm of H_2O (Table 18.2). All the above correlate well with respiratory failure and need for assisted ventilation.

Once in the ICU, more frequent bedside measurements of physiologic measures should be performed, along with around-the-clock IPPB, incentive spirometry, and chest physical therapy to optimize bronchial clearing. We strongly recommend early intubation, particularly in patients with increased secretions, which may lead to a less traumatic course and prevent further formation of atelectasis and pneumonia [27, 28].

Criteria for endotracheal intubation in patients with NMD are well addressed in the literature, and several recommendations have been made [27–32]. We usually perform orotracheal intubation; others advocate nasotracheal intubation [27, 28]. Mechanical ventilation in patients with an acute NMD is best initiated prior to the development of hypercapnic respiratory failure, since hypercapnia is a late manifestation of respiratory muscle weakness. *Thus, assisted ventilation should be started when FVC is between 10 and 15 ml/kg, NIF <20 cm H_2O, and/or MEP <40 cm H_2O* (Table 18.2) [24–32].

The optimal mode of ventilation is one that provides enough pressure and volume to prevent and reverse alveolar collapse, allows patients to participate and use their respiratory muscles without fatigue, and is associated with the least work of breathing. Unfortunately, there are no controlled studies comparing outcome of the various modes of mechanical ventilation in this setting [33–35]. Hence, the mode of mechanical ventilation used is dependent mainly on the physician's preference, experience, and availability. In our institution, the most commonly used technique is the *assist-control*

mode (AC). The ventilator delivers a positive-pressure breath at a preset Vt and rate. If a voluntary inspiratory effort is sensed, a similar machine breath will be delivered assisting the patient in his effort. *Synchronized intermittent mandatory ventilation (SIMV)* in combination with pressure support is also used. In this mode, the ventilator again delivers a preset Vt and rate, allowing the patient to breathe spontaneously in between machine breaths. If pressure support is added, the airway pressure rises to a set level augmenting the patient's spontaneous efforts. The Vt (6–8 cc/kg of ideal body weight/breath) and respiratory rate are adjusted to match the patient's minute ventilation requirements. Sighs and pauses may be added along with PEEP between 5 and 15 cm H_2O, to help reverse atelectasis and maintain normal airway peak and plateau pressures.

Weaning starts as soon as muscle strength improves and the comorbid illnesses and physiologic imbalances are reversed. If the patient is awake enough to protect the airway (MEP >40 cm H_2O), with low oxygen requirements (FiO_2 <45 %) and good strength (FVC >15 ml/kg and NIF >25 cm H_2O), a weaning trial may be started (Table 21.2) [24–32]. Several weaning methods have been studied [33–35]. We use daily spontaneous breathing trials (SBT) of continuous positive airway pressure (CPAP) with pressure support and carefully assess for signs of distress such as tachycardia, tachypnea, agitation, and diaphoresis [30–35]. Initially nocturnal rest on assisted ventilation is allowed. If the patient tolerates CPAP with minimum pressure support (less than 5 cm H_2O); has FVC greater than 30 ml/kg, NIF of >40, and MEP of >50; and has adequate gas exchange, extubation may be performed. We usually like to try patients for 2 h or more on SBT before we remove the endotracheal tube. The traditional teaching is that if patients are not able to wean off assisted ventilation in 2 weeks, a tracheostomy be performed. In practical terms, patients with NMD who are not been successfully weaned from mechanical ventilation by 7–10 days are likely to require tracheostomy and prolonged support. The advantages of tracheostomy include easy access for suctioning secretions, decreased dead space, reduction of laryngotracheal injury, and, to some degree, improved patient comfort.

Chronic Ventilatory Management

Chronic respiratory failure (CRF) is a common occurrence in patients with advanced NMD such as Duchenne muscular dystrophy (DMD) or amyotrophic lateral sclerosis (ALS). Since many of these disorders are irreversible, patients may elect long-term mechanical ventilation [36–40]. With the advances in noninvasive techniques in assisted ventilation, many chronically ill patients are surviving longer with improved quality of life [37, 38, 41]. Patients with DMD, SMA, post-poliomyelitis syndrome, and ALS are the most likely candidates for long-term mechanical ventilation [41–46]. In the United States, almost all patients with DMD and 50 % of those with post-poliomyelitis or ALS are chronically ventilated [2, 45–48]. Most patients can be supported at home initially with noninvasive nocturnal ventilation. As the disease advances, handling secretions becomes difficult and the need for continuous ventilatory support becomes a necessity to maintain life [47–52].

The use of noninvasive ventilation is as old as the poliomyelitis epidemics. It started with negative-pressure ventilators, like the iron lung, cuirass, and wraps, and later evolved into abdominal displacement devices such as the pneumobelt and rocking bed [53, 54]. The iron lung is a large pressurized apparatus that encloses a patient's body below the neck, generating subatmospheric pressures around the thorax, allowing air to flow into the lungs. Pressures then return to normal, causing passive deflation. The iron lung is probably of historic value only nowadays, although it was lifesaving during the poliomyelitis epidemics. The rocking bed, on the other hand, uses gravity to displace abdominal viscera by changing the angle of the bed between 10° and 30° several times each minute to assist in diaphragmatic excursion in patients with quadriplegia and bilateral diaphragmatic paralysis [53]. The pneumobelt is placed on the abdomen with automatic cyclical inflation and deflation provided by a positive-pressure source, which aids in diaphragmatic movement [55, 56]. Negative-pressure ventilation using cuirass and a body-wrap ventilator may be acceptable in some patients, who cannot tolerate the mask used in positive-pressure ventilation. However, it is contraindicated in patients with bulbar muscle weakness, because of the potential precipitation of upper airway obstruction [42, 43].

Noninvasive positive-pressure ventilation is the mode of choice in patients with NMD due to its efficacy, portability, and ease of use [43, 44]. It can be volume limited or pressure limited and applied via a tightly fitted nasal, facial, or oral mask. The main disadvantages are poor tolerance, infraorbital leak, nasal congestion, skin lacerations, and sinusitis. The clinical picture dictates choosing between volume- and pressure-limited assisted ventilation. Patients who are ambulatory, with relatively stable lung compliance, yet require nocturnal ventilatory support and tend to benefit from pressure-limited devices. *Bi-level positive airway pressure (BiPAP)* is the most commonly used device. Others with more progressive disease and unstable lung compliance tend to do better with volume-limited ventilation. In patients with upper airway muscular weakness, the use of *continuous positive airway pressure (CPAP)* helps prevent upper airway collapse by pneumatically splinting the airway, leading to a decrease in obstructive apnea events. CPAP also augments the patient's functional residual capacity, thus reducing the incidence of atelectasis [42–58].

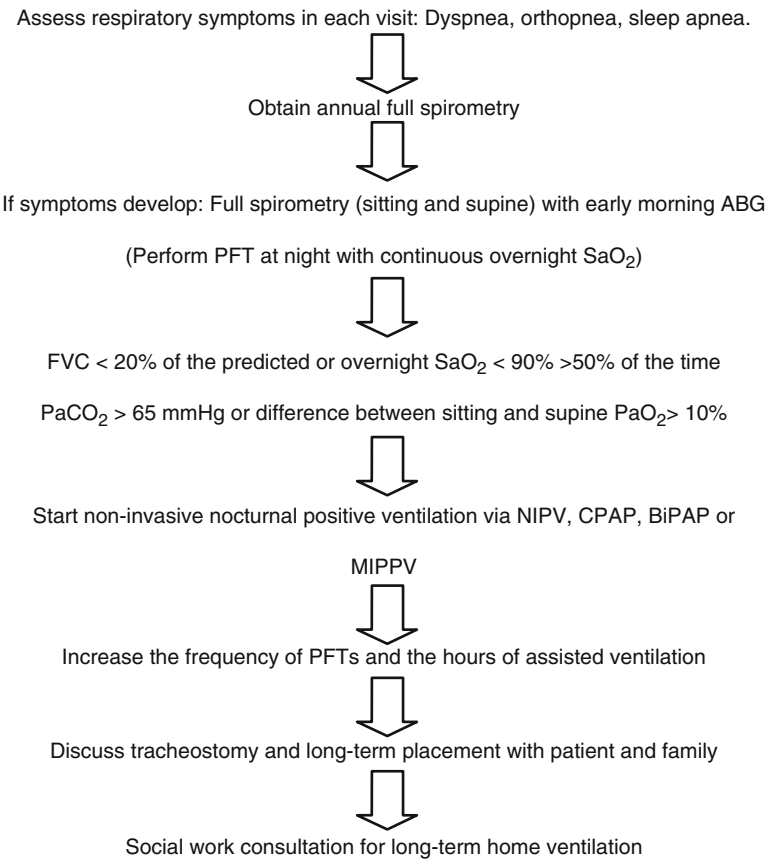

Fig. 18.2 Chronic respiratory care in patients with neuromuscular disease. Chronic respiratory care in patients with neuromuscular disease (*ABG* arterial blood gas, *PFT* pulmonary function tests, SaO_2 oxygen saturation, $PaCO_2$ partial pressure of carbon dioxide, *NIPV* negative intermittent pressure ventilation, *CPAP* continuous positive pressure ventilation, *BiPAP* bi-level positive airway pressure, *MIPPV* mechanical intermittent positive-pressure ventilation)

Recently, diaphragmatic pacing has been reevaluated, with increasing interest and research on its applications in patients with spinal cord injury and NMD [59, 60]. Obstacles to its use include the availability of immediate care in case of malfunctioning and the need for an educated and responsible patient, family, or caregiver. However, more experience has been accumulated in the past 10 years making this technique easier and safer to implant even in patients with pacemakers [61].

Strengthening exercises for inspiratory muscles and upper airway musculature is a mainstay of treatment. Although this may only produce minimal benefit, the need for ventilatory support may be delayed [62]. Eliminating and treating conditions that may worsen respiratory status, such as surgical correction of thoracic cage skeletal deformities, may help augment lung volumes [63]. Ultimately, the need for ventilatory support supervenes. We suggest to begin with several hours of nocturnal noninvasive ventilation, which improves the quality of life in patients with progressive NMD. With disease progression, the length of time needed for assisted ventilation increases, and difficulty handling secretions becomes more evident. At this point, discussion with the family regarding long-term goals and elective tracheostomy is advisable (Fig. 18.2). In addition, in home-ventilated NMD patients, caregivers must assess the efficiency of mechanical ventilation to allow for subsequent adjustments. Concomitant pulse oximetry and transcutaneous CO_2 monitoring are recommended to investigate this [64]. The choice of assisted continuous ventilatory mode and tracheostomy is usually made on an individual basis and discussed with the patient and their family using a team approach [41, 49, 51]. In this setting, tracheostomy along with continuous mechanical ventilation is labor intensive. Subsequently, delivering adequate home care may become difficult for the family and the caregivers. The need for institutional care may be necessary, and facilities with health professionals familiar and well trained in the care of patients with NMD should be considered. Several social, ethical, and economical factors are encountered and may complicate decision making regarding initiation of chronic ventilation and placement issues. It is of the utmost importance that the patient and family be involved in all decisions relating to the overall care. Discussing immediate and long-term goals and plans and taking into account the progressive irreversible nature of the disease and its impact on the patient and family's quality of life are of paramount importance.

Cardiovascular Aspects in NMD

Cardiac manifestations in neurologic diseases are common. Acute and chronic NMD may lead to various types of cardiovascular complications. In GBS, cardiac arrhythmias and

Table 18.6 Indications for cardiac pacing in NMD

Disorders of conduction
Complete heart block
Mobitz type II atrioventricular block
New bifascicular block
Asystole
Disorders of heart rate
Symptomatic sinus bradycardia
Recurrent ventricular tachycardia unresponsive to medical treatment
Junctional rhythm with atrioventricular dissociation
Medically refractory supraventricular tachycardia

dysautonomia are common and are the current leading causes of death. Various types of arrhythmias are encountered including sinus bradycardia, variable heart blocks, asystole, supraventricular, and ventricular tachycardia [65–67]. Also, variation in heart rate and blood pressure with orthostatic hypotension and diaphoresis may occur [65–67]. All patients with GBS and cardiovascular manifestations are at high risk of sudden death and should be monitored in the ICU. Hydration is the mainstay of treatment, but some patients may require vasoactive drugs, cardioversion, and even temporary pacemakers [65–67] (Table 18.6). Other NMDs that may involve the heart include periodic paralysis (related to potassium imbalance), mitochondrial myopathies, and toxic and alcoholic myopathies. Although some antiarrhythmic medications such as procainamide and quinidine may unmask or worsen MG, cardiac manifestations are not clearly associated with MG [68, 69].

Chronic NMD frequently involve cardiac muscle. DMD leads to rhythm disturbances, such as inappropriate sinus tachycardia, abnormal atrial rhythm, and rarely ventricular arrhythmia [70–72]. The electrocardiogram (EKG) may show tall right precordial R wave, increased R/S ratios with deep Q waves in V1 and V5–V6, short PR interval, and multifocal premature atrial and ventricular complexes indicative of cardiac involvement [73–76]. Asymptomatic women carriers may also show similar EKG findings [77]. Mitral regurgitation due to both papillary muscle involvement and dilated cardiomyopathy may lead to heart failure [78–83]. Dilated cardiomyopathy may also occur in women [84]. In Emery-Dreifuss and facioscapulohumeral (FSH) muscular dystrophies, there is a peculiarly high susceptibility to atrial flutter or fibrillation with atrial paralysis, requiring immediate cardiac electrophysiologic studies and possible pacemaker placement [85–87]. Myotonic dystrophy preferentially involves the Purkinje-His system, with fatty infiltration leading to intraventricular conduction abnormalities with right or left bundle branch block. This may culminate in Stokes-Adams episodes which can be prevented by placing a pacemaker [88–93]. Heart failure occurs in less than 10 % of these patients due to the rarity of myocardial involvement [94, 95]. Friedreich's ataxia may be associated with heart failure due to dilated and hypertrophic cardiomyopathies, the latter being far more common [96–98]. Charcot-Marie-Tooth disease may cause dilated cardiomyopathy and heart failure, cardiac arrhythmias, and conduction abnormalities [99]. Centronuclear myopathy is associated with myocardial fibrosis, dilated cardiomypathy, and sudden death due to cardiac involvement [100].

In summary, cardiac involvement is common in acute and chronic NMD leading to heart conduction abnormalities and cardiomyopathies. Recognizing these abnormalities early in the disease leads to timely medical management, and a low threshold should be maintained for placing a pacemaker when necessary.

Electrodiagnostic Testing in Intensive Care

Electrodiagnostic (EDX) testing in the ICU environment of critically ill patients with suspected acute NMD is often difficult. Limitations and pitfalls to performing these studies in the ICU are well recognized by most electromyographers [101]. Reviewing the history and discussing the testing plan with the ICU team often is beneficial to avoid possible pitfalls. Particular attention should be given to the patient's skin temperature since peripheral vasoconstriction is common and may lower skin temperature. A core temperature of <36 °C, muscle <34 °C, or skin <32 °C is associated with slowing of distal latencies and conduction velocities and an increase in motor and sensory amplitudes. Excessive tissue edema and subcutaneous fat may prevent supramaximal stimulation [101]. Some patients may have a bleeding diathesis, excessive sweating, skin breakdown, central lines, pacemakers, monitoring devices, or communicable diseases, which affect the choice of the procedure, the particular site, and the extremity tested. In spite of these limitations, EDX testing, including needle electromyography (EMG), nerve conduction studies (NCS), and repetitive nerve stimulation, may be performed and provide significant aid in arriving at an accurate diagnosis and prognosis [102, 103].

Testing of the respiratory system is another important part of the application of EDX testing that has not been used frequently [104]. Its major role is to investigate the cause of respiratory insufficiency by testing components of the central and peripheral nervous system involved in ventilation, including the diaphragm, phrenic nerve, spinal cord, and cerebral cortex. Phrenic motor NCS by surface stimulation, recording from the skin over the diaphragm, may be readily and easily performed in the ICU setting [104]. Repetitive nerve stimulation may be performed on the phrenic nerve as well, which may shed light on the pathogenesis of the neuromuscular weakness [104]. Diaphragmatic needle EMG examination may be performed but is cumbersome in the ICU, and patients may not be alert enough to cooperate with

testing [104]. Central causes of respiratory depression may be studied by transcortical magnetic stimulation of the motor cortex while recording from the diaphragm and by phrenic nerve somatosensory-evoked potentials [104].

In general, most EDX studies may be performed safely and with enough details in the ICU to provide sufficient information to guide diagnosis and therapy. Serial studies are often helpful in diagnosis and prognosis.

Plasmapheresis and Intravenous Immunoglobulin in the ICU Setting

Plasmapheresis and intravenous immunoglobulin (IVIG) are the most commonly used treatments in acute neuromuscular paralysis requiring ICU admission, since they are effective in GBS and MG [105, 106]. Other uses for IVIG and plasma exchange include some inflammatory myopathies, paraneoplastic syndromes, and Lambert-Eaton myasthenic syndrome. The usual dose of IVIG is 2 g/kg divided into two to five daily infusions. During plasma exchange, about 40–50 cc/kg of plasma is removed using a continuous flow machine, replacing the plasma with albumin or saline [105, 106]. A series of four to six exchanges on a daily or alternate-day regimen are often administered.

Although IVIG is usually well tolerated by ICU patients with impaired hemodynamics, recognizing its side effects is very important. The most commonly encountered side effects are a flu-like illness with headache, myalgia, malaise, fever, and chills, which respond to the administration of acetaminophen or ibuprofen, diphenhydramine, and intravenous steroids prior to each IVIG infusion [107, 108]. The headache may be so severe and intolerable requiring discontinuing the treatment, although it may occasionally respond to migraine drugs, such as sumatriptan or intravenous dihydroergotamine, prior to IVIG infusion or immediately afterward. More serious adverse reaction may include arterial thrombosis, deep venous thrombosis, pulmonary embolism, stroke, retinal necrosis, aseptic meningitis, leukopenia, and renal failure in patients with baseline renal insufficiency [107, 108]. Hyponatremia is also observed in some patients who received IVIG. More commonly, worsening of hyponatremia, from syndrome of inappropriate secretion of antidiuretic hormone associated with GBS, occurs upon institution of the IVIG. Anaphylaxis due to presence of IgA in IVIG preparations may rarely occur in patients with selective IgA deficiency [107, 108]. It is our practice, as well as some others, to obtain a quantitative serum IgA measurement prior to IVIG therapy. Reversible encephalopathy due to hypertensive crisis or vasculopathy is reported in GBS patients treated with IVIG [108]. Cortical blindness, seizures, and delirium may occur as soon as the first dose of IVIG is completed, and magnetic resonance imaging of the brain during these episodes may show a transient increase in signal intensity in the posterior aspects of the brain. Viral transmission is uncommon, but it may occur and usually the risk is highest for hepatitis C. New methods of preparing IVIG have reduced the risk of transmission of hepatitis C. There are no reported cases of HIV transmission.

Plasma exchange may be associated with a viral-like illness as well, especially in patients with reduced immunoglobulin levels. Hemodynamic instability may occur, more frequently when the patient has unstable blood pressure or autonomic dysfunction. Lightheadedness, dizziness, and cardiac arrhythmias may also occur. Impaired coagulation tests with thrombocytopenia, prolonged prothrombin, and partial thromboplastin time (due to depletion of coagulation factors) are not uncommon [109, 110]. This increases the risk of gastrointestinal bleeding in ICU patients who are usually malnourished, have vitamin K deficiency, and harbor stress gastritis. Electrolyte abnormalities, in particular hypocalcemia and hypomagnesemia, need to be monitored closely since they may worsen the underlying NMD. Complications related to venous access, including infection, bacterial endocarditis, pneumothorax, or thrombosis and thrombophlebitis, are common. Adverse reactions of both plasma exchange and IVIG are summarized in Table 18.7.

Table 18.7 Adverse reactions associated with plasmapheresis and IVIG in ICU

IVIG	Plasmapheresis
Flu-like symptoms: fatigue, malaise	Flu-like symptoms
Severe vascular-like headache	Cardiac arrhythmias
Arterial and venous thrombosis: DVT, pulmonary embolism, stroke, and retinal necrosis	Orthostatic symptoms
Hypertensive encephalopathy	Venous access complication
Aseptic meningitis	Bleeding
Renal failure (if renal function is impaired)	Thrombophlebitis, thrombosis
IgA anaphylaxis	Infection: line sepsis or bacterial endocarditis
Rarely hepatitis C	Pneumothorax, arterial puncture
Electrolyte imbalance: hypocalcemia and hyponatremia	Electrolyte imbalance (mainly Ca^{2+})
	Coagulopathy

Selected Primary Neuromuscular Disorders

NMD requiring admission to the ICU are numerous. Some of these conditions, such as GBS and MG, may present acutely with respiratory failure. Others, such as DMD patients, require hospitalization for intercurrent illness or aspiration pneumonia, which may be related directly to the underlying respiratory muscle dysfunction. Other reasons

for ICU admission include postoperative care (surgical ICU) or cardiac dysfunction (telemetry and cardiac ICU). Critical care aspects of selected NMDs are discussed in the following sections. MG and GBS, common diseases requiring ICU admission, and ALS, a common disease treated with chronic ventilation, are discussed in detail in other chapters.

Inflammatory Myopathies

Critical care issues arise when either the lung or heart is involved in inflammatory myopathies. Dermatomyositis and polymyositis occasionally present with respiratory failure, but more frequently weakness of the intercostals and diaphragm musculature occurs in the course of the disease leading to pulmonary distress and aspiration pneumonia. Moreover, pulmonary fibrosis and pneumonitis or fibrosing alveolitis is reported in 10–30 % of patients. It often occurs when an associated collagen vascular disease is present or in mixed connective tissue disease. Respiratory involvement responds usually only to steroid therapy, but only in half of patients, if instituted early. Pulmonary fibrosis carries a poor prognosis [111]. Overall, inflammatory myopathies associated with pulmonary involvement tend to be more severe and extensive, carrying a poor outcome, and may necessitate early tracheostomy and IPPV.

Cardiomyopathy, myocarditis, or pericarditis may be associated with polymyositis or dermatomyositis. This occasionally leads to congestive heart failure and may aggravate a preexisting respiratory compromise leading to ventilatory failure. Various cardiac conduction abnormalities including atrioventricular heart block, and brady- or tachyarrhythmias, may be seen; some may require pacemaker placement [112]. Close attention to gastrointestinal motility is crucial. Although bulbar muscles are rarely involved, esophageal and gastrointestinal motility may be impaired, leading to dysphagia, malnutrition, and aspiration pneumonia [111, 113, 114].

Muscular Dystrophies

Duchenne muscular dystrophy (DMD) is the most common childhood neuromuscular disorder [115]. Critical care may be needed when patients develop cardiac or respiratory complications. The onset of pulmonary dysfunction is around 17 years of age, but cardiac complications may start earlier. NIF (MIP) is the first parameter reduced on pulmonary function testing, while VC remains normal until late in the course of the disease [1–4, 19, 23]. Maximum static expiratory pressure may correlate with the severity of impaired respiratory mechanics. Pulmonary function test abnormalities may lag behind clinical deterioration, leading to a false sense of security. Nocturnal hypoventilation with hypercarbia and hypoxia is an early manifestation of respiratory compromise, resulting in daytime fatigue, tachypnea, and headache. Management of nocturnal hypoventilation includes preventive measures, such as weight loss, changing sleeping position, and suctioning at home, or the use of noninvasive ventilatory methods. Negative-pressure ventilation to correct nocturnal breathing problems may be poorly tolerated, increase the risk of aspiration pneumonia, and intermittently obstruct the upper airway. Intermittent nasal positive-pressure ventilation or via a mask (IPAP and BiPAP) may not be the optimal treatment but is effective in preventing core pulmonale and delaying tracheostomy. Since structural deformities of trunk, such as kyphoscoliosis, may cause further lung compromise and restrict ventilation, surgical correction often delays the decline in pulmonary function. Treatment of Duchenne muscular dystrophy with prednisolone (0.75 mg/kg/day) may help limb and respiratory muscle strength as evidenced by improvement of pulmonary function tests [115, 116]. Unfortunately, as the disease progresses, continuous mechanical ventilatory support via tracheostomy is the only hope for survival. Occasionally, nocturnal mechanical positive ventilation may suffice.

Cardiac involvement including fibrosis and cardiomyopathy may lead to conduction defects and congestive heart failure. Occasionally, cardiomyopathy is lethal and resistant to medical treatment. EKG abnormalities are present in all patients and include deep narrow Q waves in left precordial leads with increased amplitude of R waves in the V1 lead as discussed earlier.

Gastrointestinal complications due to gastric dysmotility are rare. Acute gastric dilatation may require immediate deflation with gastric and rectal tubes to prevent perforation; constipation and megacolon are uncommon. In advanced stages of the disease, feeding tube and enteral feeding may be required. Complications of enteral feeding and malnutrition further compromise muscle strength and cardiopulmonary function. Measuring total protein, albumin, and prealbumin in peripheral blood on a timely schedule may be necessary to monitor optimal nutrition. Following general anesthesia patients with Becker and DMD may be at risk of developing myoglobinuria, which may mimic malignant hyperthermia (see below) [117].

Limb-girdle muscular dystrophy is a heterogeneous group of muscular dystrophies characterized by progressive proximal muscle weakness in the second and third decades of life [118]. Mutations in the sarcoglycan complex, a cytoskeletal muscle glycoprotein, have been implicated as the cause of muscle dysfunction in about 10 % of patients [119].

Respiratory dysfunction, which rarely requires assisted ventilation, occurs usually late in the disease and parallels the progression of limb weakness. Selective diaphragmatic involvement may occur early in the disease. Scoliosis and kyphosis may also contribute to pulmonary dysfunction.

Sleep apnea, nocturnal hypoventilation, and pneumonia are the most common complications [120]. When respiratory failure occurs, patients may elect tracheostomy with assisted positive ventilation. Cardiac involvement is uncommon, but when present, it is usually manifested by mild congestive heart failure and, rarely, conduction defects [121, 122].

Myotonic dystrophy is the most common adult form of muscular dystrophy, with autosomal dominant inheritance (chromosome 19q13.1 with a CTG trinucleotide repeat) [123]. Pulmonary dysfunction is common but is not as severe as in other forms of muscular dystrophies. Sleep apnea and daytime hypersomnolence may occur, the latter being the most common pulmonary presentation [124]. An abnormal respiratory breathing pattern may present with ataxic, periodic, or Cheyne-Stokes breathing [123, 124]. Reduced sensitivity to hypercapnia and hypoxia with alveolar hypoventilation may be due to a central mechanism.

Patients may present to the ICU with respiratory, cardiac, or gastrointestinal complications or for postoperative care [88]. The combination of respiratory muscle weakness, poor cough and atelectasis, central hypoventilation, and mild bulbar muscle weakness may precipitate acute respiratory failure and aspiration pneumonia. This may require positive-pressure mechanical ventilation via tracheostomy with a lengthy weaning period. Older age and rapidity with which respiratory failure develops predicts poor outcome [88].

Cardiac abnormalities are common, and almost all patients may have EKG abnormalities [88–95]. Malignant bradyarrhythmias may lead to sudden death or recurrent episodes of syncope that require permanent pacemaker placement [88–95]. Phenytoin and quinidine, used to treat myotonia, are associated with lethal arrhythmias particularly if cardiac conduction abnormalities are present, such as heart block and other bradyarrhythmias [94].

Close observation for electrolytes imbalance, including magnesium, is mandatory as part of the ICU care, since such an imbalance may be associated with deleterious cardiopulmonary complications in patients with myotonic dystrophy. Gastrointestinal atony may lead to gastric dilatation and megacolon [123]. Placement of gastric and rectal tubes may be lifesaving. In postoperative care, a gastric tube for decompression is recommended.

In summary, cardiac and pulmonary complications should be monitored closely, with routine pulmonary function tests and EKG yearly. Epidural rather than general anesthesia should be used whenever possible. Careful postoperative care of patients with myotonic dystrophy should include continuous cardiac monitoring as well as gastric decompression until bowel sounds are well established [125, 126].

Emery-Dreifuss muscular dystrophy (EDMD) is a rare form of muscular dystrophy. Patients often have bradycardia, heart block, and other abnormal rhythms which may require permanent pacemaker placement [127–129]. Congestive heart failure and sudden death due to cardiomyopathy are less common [130]. Although respiratory compromise has not been reported in EDMD, this may occur in *rigid spine syndrome*, an entity that resembles EDMD with contractures mainly affecting the paraspinal muscles [131, 132]. Skeletal deformities are common, leading to scoliosis and kyphosis. Subsequently restrictive lung diseases ensue, causing respiratory failure and cor pulmonale [132]. In rigid spine syndrome, death from ventilatory failure occurs. Other patients have been maintained successfully on intermittent positive-pressure ventilation [132].

Respiratory muscle involvement is uncommon and cardiac complications are rare in *facioscapulohumeral muscular dystrophy*. Respiratory complications have been described in two situations [120]: (1) when the weakness is severe or advanced involving the diaphragm, as in aggressive childhood cases, and (2) if the bulbar muscles are weak, leading to aspiration pneumonia [120]. Cardiac arrhythmia may occur leading mainly to atrial bradycardia or standstill [133].

In summary, p*ostoperative care* is of paramount importance in patients with muscular dystrophies, mainly myotonic, limb-girdle, and Duchenne muscular dystrophies [125, 126]. Complications range from gastrointestinal atony to difficulty weaning off mechanical ventilation and cardiac arrhythmia with or without congestive heart failure. Aspiration pneumonia is a common risk in the postoperative period that may further compromise ventilation [125, 126]. Difficulty weaning and respiratory muscle weakness postoperatively may be the first manifestation of muscular dystrophy. If nutritional status is compromised postoperatively, it may be related to poor absorption secondary to gastrointestinal dysmotility. Poor gastrointestinal absorptive function decreases the bioavailability of oral medications, which are more effective if given parenterally. Preoperative assessment becomes even more important in this group of patients with mandatory EKG or 24 h Holter monitoring and pulmonary function tests at baseline. During anesthesia induction, awake intubation is preferable to provide a trigger-free anesthetic and to avoid succinylcholine and halothane. Since these patients are susceptible to malignant hyperthermia, judicious use of opioids and neuromuscular blocking agents is recommended to avoid intractable postoperative complications and a prolonged ventilatory course and complications.

Malignant Hyperthermia

Malignant hyperthermia has been described as a pharmacogenetic disorder of skeletal muscle involving dysregulated myoplasmic calcium, hypercontracture, and hypermetabolism in response to potent volatile anesthetics and depolarizing muscle relaxants [134, 135]. Other precipitating

factors are exertion or heat stress without any clear pharmacologic exposure. Susceptibility to malignant hyperthermia is usually transmitted in an autosomal dominant manner with incomplete penetrance and variable expressivity. The ryanodine receptor (RyR1) gene is the primary, but not only, site for mutations in individuals who are susceptible to malignant hyperthermia. The skeletal muscle RyR1 is located in the membrane of the sarcoplasmic reticulum, and its major function is the release of calcium necessary for contraction. The clinical presentation may be dramatic with a rapid increase in body temperature, widespread muscular rigidity, myoglobinuria, and metabolic acidosis [134, 135]. The risk of developing malignant hyperthermia increases with a positive family history and the presence of central core congenital myopathy (which has also been mapped to chromosome 19) [135]. Lethal malignant hyperthermia may also occur in patients with myotonic and limb-girdle muscular dystrophies. The caffeine contracture injection test may be used to predict susceptibility by exposing fresh muscle fibers from a biopsy and measuring muscle tension. Alternatively, genetic testing can be carried out in high-risk groups [117, 135]. Treatment is usually disappointing and is mainly supportive in addition to the use of intravenous dantrolene at a dose of 2.5 mg/kg. Dantrolene inhibits calcium release from the sarcoplasmic reticulum, which may lead to the relaxation of hypercontracted muscle fibers [134, 135]. Supportive therapy includes fever control, fluid resuscitation, and mechanical ventilation with dialysis if needed.

Acid Maltase Deficiency

Adult-onset glycogen storage disease type II is a metabolic disease caused by 1,4-glucosidase deficiency and manifests with pelvic girdle and truncal weakness. Respiratory symptoms, such as orthopnea, or frank respiratory failure as its initial manifestation is common [136]. Sleep disturbances, including sleep apnea, and frequent pulmonary infections may occur prior to diagnosis. Mechanical ventilation with positive intermittent ventilation may be required. Negative-pressure ventilation, nocturnal ventilation, and rocking bed have been used [136]. Physical therapy is useful in strengthening respiratory muscles.

Periodic Paralysis

Periodic paralysis (PP) is a clinically heterogenous group of disorders characterized by recurrent attacks of weakness and impairment of electrolyte channels transport in muscle membrane [137]. These include hypokalemic and hyperkalemic PP and paramyotonia congenita. Hyperthyroidism and thyrotoxicosis can precipitate severe attacks of weakness with hypokalemia that occurs primarily in oriental adults.

Respiratory involvement is uncommon in hyperkalemic PP and paramyotonia congenita [138], while cardiac involvement with frequent premature ventricular contractions, bigeminy and tachycardia may occur [139]. Treatment includes glucose and insulin infusion. Prevention is aimed at maintaining serum potassium concentration within the normal range to avoid cardiac arrhythmias and muscle weakness. This can be accompanied by increased ingestion of carbohydrates. In contrast, hypokalemic PP may involve respiratory muscles that leads to ventilatory failure and death [140]. Cardiac monitoring is recommended during attacks to evaluate EKG changes associated with hypokalemia, including flattening of T waves and the presence of U waves [140]. Acute treatment during the attack includes close respiratory and cardiac monitoring and potassium supplementation, which may be enhanced by use of 5 % mannitol diluent [137]. Avoiding carbohydrates and taking acetazolamide and oral potassium supplements can prevent attacks.

Secondary Neuromuscular Disorders

Several NMDs manifest following an admission to the ICU (Table 18.8). Secondary NMD are more frequent than the primary disorders and are more likely to be reversible and respond to treatment [141, 142].

Electrolytes and acid–base disturbances are frequent occurrences in critically ill patients. Muscle weakness is common with hypokalemia, hypophosphatemia, and hypomagnesemia. Hypocalcemia and acidosis are associated with muscle weakness and tetany. The latter may contribute to difficult weaning from artificial ventilation [141, 142]. Correcting electrolyte abnormalities is crucial in critically ill patients who are already at risk for neuromuscular complications.

Some medications administered to severely ill patients may be toxic to muscles, neuromuscular junction, and nerves (Table 18.9) [143]. Cyclosporine and cholesterol-lowering agents may lead to a myopathy with mitochondrial disruption. Antipsychotics including phenothiazines are associated with necrotizing myopathy and CK elevation [143]. Procainamide and beta-blockers, commonly used to control arrhythmias and blood pressure, may affect neuromuscular junction. Antibiotics including aminoglycosides, polypeptide antibiotics (colistin and neomycin), and quinolones may compromise the function of neuromuscular junction. Anticonvulsants may interfere with neuromuscular transmission and exacerbate the muscle weakness in MG. Carbamazepine overdose may cause reversible neuromuscular disease with respiratory failure [103]. Chronic steroid myopathy may cause quadriplegia and lead to respiratory

Table 18.8 Secondary neuromuscular disorders in intensive care

Muscle	Neuromuscular junction	Nerves	Spinal cord
Cachectic myopathy	Hyper-/hypomagnesemia	Critical illness polyneuropathy	Postoperative infarction[a]
Hyper-/hypomagnesemia	Hypophosphatemia	Nutritional deficiency: thiamine	Nutritional
Hypokalemia	Neuromuscular blockers	Hepatic dysfunction/uremia with uncontrolled diabetes[a]	Traumatic
Hypophosphatemia	Calcium channel blockers	Drug induced[a]	Drug induced[a]
Critical illness myopathy	Aminoglycosides	Paraneoplastic[a]	Paraneoplastic[a]
Steroid myopathy	Quinolone antibiotics	Sepsis with chronic polyneuropathy	
Drug-induced myopathy[a]	Antiarrhythmic: procainamide		
Septic myopathy	Beta-adrenergic blockers		
Rhabdomyolysis[a]			

[a]Disorders that may be the primary presentation to the ICU or secondary complications that occur after admission

Table 18.9 Agents that may be associated with neuromuscular weakness in ICU patients

Antimicrobials
Aminoglycosides
Fluoroquinolones
Nitrofurantoin
Metronidazole
Isoniazid
Antimalarial
Amphotericin B
Antineoplastics
Vincristine
Cis-platinum
Taxol
Anticonvulsants
Phenytoin
Phenobarbital
Carbamazepine
Antiarrhythmic and cardiac medications
Amiodarone
Procainamide
Beta-blockers
Diuretics

Table 18.10 Common causes of acquired rhabdomyolysis

Toxic/drugs
Drugs: epsilon aminocaproic acid, neuroleptic drugs, clofibrate, lovastatin, plasmacytoid, barbiturates, propofol
Toxins: alcohol, toluene, heroin, amphetamine, cocaine, and phencyclidine
Traumatic
Head injury
Fall, crush syndrome
Convulsions
Electric shock, lightning stroke
Prolonged myoclonus
Burns
Vascular
Disseminated intravascular coagulation
Compartment compression syndromes
Ligation of vena cava
Metabolic
Diabetic ketoacidosis
Hypothermia/hyperthermia
Hypokalemia
Infections: toxic shock syndrome, viral, bacterial

muscle weakness. Supportive treatment and discontinuation of steroids would restore muscle strength and facilitate weaning process [141, 142].

Rhabdomyolysis may represent an inherited or acquired susceptibility to necrosis of striated muscles. In the ICU, this condition is seen in association with neuroleptic drug administration, prolonged coma, and head injury [144]. Other precipitating factors include hypernatremia, increased osmolality, hypokalemia, alcohol, propofol and hypoxia during artificial ventilation [145]. A list of common causes of rhabdomyolysis is presented in Table 18.10. Clinical features include myalgias, malaise, generalized muscles weakness, respiratory muscle weakness, fever, myoglobinuria, elevated CK, anuria, hyperkalemia, hypercalcemia, azotemia, and renal failure. Weakness may outlast other symptoms. Supportive care is the mainstay of treatment, with forced diuresis using mannitol or hemodialysis whenever electrolyte abnormalities occur. Recurrence may occur and is usually triggered by increased physical activity [144].

Sepsis is common in the ICU and may cause widespread muscle weakness in patients not exposed to any myotoxic agents and with normal electrolytes [146, 147]. Respiratory failure and difficult weaning may accompany muscle weakness. The risk of sepsis-induced myopathy becomes quite high with multiple organ failure. Rarely, isolated ventilatory failure occurs, although needle EMG may reveal subclinical widespread muscle involvement [146]. Specific organisms that have been incriminated include *Escherichia coli*, Leptospira, Legionella, and *Staphylococcus aureus* [146]. Muscle enzymes may be normal or mildly elevated; needle EMG shows myopathic pattern and occasionally a mixed picture of axonal neuropathy and myopathy. Histological findings on muscle biopsy occasionally reveal microabscesses. The disease mechanism is unclear, but interference with energy utilization of muscle is suspected. Other

contributing factor may include an increase in muscle necrosis by increased muscle catabolism and proteolysis [146, 147]. Treatment involves therapy for the underlying conditions and use of supportive measures, in addition to avoiding, if possible, neuromyotoxic agents, and correcting electrolyte disturbances.

Part IV

Neuromuscular Disorders: Neuronopathies (Motor Neuron and Dorsal Root Ganglion Disorders)

Poliomyelitis and Post-poliomyelitis Syndrome

19

Kanokwan Boonyapisit

Introduction

Poliomyelitis is a highly contagious systemic infection caused by a virus of the enterovirus subgroup. The poliovirus is transmitted by fecal-oral route and causes systemic symptoms characterized by fever and malaise. In a small proportion of patients, the virus infects the central nervous system producing meningitis and acute progressive lower motor neuron weakness. Epidemics of poliomyelitis were common in the first half of twentieth century, but with the introduction of effective polio vaccination in 1955, poliomyelitis epidemics are no longer seen in developed countries but still occur in parts of sub-Saharan Africa and the Indian subcontinent.

In the last two decades, a syndrome characterized by slowly progressive weakness, fatigue, and pain, which develops decades after acute paralytic poliomyelitis, has been described. The condition is now a widely accepted entity and is known as post-poliomyelitis syndrome or post-polio syndrome.

Poliomyelitis

Etiology and Pathogenesis

Poliomyelitis is caused by the poliovirus, one of the single-stranded RNA viruses in the enterovirus subgroup of the picornaviruses [1–4]. All three serotypes of poliovirus can cause acute paralytic poliomyelitis. Poliovirus is transmitted through fecal-oral route with high infectivity rate. The virus enters the lymphatic system in the pharynx or intestine and then spreads to the central nervous system by a hematogenous route [4]. The typical clinical presentation begins with prodromal symptoms of fever and malaise, followed by manifestations of meningitis. In a small proportion of patients, the poliovirus affects the anterior horn cells and brain stem nuclei causing acute progressive lower motor neuron weakness of limb and bulbar muscles and generalized hyporeflexia [1–3].

Poliomyelitis epidemics usually occur in late summer. Before the development of polio vaccine, epidemics occurred most frequently in northern countries and primarily affecting children older than 6 months, teenagers, and young adults [1, 2]. Poliomyelitis has now nearly been eradicated. The majority of cases derive from the Indian subcontinent and some African countries [5–8]. All poliomyelitis infections that occur now in North America and European countries are due to the oral polio vaccine (OPV), which carries a risk of one active infection per 2.5 million doses. Immunocompromised patients and persons with incomplete vaccination may develop poliomyelitis from close contact with vaccine-induced poliomyelitis patients [9–11].

Clinical Manifestations

The clinical manifestations of acute poliomyelitis start after an incubation period of 3–6 days after ingestion of the poliovirus. For vaccine-induced poliomyelitis, the incubation period is longer with manifestations 2–3 weeks after vaccination [3]. Among immunocompromised patients, the time between vaccination and development of disease can be up to 6 months or longer [9, 10].

After exposure to the virus, the virus multiplies in the pharynx and lymphatic tissue of the intestine for few weeks before it is contained by immune response. Ninety percent of patients will only have viremia without symptoms. Fever, malaise, sore throat, headache, and diarrhea occur in 10 % of patients and last typically 2–3 days without progression to central nervous system infection. In a few percent of patients, the virus enters the central nervous system causing meningi-

tis, which usually resolves spontaneously in 1–2 weeks [1–3]. The infection progresses to anterior horn cell involvement causing acute paralytic poliomyelitis in 0.1–1 % of all individuals infected with the poliovirus [1, 2, 12, 13].

Acute progressive weakness often occurs after the prodromal symptoms subside or few days after the onset of clinical meningitis but can occur as late as 2–3 weeks after initial symptoms [3, 13]. The weakness progresses over hours to days to severe weakness of the extremities, which often is asymmetric, accompanied by areflexia. Prominent neck and back pain is common prior to the onset of weakness. Bulbar weakness causing dysphagia and dysphonia occurs in 10–15 % of the patients, although facial weakness is less common [1]. The common distribution of weakness differs among age groups. Severe weakness of the lower extremities is more common in young children, whereas weakness of upper and lower extremities is more common in older children and young adults. Autonomic dysfunction, which is the result of involvement of brain stem nuclei, can be found in small proportion of the patients [3]. Respiratory failure occurs in patients with severe general weakness.

Neurological examination reveals weakness, decreased muscle tone, and hypoactive deep tendon reflexes in the affected extremities. Fasciculation can sometimes be seen even early in the course of weakness. Muscle atrophy develops in a few weeks. Sensory examination is normal, although some patients may have complaints of sensory disturbance.

Improvement of muscle strength begins a few weeks after infection and maximal recovery is seen in 6–9 months. Up to 60–70 % of the patients with acute paralytic poliomyelitis have prominent residual weakness [1–3].

Differential Diagnosis

The differential diagnosis for acute poliomyelitis includes neurological conditions that present with acute progressive lower motor neuron weakness such as Guillain-Barre syndrome, acute transverse myelitis, botulism, tick paralysis, and myopathies (Table 19.1) [1, 2, 14, 15]. Acute progressive weakness associated with other viral infections such as other enteroviruses (e.g., enterovirus 71, coxsackievirus A7) and flaviviruses (e.g., Japanese encephalitis) can mimic symptoms of acute paralytic poliomyelitis [16]. The emergence of West Nile virus, which also belongs to the flavivirus family and can affect anterior horn cells, needs to be considered in North American and European countries [17].

Diagnostic Evaluation

Cerebrospinal fluid examination in poliomyelitis shows increased protein and pleocytosis, which is neutrophil predominance followed by lymphocytic predominance. An abnormal CSF examination differentiates poliomyelitis from several causes of acute progressive flaccid paralysis in particular Guillain-Barre syndrome [1–3].

Isolation of the poliovirus from throat culture, stool culture, and CSF culture can provide confirmation for the diagnosis. The throat culture and stool culture are more sensitive than CSF culture for viral isolation. Serum antibody titers for poliovirus can also be used for confirmation of the diagnosis, if there is a fourfold elevation in the titers between acute and convalescent specimens.

The electrodiagnostic studies in poliomyelitis reveal changes consistent with acute neurogenic process, involving only motor component and sparing the sensory. Sensory conduction studies are all normal. Motor conduction studies often show reduced compound motor action potential (CMAP) amplitudes in weak muscles. Needle electromyography (EMG) reveals reduced recruitment of motor unit action potentials (MUAP) in the affected muscles, although the morphology of MUAP is still normal, which reflects the acute process. Prominent fibrillation potentials can be seen in the affected muscles few weeks after the onset of weakness [1, 18].

Table 19.1 Differential diagnosis of acute paralytic poliomyelitis

Spinal cord
Acute transverse myelitis
Spinal cord compression
Other acute spinal cord syndromes, e.g., spinal cord infarction
Anterior horn cells
Viral infection
Enterovirus: poliovirus, enterovirus 71, coxsackievirus A7
Flavivirus: West Nile virus
Nerve
Infection
Diphtheria
Rabies
Guillain-Barre syndrome
Critical illness neuropathy
Porphyria
Heavy metal poisoning: arsenic, thallium
Neuromuscular junction
Botulism
Myasthenia gravis (severe cases)
Muscle
Inflammatory myopathy (severe cases)
Critical illness myopathy

Treatment and Prognosis

There is no specific treatment for acute poliomyelitis. Patients with symptoms of CNS infection or acute paralysis should be hospitalized under close observation for signs of respiratory insufficiency or autonomic dysfunction. Patients

with respiratory failure will need respiratory support in the intensive care unit. Good supportive care to prevent complications from prolonged immobilization and early rehabilitation is essential. Rehabilitation is important during the recovery period to improve physical strength and minimize deformities and contractures in affected limbs [1–3].

Mortality from poliomyelitis has improved over time due to advances in critical care. The mortality rate is often greatest in the first week due to respiratory failure and presence of circulatory insufficiency secondary to autonomic failure. Other causes of mortality are related to hospital-acquired infection and complications from prolonged immobilization [1, 2].

Prevention

In 1956, Jonas Salk introduced the trivalent inactivated polio vaccine (IPV). The Salk vaccine is administered by injection and stimulates serum IgM, IgG, and IgA directed against the virus. However, the Salk vaccine is less effective for stimulating secretory IgA, which is an important defense when the poliovirus enters the oropharynx.

Albert Sabin developed the oral live-attenuated polio vaccine (OPV), which replaced the Salk vaccine in 1962. The Sabin vaccine contains live-attenuated strains of polioviruses 1, 2, and 3, which are grown in cell culture. Multiple dosages of vaccination are required to ensure the development of immunity to all strains. The Sabin vaccine is more effective in stimulating the local secretary IgA, and the virus is excreted in the feces for 6–8 weeks after vaccination, which can also lead to immunity in close contacts. However, viral shedding carries a risk of vaccine-associated poliomyelitis in contacts who are immunocompromised [2, 3].

After the introduction of both vaccines, the polio epidemics from wild-type poliovirus have been nearly eradicated. The last major poliomyelitis outbreak in the USA occurred in 1952 prior to vaccine development [19–25]. Despite the effort of the WHO global eradication initiative since 1988 [26–28], cases continue to occur in the Indian subcontinent or African nations due to inadequate immunization programs [5–8]. All poliomyelitis reports from North America and Europe have been vaccine-associated poliomyelitis secondary to the live-attenuated polio vaccine [9, 11, 25, 27].

Currently the inactivated polio vaccine used in western countries is an enhanced potency inactivated poliovirus vaccine (IPV-e), which causes less viral shedding and provides better immunity against poliovirus compared to the OPV [3]. IPV-e is indicated in immunocompromised patients and children with immunocompromised close contacts. The IPV-e should be used in adults, since adults are generally more susceptible to vaccine-associated poliomyelitis after receiving OPV. In many countries in the North America and Europe, Australia, New Zealand, and Japan, the IPV-e is now replacing the OPV or is used in conjunction with OPV in the immunization schedule for children to enhance the efficacy of disease prevention and to reduce the occurrence of vaccine-associated paralytic poliomyelitis [29–31].

Post-poliomyelitis Syndrome

This syndrome is characterized by new weakness, fatigue, and pain, which develops several years after acute paralytic poliomyelitis in the region previously affected by acute poliomyelitis [32–40]. Patients may also have several other symptoms, sometimes outside the affected region including dysphagia, dysarthria, muscle cramps, fasciculation, generalized fatigue, and sleep abnormalities [34–40]. After first description by Cornil and Raymond in 1875, post-poliomyelitis was subsequently named "post-poliomyelitis syndrome" or "post-polio syndrome." The existence of the syndrome had first been questioned, but the post-polio syndrome is now generally accepted as a well-defined clinical entity. Epidemiologic studies of post-polio syndrome have been difficult due to poorly established diagnostic criteria. Estimates of prevalence of post-polio syndrome vary from 20 to 85 % of patients with prior poliomyelitis [33, 41–45]. Understanding of post-polio syndrome has expanded over the past two decades [46], but many aspects of clinical aspects, pathogenesis, optimal treatment, and quality of life are lacking.

Etiology and Pathogenesis

The primary underlying pathogenesis for weakness in post-polio patients is ongoing denervation of the motor units; however, the exact pathogenesis of post-polio syndrome is unclear. A widely accepted mechanism for denervation [47–50] is distal axonal degeneration in the enlarged motor units after the extensive reinnervation process that occurs after acute poliomyelitis. Terminal axonal degeneration at the motor nerve terminals can explain several clinical features in post-polio syndrome. The degeneration of distal motor axon results in slowly progressive weakness in the previously affected muscle groups. Dysfunction of motor nerve terminals, which causes defects in the neuromuscular transmission, may explain the symptoms of fatigability [50, 51].

In the patients with a history of poliomyelitis and no deterioration, the reinnervation process is effective due to sprouting of distal axons. The motor unit size may be seven to eight times greater than the normal motor unit, and muscle fiber grouping occurs but the size of muscle fibers is normal. Although the denervation process occurs within these large motor units, reinnervation also occurs by sprouting from neighboring axons. This continuous remodeling occurs in all enlarged motor units among patients with prior poliomyelitis. When the denervation process exceeds the reinnervation

process, distal axonal degeneration occurs, and followed by reduction of the motor unit size, atrophy of muscle fibers and symptoms of post-polio syndrome develop [35, 49]. The proposed theory of terminal axonal degeneration in the enlarged motor units in post-polio patients is supported by electrodiagnostic studies that demonstrate defects in neuromuscular transmission, such as increased jitter on single-fiber electromyography and abnormal decremental responses on repetitive nerve stimulation [36, 49–54]. However, the evidence of active denervation is also seen in the stable post-polio patients, which is contrary to the hypothesis that states that active denervation occurs to a greater extent in newly weak muscles [49].

Besides distal axonal degeneration, there are other less well-accepted theories for pathogenesis of post-polio syndrome [37–39]. One theory proposes motor neuron loss due to normal aging, but because of limited amount of motor neuron reserve due to prior poliomyelitis, weakness develops. Old age was found as one of the risk factors for post-polio syndrome [55]. However, other studies have found that age was only a confounding factor for the development of post-polio syndrome [43]. The studies estimating motor unit number in post-polio patients offer conflicting results. A significant reduction of motor units over a 2-year follow-up was found [56] when compared to motor unit loss among normal, age-matched subjects, and another did not show significant loss of motor units over a 15-year period [57].

Immunological mechanisms have been proposed, but support is limited for such a pathophysiology. Pathologic evaluation has shown evidence of inflammation in the spinal cord [58]. However, the etiology of inflammation is uncertain [59]. There is also conflicting evidence of whether an intrathecal immune response is present among patients [60–62].

Clinical Manifestations

The frequency of post-polio syndrome has been estimated to be as high as 64–85 % of patients with a history of poliomyelitis [43], but significant disability is estimated to occur 20–40 % of patients [33, 41, 42, 45]. The onset of symptoms typically occurs several decades after acute poliomyelitis [32] with a range of 8–71 years (mean interval of 36 years) and tends to be shorter in patients with severe weakness [34]. Patients with post-polio syndrome often have a variety of new symptoms, but the most frequent are weakness, fatigue, and pain [33–43]. Fatigue in post-polio syndrome can be generalized or limited to the affected muscles and appears to be the most disabling symptom [32, 33]. Fatigue can occur in up to 90 % of patients and can lead to significantly compromised quality of life. Generalized fatigue is often described as exhaustion, similar to that of flu-like illness [63]. Fatigue usually is worse after physical activities and in some individuals associated with increased sleep requirement and decreased concentration. Muscular fatigue is described as reduced endurance and increased weakness in the affected muscles after exertion, which improves with rest [64–67]. New weakness in patients with post-polio syndrome most commonly involves the previously affected muscles but can also involve the normal muscles, which may have been subclinically affected by acute poliomyelitis. Weakness typically progresses gradually. Episodic weakness is described by some patients, which is likely related to fatigue and reduced muscle endurance [34, 35, 39, 40].

Pain in the muscles and joints is common [68–70]. Muscle pain is described as aching after physical activity and muscle cramps. Some patients have a fibromyalgia-type syndrome [71]. Joint pain is often secondary to osteoarthritis, tendinitis, or bursitis after chronic overuse of the affected limbs.

Muscular atrophy, dysarthria, dysphagia, respiratory insufficiency, cold intolerance, muscle cramps, and fasciculation are also observed among some patients. Dysarthria and dysphagia occur in many regardless of whether there was bulbar involvement at the time of acute poliomyelitis [72]. Detailed testing of oropharyngeal function has shown abnormalities, although aspiration is rare and weight loss secondary to dysphagia usually does not occur. Respiratory dysfunction are described in up to 40 % of patients and appear to be more common in patients with prior history of respiratory failure during acute poliomyelitis [73]. Cold intolerance, probably secondary to decreased heat production in the atrophic limbs due to poorly developed circulation, is described in 30–60 % of the patients. Increased stress, anxiety, and insomnia are common. Depression is associated with greater pain and overall poor medical status [74].

Patients with significant weakness gradually become more inactive and disabled. Many patients gain weight. Ambulation especially climbing stairs is affected, and activities of daily living (e.g., cooking, writing, driving) are compromised. Adaptation in lifestyle and assistive devices may be needed in this group of patients.

Differential Diagnosis and Evaluation

There is no specific laboratory investigation that confirms the diagnosis of post-polio syndrome. In 1997, the Post-Polio Task Force developed diagnostic criteria, which required several specific clinical features and exclusion of medical, orthopedic, or neurological conditions that may cause similar weakness, fatigue, and pain [75, 76](Table 19.2). Diagnostic criteria for post-polio syndrome has not been well validated. A detailed clinical history of prior paralytic poliomyelitis is crucial and should first be confirmed in each patient. If a previous history poliomyelitis is uncertain, the examination should reveal evidence of motor neuron loss (muscle atrophy,

Table 19.2 Proposed diagnostic criteria for post-polio syndrome

1. A history of prior episode of paralytic polio with residual motor neuron loss, which can be confirmed through a typical patient history, a neurologic examination, and an electrodiagnostic examination
2. A period of neurologic recovery followed by an interval (usually 15 years or more) of neurologic functional stability
3. A gradual onset of new weakness and/or abnormal muscle fatigability and decreased endurance, with or without generalized fatigue, muscle atrophy, and/or pain
4. Exclusion of medical, orthopedic, and/or neurologic conditions that may be causing the symptoms mentioned in step 3

Table 19.3 Differential diagnosis of post-polio syndrome

Adult spinal muscular atrophy
Amyotrophic lateral sclerosis
Multiple sclerosis
Spinal cord tumor
Spinal stenosis
Radiculopathy
Cauda equina syndrome
Multifocal motor neuropathy with conduction block
Chronic inflammatory demyelinating polyneuropathy
Entrapment neuropathy
Heavy metal toxicity
Myasthenia gravis
Inflammatory myopathy

weakness, decreased or loss of deep tendon reflexes), and the other possible clinical conditions that may mimic post-polio syndrome should be excluded, such as hypothyroidism, rheumatoid arthritis, polymyalgia rheumatica, and inflammatory myopathies. Neurological disorders, which may be confused with post-polio syndrome, are shown in Table 19.3.

Appropriate laboratory investigation to exclude other disorders (Tables 19.2 and 19.3) should be performed. Serum creatine kinase is often mildly elevated among post-polio patients, but those with significant elevations require evaluation for a myopathy [77, 78].

Electrodiagnostic study (EDX) is a useful tool for exclusion of other neurological conditions. However, conventional EMG and single-fiber EMG cannot differentiate between stable post-polio patients and those with new weakness. Nerve conduction studies usually reveal decreased amplitude of compound motor action potential with preserved latencies and conduction velocities. Sensory nerve action potentials are normal. Needle EMG generally reveals evidence of ongoing denervation (e.g., fibrillation potentials) and chronic reinnervation (e.g., large motor unit action potentials with reduced recruitment). Fasciculations can be seen in affected muscles, although usually are not prominent. These EDX findings can be seen in several chronic progressive neurologic condition affecting anterior horn cells (e.g., amyotrophic lateral sclerosis, adult spinal muscular atrophy) and are not specific to post-polio syndrome. However, EDX can be used to exclude several neurologic conditions (e.g., chronic inflammatory demyelinating polyneuropathy, multifocal motor neuropathy with conduction blocks, entrapment neuropathy, myasthenia gravis, and inflammatory myopathy). Single-fiber EMG shows increased jitter and blocking in post-polio syndrome, but these abnormalities are not specific and may be seen in many other neurological diseases [49, 50, 79–82].

All patients with breathing complaints should undergo pulmonary function evaluation, since even patients without respiratory complaints may have respiratory insufficiency [83]. Patients with a vital capacity below 55 % of normal should have more extensive evaluation such as measurement of vital capacity in sitting and supine position and arterial blood gas [84, 85]. The presence of hypercapnia is a predictor of poor outcome and increased risk of respiratory failure [85, 86].

Patients with excessive daytime sleepiness and other symptoms suggestive of obstructive sleep apnea (e.g., snoring, morning headache) should undergo a polysomnogram, since obstructive sleep apnea can be found in up to 7.3 % of polio survivors [87]. Disturbance of sleep in post-polio syndrome can be secondary to primary obstructive sleep apnea or hypoventilation or both [87, 88].

Swallowing evaluation is required in patients with complaints of dysphagia [89–91]. Laryngeal and voice assessment may also be necessary for such patients [90].

Plain X-ray of the spine and joints assists in evaluation of scoliosis and joint dysfunction. Assessment with CT or MRI may be indicated in some patients to exclude other causes of back, neck, or limb pain including spinal stenosis, cervical myelopathy, and radiculopathy.

Treatment

Currently, there is no specific treatment for post-polio syndrome. Management of weakness, fatigue, pain, and other physical disabilities is best performed through interdisciplinary programs [35, 39, 40]. An investigation of 70 post-polio patients followed on average for about 2 years demonstrated improvement or resolution of symptoms, and manual muscle testing confirmed increased strength in 30 patients with good compliance to treatment protocols, while in the partial complier group ($n=32$) and noncompliant group ($n=15$), there is no change or a decline in strength with worsening of symptoms [92].

An interdisciplinary team usually involves the primary care physician, neurologist, physical therapist, psychiatrist, orthopedist, rheumatologist, pulmonologist, occupational therapist, social worker, dietician, occupational therapist, orthotist, nurse, and respiratory therapist. Education for

patients on how to keep their activities and exercise program in balance and avoid muscle overuse is required. Sections below focus on specific major issues in the care of patients [35, 39, 40, 93–97].

Management of Weakness

Exercise for post-polio patients had been a controversial subject, because of concerns that overuse would increase weakness; however, beneficial effects of various types of exercise programs have been shown. Controlled studies have shown the benefits of aerobic exercise such as bicycling, treadmill walking, and aquatic exercise in post-polio patients [98–103]. Uncontrolled studies demonstrate benefit for isotonic, isokinetic, and isometric exercises. The isotonic exercise may strengthen muscles that are mildly affected, whereas isometric exercise may strengthen muscles over painful joints [104–108]. Stretching maintains or even improves range of motion. Therapists should monitor to ensure that exercise is performed appropriately. Muscle overuse should be avoided and can be avoided by pacing, reduction of activities, and energy conservation techniques [35, 39, 40, 95–97, 109].

Orthosis and assistive devices are useful for improving mobility and activity of daily living and can be beneficial to reduce pain, joint deformities, and gait difficulties [110, 111]. Assistive devices aid in conservation of energy [112]. An ankle-foot orthosis will improve function related to ankle dorsiflexion weakness, while a locked knee orthosis or a locked knee-ankle-foot orthosis will benefit patients with quadriceps weakness [113, 114]. Crutches and wheelchairs will also improve mobility.

Management of Fatigue

Excessive fatigue is helped through energy conservation techniques: reduction of activities, resting periods during daytime, relaxation techniques, and improvement of sleep quality. Energy conservation methods involve modification of environments and activities by living on one floor, use of automatic machines for household activities, handicapped parking, and electric scooter use for a long distance. A balance must be struck between activity and prolonged muscle use that leads to fatigue. A rating scale, such as the Borg Rating Scale of Perceived Exertion (RPE), can be used to evaluate patients' perception of fatigue. RPE is a 15-point scale, which ranges from 6 to 20, with 6 indicates the lowest effort and 20 indicates the highest effort to perform activities. Patients are generally instructed to keep their daily activities or exercise below the RPE level of 14 to avoid excessive fatigue [115, 116].

Pain Management

Muscle overuse is probably the most common cause of pain. In patients who walk, pain occurs primarily in the lower extremities and low back and associated with increased exertion and faster walking speed [117]. Muscle pain in post polio is usually described as deep aching sensation within the muscles. Pain from muscle cramps, fasciculation, and fibromyalgia also occurs. Cramps and fasciculation are often related to muscle overuse and can be managed by reduction of activities, pacing, and using orthosis or assistance devices. Pain of fibromyalgia usually requires interdisciplinary approaches [71].

Other frequent causes of pain in post-polio patients occur from joint and soft tissue abnormalities. Osteoarthritis, tendinitis, and bursitis can occur secondary to joint deformities or prior history of joint fusion. Osteoarthritis of wrist and hand is common in older patients especially those who require assistance devices for walking [118]. Joint pain in post-polio patients can be managed by physical therapy, strengthening exercises of the surrounding muscles, orthosis to control deformities, and nonsteroidal anti-inflammatory drugs. Steroid injection and surgery are rarely required.

Superimposed neurological disorders, which may result from overuse, may also produce pain. Entrapment neuropathy (e.g., carpal tunnel syndrome, ulnar neuropathy) and radiculopathy occur in a good portion of post-polio patients, and each condition requires specific treatment for the particular disorders [80, 119].

Other Treatment Issues

Respiratory insufficiency is caused by muscle weakness and further exacerbated by sleep-disordered breathing, scoliosis, and kyphosis [83, 84]. Central hypoventilation rarely occurs. Problems with respiration often occur among patients who had required ventilation during acute poliomyelitis. Noninvasive ventilation may be indicated in those with significant hypoventilation [73, 120–122]. Obstructive sleep apnea should also be monitored for and treated. All post-polio patients should receive pneumococcal and influenza vaccinations.

Up to 20 % of post-polio patients have complaints of dysphagia [123], which can occur even without history of previous bulbar polio [72, 124]. Formal speech therapy provides advice regarding swallowing techniques and diet modification including purees or thickened liquids for those with severe swallowing difficulties [35, 96].

Psychosocial Issues

Many polio survivors are high achievers. Studies from several countries indicate that individuals with a history of polio have higher educational levels and higher rates of employment and marriage than other disabled populations [125–127]. Patients with post-polio syndrome may need to adjust to the added disabilities caused by the syndrome. Attitude toward the disability and family support are important influencing factors for overall life satisfaction. Depression, which is not common in patients with previous poliomyelitis, may occur

with post-polio syndrome [74, 128–130]. Interdisciplinary support through psychiatrist, psychologist, social worker, and patient groups is beneficial.

Lifestyle changes and adaptation are important. Weight reduction or stabilization program can reduce fatigue and increase mobility in overweight patients [95–97]. Modification in lifestyle may reduce symptoms from muscle overuse [131], but this should be balanced with an active lifestyle to support psychological well-being [132]. Occupational and vocational rehabilitation may be needed in some individuals [133].

Pharmacotherapy

Controlled trials of various pharmacological treatments have been performed. Challenges exist in performance of the clinical trials in post-polio syndrome. Disease progression is slow leading to the need for long evaluations. Also, there is great variation in clinical presentations, and measurement of outcome at times depends on the patients' subjective assessment.

The Cochrane Neuromuscular Disease Group reviewed the randomized and quasi-randomized trials of pharmacological treatment for post-polio syndrome and concluded that there is inadequate evidence to support the effectiveness of treatment options [134]. The pharmacologic agents reviewed were modafinil, intravenous immunoglobulin (IVIG), pyridostigmine, lamotrigine, amantadine, and prednisone. Two randomized controlled trials of modafinil found no benefit for reduction of activity limitation, fatigue, and pain compared to placebo [135, 136]. Pyridostigmine at doses of 180–240 mg/day was no different than placebo in a study of 126 subjects although there was benefit shown in some secondary outcome measures [137]. Pyridostigmine did not reduce fatigue subsequent smaller trials [138]. Lamotrigine has shown some positive effects on activity limitation and pain in an open-label study [139]. High-dose prednisone was not effective for fatigue in a small placebo-controlled trial of 17 subjects [140], and amantidine in a randomized controlled trial of 25 subjects did not demonstrate effectiveness [141]. IVIG in two randomized controlled trials using two infusions of 90 g or one infusion of 2 g/kg showed no beneficial effects on activity limitations. For muscle strength and pain, the two studies were contradictory [142, 143], therefore, more studies are needed to investigate the efficacy of IVIG in this patient population. Other pharmacologic treatments evaluated in small case series are carnitine, neurotrophic factor recombinant human insulin-like growth factor I [144], growth hormone [145], bromocriptine [146, 147], and coenzyme Q10 [148]. None showed benefit.

Prevention of Complications

Post-polio patients are at increased risk for osteopenia, osteoporosis, and fractures [149–151]. Bone density evaluation should be performed, and treatment of osteoporosis should be initiated if significant bone density reductions exist [152]. Patients with a prior history of polio also are at higher risk of falls and injuries [151]. Advice from physical therapy regarding fall precaution is essential and can help preventing serious injuries from falls.

Prognosis

Progression of post-polio syndrome is generally slow [153–155]. In some cases, disability can stabilize [57, 156, 157]. Associated conditions such as depression, entrapment neuropathy, and orthopedic or rheumatologic complications can cause functional deterioration in patients with post-polio syndrome, which with proper therapy of these conditions should have beneficial effects on their clinical outcome.

Amyotrophic Lateral Sclerosis

20

Roisin Lonergan, Hiroshi Mistumoto,
and Brian Murray

Introduction

Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disorder that primarily affects motor neurons. The characteristic form of this devastating disorder features the simultaneous presence of both upper and lower motor neuron signs with progression from one region of the neuraxis to the next and eventual death, typically from respiratory compromise. This condition first appeared in the literature in 1850 when François Aran reported a family of 11 patients of the ALS subtype, progressive muscular atrophy (PMA) [1]. Amand Duchenne first described progressive bulbar palsy (PBP) a decade later [2]. In 1869, Jean Martin Charcot, professor of neurology at the Salpêtrière, comprehensively described both the clinical and pathological features of classic ALS, and, a few years later, Heinrich Erb first described primary lateral sclerosis (PLS), a condition felt to be a subtype of ALS rather than a distinct separate entity [3, 4]. The term *motor neuron disease* was coined by Brain in 1933 to unify PMA, PBP, PLS, and ALS under one name [5]. Lou Gehrig, an American baseball player named "Iron Horse," was diagnosed with ALS in 1939, although the eponym "Lou Gehrig's disease," perhaps in response to efforts to increase public awareness of the condition, did not come into popular use for another 35 years [6]. In the 1950s, epidemiological studies identified the presence of a condition characterized by a combination of ALS, parkinsonism, and dementia in several distinct regions of the Western Pacific including the Marianas Islands, the Kii Peninsula of Japan, and the Irian Jaya region of New Guinea [7–9]. A great breakthrough in the understanding of ALS came when, in 1993, Rosen et al. showed that 15–20 % of familial ALS patients manifest a mutation in the Cu/Zn superoxide dismutase (SOD1) gene located on chromosome 21 [10]. Since then, multiple different SOD1 mutations have been discovered [11] along with mutations in other "ALS" genes including FUS, optineurin, dynamin, and C9ORF72.

There has always been some confusion regarding the terminology of ALS. In Europe it is better known as Charcot's disease or *motor neuron disease*, whereas, in the USA, the terms amyotrophic lateral sclerosis, ALS, and Lou Gehrig's disease are in more common use. Perhaps the most important distinction to be made is whether to call the disease ALS or motor neuron disease; the former is considered to be more specific. The World Federation of Neurology Research Group on Neuromuscular Diseases has grouped sporadic ALS, PMA, and PBP together as disorders of motor neurons of undetermined etiology [12].

Epidemiology

The incidence and prevalence rates for non–Western Pacific ALS are similar across the globe. The annual incidence of ALS is roughly 2 per 100,000 population with a prevalence rate of about 6 per 100,000. Differences in methods of case identification, database maintenance, death certification, and treatments may account for the variations seen from region to region [13, 14]. Several different risk factors such as race, age, sex, and occupation have been analyzed separately with a view to better understanding the disease. The incidence and prevalence rates appear to be higher in Caucasians than in non-Caucasians in western countries although this may be a reflection of underreporting rather than a true racial predisposition [15]. Age is the single most important risk factor for ALS with an age-related increase in mortality up until the

eighth decade and peak mortality rate between the approximate ages of 65 and 75 years [13, 16]. Men develop ALS more often than women, the male-to-female sex ratio being 1.4:1–2.5:1. On the other hand, most studies show that bulbar-onset ALS displays a female predominance [17–20]. Epidemiological studies identified an increased mortality risk from ALS among electrical utility workers, the risk being greater with more prolonged exposure to electromagnetic fields [21, 22]. An increasing body of evidence indicates an association between higher levels of physical fitness and ALS, which appears to be independent of physical trauma or actual muscle strength [23–25]. Somewhat paradoxically, however, smoking also appears to be an independent risk factor [26]. Rarely, one encounters reports of "ALS clusters" (including conjugal ALS) which provide tantalizing evidence that local environmental or toxic factors play a significant part in the pathogenesis of the disease, but there is insufficient evidence to associate ALS with pesticides, heavy metals, or solvents despite interesting studies suggesting that they may play a pathogenic role [27, 28]. However, certain toxins have gained particular attention, namely, β-N-oxalylamino-alanine (BOAA) and cycasin. BOAA is the cause of *lathyrism* in India, a condition characterized by UMN signs, occurring in individuals who have consumed chickling pea flour. A similar condition, *konzo*, seen in East Africa, may be related to ingestion of insufficiently prepared cassava roots which yield an aminothiazolidine carboxylic acid which is similar to BOAA. Cycasin is a cycad nut-derived toxin found in high concentration in certain foodstuffs of the Chamorro Indians of Guam, but the exact role of cycasin in the pathogenesis of *ALS–parkinsonism–dementia complex* remains uncertain.

Clinicoanatomic Correlation

Both the classic and familial forms of ALS feature a combination of upper motor neuron (UMN) and lower motor neuron (LMN) signs (Table 20.1) affecting limb, trunk, and bulbar musculature. The UMN syndrome is the result of an interruption of the corticospinal and corticobulbar tracts occurring over a protracted time. These tracts originate in the primary motor cortex, premotor areas, temporal cortex, and sensory cortex; converge in the internal capsule; pass through the ventral midbrain; and separate into bundles in the basis pontis (Fig. 20.1). At this level, the corticobulbar tract separates off and bilaterally projects to the motor neurons of cranial nerves V, VII, IX, X, and XII. In the medulla, some of the corticospinal bundles coalesce ventrally to form the pyramids with 75–90 % of these fibers decussating at the level of the lower medulla to form the lateral corticospinal tracts [29]. The latter project to ipsilateral motor neurons, innervating the extremities, and associated interneurons in

Table 20.1 Signs in ALS

Upper motor neuron	Lower motor neuron	Others
Weakness	Weakness	Dementia [b]
Spasticity	Atrophy	
Poor dexterity	Fasciculations[a]	Atypical/rare:
Pathologic reflexes	Cramps	Sensory loss
Hyperreflexia	Hyporeflexia	Sphincter dysfunction
Pseudobulbar signs		Extraocular dysmotility
Retained reflex in atrophic limb		

[a]Debate as to origin of fasciculations (see text)
[b]Dementia is no longer considered rare or atypical (see text)

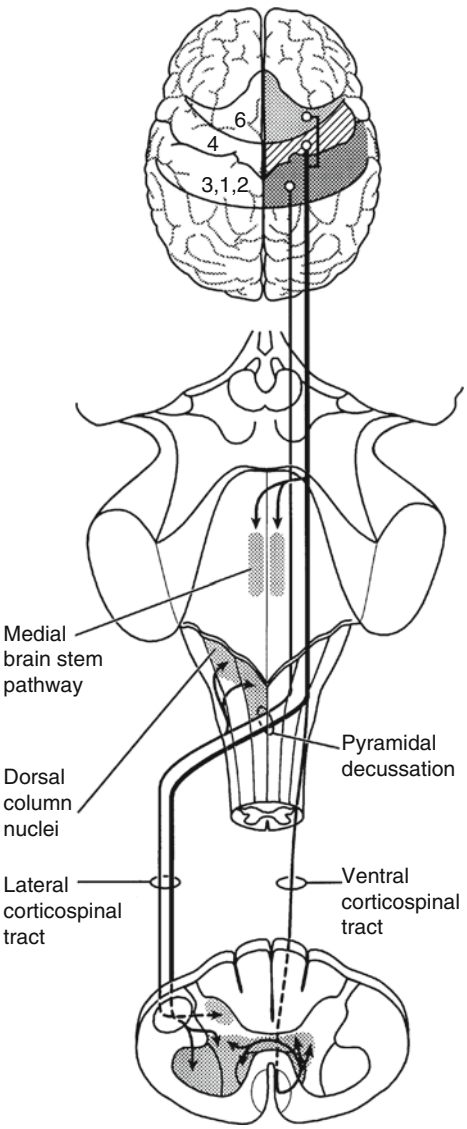

Fig. 20.1 Anatomic pathways involved in amyotrophic lateral sclerosis. The corticospinal tracts originate from multiple areas of the cortex (Brodmann's areas *1*, *2*, *3*, *4*, and *6*), pass through the brainstem, and emerge as both crossed and uncrossed corticospinal tracts that synapse upon alpha motor neurons and interneurons in the anterior horns of the spinal cord. The corticobulbar tracts (not illustrated) also originate from a broad region of cerebral cortex including connections to the limbic system

the lateral anterior horn. The remaining corticospinal fibers descend as the uncrossed anterior corticospinal tracts to project onto ventromedial motor neurons and interneurons which innervate axial and postural muscles. Recent electrophysiological evidence suggests that there is preferential involvement of the fast-conducting direct corticospinal tracts in ALS while sparing the slower, polysynaptic pathways [30]. Axons within these tracts provide excitatory input to alpha motor neurons, gamma motor neurons, and Ia inhibitory interneurons. Brainstem nuclei are intimately connected to the motor neurons in the anterior horn via the vestibulospinal, tectospinal, and reticulospinal tracts. In addition, an independent limbic motor system with medial, lateral, and periaqueductal gray components influences somatic motor neurons together with emotional, autonomic, endocrine, and visceral functions [31].

The lower motor neurons in the spinal cord are centered in the anterior horns forming longitudinally arranged columns extending from one to four spinal segments. Motor neurons that innervate the distal muscles of the extremities are more dorsally located in the anterior horn, whereas those innervating proximal muscles are more ventrally positioned. The individual cells are composed of large alpha motor neurons, medium-sized beta motor neurons, gamma neurons (fusimotor neurons), and interneurons. The alpha motor neurons are among the largest neurons in the nervous system and possess long axons together with broad dendritic receptive fields.

Clinical Presentation

Typical Features

The classic form of ALS is characterized by the coexistence of both UMN and LMN signs (see Table 20.1). Weakness, the most common presenting complaint, typically begins in the limbs, is asymmetric, and progresses over time to adjacent myotomes in the same limb and thence to the opposite side. It has recently been reported that onset in the upper limb is usually in the dominant limb, but the same cannot be said of the lower limb, where "footedness" appears not to play a role [32].

The UMN syndrome comprises those abnormalities attributable to involvement of the corticospinal and corticobulbar tracts which include loss of dexterity, weakness, spasms, spasticity, hyperreflexia, and pseudobulbar palsy. Poor dexterity is often described as clumsiness or slowness of certain activities, such as buttoning clothing or tying shoelaces. Complaints of muscle slowness, fatigability, or stiffness are common. Spasticity, the defining feature of the UMN syndrome, is thought to arise from increased excitability of the lower motor neurons caused by denervation hypersensitivity of the anterior horn cell interneuron population in the setting of damage to the integrity of the corticospinal tract [33].

With loss of inhibitory pathways in the spinal cord, muscle stretch reflexes become exaggerated so that even the slightest of hammer taps may elicit a response. A deep tendon reflex may spread to muscles that should not be involved in the tested reflex arc (i.e., "pathologic spread"). Easily elicitable reflexes in the setting of a flaccid, atrophic limb should also be considered an UMN sign. A study comparing the corneomandibular reflex in ALS to that in stroke (with resulting pseudobulbar palsy) showed that this reflex is a sensitive indicator of ALS [34].

Primitive reflexes may become disinhibited as a result of loss of UMN control. The most important is the Babinski sign whose presence correlates well with corticospinal tract involvement but which may be masked by muscle atrophy (in such a situation one should look for contraction of the tensor fascia lata when one stimulates the sole of the foot) [35]. Hoffmann's and Tromner's signs may be present, although these primitive reflexes may be seen in some normal individuals and, thus, should be interpreted as definitely pathologic only if there are associated UMN signs.

Compared to the UMN type, weakness in the LMN syndrome is more pronounced and often associated with significantly greater degree of muscle atrophy. Additionally, the reflexes are hypoactive or even lost. Weakness is typically focal in onset, is painless, and subsequently spreads to contiguous muscles. The most common site of onset is the distal extremity, the intrinsic muscles of the hand being more frequently affected than elsewhere. One should assess for clinical evidence of the "*split hand*," a phenomenon whereby the muscles of the lateral aspect of the hand are more severely involved than those of the medial aspect (see the electrodiagnostic examination below). When onset presents as foot drop, wrist drop, or claw hand alone, the presentation is said to be "pseudoneuritic" (although some prefer to restrict this term to lower limb onset, also known as "flail leg"). Involvement of cervical paraspinal musculature can present as head drop, whereas involvement of thoracic and lumbar paraspinal muscles can lead to bent spine and marked camptocormia [36]. As motor units continue to be lost, muscle atrophy occurs, which, in ALS, is most commonly seen in the form of intrinsic hand muscle wasting or sharpening of the tibial border. With severe degrees of atrophy, loss of muscle stretch reflexes, palpable flaccidity, and trophic joint changes occur. The latter may be associated with painful contractures and pericapsulitis.

Fasciculations are an important sign in ALS, presenting as involuntary, painless, rapid twitches in muscles of the limbs and the trunk. They represent spontaneous contractions of muscle fibers belonging to a particular motor unit. It is postulated that fasciculations arise from hyperexcitable

distal motor axons, although there is some evidence in support of a supraspinal origin. While a relatively uncommon presenting symptom, they are eventually seen in almost all ALS patients, and accordingly, their absence should prompt one to carefully rethink the diagnosis. Cramps or "charley horses" are often described by patients with ALS and occur in a far more widespread distribution than that seen in the normal population. These sudden, involuntary, painful, sustained muscle contractions can arise at rest and may awaken the patient from sleep. Yet again, they are rarely the presenting complaint but are frequently seen as the disease progresses.

The bulbar palsy syndrome in ALS typically involves damage to both upper and lower motor neurons. The patients present with dysarthria, dysphagia, sialorrhea, aspiration, and pseudobulbar signs. As in limb involvement, there are both UMN and LMN syndromes referable to the bulbar region. The UMN syndrome may present with spastic dysarthria characterized by a slowness of oral and tongue movement and a strained vocal quality. Dysphagia, initially more for liquids than solids, may also occur. There may be a hyperactive gag reflex and a brisk cough reflex. One may also elicit a brisk snout reflex and jaw jerk, which may even become clonic. UMN involvement affecting the muscles of mastication may lead to a slowness and stiffness of chewing (patients complain of taking a long time to eat) or jaw pain after prolonged chewing. The pseudobulbar affect is a feature peculiar to the UMN bulbar syndrome that presents as inappropriate, spontaneous, forced crying, laughing, or yawning. It is thought to arise from disruption of the bilateral corticobulbar pathways bearing fibers of the limbic motor control system [37].

Compared to the UMN bulbar syndrome, LMN bulbar impairment leads to greater degrees of weakness affecting the face (particularly the perioral region), palate, and tongue. In the earlier stages, the patient may have a horizontal smile, be unable to pucker the lips or whistle, and may have difficulty holding air in the cheek. With more advanced bulbar weakness, there is additional difficulty elevating the palate, the gag and jaw jerks disappear, and the tongue becomes increasingly, and often somewhat asymmetrically, atrophic and flaccid (Fig. 20.2). Fasciculations may also be seen on the surface of the tongue. It is important to differentiate these pathologic movements from the twitches that may be seen in normal, anxious individuals and view the tongue while at rest on the floor of the mouth as protrusion may exaggerate normal surface undulations.

Excessive drooling (sialorrhea) is a frequent complaint caused by impaired automatic swallowing and clearance of oral secretions. When neck extensor weakness coexists, this disturbing problem is worsened. Both silent and symptomatic aspiration, a major concern in ALS, may present as frequent bouts of mealtime choking and coughing, nocturnal awakenings, or even fatal laryngospasm.

Fig. 20.2 Tongue atrophy in amyotrophic lateral sclerosis. Note the scalloping of the lateral tongue surface

Diaphragmatic and intercostal muscle involvement is frequent in ALS, albeit rarely at disease onset [38–40]. Patients may complain of sleep disturbance, orthopnea, dyspnea on exertion, dyspnea at rest, or morning headaches. Thus, one should look for use of accessory muscles of respiration, paradoxical abdominal movements, and signs of CO2 retention such as cyanosis, chemosis, papilledema, and bounding pulses. The voice may become softer and weaken at the end of long sentences, and frequent sighs may be observed. Many abnormalities of sleep architecture are described in ALS, including increased sleep latency, persistence of EMG activity during REM sleep, frequent awakenings, and a reduction in total sleep time. It has been postulated that both bulbar and diaphragmatic weaknesses may result in increased hypopneas and apneas, even at an early stage, that may lead to excessive daytime sleepiness and increase the amount of perceived muscle fatigue. In fact, fatigue similar to that seen in neuromuscular transmission disorders is a common complaint in ALS and is associated with disease severity [41]. The pathogenesis of this fatigue is unclear with evidence implicating sources from the level of cerebral cortex to beyond the neuromuscular junction [42], but it is important to consider the possibility that fatigue may be a side effect of riluzole, the most commonly used therapeutic drug in ALS. Many of the common symptoms and signs of ALS, such as sighing, fatigue, frequent crying, sleep disturbance, and weight loss, are also seen in and may actually represent depression [41]. Weight loss may be severe in ALS. It does not appear to be simply related to reduced caloric intake, and there is evidence that some patients suffer from a form of "ALS cachexia" [43, 44].

Atypical Features

It has become clear that a spectrum of cognitive impairment, once considered uncommon in ALS, often accompanies

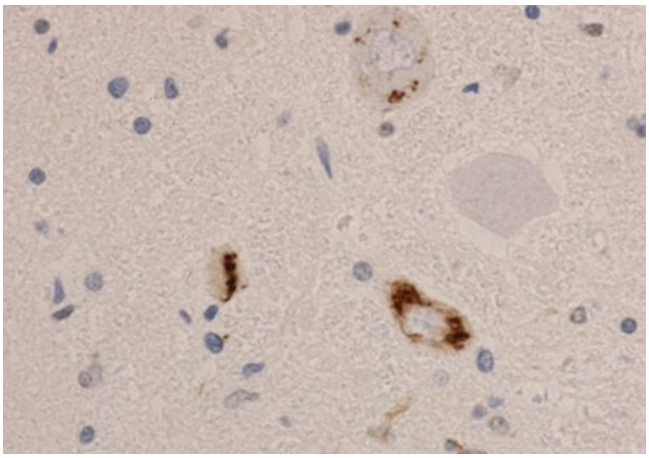

Fig. 20.3 Pathological TAR DNA-binding protein, TDP-43 (*brown*), in the hippocampus of a patient with sporadic ALS (Courtesy of Professor M Farrell, Beaumont Hospital, Dublin, Ireland) (For a more detailed discussion, see Neumann et al. [54])

motor neuron degeneration [45–50]. The range of cognitive syndromes reflects frontotemporal dysfunction, including a cognitive-behavioral syndrome, a dysexecutive syndrome, and a frank frontotemporal dementia. Both sporadic and familial variants of ALS can be affected. Neuroimaging, neuropsychological, and pathological studies demonstrate abnormalities beyond the primary motor cortex with evidence that language deficits, especially anomia, may be relatively frequent in ALS patients but are often masked by dysarthria. A recent prospective population-based study of cognitive function identified that comorbid dementia occurs in approximately 14 % of patients with a new diagnosis of ALS. Cognitive impairment, predominantly but not exclusively in the form of executive dysfunction, was present in more than 40 % of ALS patients without overt evidence of dementia [51]. Thus, although cognitive impairment in ALS is not a universal feature, it may previously have been underreported and its manifestations may be more heterogeneous than previously recognized. In addition to motor-onset ALS presentations, a subgroup of patients (maybe up to 30 %) may initially present with FTD, later developing ALS symptoms [52]. The clinical overlap in most cases of FTD with ALS is reflected by significant pathologic overlap between clinically pure FTD and those with classic ALS—i.e., underlying frontotemporal lobar degeneration (FTLD) with linear spongiosus, atrophy, neuronal loss, and pathological TDP-43(transactive response DNA-binding protein) ubiquitinated inclusions in astrocytes and neurons [53] (Figs. 20.3 and 20.4). Thus, recent pathologic findings suggest that FTD–ALS is part of a clinicopathologic spectrum of TDP-43 proteinopathy. The inheritance of ALS and FTD as a single trait has been recently described, confirming an intronic expansion of the GGGGCC hexanucleotide repeat within the C9ORF72 gene as the cause of a large proportion of familial ALS–FTD, in addition to apparently sporadic disease [55, 56]. C9ORF72 cases show features of a relatively rapidly progressive, but otherwise typical, variant of ALS associated with familial and sporadic presentations. All show classical ALS pathology with TDP-43 inclusions along with extra-motor pathology in the frontal cortex and the hippocampal CA4 subfield [57–59]. Better understanding of the pathological subtypes and clinical phenotypes of these ALS–FTD overlap syndromes is essential to inform development of effective targeted therapies, particularly as these conditions are often the most rapidly progressive neurodegenerative diseases.

The extraocular muscles and those muscles subserving bladder and bowel functions are relatively spared in ALS although advanced patients maintained on ventilators may eventually develop overt dysfunction in these areas. If one performs quantitative testing of saccades, one may detect a reduction of saccade velocities and smooth pursuit movements [60, 61]. A recent study replicated findings that visual acuity, gaze impersistence, voluntary upgaze restriction, eyelid opening apraxia, and saccadic horizontal smooth pursuits are more frequent in patients with ALS than in similar-aged controls. These ocular motility abnormalities are potential clinical markers of neurodegeneration beyond upper and lower motor neuron disease in ALS, suggesting dysfunction of supranuclear control. Several autopsy studies demonstrated neuronal loss in many subcortical regions subserving eye movement control. Further study is required regarding their application to disease categorization and outcomes assessment [62].

Within the sacral cord, the motor neurons of Onufrowicz that control the muscles of the pelvic floor, anal sphincter, bladder, and urethra are essentially spared in ALS. However, while frank urge incontinence and bowel dysfunction are rarities, mild urgency of micturition and urinary retention may occur [63].

The sensory system is also characteristically spared which perhaps contributes to the rarity of decubitus ulcers in this population of immobilized patients (local autonomic reflexes being intact). Despite an overall absence of objective signs, some patients do report vague sensory complaints in the distal extremities; detailed quantitative sensory testing and somatosensory evoked potential studies identified objective sensory disturbances in a small proportion of patients, suggestive of a disruption of the ascending afferent system [64]. There appears to be specific changes in the skin composition in ALS patients. Studies have revealed increased levels of type III procollagen in the skin and serum of ALS patients as compared to controls with excessive deposition of β-amyloid protein and increased dermal ciliary neurotrophic factor and insulin-like growth factor I (IGF-I) suggesting that a metabolic alteration growth factors may take place in the skin of patients with ALS. Perhaps this helps explain the low incidence of pressure sores in immobilized patients with ALS [65]. Extrapyramidal involvement may occur in about 5 % of

ALS patients and may present as an impairment of postural reflexes or retropulsion during attempted ambulation [66].

When one considers these facts, it appears reasonable to conclude that ALS is a widespread, multisystem disorder rather than a pure "motor neuron disease," although it does appear that the motor neuron pool is particularly vulnerable to damage from the injurious processes involved.

ALS Subtypes

Bulbar palsy can be the initial symptom in ALS (Table 20.2). It is most commonly seen in postmenopausal women and may

Table 20.2 Presentations of ALS

Spinal (classic, sporadic)

ALS–FTD (ALS–frontotemporal dementia)
ALS–parkinsonism–dementia complex

portend a worse prognosis. Various studies report that bulbar-onset ALS accounts for 19–28 % of all presentations. Clinically, affected individuals present with dysarthria and dysphagia. The pattern of speech impairment may be more strained, as seen in the UMN predominant presentation, or more slurred as seen in the LMN pattern. Combinations of tongue weakness, wasting, fasciculations, slowness, and lower facial weakness are seen. Often there is coexistent UMN jaw jerk exaggeration and a hyperactive gag (although the LMN type may have no gag at presentation). Emotional lability is frequent and can be embarrassing for the patient. There is often a history of recurrent cough during meals, and there may also be weight loss and aspiration events. This disturbing condition advances locally first and spreads first to the lower cervical/upper thoracic region and thence to lumbosacral myotomes by which time the patient has increasing difficulties with speech and swallowing. Very rarely, the disease does not advance beyond the bulbar region at all; this is true *progressive bulbar palsy (PBP),* an exceedingly rare disease.

Between 2 and 3.7 % of all ALS patients present as a pure UMN syndrome called *primary lateral sclerosis (PLS)* that never goes on to involve the lower motor neurons. Age of onset is typically between 50 and 55 years and the rate of progression may be very slow. A common presentation is that of spastic paraparesis progressing rostrally over many years to eventually cause pseudobulbar palsy. The most recent natural history study suggests that clinically pure PLS can be defined by isolated UMN signs 4 years after symptom onset and is a syndrome of slow progression with high levels of function and longer survival compared with ALS [67]. Diagnosis of PLS cannot be made with certainty before the fourth year of symptoms because many patients develop LMN signs within that time frame (this rendering a diagnosis of upper motor neuron–onset ALS) [68, 69]. Although detailed neuropsychological test batteries may reveal subtle cognitive changes in PLS, overt dementia is uncommon [70, 71].

Progressive muscular atrophy (PMA), the rarest "ALS" presentation (2.4 %), presents as a pure LMN syndrome and tends to harbor a more favorable outcome. Clinically, it is characterized by signs of lower motor neuron dysfunction. By definition, the condition must be pure LMN before designation as PMA, but, as with PLS, one must continue to reevaluate patients for later development of UMN signs [72]. Comparison of survival of patients with PMA or ALS and analysis of clinical features that influence survival in PMA suggest that, although patients with PMA tend to live longer than those with ALS, shorter survival in PMA is associated with the same risk factors that predict poor survival in ALS. Additionally, PMA, also a TDP-43 proteinopathy, is progressive, and UMN involvement can eventually occur. For these reasons, PMA should be considered a form of ALS [73].

Mention should be made of three distinctive presentations of ALS: Mills' (hemiplegic) variant, flail-arm syndrome and flail-leg syndrome. *Mills' variant* is a well-recognized, hemiplegic presentation featuring a combination of UMN and LMN signs isolated to one side [74]. The *flail-arm syndrome*, also known as brachial amyotrophic diplegia, occurs in about 10 % of patients and presents as relatively symmetric proximal and distal bibrachial wasting with additional evidence of corticospinal tract involvement (positive Babinski sign). *Flail-leg syndrome* represents a pseudopolyneuritic variant of ALS and occurs in approximately 6 % of all patients. Survival in both syndromes is significantly better than in classical ALS [75].

Familial ALS

Familial ALS (fALS) describes the 5–10 % of all cases in whom ALS is known to be an inherited trait. The true frequency of fALS is probably higher, and reduced penetrance may account for apparently sporadic disease. There are autosomal dominant, autosomal recessive, and X-linked dominant forms, some juvenile, and others adult, onset. Familial ALS-known genes and phenotypes are outlined in Table 20.3.

Familial ALS should be suspected when family members of successive generations are definitely affected by the disease. However, family history may be incomplete, and phenotypic variability abounds so that few clinical features separate sporadic from familial forms. Overall, fALS has a younger age at presentation, lacks male predominance, and has shorter disease duration and a predilection for lower extremity onset. Most ALS research in the past has focused on the neurotoxicity of mutant SOD1, and this has directed therapeutic research. More recently, TDP-43 has been identified as the major pathological protein in sporadic ALS, ALS–FTD, and *SOD1*-negative familial ALS [10, 83–85].

Up to 20 % of fALS patients are associated with a mutation in the Cu/Zn superoxide dismutase 1 (SOD1) gene on chromosome 21, and since its discovery, many different mutations have been described in all five exons [10, 86]. Cumulative evidence suggests that a toxic gain of function rather than a loss of function is conferred by the mutations. The most common is an alanine for valine substitution at codon 4 (shortened to A4V) that seems to correlate with shorter patient survival (mean 1.5 years). Usually SOD-1 fALS is autosomal dominant, but aspartate for alanine substitution in exon 4 (D90A,) seen most commonly in Scandinavians is recessive. The alsin mutation on chromosome 2q33 (known as ALS2) and affecting predominantly Tunisians, Saudi Arabians, and Kuwaitis has a mean age of onset of 12 years and progresses very slowly. Both PLS and ALS presentations occur. The disorder is proposed to occur

Table 20.3 Familial ALS: genes and features

ALS	Gene mutation	Chromosome and gene product function	Inheritance	Details
ALS 1	SOD1	21q21; oxidative stress	AD (rarely AR)	Late onset >30 years, 15–20 % all familial ALS (1–2 % all ALS) [10]
ALS 2	ALSIN	2q33; trafficking and signaling	AR	Rare, juvenile ALS; loss of function of gene product
ALS 3	Not identified	18q21	AD	
ALS 4	(SETX) Senataxin	9q34, RNA processing	AD	Juvenile onset, slowly progressive, distal amyotrophy, and UMN signs, not bulbar
ALS 5	Spatacsin	15q15-q22	AR	Juvenile onset
ALS 6	FUS–TLS	16q21; RNA processing	AD	5 % non-SOD1 familial ALS, 1 % sporadic ALS [76]. FUS is immunoreactive with TDP43 and ubiquitin [56]. Associated with FTD and hallucinations
ALS 7	Not identified	20ptel-p13	AD	Rare, late onset
ALS 8	VAPB (vesicle-associated membrane protein)	20q13.3; trafficking and signaling	AD	Heterogenous phenotype [77]
ALS 9	Angiogenin	14q11.2; RNA processing	AD	Adult onset
ALS 10	TDP-43 (transactive response DNA-binding protein)	1p36.2; RNA processing	AD	ALS with limb/bulbar onset. Although not specific to ALS, the frequency of TDP-43 inclusions in familial (2–5 %) and sporadic ALS suggest pathogenic role [78, 79]
ALS 11	FIG-4	6q21; trafficking and signaling	AR	ALS/PLS onset. Familial and sporadic ALS [80] FIG-4 mutation also causes CMT4J
X-linked AD	Ubiquilin 2	Xp11; protein turnover	X-linked AD	Combined UMN/LMN
ALS12	OPTN; optineurin	10p13; trafficking and signaling	AR, AD	[81]
Dynactin	Dynactin (p150 glued subunit) (Puls et al. 2005)	2p13; trafficking	AD	Distinctive phenotype: early bilateral vocal cord paralysis, then intrinsic hand muscles, legs, face. Other mutations: ALS or FTD
FTD–ALS overlap				
ALS–FTD 1	Not identified	9q21-q22	AD	
ALS–FTD 2	Not identified	9p21.3	AD	
ALS–FTD 3*	CHMP2B	3, trafficking and signaling	AD	ALS, ALS–FTD, PMA [82]
*Autosomal-dominant ALS–FTD		9q21-22	AD	
C9ORF72 hexanucleotide repeat expansion	GGGGCC hexanucleotide repeat within the *C9ORF72* gene	9		Familial and sporadic ALS. Associated with TDP-43 proteinopathy. Classic ALS and extra-motor pathology [57]
FTD with some ALS features—progranulin	Progranulin (PGN)	17		Neuronal and glial TDP43-positive, tau-negative ubiquitinated inclusions
DDPAC (disinhibition–dementia–parkinsonism–amyotrophy complex)	TAU	17	AD	Tau-immunoreactive inclusion bodies in affected regions of CNS

through loss of function of the gene product (which is important in cell trafficking) [87]. Autosomal dominant ALS 10, associated with a TDP-43 (transactive response DNA-binding protein) mutation, is characterized by ALS with limb/bulbar onset and is not reliably distinguishable from sporadic ALS aside from family history [78, 79]. Most recently, the gene underlying inheritance of ALS and FTD as a single trait within the same family has been described, with confirmation that a hexanucleotide expansion on chromosome 9 underlies a large proportion of familial ALS and FTD, in addition to apparently sporadic disease [57]. Other implicated genes include FUS–TLS (chromosome 16q21) [76], ubiquilin [56], senataxin [88], FIG-4 (chromosome 6q21) [80], and optineurin/OPTN [81]. As outlined in a later section of this chapter, these various genes have overlapping functions, some associated with RNA processing, some concerned with endosomal trafficking/cell signaling, and others involved in oxidative stress responses. Intracellular inclusion bodies are found in many of these genetic disorders including SOD1, TDP-43, FUS/TLS, and optineurin [89].

Western Pacific ALS

A combination of ALS and Parkinsonism on the island of Guam was first described by Mulder et al. in 1954. This was followed by Hirano's first complete pathological description of the syndrome of Guamanian ALS–Parkinsonism–Dementia Complex [90]. Subsequently, the incidence of ALS was noted to be particularly higher in West New Guinea and the Kii Peninsula of Japan, being between 50 and 150 times, than elsewhere [7–9, 90]. Clinically, about 5 % of patients develop a predominantly ALS type of disorder, whereas 38 % manifest principally with a combination of parkinsonism and dementia. The pathology is similar to that of Alzheimer disease, with prominent loss of CNS neurons and the presence of abundant tau-immunoreactive neurofibrillary tangles. However, the characteristic pathology of Guamanian ALS and PDC also includes TDP43-positive inclusions in neurons and glial cells. α-Synuclein pathology also is detectable in the amygdala of affected brain tissue [91]. Various environmental substances, including cycad seeds, aluminum, and silicon, have been studied with regard to its pathogenesis, but their roles, including that of cycad seeds in neurotoxicity, is still subject to debate [92–94]. The cycad seed has many uses: in West Papua and Guam as a topical medicine for skin lesions and in Japan as an oral medicine [95, 96]. Cox and Sacks (2002) proposed a process of biomagnification of cycad toxins in Guam through the Chamorro practice of eating flying foxes, which themselves feed on cycad seeds. ALS–parkinsonism–dementia complex is beginning to disappear from the endemic regions, and it has been proposed that this may be due to altered exposure to an unidentified trigger as well as changes in social/cultural practices in endemic regions. The cycad-derived BMAA (beta-methylamino-L-alanine) neurotoxin hypothesis has wider implications for research in SALS worldwide. It has been recently shown that protein-bound BMAA is present in the brains of North American patients dying with ALS and Alzheimer disease, and it has been hypothesized that such patients may be genetically susceptible to BMAA-induced neurodegeneration [97, 98].

Etiology and Pathogenesis

The cause of ALS remains unknown, but there are several intertwining strands of evidence that together suggest multiple molecular mechanisms that may ultimately combine to effect loss of motor neurons and their support systems. Much of this evidence stems from research in the field of fALS. As the first ALS-associated gene, superoxide dismutase 1 (SOD-1) is an antioxidant protein. One of the most studied areas in this regard is *oxidative stress* wherein overproduction of, or failure to clear, potentially harmful oxygen free radicals in aging motor neurons may precipitate eventual cell failure (probably in concert with other pathogenic processes). Markers of free-radical damage are elevated in tissue samples of patients with ALS, and signs of oxidative stress have been identified in the organelles of cells from fALS cases (notably SOD 1-associated diseases) and in animal models of fALS [99, 100]. *Excitotoxicity* is another mechanism whereby overstimulation/activation of glutamate receptor subtypes (most notably amino-3-hydroxy-5-methylisoxasole-4-propionic acid, AMPA receptors) leads to disordered calcium homeostasis and triggers intracellular protein breakdown and generation of harmful levels of oxygen free radicals. Evidence to support this theory includes elevated glutamate levels in cerebrospinal fluid levels of ALS cases and reduced activity/expression of the major excitatory amino acid transporter EAAT2 not only in ALS cells but also in animal model studies [101–103]. Most recently, a new ALS-associated gene has been identified: the gene product (D-amino oxidase, DAO) is a protein involved in oxidative deamination of amino acids involved in glutamate receptor activation [104].

A burgeoning theory in ALS pathogenesis is that of *altered cellular energy* [43]. Motor neurons have particularly high energy requirements as they pertain to cell soma size, axonal transport, and activation of large terminal arborizations. As mentioned earlier in this chapter, there appears to be an association between higher metabolic rate/physical fitness and ALS. Furthermore, upper limb onset is more often in the dominant limb. Mitochondria play a major role in the energy production in cells, and there is evidence to implicate dysfunction of these organelles in the pathogenesis of the disease. Oxidative damage impairs respiratory chain function in the mitochondria of patients with ALS, and mutant SOD1 protein can adhere to the mitochondrial membrane and disrupt chaperone-assisted organelle folding [103, 105, 106]. There may be abnormal transport, and therefore reduced numbers, of mitochondria in the terminal axons, thus depriving them of vital energy at a site of high energy requirement [107]. An ALS presentation with ragged-red fibers has been reported in five families and is associated with mtDNA mutations in some patients [108–110].

Other organelle systems under scrutiny in the molecular pathogenesis of ALS are endosomes and neurofilaments. Endosomes are a cargo delivery system from the cell surface to the interior. Recently discovered mutations in genes such as Alsin (ALS2), VAPB (vesicle-associated membrane protein-associated protein B) [77], VCP (valsolin-containing protein) [111] FIG4 (polyphosphoinositide phosphatase) [80], optineurin [81], and CHMP2B (charged multivesicular protein 2B) [82] support a theory of altered endosome mobility within cells in ALS. Motor soma and axons are rich in neurofilaments, microtubules, kinesins, and dyneins, all of which are critical in bidirectional axonal transport. However,

this system can be impaired in ALS not only via oxidative stress but also through (rare) mutations in genes for neurofilament heavy chains, peripherin, and tau. This process may precipitate a form of axonal strangulation that disrupts transport of cargo and indeed energy to where it is required both proximally and, especially, distally.

An *inflammatory process* likely plays an important role in the cell injury process in ALS. Studies of mutant SOD1 models have yielded evidence of early activation of microglial cells, astrocytes, and an overall pro-inflammatory T-cell response [112]. Furthermore, it is known that certain viral infections and paraneoplastic inflammatory disorders can selectively damage motor neurons and cause an ALS-like presentation (polioviruses, HIV, West Nile virus, anti-Hu antibody syndrome). This body of evidence suggests some promising therapeutic targets despite the fact that anti-inflammatory therapeutic trials have disappointed to date.

The pathological hallmark of ALS is the presence of the ubiquitinated intracellular inclusion body in motor neurons and glial cells; TDP-43 (43 kDa transactive responsive sequence DNA-binding protein) is normally a largely nuclear protein and is important in transcription, splicing, and micro RNA processing. TDP-43 is the major protein in sporadic ALS but it is mislocalized so that it mostly lies in the cytoplasm in the form of a *protein aggregates*. This type of protein mislocalization has been observed in many other neurodegenerative disorders such as Huntington's disease and the dominantly inherited spinocerebellar ataxias. It is also seen in some forms of familial ALS including those related to TDP-43, SOD-1, FUS, and ubiquilin (see "Familial ALS"). The accumulation of misfolded cytoplasmic proteins into aggregates may, at least initially, be a normal cytoprotective process in the cell mediated via the endoplasmic reticulum unfolded protein stress response. How these protein aggregates cause ALS is still unclear, but it is likely through an imbalance in lost nuclear function in concert with disruption in cytoplasmic function.

Many of the recent studies in ALS report genetic disorders that involve RNA regulatory genes such as TDP-43, FUS, ANG [113], and SETX which in turn support an evolving theory of *aberrant RNA metabolism* in the pathogenesis of this disease (see Table 20.3 with genetic mutations and their gene functions). Various processes may be involved from regulation of transcription to alternative splicing and mRNA transport.

Pathology

Gross pathologic specimens may exhibit atrophy of the motor cortex together with grayness and atrophy of the ventral spinal roots. There may be a gray appearance to the lateral columns of the spinal cord suggesting sclerotic changes caused by gliosis. In addition, there may be gross muscle atrophy. Microscopically, there is evidence of both upper and lower motor neuron loss. As such, there is some degree of loss of large motor neurons of the anterior horns of the spinal cord and/or brainstem motor nuclei (V, VII, IX, X, and XII) and loss of large pyramidal cells in the motor cortex and/or large myelinated axons of the corticospinal tracts. Degeneration of the corticospinal tracts occurs at the same level, and both normal and abnormal neurons are intermixed, reflecting different stages of neuronal degeneration. Lipofuscin accumulation and loss of Nissl substance is seen in degenerating neurons.

At the cellular level, ALS is characterized by the abnormal accumulation of insoluble ubiquitinated proteins in the cytoplasm of degenerating motor neurons [91, 114, 115]. These ubiquitin-immunoreactive inclusions, most common in lower motor neurons, are a highly sensitive and specific marker for ALS. In the past 5 years, the TAR DNA-binding protein, TDP-43, has been identified as a major component of the neuronal inclusions in sporadic ALS (see Fig. 20.3), as well as in the most common pathological subtype of frontotemporal dementia (frontotemporal lobar dementia with ubiquitinated inclusions [FTLD-U]) [54].

In combination with recent studies showing both clinical and pathological overlap between ALS and frontotemporal dementia, these findings support the view that sporadic ALS and some FTD represent a spectrum of neurodegenerative disease linked mechanistically to pathological TDP-43 (see Fig. 20.4 a, b).

A recently described hexanucleotide intronic expansion of the GGGGCC hexanucleotide repeat within the *C9ORF72* gene on chromosome 9 underlies a large proportion of familial ALS and FTD in addition to apparently sporadic disease [55]. These *C9ORF72* cases demonstrate features of a relatively rapidly progressive, but otherwise typical, variant of amyotrophic lateral sclerosis associated with familial and sporadic presentations. All show classical amyotrophic lateral sclerosis pathology, but extra-motor pathology in the frontal cortex and the hippocampal CA4 subfield neurons distinguishes *C9ORF72* cases. Inclusions in CA4 neurons, absent in non-*C9ORF72* cases, indicate that this pathology predicts mutation status [57, 116]. Although the mechanism is not clear, phenotype is determined by initial location and spread of degeneration [59].

Diagnosis

The Clinical Examination

The diagnosis of ALS is largely made on the basis of the clinical examination, with ancillary testing used to confirm the clinical suspicion and to refute alternative diagnoses.

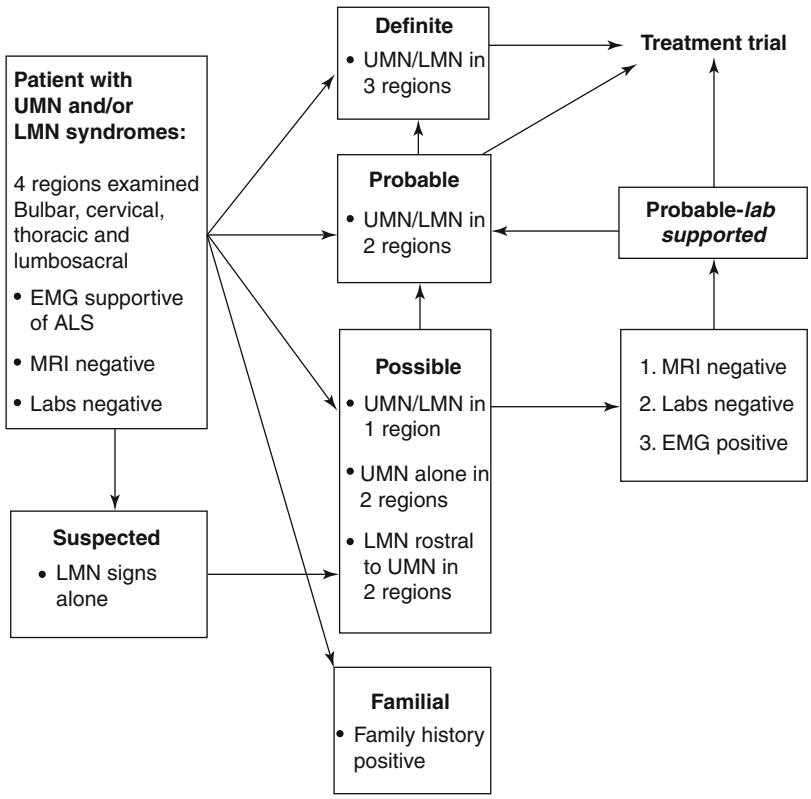

Fig. 20.5 Simplified diagnostic algorithm for the diagnosis of amyotrophic lateral sclerosis. Currently, neuroimaging and blood testing are used as tests to exclude other diagnoses. The electrodiagnostic examination is an ancillary test to aid in making the diagnosis. Regular reexamination is critical (For a detailed review, see Ref. [117] (World Federation of Neurology, Revised Criteria))

A meeting of the World Federation of Neurology at El Escorial, Spain, provided a set of clinical, electrodiagnostic, and pathological criteria for the diagnosis of ALS. The clinical criteria divide candidates into those with *definite, probable, possible,* and *suspected* ALS, based upon the particular pattern of LMN and UMN signs seen in bulbar, cervical, thoracic, and lumbosacral regions (Fig. 20.5). A further review of the criteria, carried out at Airlie House, includes the criterion of spread of disease from region to region and spread within a region [118]. In addition, these criteria demand an absence of electrodiagnostic, pathologic, or radiologic evidence in support of other diseases that may mimic ALS. These criteria have proved important in research and clinical fields, allowing accurate research trial selection and assistance in the day-to-day management of patients.

Definite ALS implies that both UMN and LMN signs are seen together in at least three separate central nervous system regions. *Probable* ALS refers to the presence of UMN and LMN signs in only two regions wherein the UMN signs lie rostral to the LMN signs. If only one region is affected or UMN signs are seen alone in one region with additional electromyographic (EMG) evidence of LMN dysfunction in two regions, the clinician may use neuroimaging and clinical laboratory testing to exclude alternative diagnoses and classify the patient as *probable-laboratory-supported* ALS. Clinically suspected ALS refers to a pure LMN presentation and is regarded as insufficient to allow patient inclusion in a research study.

The revision of the original criteria was implemented to allow earlier access of patients into clinical trials and highlights the importance of EMG and ancillary testing in the diagnostic work up of the candidate patient. There are occasions when UMN and LMN signs are found in only one region and ancillary tests fail to support a diagnosis of ALS. Such patients fall into the *clinically possible* category but follow-up evaluation must be performed to assess for disease progression at which time the patient may be upgraded to a probable or definite category.

Electrodiagnostic Studies

The electrodiagnostic (EDX) examination is an indispensable part of ALS evaluation, essentially serving as an extension of the clinical examination and most useful in identifying LMN dysfunction. Not only may EDX reveal characteristic changes in those regions clinically manifesting signs but also serves to disclose asymptomatic areas of involvement. Since the 1960s, the "Lambert criteria" have aided the electrodiagnostician in making the diagnosis of ALS [119]. These criteria include (1) normal sensory nerve action potentials (SNAPs), (2) motor conduction velocities no less than 70 % of the lower limit of normal values for age, and (3) fibrillation and fasciculation potentials in bulbar and/or limb muscles with reduced number of motor unit action potentials (MUAPs) and increased duration and amplitude.

However, only more advanced patients may meet such criteria, potentially excluding some patients from therapeutic trials. Thus, new criteria were devised at a meeting in El Escorial, Spain, in 1990, which, upon critical review, were later modified [118].

Motor and sensory conduction studies are part and parcel of the EDX examination in ALS and are principally used to exclude alternative diagnoses. Characteristically, the SNAPs are normal. However, coexistent entrapment neuropathies, peripheral polyneuropathies, and the normal effects of aging may reduce SNAP amplitudes. With significant axon loss, low compound muscle action potential (CMAP) amplitudes with modest degrees of slowing may be found. When widespread, this "generalized low motor-normal sensory" pattern is characteristic of more advanced ALS and often portends a worse prognosis [119, 120]. However, it is not specific for the diagnosis and may be seen in spinal muscular atrophies, diffuse myelopathies, certain neuromuscular transmission disorders, polyradiculopathies, and myopathies. Of interest is the finding of the "split hand," i.e., low-amplitude median and ulnar CMAPs recorded from the thenar eminence and first dorsal interosseous muscles, respectively, with a normal or near normal ulnar CMAP amplitude recording from the hypothenar eminence. A possible explanation for this pattern is relative increased cortical representation of the thenar eminence musculature, but it is also possible that the neurons innervating these muscles are more liable to oxidative stress [121]. Median distal motor latencies may also be prolonged out of proportion to the degree of axon loss, which probably reflects the relatively slow conduction along the terminal axons of collateral sprouts. As with conventional motor conduction studies, F-wave latencies remain within normal limits until significant degrees of axon loss have occurred, and, with progressive motor axon loss, they may disappear altogether.

On needle EMG of affected muscles, features of both active and chronic denervation must be observed. Active denervation consists of fibrillation potentials and positive sharp waves, whereas chronic denervation consists of MUAPs that are increased in duration, occasionally increased in amplitude, and often polyphasic. In addition, these MUAPs usually fire at a rapid rate (>10 Hz) unless there is significant upper motor neuron disease, wherein slower rates of firing may occur. Moment-to-moment MUAP amplitude variation, representing motor unit instability, may often be appreciated. Fasciculation potentials are a characteristic feature, seen in almost all patients; they typically occur in a widespread distribution and often have an abnormal configuration (depending on the motor unit generating them). If fasciculation potentials are not readily detected during the EDX examination, considerable doubt must be cast upon the diagnosis. The Awaji algorithm has been devised to increase the importance of fasciculation potentials in the diagnosis of suspected ALS and is particularly helpful in the early diagnosis of bulbar-onset disease. The algorithm uses fasciculations as evidence of active denervation as long as the muscle that is being studied shows additional chronic neurogenic change [122–124]. Neither fibrillation nor fasciculation potentials are easily appreciated in the tongue, as it is difficult to achieve adequate relaxation, and the MUAPs normally appear rather similar to fibrillation potentials in terms of both their size and configuration. Ultrasound of the tongue may prove to be a useful test to diagnose fasciculations not only in the tongue but also in other muscles [125]. Repetitive discharges, also known as doublets, are a particularly frequent finding in ALS where the interval between the first and second waveform is short but variable suggesting that both are derived from the same cell soma. It is postulated that they represent hyperexcitability of the cell membrane.

As in the clinical examination, the EDX features must be observed in a certain topographical distribution. In fact, none of the previously described EDX findings are specific for ALS. Rather, it is the widespread pattern of involvement that is characteristic, affecting multiple segments of the neuraxis with progression over time. Changes should be found in at least two of the four regions (bulbar, cervical, thoracic, and lumbosacral regions). In cervical and lumbosacral regions, at least two muscles derived from different roots and peripheral nerves must be involved. Abnormalities in the opposite limb should only be included if they involve a separate spinal cord segment. When the bulbar region is assessed, changes must be observed in at least one muscle (including tongue, jaw muscles, and facial muscles). Similarly, if one examines the thoracoabdominal segments, one should demonstrate EDX changes in abdominal muscles or in a paraspinal muscle at or below the T6 level. Evaluation of higher thoracic segments may be misleading as denervation changes derived from cervical segments may manifest as far caudally as the T6 level. The EDX examination should ideally be performed on three or more regions and should assess all the major segments in the limbs examined. In conjunction with the inclusive criteria as described previously, there are a number of EDX findings considered incompatible with the diagnosis of ALS, including marked conduction slowing, conduction block and abnormal sensory responses otherwise unexplained by advanced age or coexisting neuropathy.

A number of special EDX techniques may be employed in the evaluation of patients with suspected ALS; these techniques have been helpful as outcome measures in the assessment of efficacy in therapeutic trials. Manual and computer-based motor unit number estimation (MUNE) techniques have been used to monitor disease progression (see Chap. 9) and can help distinguish subtypes of ALS [126]. Swash and de Carvalho devised the Neurophysiological Index derived from the CMAP, distal motor latency, and

F-wave frequency to determine rapid from slowly advancing disease [127]. Repetitive stimulation studies, although not routinely performed, may show a decrementing response (albeit usually less dramatic than that seen in myasthenia gravis) that is likely due to impaired neuromuscular transmission at the immature nerve terminals of collateral sprouts. Similarly, increased fiber density, abnormal jitter, and blocking may be detected during single-fiber EMG [128]. Macro-EMG refers to the use of a specialized recording electrode that samples all muscle fibers within a single motor unit and estimates the degree of motor unit loss and the extent of collateral reinnervation. Other methods for evaluating chronic partial denervation include turns/amplitude analysis, EMG decomposition, and quantitative motor unit potential analysis (see Chap. 9). Transcranial magnetic stimulation (TMS) studies can provide useful information in assessing the central motor pathways in ALS. Many, but not all, patients with sporadic ALS have low motor evoked potential amplitudes on TMS, with prolongation of both the response threshold latencies and central motor conduction times. A gradual reduction in the motor evoked potential amplitudes over time is a particularly useful way to determine upper motor neuron system involvement in apparently pure lower motor neuron disease and also is a valuable technique to monitor disease progression [129].

Neuroimaging

The most important role for neuroimaging remains exclusion of structural, inflammatory, or infiltrative disorders that may mimic ALS. All patients should undergo brain and spinal cord imaging. However, in addition, more sophisticated techniques may allow discernment of abnormal signal in the motor tracts in ALS. In patients with more severe disease, signal change reflecting wallerian degeneration may be visualized on proton density-weighted MRI (Fig. 20.6). FLAIR and T2-weighted fast-spin echo sequences are less specific in detection of such corticospinal tract signal changes. Nonspecific atrophy of the frontal and parietal cortex may also be seen. Surface-based cortical morphology analyses performed on structural 3T MRI data reveal cortical thinning of the primary motor cortex, which may be a diagnostic marker for upper motor neuron degeneration in ALS; relative thinning in temporal regions has been associated with a rapidly progressive disease course [130]. The search for ALS biomarkers has led to the investigation of other imaging techniques such as magnetization transfer ratio (MTR) imaging, magnetic resonance voxel-based morphometry, magnetic resonance spectroscopy, and diffusion tensor MRI (DTI). The latter demonstrates that corpus callosum involvement is a consistent feature of ALS, with extension of reduced fractional anisotropy in primary motor cortices, supplementary motor regions, and in temporal lobe regions. Whole brain-based and DTI tractography analysis can define a distinct white-matter pathoanatomy of different MND geno-/phenotypes [131]. Furthermore, DTI of white-matter tracts has also demonstrated structural differences between ALS and PLS [132], and differences in intracerebral corticospinal tract changes of patients with familial and apparently sporadic ALS have facilitated study of genotype/phenotype interactions [133]. FDG-PET studies reveal frontal and temporal hypometabolism (parietal hypometabolism often also present), with relatively preserved perirolandic metabolism [134].

Although functional imaging with blood oxygenation level–dependent (BOLD) functional MRI and magnetoencephalography may reveal abnormal activity in motor and non-motor areas in ALS, further studies are needed to determine their role in UMN assessment [135, 136]. Additional research is also necessary to clarify the role of transcranial magnetic stimulation (TMS), alone or in combination with DTI, in the evaluation of the UMN system.

Laboratory Testing

There is no serologic test to diagnose sporadic ALS. Indeed, normal results are supportive of the diagnosis. Testing of serum, urine, and CSF is primarily performed to exclude alternative diagnoses, the array of tests being tailored to each particular presentation (see section on "Differential Diagnosis"). Nevertheless, there are certain blood tests performed at initial evaluation. These include complete blood count, chemistry panel (including calcium, phosphate, and magnesium), creatine kinase (CK), VDRL, HIV, erythrocyte sedimentation rate, serum protein immunofixation or immunoelectrophoresis and anti-GM1 antibody assay, angiotensin-converting enzyme (ACE) and glycosylated hemoglobin (HbA1c), thyroid function studies including thyroid-stimulating hormone, serum parathormone (if calcium is raised), and vitamin B12 levels. Anti-neuronal antibody testing, to exclude a paraneoplastic syndrome, should be considered, as paraneoplastic encephalomyelitis may present as myelopathy with motor neuron symptoms alone, resembling ALS (although sensory and autonomic features may occur later). Associated anti-neuronal antibodies, including anti-amphiphysin, anti-Hu, anti-Ma, and anti-CRMP5, may be detected [137, 138]. By definition, these tests should be normal except for possible modest elevation of CK which commensurate with the degree of muscle atrophy in early disease in active males.

Patients older than 50 years and smokers of any age should have a chest radiograph and fecal occult blood testing. If any chest lesion is identifiable, or if the presentation is subacute with atypical features such as sensory loss, a

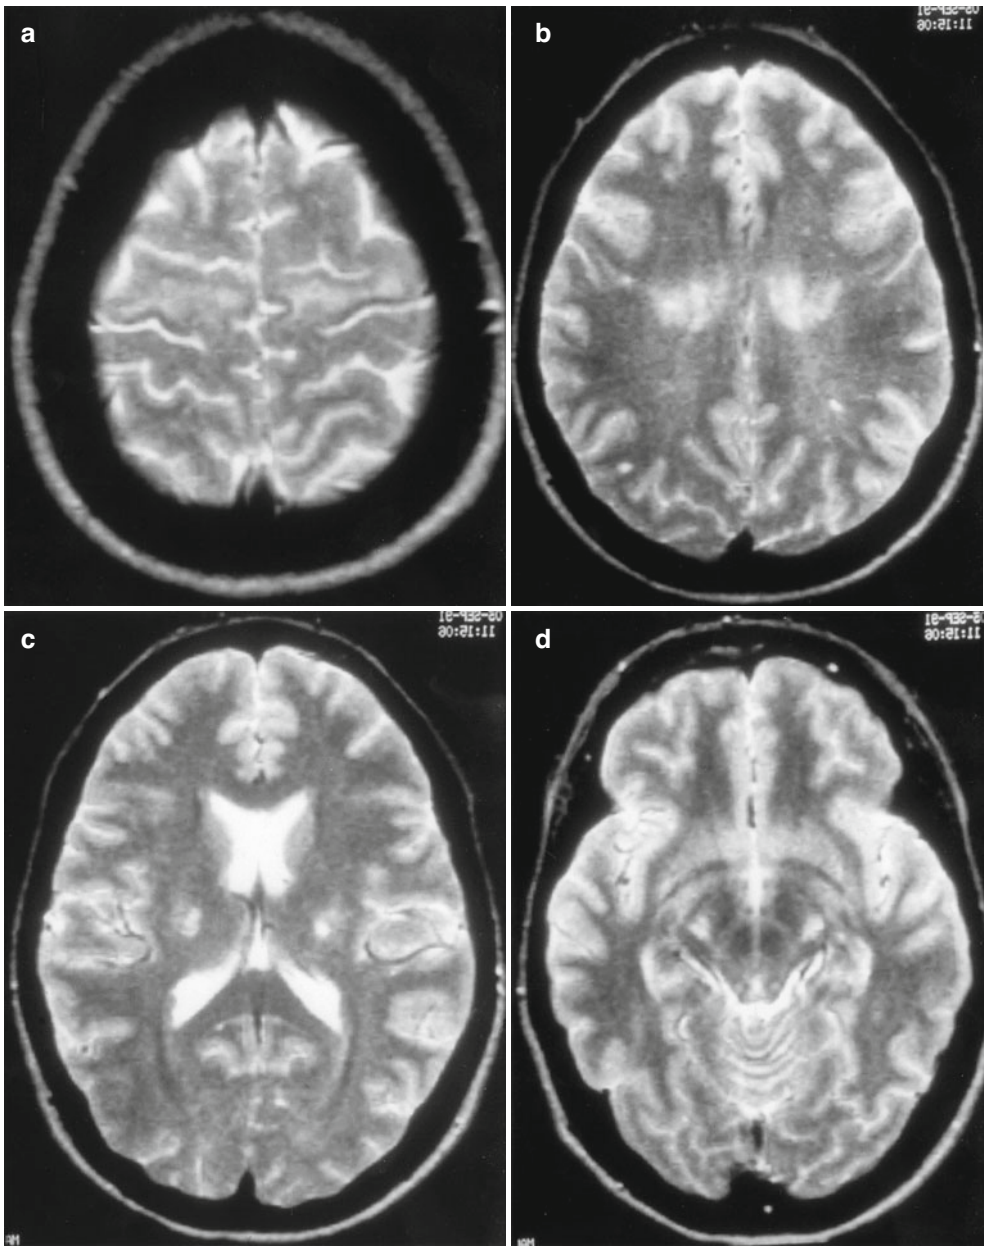

Fig. 20.6 (**a**–**d**). T2-weighted cerebral magnetic resonance images at four levels in a female patient with rapidly progressive amyotrophic lateral sclerosis. Note the increased signal intensity in the corticospinal tract as it extends from the motor cortex to the brainstem

paraneoplastic anti-neuronal antibody screen, particularly anti-Hu antibody levels, should be performed. Some patients may have clinical features suggesting a neuromuscular junction disorder and should have testing for antibodies against the acetylcholine receptor or voltage-gated calcium channel. If there is biochemical evidence of adrenal insufficiency, it is prudent to obtain a very long-chain fatty acid (VLCFA) assay to investigate for possible adrenomyeloneuropathy. Young-onset ALS with atypical clinical features such as early dementia, cramps, and tremor should prompt the physician to obtain a leukocyte hexosaminidase-A assay. Young age at onset, with perioral fasciculations and gynecomastia, should prompt genetic assessment for the trinucleotide repeat expansion on the androgen receptor gene associated with Kennedy's disease (spinobulbar muscular atrophy). If there is a positive family history of ALS or frontotemporal dementia in otherwise typical ALS, it is important to counsel the patient in preparation for appropriate mutation analysis. Reserve cerebrospinal fluid examination for cases with features suggestive of an infectious or infiltrative process such as lymphoma or basal meningitis or suspected CIDP. No specific features on muscle biopsy distinguish ALS from other neurogenic disorder. (It may reveal changes of chronic denervation and muscle fiber regeneration and, in long-standing patients, replacement of muscle fibers by fibro fatty tissue.) Thus, reserve biopsy for cases that are more suggestive of a myopathy.

Differential Diagnosis

Many diseases, both neurologic and systemic, may mimic ALS, making the differential diagnosis rather extensive. Depending upon the particular study, the misdiagnosis rate varies between 27 and 42 %, with more misdiagnoses occurring in patients over 60 years [139]. One may approach the differential diagnosis in terms of the anatomy, symptoms, or clinical presentation. For this discussion, we discuss the differential in terms of nervous system anatomy (Table 20.4).

Brain

Certain early manifestations of *Parkinson's disease* bear resemblance to ALS such as increased tone, hypophonia, sialorrhea, and dysarthria. However, tremor and response to levodopa help to distinguish the two conditions. Furthermore, the EMG fails to show widespread changes of denervation. Similarly, *multiple system atrophy (MSA)* may present with long tract signs and amyotrophy. However, ataxia, dysautonomia, sphincter disturbance, and oculomotor disturbances are common in MSA and rare in ALS. Also, there is evidence of external anal sphincter chronic denervation in MSA on needle EMG. *Spinocerebellar ataxia type 3 (Machado Joseph disease)* may exhibit spasticity and distal extremity wasting, usually with prominent extrapyramidal and oculomotor signs. Rarely, mild phenotypes of *Huntington's disease*, particularly when lacking a family history, may resemble ALS with increased tone and dysarthria. However, the progression of both disorders is dissimilar, and there are characteristic basal ganglionic MRI findings seen in Huntington's disease. *Stroke* with multiple subcortical ischemic lesions may produce marked pseudobulbar affect, weakness, and corticospinal tract signs, but MRI, especially T2-weighted and FLAIR images, should readily demonstrate these changes.

Polyglucosan body disease is a rare, late-onset, slowly progressive disorder characterized by combined UMN and LMN signs, cognitive decline, distal sensory loss, and disturbances of bladder and bowel function. MRI of the brain may reveal diffuse white-matter signal increase on T2-weighted images, but diagnosis is based on characteristic pathological changes in tissue from peripheral nerve, cerebral cortex, spinal cord, or skin. Axons and neural sheath cells contain non-membrane-bound cytoplasmic periodic acid–Schiff-positive polyglucosan bodies. Ultrastructural examination shows inclusions consisting of 6–8-nm branched filaments, most abundant in myelinated nerve fibers. In Ashkenazi Jewish patients (and one reported non–Ashkenazi Jewish patient), the disorder was caused by mutations of the glycogen-branching enzyme (GBE) gene, with subsequent deficiency of the protein product. However, adult polyglucosan body disease occurs in many different populations, and considerable molecular heterogeneity has been observed, with otherwise typical cases lacking GBE mutations despite deficiency of enzyme activity [140, 141]. Incidentally, two types of polyglucosan body may be seen in typical ALS—Lafora bodies and corpora amylacea—although neither could be considered characteristic pathological features.

Brainstem and Spinal Cord

Cervical spondylosis is probably the most important consideration in the differential diagnosis of ALS, and may closely mimic ALS, potentially presenting with asymmetric weakness of all extremities and UMN signs due to spinal cord compression and LMN signs due to foraminal stenosis. Lesions at the foramen magnum and various medullary lesions, such as infarct, syrinx, demyelination, and neoplasm, may simulate the bulbar presentation of ALS, rendering neuroimaging essential in the evaluation. Although *syringomyelia* may present with weakness and wasting, a characteristic pattern of dissociated sensory loss typically occurs and the disease progresses at a much slower pace in a generally younger population than ALS. A combination of UMN and LMN signs may be seen in *multiple sclerosis* in the setting of plaque formation at root exit zones. Characteristic MRI and CSF findings help to differentiate multiple sclerosis from ALS. Another consideration, in patients presenting in their third or fourth decade, is *adrenomyeloneuropathy*, a peroxisomal disorder caused by a defect in beta-oxidation of very long-chain fatty acids. Patients present with spastic paraparesis, areflexia, sphincter disturbance, and sensory loss. The diagnosis is established by demonstrating increased plasma levels of very long-chain fatty acids [142]. The prominence of sensory findings usually distinguishes ALS from subacute combined degeneration due to *vitamin B12 deficiency*. However, since patients may occasionally lack sensory features, it is prudent to routinely measure a vitamin B12 level to exclude this eminently treatable condition.

"Four-A" syndrome (Allgrove syndrome), a very rare autosomal recessive disorder that derives its name from the combination of achalasia, alacrima, adrenocorticotrophic insufficiency, and amyotrophy, can manifest from the first decade of life with dysphagia and adrenocortical insufficiency. A broad range of neurological problems can arise later in life including cognitive deterioration, optic atrophy, seizures, autonomic disturbance (dry mouth, postural hypotension, and syncope), and bulbospinal amyotrophy (amyotrophy of limbs and tongue, with tongue fasciculations and pyramidal signs) [143]. The AAAS gene is located on chromosome 12q13 and encodes *aladin* in the neuroendocrine system with

Table 20.4 Differential diagnosis of ALS

Anatomical location	Disorder	Test
Brain	Parkinson's disease	Levodopa
	Huntington's disease	MRI, CAG repeat
	Cerebrovascular disease	MRI brain
	Prion disease, HIV	EEG, CSF, biopsy
	Multiple systems atrophy	Autonomic testing
	Spinocerebellar atrophy	Genetic testing
Brainstem and spinal cord	Brainstem glioma, plaque, infarct	MRI
	Foramen magnum mass	
	Syringobulbia	
	Kennedy's disease	CAG repeat
	Spondylosis, syringomyelia, MS, SCDC, HTLV-1/2, HIV/2	MRI, EMG, CSF
	Adrenomyeloneuropathy	Serology, B12 levels
	Hereditary spastic paraparesis	VLCFAs Gene tests
Anterior horn cell	Spinal muscular atrophy	
	Kennedy's disease	CAG repeat, EMG
	Monomelic amyotrophy	
	Hexosaminidase A deficiency	Hexosaminidase A assay
	Post-polio syndrome	
	West Nile virus	WNV IgM serum and CSF
	Paraneoplastic	
		Anti-Hu, Anti-Ma, anti-amphiphysin
Root, plexus, and nerve	Radiculopathy	EMG, MRI
	Diabetic polyradiculoneuropathy	EMG, glucose
	Polyradiculopathy (CIDP, GBS, porphyria, HIV, CMV, lyme, syphilitic, postradiation)	EMG, labs, serology
	Neuralgic amyotrophy	
	POEMS, MMNCB, mononeuropathies	EMG
		EMG, SPI, anti-GM1
Neuromuscular Junction	Lambert–Eaton syndrome	Repetitive stimulation
	Myasthenia gravis	EMG, SFEMG, AchR AB assay
Muscle	Inclusion body myositis	Biopsy
	Oculopharyngeal dystrophy	GCG repeat, biopsy
	Myotonic dystrophy	CTG repeat,
	Isolated neck extensor myopathy	EMG
	Metabolic and congenital myopathies	EMG, Biopsy
Systemic	Hyperthyroidism	TSH, T4
	Hyperparathyroidism	$Ca^{++,}$ PTH assay
	Benign fasciculations	EMG
	Cramp–fasciculation syndrome	EMG
	Paraneoplastic syndrome	Anti-neuronal Abs, imaging, CSF

HIV human immunodeficiency virus, *MS* multiple sclerosis, *SCDC* subacute combined degeneration of the cord, *CK* creatine kinase, *HTLV-1* human T-lymphotropic virus, *VLCFAs* very long-chain fatty acids, *CIDP* chronic inflammatory demyelinating polyneuropathy, *GBS* Guillain–Barré syndrome, *CMV* cytomegalovirus, *SPI* serum protein immunofixation, *AchR AB* acetylcholine receptor antibody, *PTH* parathormone, *anti-neuronal Abs* anti-neuronal antibodies, *CSF* cerebrospinal fluid

roles in regulation of the cell cycle, cell signaling, and the cytoskeleton.

Both *hereditary spastic paraparesis* (HSP) and *tropical spastic paraparesis* should be considered in the differential diagnosis of slowly evolving spastic paraparesis. However, the former is differentiated by a family history together with very slow progression, sphincter disturbance, and an absence of LMN, bulbar, or respiratory involvement [144]. Tropical spastic paraparesis, a chronic myelopathy associated with human T-lymphotropic virus type 1 (HTLV1), presents in the third or fourth decade with UMN signs involving the bladder and lower extremities. Human T-cell leukemia virus

type 1 (HTLV-1) is a replication-competent human retrovirus associated with two distinct types of disease only in a minority of infected individuals: the malignancy known as adult T-cell leukemia (ATL) and a chronic inflammatory central nervous system disease HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP). HTLV-2 may also cause a similar myelopathy [145]. Antibodies against HTLV1 may be detected in serum and CSF, and MRI often shows evidence of demyelination. Another virus that should be considered is human immunodeficiency virus (HIV) which may present with a vacuolar myelopathy in the setting of a low CD4 count. However, both sensory and sphincter complaints are much more prominent in HIV myelopathy than in ALS.

Anterior Horn Cell

Although most *spinal muscular atrophies* (SMAs) are disorders of childhood and youth, some crossover with the ALS population exists in the form of juvenile-onset ALS and adult-onset SMA. Overall, the SMAs usually manifest with slowly progressive, symmetrical, proximal muscle weakness and atrophy without additional UMN signs (see Chap. 21). *Kennedy's disease*, or X-linked bulbospinal neuronopathy/spinal and bulbar muscular atrophy (SBMA), is a rare X-linked trinucleotide polyglutamine disorder, caused by an abnormally large expansion of tandem CAG (cytosine–adenine–guanine) repeats in exon 1 of the androgen receptor (AR) gene on chromosome Xq11-12 (see Chap. 22). It is characterized by degeneration and loss of lower motor neurons in brainstem and spinal cord and typically presents in males in the third or fourth decade with weakness and wasting of bulbar, facial, and limb girdle muscles; tremor; perioral fasciculations; mild cognitive impairment; sensory disturbance; and signs of endocrine dysfunction such as diabetes mellitus, gynecomastia, and testicular atrophy [146]. In normal individuals, the CAG repeat ranges in size between 9 and 36, and expansion over 38 and up to 62 is pathogenic [147]. Additional useful features that help to separate Kennedy's disease from ALS include a moderately high CK and low SNAPs. To confirm the diagnosis, a genetic test that detects the CAG repeat expansion of the androgen receptor gene is available.

ALS rarely occurs in an individual with a history of poliovirus infection.

A separate anterior horn cell disorder, the *post-poliomyelitis syndrome* (PPS), is a late consequence of prior infection with poliovirus (see Chap. 19). It typically presents, after a prolonged stable course following the original paralytic illness, as worsening of weakness in previously affected muscles and ill-defined pain in the low back, neck, and many joints together with significant fatigue, dizziness, and somnolence. While many of these complaints are shared with ALS, there is a paucity of UMN signs and the rate of progression in PPS is very slow. Criteria for the diagnosis of PPS include a history of paralytic poliomyelitis, partial or complete recovery of neurological function followed by a period of stability (usually decades), persistent new muscle weakness or abnormal muscle fatigability, and exclusion of other causes. The condition is thought to occur as a result of distal degeneration and premature neuronal dysfunction of preexisting, enlarged polio-affected motor neurons. Potential contributing factors include aging (with motor neuron loss), overuse, and disuse. Although no specific treatment exists, a multidisciplinary management program can be useful in modifying symptoms [148]. West Nile arthropod-borne flavivirus infection can cause epidemics of meningitis and encephalitis. A small proportion of patients (<1 % overall but 10–50 % with neuroinvasive disease) develop a polio-like, and sometimes painful, disorder characterized by acute asymmetrical flaccid paralysis, due to viral infection of anterior horn motor neurons in the spinal cord that can precipitate respiratory failure and even death [149].

Acidic-hexosaminidase deficiency, or Hex A deficiency, a GM2 gangliosidosis that causes a recessively inherited progressive neurologic disorder, may present from childhood to the fifth decade and may resemble ALS. It is most often, but not exclusively, seen in the Ashkenazi Jewish population [150]. The enzyme has two subunits, alpha and beta, and hydrolyzes lysosomal GM2 gangliosides in neuronal membranes. Complete absence of the alpha polypeptide results in Tay–Sachs disease, which manifests in infancy with encephalopathy, myoclonic seizures, macular cherry-red spots, and death. Compound heterozygotes with less severe mutations in one of the alpha subunits resulting in a deficiency of the enzyme develop later-onset disease characterized by elements of LMN weakness, dysarthria, cerebellar ataxia, cramps, spasticity, cognitive deterioration, and tremor. EDX studies may reveal prominent complex repetitive discharges on needle EMG and abnormal SNAPs. Overall, this rare disorder should be considered in atypical cases of ALS, in particular in a young person. It can be confirmed by serum analysis of Hex A activity in leukocytes and Hex A gene mutation analysis [151].

It may be difficult to differentiate monomelic-onset ALS from benign *monomelic amyotrophy* (MMA), a condition originally reported in Japan and India, which typically presents as focal atrophy of one limb, or part thereof, predominantly affecting young men in their second and third decades. Segmental anterior horn cell involvement causes wasting and weakness of predominantly one upper or lower limb, without evidence of sensory dysfunction. Reflexes may be either reduced or normal, and fasciculations are prominent. Progression may occur for a few years with eventual stabilization [152]. Needle EMG may reveal relatively sparse

fibrillation potentials in affected muscles along with neurogenic changes in both affected and clinically uninvolved limbs. MRI may reveal focal cervical cord segmental atrophy and ventral root atrophy if performed late in the disease.

Paraneoplastic disease particularly that associated with lymphoma may present subacutely with LMN manifestations arising typically in the lower extremities, although there are rare patients that present with a combination of both UMN and LMN signs, thus bearing close resemblance to ALS. One should consider this diagnosis if a paraprotein is detected in the blood. Apart from lymphoma, a similar motor neuron disease may be the presenting manifestation of Waldenstrom's macroglobulinemia and myeloma. Paraneoplastic encephalomyelitis may present as a transverse myelopathy with motor neuron symptoms alone, resembling ALS (although sensory and autonomic features and ataxia may occur later). Associated anti-neuronal antibodies, including anti-amphiphysin, anti-Hu, anti-Ma, and anti-CRMP5, may be detected. The anti-amphiphysin presentation is usually PLS-like, but with rapid deterioration (thus unlike true PLS) and the anti-Ma, associated disorder varies but can be like PMA [137, 153]. The association of ALS with solid malignancy is somewhat unclear; one study reported a frequency of tumor in ALS patients more than twice that of controls, but patients with both ALS and cancer do not differ clinically from patients with ALS without cancer. Furthermore, with rare exceptions, ALS does not respond to tumor treatment [154–156].

Radiculopathies, Polyradiculoneuropathies, and Polyradiculopathies

Compressive radiculopathy must be considered in the differential diagnosis of any patient presenting with focal LMN signs in a limb. Foot drop may either be the first symptom of ALS or an L5 radiculopathy, and hand interosseous wasting may occur in both ALS and C8 radiculopathy. While pain and sensory loss may serve as clues to the presence of a nerve root lesion, some patients with radiculopathy present with weakness alone. EDX studies reveal changes restricted to a particular root distribution, and MRI or CT myelography reveals nerve root compromise in the clinically manifesting root distribution. *Neoplastic* (such as lymphoma, or leukemia related), *radiation-induced,* and *infectious* (viral and spirochetal) *polyradiculopathies* may superficially mimic ALS. Additional historical clues and characteristic signs such as skin or retinal changes may point to alternative diagnoses, with appropriate serology and CSF analysis required to identify the specific cause. *Diabetic polyradiculoneuropathy* is a rare condition that may present as progressive asymmetric weakness in the proximal lower extremities thus simulating PMA (see Chap. 31). In its most severe form, diabetic cachexia, multiple roots extending from the cervical to sacral areas are involved, but pain and sensory loss are typically prominent findings and EDX often reveal associated polyneuropathy.

Neuropathies and Plexopathies

Multifocal motor neuropathy with conduction block (MMNCB) is a rare disorder (see Chap. 22), characterized by onset of focal motor weakness, usually in a distal upper extremity. Those sites typically involved in entrapment neuropathies are spared and both fasciculations and cramps are common. Progression is very slow, over months or even years. An important clue to the diagnosis is the absence of muscle atrophy despite very significant weakness, until late in the disease course. The pattern of motor weakness is typically restricted to multiple separate peripheral motor nerves with a striking absence of sensory involvement. As the name implies, MMNCB is defined by demyelinating conduction block in affected motor nerves [157]. A variable percentage of patients have a high titer of serum antibodies against GM1 ganglioside, a neuronal membrane glycolipid present in high concentrations at nodes of Ranvier. However, these antibodies are not specific for MMNCB and their absence does not rule out the diagnosis.

Up to 10 % of ALS patients have a monoclonal gammopathy in the absence of any disease association, such as neoplasm or motor neuropathy with conduction block, although only about half of these patients have high titers. Of particular interest, however, is the motor neuropathy seen with *POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, and skin changes)* (see Chap. 30). This disorder can lead to a wasted appearance as seen in ALS, but may have tremor, papilledema, but no UMN features. One should perform a skeletal survey to seek out an osteosclerotic myeloma lesion, and CSF analysis may reveal elevated protein levels (often in excess of 100 mg/dl). The EDX studies are invaluable in revealing a sensory and motor polyneuropathy pattern characterized by generalized slowing of motor conduction velocities. Because of their demyelinating features on EDX, POEMS and MMNCB may closely resemble *chronic inflammatory demyelinating polyneuropathy (CIDP),* albeit with less sensory phenomena. CIDP may be difficult to distinguish clinically from ALS, although it classically features hypo-/areflexia and sensory changes and also is associated with elevated CSF protein concentrations. Yet again, performing EDX studies is essential to identify the characteristic changes of CIDP. In general, differentiating *Guillain–Barré syndrome (GBS)* from ALS poses less of a problem; there are unusual patients that lack sensory features and progress asymmetrically in a manner similar to PMA. Also, there are acute axonal variants of GBS that affect predominantly motor fibers (acute motor axonal neuropathy). However, the fast rate of progression of GBS

and reflex loss serve as diagnostic clues, and ancillary testing with EDX studies and CSF clarifies the issue.

Neuralgic amyotrophy or Parsonage–Turner syndrome, also known as brachial neuritis, may resemble limited forms of ALS such as monomelic-onset disease. This disorder, however, is classically preceded by significant deep, aching pain in the affected limb and shoulder that lasts several days and then fades away only to be replaced by motor weakness. The nerves involved are all largely motor in nature, often including one or more of the following: the long thoracic, suprascapular, axillary, anterior interosseous, and phrenic nerves. The EDX examination may reveal bilateral upper limb neurogenic changes on needle EMG, even in the presence of unilateral symptoms, but they are not as widespread as seen in ALS. In fact, involvement of motor nerve fibers can be curiously patchy, such as severe changes in infraspinatus but sparing of supraspinatus, although both muscles are innervated by the same nerve. This disorder usually improves spontaneously, but recovery can take months and there is recent evidence that early treatment with immune therapy may help speed recovery [158, 159].

Disorders of the Neuromuscular Junction

Myasthenia gravis (MG), an autoimmune disease characterized by antibodies directed against the acetylcholine receptor, may present with weakness of bulbar and neck extensor muscles without extraocular manifestations, thus mimicking bulbar-onset ALS (see Chap. 48). Patients may also present with significant respiratory compromise. Clues to the diagnosis of MG include the absence of UMN signs and fasciculations. One can confirm the diagnosis of MG by checking acetylcholine receptor antibodies and performing repetitive nerve stimulation looking for a decremental response and/or single-fiber EMG studies looking for abnormal jitter. However, in more severe patients of ALS, a decremental response may occur, albeit to a lesser extent than typical of MG. Similarly, single-fiber EMG studies may reveal increases in jitter and in fiber density in ALS just as in MG. To further blur the picture, edrophonium testing may be positive in both conditions. On the other hand, it is very rare to detect fibrillation potentials in MG, and fasciculations are not a feature of MG unless patients are overtreated with cholinergic agents. *Lambert–Eaton myasthenic syndrome* (LEMS) is an autoimmune disorder, caused by antibodies directed against voltage-gated calcium channels on the presynaptic nerve terminal (see Chap. 49). It typically presents with limb girdle weakness without atrophy or fasciculations and often with associated signs of autonomic dysfunction such as dry mouth and impotence. One of the characteristic features of LEMS is the transient increase in muscle strength and deep tendon reflexes after a brief contraction. On EDX examination, there may be generally low-amplitude CMAPs as may be seen in advanced ALS. However, EDX studies distinguish LEMS from ALS by the demonstration of post-tetanic facilitation and by the absence of fibrillation and fasciculation potentials [160].

Myopathies

Inclusion body myositis (IBM) may mimic ALS, sharing distal muscle involvement, painless asymmetric weakness, and difficulty swallowing. However, fasciculations are conspicuously absent and there are no UMN signs [161]. The CK levels are often similar in both conditions (slightly elevated or normal), but needle EMG features predominantly myopathic rather than neurogenic changes in IBM. Muscle biopsy is required to confirm the presence of rimmed vacuoles and intranuclear inclusions, the characteristic abnormalities of IBM. In addition to IBM, there are *sporadic and inherited distal myopathies* that appear between the ages of 40 and 60 years and present as weakness and wasting of distal upper and lower extremities; they may be diagnosed by EMG and muscle biopsy. Distal muscle weakness is also characteristic of *myotonic dystrophy,* but there are several clinical features such as a distinctive facial appearance, myotonia, and systemic abnormalities including cataracts, frontal balding, and diabetes mellitus, which help to lead to the correct diagnosis. Needle EMG reveals prominent myotonic discharges. Testing for the presence of an abnormally large expansion of the CTG trinucleotide on the serine–threonine protein kinase gene located on chromosome 19 confirms the diagnosis. *Oculopharyngeal muscular dystrophy*, an uncommon myopathy caused by a trinucleotide repeat expansion, may mimic progressive bulbar palsy (see Chap. 60). Indeed, as the disease advances, weakness spreads to the shoulder girdle, but the condition usually involves the eyelids and extraocular muscles, thus setting it apart from ALS and its variants. A muscle biopsy may be required to confirm the diagnosis, especially in those rare patients that present with dysphagia and subtle extraocular manifestations. Another interesting disorder, *isolated neck extensor myopathy*, presents in older individuals with dropped-head syndrome and is associated with signs of active denervation in cervical paraspinal muscles. This may be initially mistaken for ALS, but the weakness does not spread to other regions.

Systemic Disease

Hyperthyroidism may present with corticospinal tract signs, fasciculations, weight loss, and weakness, thus simulating ALS. However, there usually are additional signs such as heat intolerance, anxiety, tremor, tachycardia, insomnia, and goiter that lead to the correct diagnosis. It is prudent to include a thyroid-stimulating hormone assay in the screening

evaluation of ALS. *Hyperparathyroidism* may present with clinical weakness and even a myopathy and as such may mimic the PMA form of ALS. There may be a high level of ionized calcium, and the diagnosis is confirmed by elevated serum parathormone.

Benign fasciculations typically occur in people under the age of 30 years, and often have a relapsing–remitting course over months or years without any other abnormalities. They occur in a wide variety of disorders and are frequent in the normal population. Fatigue, stress, alcohol, caffeine, and vigorous exercise exacerbate them. Similarly, one must be able to recognize *cramp–fasciculation syndrome*, a benign condition that may be sporadic or inherited, manifests as cramps and fasciculations in the calves, and responds to carbamazepine. There are certain features on needle EMG that reportedly serve to differentiate benign from ALS-associated fasciculations. The latter tend to have a more complex waveform and may be induced by joint displacement, and benign fasciculations, as suggested by the name, are not associated with clinical and EDX features of a widespread disorder of anterior horn cells.

As already outlined, motor neuron disease may rarely occur as a paraneoplastic phenomenon. Patients present with features typical of pure ALS or manifest as PMA or PLS. Other motor neuron manifestations may represent only one part of a larger paraneoplastic syndrome, such as anti-Hu antibody–associated encephalomyelitis, presenting initially as a transverse myelopathy with motor neuron symptoms alone, resembling ALS. Atypical features (sensory and autonomic features and ataxia) may occur later on, and associated anti-neuronal antibodies, including anti-amphiphysin, anti-Hu, and anti-CRMP5, may be detected. Most paraneoplastic motor disorders are typically unresponsive to treatment of the underlying malignancy.

HIV infection may also mimic ALS clinically. A retrospective review of 1,700 cases of HIV-1-infected patients with neurological symptoms identified six cases presenting as a reversible ALS-like syndrome representing a 27-fold increased risk of developing an ALS-like disorder in that particular HIV-1 patient population [162]. Overall, patients were younger than the typical ALS population, and onset was characteristically in a monomelic pattern followed by rapid spread to other regions over a period of weeks, characterized by UMN and LMN involvement, with fasciculations, cramps, and bulbar symptoms. Two patients also had rapidly progressive dementia, suggesting an additional diagnosis of AIDS–dementia complex. Sensory and sphincter disturbances were not apparent. CSF protein levels were sometimes mildly increased, and lymphocytic pleocytosis was evident in three patients, but all remaining laboratory results (HIV-1 seropositivity apart) were negative. EDX revealed widespread anterior horn cell disorder in the absence of demyelinating conduction block, and MRI in one patient showed diffuse white-matter signal increase suggestive of AIDS–dementia complex. In each case, antiretroviral therapy was beneficial either in stabilizing or curing the disease, but subsequent cases have been described that failed to recover despite treatment [117]. Another case report found similar clinical features in a 32-year-old HIV-positive patient who responded to antiretroviral therapy, and resolution of motor symptoms coincided with a lack of detectable HIV in plasma and CSF. MRI abnormalities also resolved almost completely [163]. Flail-arm ALS-like variants have also been described in HIV, with MRI signal changes in the anterior cervical spinal cord.

Table 20.5 Prognostic indicators in ALS

Better prognosis	Worse prognosis
Younger (<50 years)	Older
Spinal onset	Bulbar onset
Progressive muscular atrophy	Dyspnea onset
Primary lateral sclerosis	Some familial forms
Flail arm	
Slow deterioration	Rapid deterioration
Normal compound muscle action potentials	"Low motor–normal sensory"
No decrement on repetitive nerve stimulation	Decrement on repetitive nerve stimulation
Mild at diagnosis	Severe at diagnosis
Long duration from onset to diagnosis	Short duration from onset to diagnosis
Well nourished	Malnourished
Psychological well-being	Psychological distress
Normal serum chloride	Low serum chloride
Fasciculations mild or absent	Fasciculations widespread
Attends multidisciplinary care	

Natural History and Prognosis

Despite the recent advances in understanding the natural history of ALS, it remains difficult to accurately predict the course and prognosis in individual patients (Table 20.5) [16]. Up to 30 % of anterior horn cells may be lost by the time a patient with ALS actually presents with weakness, which suggests that ALS may be subclinical for months or even years before symptom onset. During this preclinical stage, the rate of denervation may be balanced by the rate of collateral reinnervation, but the rate of denervation eventually supercedes. Original thinking was that the pattern of decline was linear from onset (Fig. 20.7) [6, 16], but recent work has shown that deterioration in ALS is nonlinear: the early and late phases of the illness show the most rapid rates of decline. Older age and bulbar signs are associated with a steeper decline and, along with more rapid initial rate of decline, predict survival [164]. When onset is in one arm, the progression of disease is typically to the contralateral arm, then the ipsilateral leg,

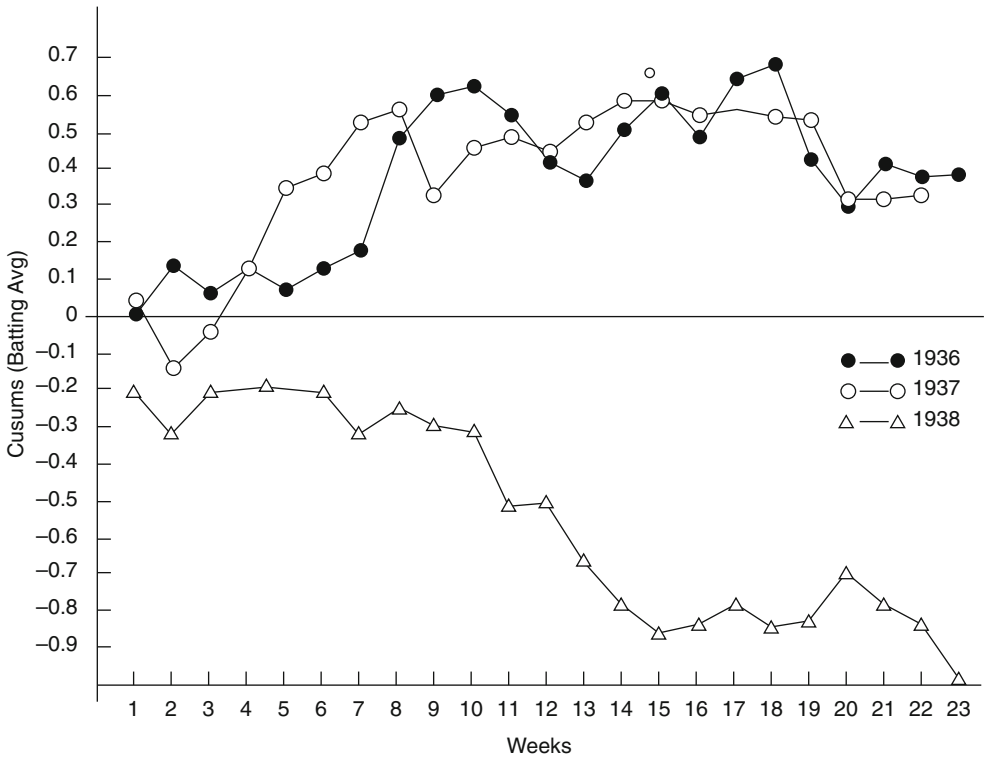

Fig. 20.7 Decline in function over time in amyotrophic lateral sclerosis as depicted by this graph representing cumulative sum (CUSUM) statistical analysis of Lou Gehrig's batting average on a weekly basis from 1936 to 1938. Note the linear decline in function in 1938 (Reproduced with kind permission from Kasarskis and Winslow [6]) (Note: a recent study suggests that progression is nonlinear. Gordon et al. [164])

contralateral leg, and, finally, the bulbar region. With lower extremity onset, a similar pattern of progression follows, the bulbar region being affected last. Bulbar-onset ALS progresses first to the arms and then to the legs [17, 165]. Mean duration of the illness from symptom onset to death is approximately 3 years (mean duration ranges from 23 to 43 months). Roughly 20 % of patients live 5 years and 10 % of patients follow a more benign course, surviving for more than a decade [16].

When one analyzes the cumulative data from several different studies using mean survival times, it is evident that PLS harbors the best prognosis of all types of ALS, with a mean survival time of 224 months in one study and 168 (14 years) in another [17, 166, 167]. By definition, PMA indicates a disorder limited to lower motor neurons for more than 4 years and thus harboring a relatively good prognosis with one series of patients living a mean of 159 months from clinical onset [17, 72]. There are conflicting data on the prognosis of bulbar-onset ALS; while it is often associated with a shorter survival (disease duration has been reported to be between 12 and 27 months), it is argued that one must factor in the generally older age and many patients may be referred to inappropriate clinics prior to diagnosis. A recent study showed that the time to anarthria predicted loss of ambulation which in turn predicted a further 3-month survival [18]. The many forms of familial ALS do not portend a uniform prognosis: it is important to try to identify the causative mutation to allow more accurate prognostication. Both the flail-leg (pseudoneuritic) and flail-arm presentations are associated with longer survival [75].

When dyspnea is the presenting feature of ALS, there is a statistically significant shortening of disease duration. Moreover, a decline in pulmonary function, as tested by serial forced vital capacities, is a strong predictor of a poor prognosis [16, 40]. The severity and duration of disease at presentation also have prognostic implications, with more severe disease portending a worse prognosis and a long interval between onset and diagnosis being more favorable [16]. The ALS CNTF Treatment Study Group identified low serum chloride as a poor prognostic indicator, reflective of a compensatory metabolic response to respiratory acidosis that occurs in the later stages of the disease [168]. The role of psychological well-being on survival has also been investigated with indicators that psychological distress significantly predicts a less favorable prognosis [16]. A "generalized low motor–normal sensory" pattern seen on nerve conduction studies, a decremental response on repetitive nerve stimulation, and a rapid rate of decline of MUNE (motor unit number estimation) are all associated with poorer prognosis. There is limited evidence to support the lack of fasciculations as being prognostically favorable. Malnutrition with low body mass index is an independent risk factor for poor outcome [169].

Treatment and Clinical Trials

The past two decades have yielded theories of ALS pathogenesis each with potential for translation into future therapeutics. Interventions to counter nuclear protein

mislocalization may show promise as may agents involved in cell trafficking/signaling, inflammatory responses, excitotoxicity, and mitochondrial regulation. Clinical trials in ALS have examined a broad spectrum of drugs for their potential anti-glutamatergic activity (e.g., talampanel, lamotrigine, branched-chain amino acids, topiramate, dextromethorphan, and gabapentin) and neuroprotective and/or antioxidant effect (vitamin E, L-deprenyl, *N*-acetylcysteine, xaliproden Sanofi SR57746A), most with negative results. In addition, several recombinant neurotrophic factors (including ciliary neurotrophic factor, brain-derived neurotrophic factor, insulin-like growth factor (IGF-1, myotropin), and glial cell–derived neurotrophic factor) have been studied in well-designed trials, but without significant clinical efficacy. A phase III trial of IGF-1 polypeptide is underway. Other agents, ultimately non-efficacious in ALS, include creatine, coenzyme Q10, minocycline, rapamycin, ceftriaxone, celecoxib, glatiramer acetate, tamoxifen, minocycline, TCH346, ONO 2506 PO, and lithium. Further details regarding ongoing trials are available at www.wfnals.org.

Despite high cost and modest efficacy, riluzole, with a modest effect on prolonging life in ALS patients, remains the only approved agent (Fig. 20.8) [172]. Its mechanism of action is not completely clear, but may include modification of N-methyl-D-aspartate (NMDA) receptor-mediated responses, stabilization of the inactivated state of voltage-dependent sodium channels, and inhibition of glutamate release from presynaptic terminals while increasing extracellular glutamate uptake. When taken for 18 months (in patients with clinically probable or definite El Escorial ALS, with symptoms less than 5 years, FVC >60 % and age <75 years), 100 mg (taken as 50 mg twice daily) probably prolongs median survival by 2–3 months [173]. Preliminary developments in areas of stem cell therapies, RNA interference, viral vector-mediated gene therapy, and immunotherapy offer promise of novel therapeutic strategies. Based on the likely role of mitochondrial dysfunction in ALS pathogenesis, dexpramipexole, the putative mitochondrial modulator (KNS-760704) has undergone preliminary trials (http://clinicaltrials.gov), which suggest safety and tolerability and possible attenuation of ALS functional rating scale decline, thus supporting further testing [174].

Although it is difficult, care must be taken to break the diagnosis of ALS in such a way that the patient and the family understand the diagnosis and its implications but do not feel that hope has been taken away. Thus, one should provide sufficient information regarding the disease itself, including treatment trials and research progress.

It is vitally important to maintain patient autonomy in all decision-making processes and, at the appropriate time, to adequately discuss difficult topics, such as advance directives and issues regarding terminal care. Those patients with more recent diagnoses and with more rapid declines in pulmonary function are more likely to seek interventions such

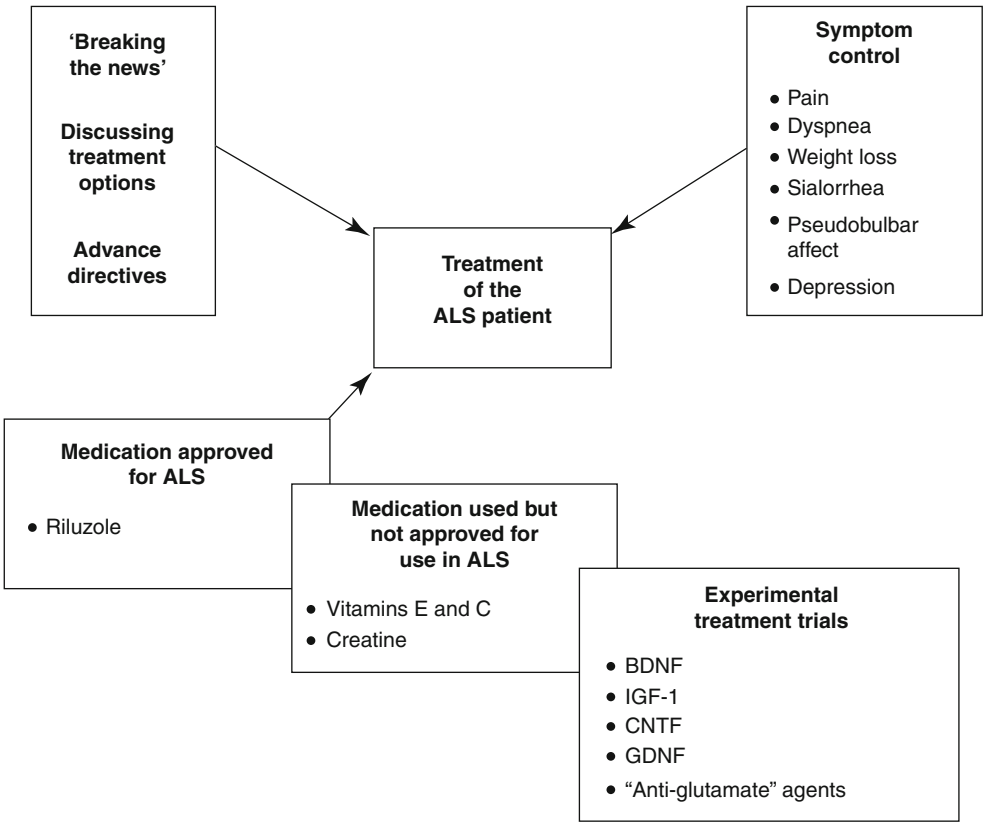

Fig. 20.8 Simplified algorithm for the treatment of amyotrophic lateral sclerosis (For a more detailed discussion, see Refs. [170, 171])

as ventilatory assistance and enteral feeding tubes. Overall, it is best to impart information, particularly that pertaining to prognosis, in a stepwise manner and not to overwhelm the patient as soon as the diagnosis is made. There is no specific treatment currently available that halts or reverses the disease, but there are several paths to optimally manage the many distressing symptoms of ALS. The recommendations for the symptom management of ALS are clearly defined in the practice parameter report by the Quality Standards Subcommittee of the American Academy of Neurology [170, 171].

Symptom Management

Sialorrhea, Pseudobulbar Affect and Depression

Daytime sialorrhea may be treated with anticholinergic preparations such as benztropine, transdermal hyoscine, glycopyrrolate, trihexyphenidyl, and atropine or, as is more commonly practiced, by utilizing the anticholinergic properties of the tricyclic antidepressants (TCADs). In order to reduce thick mucus, adding a beta-blocker, such as propranolol, may be helpful. Mechanical insufflation–exsufflation further enhances clearance of mucous plugs. Alternative approaches include injection of botulinum toxin A into the parotid glands which, by blocking autonomic cholinergic fibers subserving secretomotor function, may lead to a substantial reduction in saliva production and parotid irradiation [175, 176].

Pseudobulbar affect may be effectively controlled with tricyclic antidepressant (TCAD) treatment although one may also use a selective serotonin reuptake inhibitor (SSRI), such as fluvoxamine or quinidine/dextromethorphan. Depression, with or without anxiety, may be treated with a variety of antidepressant preparations such as the TCADs and SSRIs, whereas isolated anxiety may be responsive to benzodiazepines or buspirone. Patients may have pseudobulbar, depressive, and sialorrheic symptoms simultaneously, and it is often possible to treat all complaints with one medication.

Nutrition

Attention must be paid to the nutritional needs of the patient. Particularly with advancing dysphagia, assessment of swallow at the earliest possible stage is advised, in order to devise strategies to maximize caloric intake, prevent dehydration, and reduce aspiration risk. Initial management should focus on appropriate forward head positioning, chin tuck, thickening of liquids, and dietary supplementation. As dysphagia worsens and the patient loses more weight, the physician should recommend a percutaneous endoscopic gastrostomy (PEG), a procedure that may help maintain weight [171], enhance patient quality of life, and also prolong survival by 1–4 months. To minimize risks, evidence suggests that PEG should be performed before vital capacity (VC) falls below 50 % of predicted [177]. Although it may be possible to insert PEG with noninvasive ventilator (NIV) assistance, radiologically inserted gastrostomy (RIG) or percutaneous radiological gastrostomy (PRG) may be a safer alternative in some patients [178]. Importantly, patients who receive a PEG or RIG tube can continue to eat by mouth: the purpose of enteral feeding is to provide calories and fluid. Aspiration is a continued risk to the patient even after PEG tube insertion, and if recurrent aspiration of PEG contents becomes a persistent problem, one can either recommend percutaneous enteral jejunostomy (PEJ), which further reduces (but still does not eliminate) the risk, or a tracheostomy. In aphonic patients with recurrent aspiration, one could also consider conservative laryngectomy or laryngeal diversion. Most guidelines state that supplementary enteral feeding should be considered when body weight falls by > 10 % of the pre-diagnostic or baseline weight [179].

Pain, Spasticity, and Muscle Cramps

Pain, commonly from pericapsulitis, bursitis, cramps, or spasticity, may pose a significant problem in advanced stages of ALS, and the physician must be aggressive in controlling such discomfort. This should start with physical therapy, using passive joint-stretching techniques, followed by treatment with nonsteroidal anti-inflammatory drugs (NSAIDS). Various heating agents, including diathermy and ultrasound, are useful in pain management and in performance of range-of-motion exercises. In addition, transcutaneous electrical nerve stimulation (TENS) is often effective in relieving joint and connective tissue–related pain. Lancinating pains may be responsive to carbamazepine, phenytoin, clonazepam, and amitriptyline, but if pain remains poorly controlled, the physician should not be hesitant to use opioids and, particularly in the preterminal stages, morphine or a fentanyl patch. Several agents, such as baclofen, tizanidine, benzodiazepines, and dantrolene either alone or in combination, may be effective in managing spasticity although patients may experience additional weakness as a troublesome side effect. When cramps are severe, one may employ muscle-stretching exercises in combination with quinine sulfate, baclofen, carbamazepine, diazepam, or phenytoin. In the preterminal phase of ALS, the patient may suffer considerably from distressing dyspnea which can be managed using benzodiazepines, opiates, supplemental oxygen, and, for terminal restlessness, chlorpromazine.

Mobility and Assist Devices

With advancing disease, it is important to continually make adjustments so as to maximize patient function and independence. A number of adaptive devices are available to assist in this regard, including AFO braces for foot drop, specialized neck-support collars for head drop, and various hand/wrist

splints. Increasingly sophisticated communication assist devices are becoming available to aid anarthric patients. Likewise, there are many kinds of wheelchairs, including motorized models that may be customized for each patient's needs. Home assessments by nurses, occupational therapists, and physical therapists are of great benefit when choosing the optimal equipment. Apart from assist devices, it is important that the patient initiates an appropriate program of therapeutic exercise with particular focus on range-of-motion stretching maneuvers. There is some concern that excessive exercise to the point of fatigue may be deleterious and may even be an underlying precipitant of the disease itself, although this has not been borne out in the literature.

Respiratory Function

Dyspnea-onset ALS and a progressive decline in pulmonary function portend a poorer prognosis, but visible signs of early pulmonary compromise may go unnoticed until an adverse event, such as aspiration pneumonia, occurs. Measuring the FVC at regular intervals serially assesses declining pulmonary function and assists the patient and the physician in appropriately projecting ahead. Whether or not the patient wishes for mechanical ventilation should be planned as early as possible. Most patients and physicians prefer the noninvasive approach.

Erect forced vital capacity (FVC) is the most commonly measured index of pulmonary function in ALS, but supine FVC provides a more accurate assessment of diaphragmatic weakness. To detect nocturnal hypoventilation, maximal inspiratory pressure (MIP) and nocturnal oximetry may be more effective. Trans-diaphragmatic sniff pressure (sniff Pdi) and the Sniff nasal inspiratory pressure (SNIP) are also useful indicators of hypercapnia and nocturnal hypoxemia [171]. SNIP is a good measure of diaphragmatic strength and is probably more accurate than vital capacity, although both measurements underestimate respiratory function in patients with bulbar impairment. A SNIP of 32 % (~25 cm H2O) or less is highly predictive of respiratory failure [180–183]. Observational studies and a randomized controlled trial show that NIV improves survival and quality of life. In patients with severe bulbar impairment, NIV improves sleep-related symptoms, but is unlikely to confer a large survival advantage [184]. Sociocultural factors (age, gender, marital status) influence the probability of receiving NIV, and these obstacles should be addressed to encourage NIV use in all ALS patients with respiratory failure [185].

Although evidence exists that NIV improves quality of life and may prolong survival in ALS, it does not prolong life indefinitely, and patients still face the difficult decision of whether to use an invasive ventilator. While invasive ventilation may prolong a patient's life for many years, the patient may develop additional "atypical" signs of disease such as overt cognitive decline, extraocular muscle palsies, and sphincter disturbance, which may later place a great burden upon patient and family. When initiating ventilatory therapy, there should be an agreement as to when, or if, it should be withdrawn. Decisions regarding withdrawal of ventilatory support, or augmentation when noninvasive means of ventilatory assistance are insufficient, must be based on effective and compassionate end-of-life care. In the event of initiating ventilatory withdrawal, sufficient opiates and anxiolytics should be used to minimize patient discomfort.

Because ALS is a progressive neurodegenerative disease with a predictable clinical course, palliative care should be initiated at, or soon after, diagnosis. The majority of skeletal muscles are eventually affected, and multiple ensuing problems require multidisciplinary input, including symptomatic therapy, rehabilitation to maintain muscle function, nutritional and respiratory support, communication device introduction, and psychological support for both patient and family or caregivers. Social, ethical, financial, and legal issues, including advance directives, should be addressed long before decisions regarding enteral feeding and assistive ventilation are required. Management goals must be reassessed regularly [186]. Hospice care, at home or in a residential hospice, provides highly effective palliative services to patients and families. Its philosophy strongly affirms life, promoting maintenance of independence and dignity as much as possible [187].

Spinal Muscular Atrophies

21

Bakri H. Elsheikh and John T. Kissel

Introduction

The spinal muscular atrophies (SMAs) are a heterogeneous group of disorders affecting the lower motor neurons leading to muscle weakness and atrophy. Though the term SMA has traditionally been applied to both inherited and acquired disorders, its use should be restricted to disorders related to a genetic defect. Classification of the different forms of genetic SMA is by the mode of inheritance and the clinical phenotype (i.e., whether the predominant weakness is proximal or distal) (Tables 21.1 and 21.2). Several different causative genes have been identified for various types of SMA, but by far the most common is related to the survival motor neuron (SMN) gene on chromosome 5q11.12–13.3. This is an autosomal recessive disorder that usually presents in infancy or early childhood and is associated with predominantly proximal muscle weakness and atrophy.

The initial clinical description of childhood SMN-related SMA was made over a century ago by Werdnig and Hoffmann [1, 2]. Werdnig reported two patients with early infantile hereditary progressive muscular atrophy presenting as a dystrophy but on a neurogenic basis. Hoffman first coined the term spinal muscular atrophy [3]. Autopsy of their cases revealed atrophy of the ventral roots and loss of motor neurons in the anterior horn [1, 2]. Subsequently, others described later-onset patients of variable severity, including an adult-onset form of the disease [4–7]. Dubowitz highlighted the relationship between disease severity and age of onset [6]. Several attempts to classify the common autosomal recessive proximal SMAs were made [8, 9], culminating in the adoption of a widely used consensus classification by an International SMA Consortium based on the age of symptom onset and maximal motor milestone achieved [10]. This scheme embraced the wide spectrum of childhood SMA phenotypes that ranged from infants with severe disease and early death to children and adolescents with milder weakness and a normal life span (SMA types 1–3). Subsequent modifications to this scheme recognized a type 4 with adult onset (and generally mild weakness) and a type 0 which is present at birth and associated with very early death (Table 21.3).

Table 21.1 Classification of the proximal spinal muscular atrophies

Autosomal recessive	*Locus*	*Gene*
SMA 1–4	5q	Survival motor neuron (SMN1)
Congenital with arthrogryposis	5q	Survival motor neuron (SMN1)
Congenital axonal neuropathy	5q	Survival motor neuron (SMN1)
SMA with pontocerebellar hypoplasia	14q32.2	Vaccinia-related kinase 1 (VRK1)
SMA with congenital fractures	Unknown	Unknown
Autosomal dominant	*Locus*	*Gene*
Adult proximal SMA (Finkel type)	20q13.22	Vesicle-associated membrane protein-associated protein B (VABP)
Benign congenital with contractures	Unknown	Unknown
SMA with lower extremity predominance	14q32	Unknown
Scapuloperoneal syndromes	12q24	Vanilloid transient receptor protein (TRPV4)
X-linked	*Locus*	*Gene*
Bulbospinal muscular atrophy (Kennedy's)	Xq12	Androgen receptor gene
Infantile SMA with arthrogryposis	Xp11.3	Ubiquitin-activating enzyme1 (UBE1)

Table 21.2 Classification of the distal spinal muscular atrophies (non-SMN variants)

Autosomal dominant	*Locus*	*Gene*	*Onset*	*Clinical features*
Distal SMA 1	Unknown	Unknown	Juvenile	Symmetric distal leg weakness and atrophy, slow progression, pes cavus, hammer toes
Distal SMA 2a	12q24	HSPB8/heat shock protein 22	Age 14–35	Early extensor hallucis longus involvement, complete paralysis of distal leg muscles, and some thigh weakness after 10 years. Young adults with rapid progression
Distal SMA 2b	7q11	HSPB1/heat shock protein 27	Age 21–54	Early distal leg involvement with progression to the arm and proximal leg in 5–10 years
Distal SMA 2c	5q 11	HSPB3/heat shock protein	Mid 20s	Distal leg, slow progression
Distal SMA 5a	7p14	GARS	Age 5–20	Weakness and atrophy of the hands, occasional upper motor neuron findings, very slow progression
Distal SMA 5b	11q12	BSCL2	Age 2–40	Hand amyotrophy and spastic paraparesis (Silver syndrome)
Distal SMA 7a	2q14	Unknown	First to second decade	Early vocal cord paralysis, hand weakness and atrophy, legs later
Distal SMA 7b	2q13	DCTN1	Early adulthood	Early VC paralysis causing breathing difficulty, face and distal limb weakness and atrophy, hands (thenar predilection) > legs
Distal SMA with UMN signs	9q34	SETX6	Juvenile	Distal leg atrophy and weakness, later arm Variable upper motor neuron findings
Autosomal recessive	*Locus*	*Gene*	*Onset*	*Clinical features*
Distal SMA 6 (SMARD1)	11q13	IGHMBP2	Infant	Severe diaphragmatic paralysis, cardiomyopathy, and lactic acidosis
Distal SMA 3	11q13	Unknown	Juvenile	Slow progression
SMA (Jerash type)	9p21.1–p12	Unknown	Age 6–10	Weakness and atrophy of the legs associated with pyramidal features, arms involvement 2 years after onset
Distal SMA 4	P36	PLEKHG5	Juvenile	Severe diaphragmatic and distal limb weakness
Distal SMA 2b	7q11	HSPB1/heat shock protein 27	Age 21–54	Early distal leg involvement. In 5–10 years, arm and proximal leg

GARS glycyl tRNA synthetase, *BSCL2* Berardinelli-Seip congenital lipodystrophy 2, *DCTN1* dynactin, *SETX6* sentaxin, *IGHMBP2* immunoglobulin mu-binding protein 2, *PLEKHG5* pleckstrin homology domain-containing, family G, *UMN* upper motor neuron

Table 21.3 Classification of SMN-related spinal muscular atrophy [10]

Type	Eponyms	Onset	Course	SMN2 copy number
0	–	Prenatal	–	1
1	Werdnig-Hoffman disease	0–6 months	Never sits independently Life expectancy <2 years	2
2	Intermediate form; chronic Werdnig-Hoffman disease	<18 months	Able to sit independently but not walk. Life expectancy into third or fourth decade	3 or 4
3a	Kugelberg-Welander disease	<3 years	Able to walk. Normal life expectancy	3 or 4
3b	Kugelberg-Welander disease	>3	Able to walk. Normal life expectancy	4
4	Adult SMA	>20 years	Able to walk. Normal life expectancy	4–8

The understanding of the molecular genetics of SMA began in 1990 with the linkage of the disease to the long arm of chromosome 5 [11]. Five years later, the causative gene was identified as the *survival motor neuron* (*SMN*) *gene* [12]. Since that time, major advances in the field have provided significant insights into the molecular pathogenesis of SMA and better understanding of the disease severity and phenotypic variability. These discoveries have also led to identification of possible therapeutic targets and resulted in acceleration of research to explore multiple potential therapeutic strategies [13].

Epidemiology

SMA is the second most common autosomal recessive disorder after cystic fibrosis and is the leading genetic cause of infant mortality. The incidence is estimated to be 1 in 6,000–10,000 live births leading to approximately 600 new cases of SMA per year in the USA [14–17]. The carrier frequency is approximately 1 in 40 with about six to seven million carriers in the USA. There is unexplained slight male preponderance [18, 19]. Because of the high rate of mortality for type 1 disease, the relative frequency of the

different types is somewhat difficult to state precisely, with prevalence figures understating the frequency of SMA 1. Overall figures suggest that the relative prevalence of the disease is that approximately 45 % of cases are type 1, 23 % are type 2, 30 % type 3 (16 % 3a and 14 % 3), and only 2 % type 4.

Clinical Manifestations

SMN-Related Spinal Muscular Atrophy

SMA Type 1

Type 1 SMA presents in the first 6 months of life; mothers often describe decreased fetal movement during pregnancy in the third trimester. Infants usually present with profound hypotonia, impaired head control, weak cry, poor feeding, severe diffuse weakness affecting predominantly the proximal muscles, and respiratory distress (Fig. 21.1) [20]. By definition, affected patients are never able to sit independently [10]. Because of absent or minimal facial involvement, patients appear surprisingly alert for their degree of weakness [21]. The patients do not exhibit signs of extraocular muscle or cerebral involvement, and children with SMA typically have a normal IQ. In fact, older children with SMA as a group have a higher verbal IQs compared to controls, possibly because the development of cognitive skills may be compensatory for their physical restrictions [22]. Other findings include tongue atrophy and fasciculations, which are observed in 50 % of cases [5, 21]. Patients also assume a "frog-leg" appearance with externally rotated and abducted thighs with flexed knees (Fig. 21.2). Deep tendon reflexes are absent. Paradoxical breathing with flattening of the upper chest and flaring of the lower chest with abdominal protrusion during inspiration (bell-shaped chest) is noted because of weakness of the intercostals with relative sparing of the diaphragmatic muscles (Fig. 21.3). In addition to dysphagia, constipation is common [21, 23]. Mild contractures at the knees and rarely the elbows may occur late in the course, but severe early contractures should suggest another diagnosis. There are rare reports of various cardiac abnormalities and digital vascular necrosis and thrombosis in severe SMA [24, 25].

Historically, children with SMA 1 usually die in the first 2 years of life from respiratory complications [26–28]. However, survival has increased in recent years due to advances in proactive pulmonary, nutritional, and supportive care [29, 30]. A modification of this basic phenotype is seen with so-called type 0 disease. These babies have a more severe phenotype with a prenatal onset of symptoms, a requirement of respiratory support, and early death by the age of 1 month.

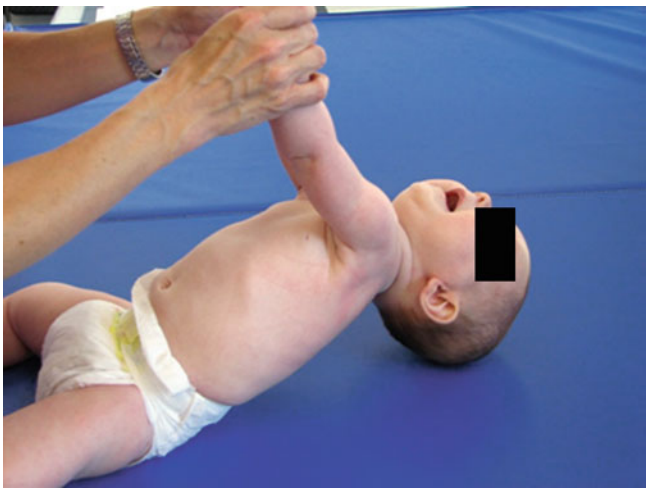

Fig. 21.1 Eight-month-old infant with SMA 1 being pulled to a sit. There is marked proximal weakness and head lag

Fig. 21.2 Eighteen-month-old with SMA 1 showing classic "frog-leg position" with externally rotated and abducted thighs and knee flexion

Fig. 21.3 Eighteen-month-old with SMA 1 showing paradoxical breathing and "bell-shaped" chest with inspiration. Note the slight flaring of the lower rib cage with retraction of the upper chest and protrusion of the abdomen

SMA Type 2

These patients usually present between the ages of 6 and 18 months with decreased tone and delayed motor milestones, but eventually they are able to sit unsupported. In one study, 73 % of 175 patients with SMA 2 achieved the ability to sit within a normal age range (i.e., up to 9 months); the remaining 27 % sat by age 10–30 months [31]. The strongest patients in this category sometimes are able to stand using a long leg brace or standing frame, but they are never able to walk independently (Fig. 21.4). Weakness is invariably more severe in the legs. The facial and extraocular muscles are spared. Tongue atrophy and fasciculations are often noted. The majority (~70 %) will have no deep tendon reflexes, although retained reflexes can be seen in stronger muscle groups. Patients have normal sensation. Patients sometimes develop a fine tremor of the fingers referred to as minipolymyoclonus [32]. Dysphagia and restrictive lung disease can occur, but respiratory compromise is proportional to the degree of weakness and thus less common and severe than in SMA 1 [33–35]. In type 2 patients, however, other factors often contribute to further compromise in pulmonary status, including scoliosis, recurrent aspiration, and infections as well as sleep-disordered breathing [36, 37]. Joint contractures (Fig. 21.5), kyphosis, and scoliosis worsen overtime. Osteopenia and a tendency to be overweight are also common in this population [38, 39]. Usually, there is an accelerated phase of strength decline followed by long plateau period [40].

SMA Type 3

This is a relatively mild form of the disease with onset after age 18 months. Two subtypes have been identified on clinical grounds basis, SMA 3a and SMA 3b, with the latter presenting after 3 years of age and generally having milder disease. By definition, **a**ll patients achieve the ability to stand and walk; in 10 %, this is delayed until after 18 months of age [29, 31]. Patients usually present with recurrent falls and difficulty arising from the floor or going up steps. The weakness is predominately proximal with legs more involved than the arms. A peculiar feature of some SMA 3 patients is their retained ability to ambulate despite severe weakness. This might be related to the segmental distribution of weakness allowing for compensatory mechanisms [41]. Patients have a waddling gait and protuberant abdomen related to weakness of the hip abductors and abdominal muscles, respectively. This group also shares with other SMA types minimal to absent facial involvement, normal extraocular muscle movement, normal sensation, decreased to absent deep tendon reflexes, and minipolymyoclonus [32]. Fasciculations in limb muscles can be seen. Calf hypertrophy is noted in some patients, leading to a mistaken diagnostic impression of Duchenne or other type of muscular dystrophy [42, 43]. Pulmonary function is often normal in this group, but restrictive lung disease and sleep-disordered breathing are noted in those with more severe weakness.

Fig. 21.4 Thirty-month-old girl with SMA 2. She could sit unassisted but could stand only with the aid of the parapodium

Fig. 21.5 Supine view of 6-year-old boy with SMA 2. There are obvious contractures at the hips and knees, as well as less obvious ankle contractures

Although SMA 3 is a progressive disease, the disorder is similar to SMA 2 in that there are periods of disease

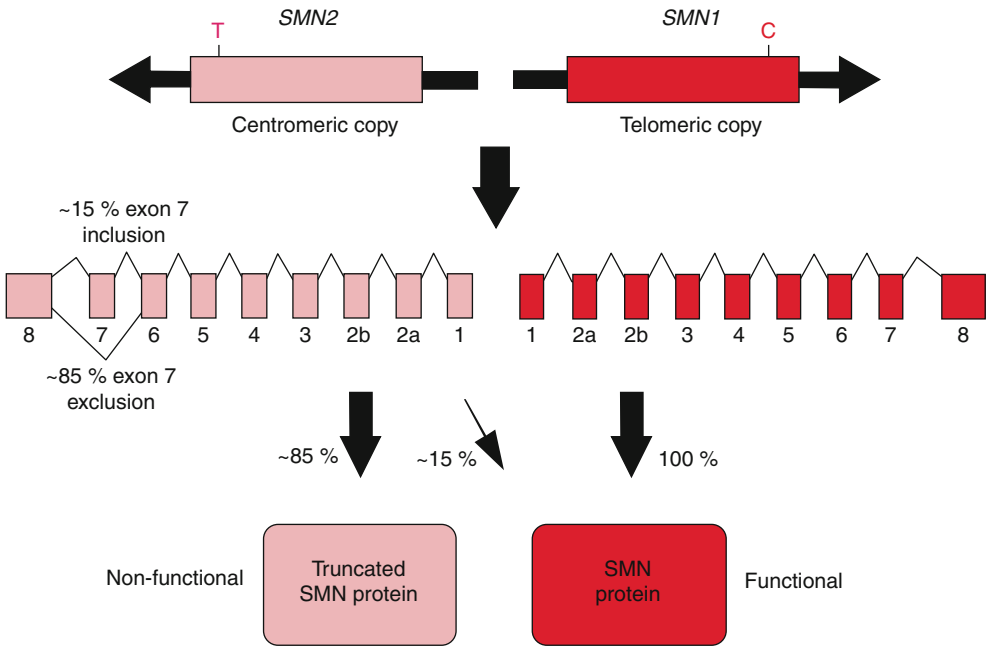

Fig. 21.6 Schematic diagram of the human SMN genes and the resultant pre-messenger RNAs transcribed from these genes. Patients with SMA have deletions or mutations in both SMN1 genes. SMN2 gene is expressed in these patients, although most of this SMN2 lacks exon 7 because of a C-to-T transition at position 6 of exon 7. The truncated SMN protein is unstable, nonfunctional, and rapidly degraded. A proportion of full-length messenger RNA containing exon 7 is produced by the SMN2, however, resulting in full-length and functional SMN protein (Reproduced with permission from Kolb and Kissel [13])

progression followed by long plateau periods that may last for years [40]. The distinction between types 3a and 3b is clinically significant in this regard in terms of prognosis. In one study, for example, 58 % of SMA 3b patients were ambulatory at the age of 40 compared to only 22 % of 3a patients [27].

SMA Type 4

Patients with type 4 disease present with the insidious onset of muscle weakness in adult life, with a mean age of onset in the 30s [44]. The majority of adult-onset SMA represents autosomal recessive disease although some non-SMN-related cases are inherited as autosomal dominants [45, 46]. The pattern of weakness is similar to that of limb girdle muscular dystrophy, and patients usually present with difficulty getting up from the floor, rising from a chair or going up steps with or without rail assistance. Fasciculations in the limb muscles are common and sometimes lead to a mistaken diagnosis of amyotrophic lateral sclerosis. Pulmonary involvement, dysphagia, and scoliosis are rare. Patients with SMA 4 tend to remain ambulatory.

Pathogenesis and Pathology

SMN-related SMA results from a genetic defect on chromosome 5; other types of SMA and most of the variants are linked to other chromosomes (Tables 21.1 and 21.2) [11, 47]. The survival motor neuron (*SMN*) gene exists in two almost identical forms: a telomeric (*SMN1*) and centromeric (*SMN2*). The *SMN2* gene differs from *SMN1* by a single cytosine to thymidine substitution in exon 7 that results in its exclusion during transcription, due to either disruption of an exonic splice enhancer or creation of an exonic splice silencer (Fig. 21.6). *SMN1* produces predominately a full-length transcript, whereas *SMN2* produces an alternatively transcribed product lacking exon 7, which results in low-level production of a rapidly degraded, unstable protein. Due to alternative splicing, however, about 10–15 % of the protein produced by the *SMN2* gene is full length [13].

SMN1 is homozygously deleted in 95 % of all SMA 1, 2, and 3 patients and in approximately 70 % of SMA type 4 patients [12, 45]. Most of the other 5 % are compound heterozygotes involving an *SMN1* deletion on one chromosome and an *SMN1* intragenic mutations (either a missense or frameshift mutation) on the other chromosome. There is no known clinical sequel for *SMN2* mutations, and the *SMN2* gene is actually absent in 10–15 % of the normal population. In the setting of homozygous *SMN1* deletion that occurs in SMA, the presence of one or more copies *of SMN2* is necessary for survival and is the major determinant of the phenotype. Thus, the number of SMN2 copies is inversely related to the disease severity and correlates with SMA type [48–53]; SMA type 0 typically has one SMN2 copy, SMA 1 has two copies, SMAs 2 and 3a have three to four copies, SMA 3b has four copies, and SMA 4 has four to eight copies (Table 21.3).

Although SMN2 copy number is clearly the most important determinant of severity, other modifiers have been identified. A second gene, the neuronal apoptosis inhibitory protein (*NAIP*), was initially felt to be a modifier gene, but subsequent studies did not confirm this [54]. More recently, several patients have been identified with a second

c.859 G > C mutation in exon 7 that resulted in a marked increase in full-length SMN protein production and a milder phenotype in three adults with SMA type 3b reported who had only two copies of *SMN2* [55, 56]. Another gene mutation, *plastin 3*, was also found to be a possible protective modifier of SMA in females [57–59].

The function of the SMN gene and thus the pathogenesis of SMA are not yet fully understood. The SMN protein is found as part of a multi-protein complex, the SMN complex. It is present in the cytoplasm and in the nucleus; in the latter it is present in structures called "gems" [60, 61]. The most accepted function of SMN protein is that it plays a key role in spliceosomal small nuclear ribonucleoprotein (sNRP) assembly. The deficiency of the ubiquitously expressed SMN protein results in motor neuron degeneration [62, 63]. The reason behind the selective vulnerability of the motor neuron remains to be fully elucidated, as does a possible role for SMN protein at the neuromuscular junction and other sites in the motor unit. The emerging theory hypothesizes downstream deleterious impact of defective RNA processing on motor neurons' development, survival, or both [64]. Of note lately there is emerging evidence of possible involvement of other organ systems in SMA [24, 25].

Differential Diagnosis

The differential diagnosis for SMA 1 includes all other causes for a floppy and hypotonic infant (see also Chap. 77) [65]. The most frequent causes of a hypotonic infant are central involving the cerebral hemisphere, basal ganglia, brain stem, or cerebellum. Clues to such diagnoses are altered level of consciousness, seizures, and persistence of infantile reflexes such as continued presence of Moro, tonic neck, or grasp reflexes after 6 months of age. Spinal cord injuries are suspected in the setting of traumatic birth, breech presentation, or bowel and bladder dysfunction.

Peripheral causes of neonatal hypotonia like the congenital myopathies (e.g., nemaline myopathy, central core myopathy, myotubular myopathy, multicore disease, and congenital fiber-type disproportion) should be considered when facial and extraocular muscle weakness are prominent or dysmorphic features, ptosis, and high arch palate are present. Congenital myotonic dystrophy and other congenital dystrophies are associated with mental retardation, seizures, and facial and extraocular muscle weakness. Examination of the mother can provide clues to the diagnosis of congenital myotonic dystrophy. Similarly, an established diagnosis of myasthenia gravis in the mother provides a clue to the diagnosis of transient neonatal myasthenia. Congenital myasthenic syndromes and infantile botulism cause floppiness as well. Ptosis and extraocular muscle weakness are common to both, whereas constipation and dilated unreactive pupils suggest botulism. Metabolic myopathies such as Pompe's disease cause hypotonia with clues such as hepatomeglay, macroglossia, and cardiomyopathy.

Chromosomal disorders, such as Prader-Willi syndrome, result in hypotonia, mental retardation, obesity, short stature, and hypopigmentation. Peroxisomal disorders such as Zellweger's disease, neonatal adrenoleukodystrophy, and infantile Refsum's disease are associated with dysmorphic features, mental retardation, retinopathy, and hearing deficits.

The differential diagnosis for proximal weakness in older children and adolescents (i.e., SMAs 2 and 3) includes congenital and metabolic myopathies, dystrophinopathies, limb girdle dystrophy, and inflammatory myopathies. Electrodiagnostic studies and muscle biopsy help distinguish this group. Similarly, myasthenia gravis is distinguished based on additional features such as ptosis and extraocular muscle weakness as well as serology and electrodiagnostic studies. Immune-mediated peripheral neuropathies, Guillain-Barre syndrome and childhood chronic inflammatory demyelinating polyradiculoneuropathy, characterized by proximal predominant weakness and areflexia are distinguished from SMA by the prominent demyelinating features on the electrodiagnostic studies and the high CSF protein. Other motor neuron processes such as hexosaminidase A deficiency can resemble SMA; however, cognitive decline, developmental regression, personality change, ataxia, spasticity, and seizures are additional clues.

Prevention

Prenatal diagnosis of SMA is available using amniotic fluid or chorionic villous sampling [66–69]. Carrier detection testing using quantitative PCR-based assay also allows carrier detection by determination of the number of *SMN1* copies, with a carrier usually having only one copy of *SMN1*. As with all genetic testing, however, caution must be exercised in the interpretation of results, since in 2 % of carriers, both copies of SMN1 are present in the same chromosome (cis configuration). An individual with such an arrangement would therefore test as a noncarrier (i.e., two copies of *SMN1*) while still harboring a chromosome lacking SMN1. In addition, routine SMA carrier testing also does not detect intragenic mutations [70]. Patients or their parents should only have such testing in the context of formal genetic counseling [70]. Newborn and carrier screening is feasible, and despite the absence of effective treatment at this stage, there appears to be a significant value for presymptomatic and early detection to explore effective treatments before irreversible neuronal loss occurs [71, 72].

Diagnosis and Laboratory Evaluation

Diagnosis of SMA depends on molecular genetic testing, and the availability of such testing has made muscle biopsy, and in many cases electrodiagnostic testing, unnecessary. Homozygous deletion of SMN1 is detected by demonstrating an absence of exon 7. The test is commercially available and it has 95 % sensitivity and near 100 % specificity [12]. As already discussed, 2–5 % of SMA patients are compound heterozygotes for *SMN1* deletion and *SMN1* intragenic mutation [69]. The role of electrodiagnostic testing and muscle biopsy is substantial in those with negative genetic testing or with variants.

As in most motor neuronopathies, electrodiagnostic studies in SMA typically reveal normal sensory nerve action potentials; however, they can be reduced in some patients [28]. The compound muscle action potential amplitudes are reduced, and the conduction velocities are usually normal but can be reduced in some patients [28]. Needle electromyography demonstrates active denervation and reinnervation as evidenced by fibrillation potentials and positive sharp waves, fasciculations, and large-amplitude, long-duration, fast-firing motor unit action potentials. Regular spontaneous motor unit action potentials occur in SMA type 1 [73, 74].

Mild to moderate creatine kinase elevation is frequently seen, sometimes leading to a false suggestion of underlying muscle disease [75]. Muscle biopsy in SMA type 1 is almost never needed but if performed in difficult to diagnose cases shows intermixed hypertrophic type 1 fibers and sheets of atrophic round fibers. The muscle biopsy of newborns with SMA 1 reveals universally small fibers, with type 1 fibers being smaller than type 2, making the histological diagnosis difficult [76, 77]. In SMA 2 the findings are similar to type 1 in some patients, and in others hypertrophic type 2 fibers and fiber-type grouping are noted. The latter is common in SMA 3; in addition, secondary myopathic features including fiber splitting, increased internal nuclei, and endomysial connective tissue can be seen [28]. Similar changes can be seen in non-SMN-related SMA.

Management

The presence of multiple animal models (including several murine, zebrafish, and Drosophila models) that closely mimic the human disease has not only increased the understanding of the pathogenesis of SMA but also has permitted effective screening for various therapeutic agents [78, 79]. Despite success in these animal models with several compounds, numerous human therapeutic trials over the past decade have not identified an effective agent. To date, there is therefore no drug treatment for SMA that has been proven to have significant efficacy [80, 81]. Among the several strategies explored include efforts to enhance neuroprotection (gabapentin and riluzole), anabolic effects (albuterol), and energy metabolism (creatine and carnitine) and, most notably, to increase *SMN2* expression or stability (valproic acid, hydroxyurea, phenylbutarate) [82–92]. In addition, other strategies being tested include gene therapy, stem cell therapy, and antisense oligonucleotide-based therapy aimed at either replacing the SMN1 gene entirely or genetically converting SMN2 message into SMN1 [13, 93, 94].

The mainstay of treatment for SMA is therefore focused on aggressive supportive care with emphasis on a multidisciplinary team approach. The published guidelines by the international SMA Standard of Care Committee establish an expert consensus approach to practice guidelines for clinical care of SMA patients [95].

Pulmonary Management

Pulmonary complications are the major source of morbidity and mortality in SMA 1 and 2 and for a small percentage of SMA 3 patients. The standard of care consensus statement recognized the key respiratory problems in SMA as weak cough, reduced clearance of secretions, recurrent infections, poor development of the chest wall and lungs, and sleep-disordered breathing [95]. Early referral for respiratory care cannot be overemphasized. Breathing effectiveness can be assessed by observing cough ability, breathing pattern, respiratory rate, work of breathing, and presence of cyanosis. The clinical observations and pulse oximetry are invaluable tools, particularly in young children who cannot participate in pulmonary function testing [96].

Airway clearance can be achieved using manual cough assist or insufflation-exsufflation devices. Chest physical therapy and postural drainage are also useful [95–97]. Education of the parents and caregivers on the evaluation methods, use of home pulse oximetry, and providing a treatment strategy using clearly outlined protocols are the cornerstone for optimal pulmonary management [96]. Other recommended therapies include routine vaccinations, adequate hydration, nutritional support, and gastroesophageal reflux management [95]. There is no evidence to support the chronic use of mucolytic drugs. There should be a low threshold for treatment of pulmonary infections. Overall goals of care should be discussed with the family, and respiratory support provided accordingly. Respiratory support is indicated for carbon dioxide retention, for sleep-disordered breathing, or as a palliative measure to decrease the work of breathing. Noninvasive ventilation using bi-level positive airway pressure machines (BiPAP) results in fewer hospitalizations, prolongs life, alters chest wall deformity, and may improve lung development and function [98–100]. It is most helpful in combination with airway clearance measures. The

use of tracheotomy and chronic ventilation is an ethical dilemma and somewhat controversial in SMA 1 [101]. The decision making should be a process that involves explanation and discussion with the family about the expected outcome and quality of life as well as exploration of other options such as palliative care.

Gastrointestinal and Nutrition Management

The major gastrointestinal and nutritional complications of SMA are related to bulbar dysfunction causing dysphagia and increased aspiration risk, gastroesophageal dysmotility leading to constipation, delayed gastric emptying, gastroesophageal reflux, and undernutrition in the non-sitters and overnutrition in the sitters and walkers [21, 23, 95]. Chewing and mouth opening difficulties also occur in some patients, especially type 1 patients [102]. Swallowing evaluation early in the course is mandatory for essentially all patients. This is usually done by speech or occupational therapist. Video fluoroscopic swallow studies are often helpful in identifying the type and extent of dysphagia. Changing food consistency by thickening liquids can be beneficial. The option of considering gastrostomy tube for feeding is individualized, and decision should be part of overall goal of care and should follow extensive discussions with family of patients with poor intake early in the course. Most infants will benefit from Nissen fundoplication, usually done concomitantly with the placement of gastric feeding tube using a laparoscopic approach [103, 104]. However, some physicians reserve this procedure for those who fail medical treatment for reflux with H2 blocker and proton pump inhibitors. Delayed gastric emptying can be helped by use of metoclopramide or erythromycin. It is important to establish a bowel regime early in the course to avoid chronic constipation and fecal impaction. The majority of SMA patients with constipation will respond to dietary management by increasing fiber and water content [20].

There are many challenges when it comes to proper assessment and treatment of growth and nutritional status in SMA because of the paucity of quality data and the vast amount of undocumented information available on the Internet and similar resources. However, history, examination, growth charts, and 3-day dietary records and 24-h food recall are usually useful to capture data to help nutritional decisions [95, 105]. Non-sitters and some of the sitters are at risk of failure to thrive, whereas sitters and walkers are at risk of becoming overweight or frankly obese [95]. Caution must be exercised when using body mass index (BMI) as the sole parameter because of the risk of underestimation of body fat content. One study showed evidence of increased fat mass and high incidence of SMA patients being overweight despite the low BMI [39]. Currently, there is no hard evidence that high or low protein or fat content in the diet is beneficial for the underlying disease and no evidence to support the use of specific vitamins or minerals. Evaluation and follow-up by a dietitian familiar with the disease are essential, and dietary regimens must often be individualized.

Fig. 21.7 Posterior view of 5-year-old girl with SMA 2. There is significant thoracolumbar kyphoscoliosis

Orthopedic Care and Exercise

The major orthopedic complications in SMA are related to scoliosis, kyphosis, contractures, mobility impairment, osteopenia, and fractures [95]. In addition to deformity, scoliosis results in decreased function, impairs sitting ability, and contributes to pain and respiratory impairment (Fig. 21.7) [65]. Overall, development and progression of spinal deformity correlates with weakness, and scoliosis is more severe in sitters than walkers. It is usually noticed in the SMA 2 patients between the ages of 2–5 years and at later ages in the type 3 patients, particularly after the loss of ability to walk [20, 65]. Use of back bracing provides symptomatic relief of back pain in some of the patients, and it can allow for a better seated position, but there is no evidence that it limits or prevents progression [65]. Surgical correction results in improvement in sitting, balance, comfort, and appearance and delays

decline of pulmonary function [106–110]. Timing of surgical correction must take into account the degree of curve, child growth, and pulmonary function.

A variety of assistive devices are available to help maximize function, prolong independency, and improve quality of life for both patients and caregivers. Proper selections are individualized based on specific patient needs and should be done under the guidance of the physical and occupational therapist. This further emphasizes the need for multidisciplinary team approach. Lightweight orthotics, walking frames, and power wheelchairs are examples of such devices.

There is paucity of human data when it comes to the role of exercise in SMA. There is a theoretical concern that excess exercise can accelerate the loss of motor neuron, but animal studies demonstrate that regular running in SMA mice led to better motor function, a longer life span, and more surviving motor neurons [111]. The consensus guidelines encouraged routine exercise such as swimming and adaptive sports to maintain and optimize fitness and endurance [95].

Palliative Care

In patients with SMA 1, early and extensive discussions with families should include the option of palliative care [112]. There is lack of consensus as to the appropriate level of care as well as there are conflicts regarding interventions that may prolong life without necessarily impacting the quality of life [95]. Families are entitled to an honest and unbiased opinion to help them through the decision-making process [112]. This can only be achieved with appropriate input from a multidisciplinary team, including experts in palliative care. Lay and family support organizations can also be indispensable in providing information and emotional support during this process.

Prognosis

Historically children with SMA 1 usually die in the first 2 years of life because of respiratory complications [26–28]. Survival in SMA 1 has increased in recent years due to proactive care with advances in pulmonary care and aggressive nutritional support [29, 62]. In 1997, Zerres and colleagues published an analysis on the natural history of 569 clinically diagnosed SMA patients. They reported that 68 % of SMA 2 patients are alive at the age of 25 and SMA 3 patients have normal life expectancy. They also found that ambulation was retained after 10 years in 70 % of SMA 3a compared to 96 % of SMA 3b but after 20 years in only 33 % of SMA 3a compared to 84 % of SMA 3b. After 40 years, 22 % of SMA 3a patients were still ambulatory compared to 58 % with SMA 3b [28].

SMN-Related SMA Variants

Congenital SMA with Arthrogryposis

Arthrogryposis is characterized by multiple contractures and is usually nonfamilial and nonprogressive. It can be caused by any process that limits intrauterine movements, including congenital myopathies, congenital muscular dystrophies, and anterior horn cell disorders. Rarely, and for reasons not entirely clear, SMN-related SMA can present with prominent arthrogryposis at birth. Several reports however have linked SMN1 deletion mutation to infants presenting with neurogenic arthrogryposis [113, 114]. These cases need to be differentiated from the X-linked form of SMA described below.

Congenital Axonal Neuropathy

This is an unusual and severe form of SMA caused by a large deletion of the *SMN* gene and loss of markers Ag1-CA and C212 in the paternal haplotype. The three siblings described all died in the first 3 weeks of life after presenting with generalized weakness, asphyxia, facial diplegia, and external ophthalmoplegia [115]. Electrodiagnostic studies revealed unexcitable sensory and motor nerves, and autopsy showed loss of myelinated fibers and axonal damage in sensory and mixed nerves. Though the anterior horn cell number was normal, many of the neurons showed chromatolytic changes [115].

Non-SMN-Related SMA

SMA with Pontocerebellar Hypoplasia

This autosomal recessive disease has been linked to a mutation in vaccinia-related kinase 1 (*VRK1*) gene mapped to chromosome 14 q32.2 [116]. It is described as one of the so-called SMA-plus syndromes, a term used to identify a group of disorders that manifest as SMA but with additional or atypical features. The group includes SMA with respiratory distress (SMARD), infantile X-linked SMA with arthrogryposis and congenital fractures (SMAX2), and SMA 1 with arthrogryposis and bone fractures, in addition to SMA with pontocerebellar hypoplasia (PCH type1). SMA patients with PCH1 have variable disease severity that combines features of anterior horn cell and cerebellar deficits [117, 118]. Some patients have symptom onset within 6 month and a life span of 2–4 years, while others have more severe forms with onset in the prenatal period or immediately after birth and death within months [119]. The mutation in *VRK1* was first identified in three children

from consanguineous family of Ashkenazi Jewish decent with early features of microcephaly, poor sucking, delayed motor development and subsequent development of upper limb ataxia, equinovarus, and brisk deep tendon reflexes. Another study using deep sequencing to identify novel genes for recessive cognitive disorders identified *VRK1* homozygous missense mutation in four siblings with moderate to severe intellectual disability and pontocerebellar hypoplasia phenotype [120].

SMA with Congenital Fractures

This is an autosomal recessive SMA variant without an identified linkage to date. Patients have normal *SMN* genes. In addition to the severe weakness, hypotonia, and respiratory difficulty, patients have osteopenia and congenital fractures [121, 122]. Additional features reported in some of the patients include hypertrichosis and congenital heart defects. Electrodiagnostic studies show evidence of active denervation, and autopsy studies show generalized type 1 and 2 fiber atrophy and loss of the anterior horn cells [123, 124].

Adult Proximal SMA (Finkel Type)

Approximately 30 % of adult-onset proximal SMAs are autosomal dominant disorders not linked to the SMN protein [125]. There are no distinctive phenotypic features when compared to the autosomal recessive form. Patients present after the third decade with slowly progressive weakness and atrophy of the proximal leg muscles with later involvement of the arms. Generalized areflexia and fasciculations are typical. Overall patients have a benign course [8, 126–128]. Linkage to chromosome 20q13.3 and missense mutation in vesicle-associated membrane protein (*VAMP*)/synaptobrevin-associated membrane protein B gene (*VAPB*) was described in a large white Brazilian family [129]. The same mutation was identified in other family members with atypical and typical amyotrophic lateral sclerosis phenotypes [129].

SMA with Lower Extremity Predominance

This is one of the rare autosomal dominant proximal forms of SMA that is linked to chromosome 14q32. The symptoms onset is in early childhood with a static or slowly progressive course. The patients described has a peculiar pattern of weakness that is confined to the legs mostly affecting the quadriceps and hip muscles and is associated with severe atrophy of the quadriceps muscles [130].

Scapuloperoneal Syndrome

Scapuloperoneal syndromes are characterized by weakness of the shoulder girdle and the leg anterior compartment muscles. The phenotype is seen in both myopathic and neurogenic processes, most commonly in association with muscle diseases such as facioscapulohumeral muscular dystrophy and limb girdle muscular dystrophy. An autosomal dominant SMA scapuloperoneal syndrome linked to chromosome 12q24.1 has been reported in large New England kindred of French Canadian descent [131]. In addition to progressive scapuloperoneal atrophies, the patients have distinctive features of congenital absence of muscles and laryngeal palsy. Males are more severely affected than females, and there is increase disease severity in successive generations [132]. The responsible mutation is identified in the vanilloid transient receptor potential cation-channel gene TRPV4 [133]. The condition is allelic to the axonal sensory motor neuropathy form of Charcot-Marie-Tooth disease (CMT2C).

X-Linked Bulbospinal Muscular Atrophy (Kennedy Disease SMAX1)

This is an X-linked recessive disease caused by CAG trinucleotide repeat expansion in the androgen receptor gene [134, 135]. The symptoms start in the fourth decade with insidious slowly progressive atrophy and weakness of the bulbar and proximal limb muscles. Rarely, a rapid progressive course is noted [136]. Facial and perioral grouped fasciculations are a characteristic feature. Tongue atrophy and fasciculations are often noted. Jaw drop with prominent temporalis and masseter muscles weakness can be a presenting feature [137]. Dysarthria and dysphagia may occur. Additional features include gynecomastia, testicular atrophy, infertility, and diabetes mellitus. Asymptomatic sensory neuropathy is a common finding. Muscle cramps, fatigue, and mild CK elevation can be early symptoms in young males and rarely seen in female carriers [138, 139]. Overall the neurologic impairment is usually mild without major bulbar or respiratory dysfunction, and the long-term survival is only mildly reduced [140]. Several trials in patients with Kennedy disease have showed no effect. Recently, androgen-reducing treatment with dutasteride, a 5-alpha-reductase inhibitor, had no effect on progression of muscle weakness [141]. Also, leuprorelin, which suppresses the accumulation of the pathogenic androgen receptors, has no effect on

Fig. 21.8 Eight-month-old boy with presumed infantile SMA with arthrogryposis. Note the severe lower extremity contractures

swallowing function [142]. The disorder is described in more detail in Chap. 22.

Infantile SMA with Arthrogryposis

This is an X-linked recessive disease associated with mutation in the ubiquitin-activating enzyme 1 (*UBE1*) gene [143–145]. The presentation is at birth with severe hypotonia, areflexia, and multiple congenital contractures [144] (Fig. 21.8). The phenotype resembles that of SMA with additional features, including congenital or early-onset proximal and digital contractures, facial weakness and other facial dysmorphic features, and urogenital abnormalities [146]. Death usually occurs in infancy from respiratory compromise.

Distal Spinal Muscular Atrophies (Hereditary Motor Neuropathy)

This term identifies a heterogeneous group of inherited disorder characterized by distal symmetric weakness without clinical or electrodiagnostic evidence of sensory loss [147]. The latter defines the group compared to the hereditary sensory and motor neuropathies (or CMT group), and the term "distal" defines the group in contrast to proximal SMA. The terms hereditary motor neuropathy and distal SMA are often used synonymously; however, the pathology of distal SMA in theory is related to anterior horn cell degeneration [148]. Harding classified the group into seven phenotypes according to age at onset, mode of inheritance, and presence of additional features [142]. Additional groups are identified in the last decade as well advances in molecular genetics led to identification of several causative genes (Table 21.2) [47, 149–165].

The distal SMAs (see below) tend to mimic CMT, with the important difference being the absence of clinical or electrophysiologic evidence of sensory involvement in the distal SMAs. In some of the entities, however, the distinction is not clear or absolute. For instance, certain heat shock protein mutations have been described in both CMT2 and distal SMA (see also Chap. 26). The distal myopathies are group of hereditary disorders characterized by distal leg or arm muscle weakness and atrophy and should be distinguished from distal SMAs. Creatine kinase elevation, myopathic changes on the electrodiagnostic studies, and vacuolar changes on muscle biopsy help distinguish the two groups. Hirayama disease should be considered in the differential diagnosis of distal SMA. This is a transiently progressive motor syndrome with resultant asymmetric atrophy and weakness of the distal upper extremity. The pathogenesis of this disorder is uncertain; however, chronic intermittent lower cervical cord compression and ischemia during neck flexion are implicated in the majority. Flexion and extension cervical spine MRI could show a crescent-shaped signal posterior to the cord caused by engorged venous plexus.

Atypical Motor Neuron Disorders

22

J. Americo M. Fernandes Filho and Eroboghene E. Ubogu

Introduction

There are several disorders that primarily affect the motor nervous system and mimic amyotrophic lateral sclerosis (ALS) (Table 22.1) [1, 2]. These disorders are often referred to as *atypical motor neuron disorders*. While many of the atypical motor neuron disorders have several features in common with ALS, they may be differentiated by their specific clinical, laboratory, electrophysiologic, and pathologic characteristics.

ALS is characterized by the degeneration of upper motor neurons in the brain and lower motor neurons in the brainstem and spinal cord, including anterior horn cells and cranial nerve nuclei (see Chap. 20). Patients with ALS typically manifest with a combination of focal limb atrophy, weakness, and more widespread muscle wasting and fasciculations. Upper motor neuron signs, including spasticity and pathologically brisk muscle stretch reflexes, are often present in the same spinal segments as the muscle atrophy. If upper motor neurons signs are not present at the time of presentation, they usually develop later in the disease course. In contrast to ALS, the atypical motor neuron disorders often lack upper motor neuron signs. Furthermore, few of these disorders are presumed immune-mediated, and weakness is secondary to motor nerve pathology, rather than anterior horn cell disease. The motor nerve pathology may be demyelinating, axonal, or a combination of both. Some of the atypical motor neuron disorders present with weakness in association with cerebellar, extrapyramidal, sensory, and cognitive dysfunction. Atypical motor neuron disorders may be seen as a remote effect of some neoplasms or secondary to various toxins, drugs, metabolic disorders, or as a result of electrical injuries, radiation, or infections, previous poliomyelitis, or spinal cord lesions. Recognition of these atypical motor neuron disorders is important because several are potentially treatable or may not carry the same grave prognosis as ALS. Others may be inherited, emphasizing the importance of early recognition for genetic counseling and family planning.

Clinical Clues That Suggest an Atypical Motor Neuron Disease

Although each disorder has distinctive clinical features, there are several clues that help differentiate patients with atypical motor neuron disorders from those with ALS (Table 22.2). Several important clues on the neurological examination may suggest an atypical disorder. The first clue is a *non-myotomal pattern of weakness*, whereby patients develop weakness in the distribution of individual named peripheral nerves, rather than in the distribution of myotomes. This pattern of weakness suggests that the pathology lies in peripheral nerves rather than at the level of the anterior horn cells. The second clinical clue is *weakness out of proportion to muscle wasting in affected limbs*, which suggests that the weakness is secondary to demyelination, such as conduction block within peripheral motor nerves (see below), a finding uncharacteristic of ALS. With initial demyelination, the axon remains intact, and early-stage muscle wasting is either absent or minimal. *Non-regional spread of weakness* is another clinical clue that suggests an atypical motor neuron

Table 22.1 Atypical motor neuron diseases

Immune-mediated motor neuropathies
Multifocal motor neuropathy with conduction blocks
Other presumed immune-mediated lower motor neuron syndromes
Nonimmune-mediated lower motor neuron syndromes
Spinal muscular atrophy
X-linked bulbospinal muscular atrophy (Kennedy disease)
Monomelic amyotrophy (Hirayama disease)
Brachial amyotrophic diplegia (flail arm syndrome)
Progressive muscular atrophy
Progressive bulbar palsy
Fazio-Londe disease and Brown-Vialetto-Van Laere syndrome
Hereditary spastic paraplegia
Autosomal dominant
Autosomal recessive
X-linked
Multiple system disorders with prominent motor signs
Adult-onset hexosaminidase A deficiency (Late-Onset Tay-Sachs Disease)
Spinocerebellar degenerations
Autosomal dominant cerebellar ataxias
Autosomal recessive cerebellar ataxias
Adult polyglucosan body disease
Other multiple system disorders
Shy-Drager syndrome (multiple systems atrophy)
Guamanian Parkinson-amyotrophic lateral sclerosis
Hallervorden-Spatz disease (pantothenate kinase-associated neurodegeneration)
Creutzfeldt-Jakob disease
Huntington's disease
Pick's disease
Other atypical motor neuron diseases
Hyperparathyroidism
Electrical injury associated with motor neuron disease
Infectious/post-infectious
Retroviral-associated motor neuron syndrome
Post-radiation motor neuron disease
Paraneoplastic disorders with motor neuron dysfunction
Toxins/drugs
Post-poliomyelitis syndrome

disorder. Whereas weakness in patients with ALS tends to spread in a regional fashion, for example, right arm to left arm, rather than right arm to left leg, this is not necessarily the case in the atypical motor neuron disorders. The *lack of upper and lower motor neuron signs in the same spinal segments* may also suggest an atypical disorder. While patients with ALS generally have brisk or at least preserved reflexes in the same distribution as weak atrophic muscles, this pattern is not characteristic of many of the atypical motor neuron disorders. Failure to find upper and lower motor neuron signs in the same spinal segments should therefore prompt a search for an atypical disorder.

Table 22.2 Clinical clues that differentiate atypical motor neuron diseases from typical ALS

Non-myotomal pattern of weakness
Insignificant muscle wasting in chronically weak limbs
Non-regional spread of weakness
Lack of concurrent upper and lower motor neuron signs in the same spinal segments
Associated sensory symptoms or signs or both
Bladder or bowel dysfunction
Extraocular movement dysfunction
Cerebellar, extrapyramidal, cognitive or psychiatric dysfunction or both
Duration of illness longer than 5 years
Lack of bulbar involvement after 1 year
Onset of illness before age 35
Positive family history
History of spontaneous remissions
History of malignancy, radiation, old poliomyelitis, or electrical injury

Likewise, any evidence of extraocular muscle weakness, significant bladder or bowel dysfunction, sensory alterations, cerebellar, extrapyramidal, cognitive, or psychiatric dysfunction should question the diagnosis of ALS. Clues in the medical history that may suggest an atypical disorder include duration of illness greater than 5 years, lack of bulbar involvement after 1–2 years, onset before age 35, family history of a similar disorder (although a small percentage of ALS is familial), and a history of malignancy, radiation, previous poliomyelitis, or electrical injury.

Immune-Mediated Motor Neuropathies

Multifocal Motor Neuropathy with Conduction Block

Multifocal motor neuropathy with conduction block (MMN) is a disorder of motor nerves characterized by slowly progressive, asymmetric, primarily distal upper extremity limb weakness, although proximal weakness may predominate. Upper motor neuron signs are notably absent [3–5]. Two key laboratory features are associated with this disorder, distinguishing it from ALS. First, electrodiagnostic (EDX) testing shows *conduction blocks* along motor nerves exclusive of entrapment sites [6–8] (Fig. 22.1). Second, highly elevated levels of antibodies to GM1 gangliosides are found in the serum in 30–60 % of patients, supportive of an immune-mediated pathogenesis (see below) [3–5]. Lewis and Sumner first described the disorder in their case series in 1982, but the association with anti-GM1 antibodies was not described until 1988 by Pestronk [3, 9–11].

Fig. 22.1 Conduction block in a patient with multifocal motor neuropathy. Motor nerve conduction of the median nerve recording from abductor pollicis brevis muscle, stimulating at the wrist (*top tracing*) and antebrachial fossa (*bottom tracing*). Note the significant drop in area and amplitude of the compound motor action potential between stimulating sites (sensitivity = 2 mV/div; sweep speed = 5 ms/div)

Etiology and Pathogenesis

The pathogenesis of MMN is generally presumed to be autoimmune, based on its association with antibodies to GM1 gangliosides in many cases, and marked clinical improvement following immune-modulating therapy. However, the specific pathogenic role for antibodies against GM1 gangliosides in MMN and other lower motor neuron syndromes is not well defined. Gangliosides are a family of glycolipids composed of lipid (ceramide) and carbohydrate moieties with sialic acid, which are found in abundance on the external surface of the neural membrane. They are thought to have a role in maintenance and repair of nervous tissues, stabilization of paranodal junctions, and clustering of ion channels [12]. GM1 is ubiquitously expressed, but probably more abundant in motor than in sensory nerves. IgG anti-GM-1 antibodies are associated with pure motor axonal forms of Guillain-Barré syndrome (GBS). High-level IgM anti-GM-1 antibody titers can be detected in approximately 50 % of patients with MMN. Low titers of IgM anti-GM1 antibodies have been detected in small number of patients with motor neuron disease (MND). High titers of IgM anti-GM1 antibodies may distinguish MMN from MND and other neuropathies, serving as a potential biomarker for this disorder [13].

The actual mechanism by which these antibodies might damage motor nerves or nerve terminals is unclear. Data from experimental models in GBS revealed effects of GM1 antibodies on the function of peripheral nerves that may be relevant for MMN pathogenesis. Binding of anti-GM1 antibodies to GM1-rich paranodal junctions may alter paranodal anatomy and cause mislocalization or disruption of sodium and potassium channel clusters. Antibodies may activate the classic complement pathway leading to deposition of complement factors, including the membrane attack complex, compromising axonal membrane integrity with sodium channel cluster disruption. These experimental findings may provide pathogenic mechanisms that lead to conduction block and ultimately axonal loss [12]. However, MMN patients with and without anti-GM1 IgM titers have similar clinical features. Seronegative patients could contain unidentified antibodies against molecules with similar function to GM1. IgM antibodies extracted from the sera of patients with MMN were found to bind to a mixture of lipids containing GM1, galactocerebroside, and cholesterol [14]. Disulfated heparin disaccharide has been identified as a potential antigen in patients with motor neuropathies [15]. Cases of MMN and other immune-mediated neurological disorders such as demyelinating neuropathies, myasthenia gravis, and multiple sclerosis have been reported following use of monoclonal antibody therapy [16], suggesting a role of systemic immune dysregulation in the pathogenesis of these disorders.

Clinical Presentation

The prevalence of MMN is not well known but is estimated at about 0.6 per 100,000 population [17]. The disease is more prevalent in males (male to female ratio = 2.7 to 1). The age of onset is usually in the third to fifth decades. Patients present with slowly progressive asymmetrical weakness, usually in the distal upper extremities, although proximal involvement may occur [5, 18]. Weakness usually starts in the hands or forearm, but the first symptoms may present in the distal leg (20–30 %) or occasionally in the upper arms (5 % of cases) [12]. Differential weakness in muscles supplied by the same motor nerve has been reported. This has been described with finger extensors, causing different degrees of finger drop on attempted extension [19]. Neurological examination reveals lower motor neuron involvement consisting of fasciculations and weakness, often prominent in the distribution of named peripheral nerves. During the early stages of the disease, weakness may be limited to the distribution of a single named nerve, often leading initially to a misdiagnosis of an entrapment neuropathy [3]. For example, it is not uncommon for a patient to present with a slowly progressive wrist drop or intrinsic hand muscle weakness, misdiagnosed initially as entrapment of the radial nerve at the spiral groove or ulnar neuropathy at the cubital tunnel, respectively. Muscle atrophy is not prominent in weak muscles, despite the degree and chronicity of weakness. However, over the long term, atrophy may occur [18]. Upper motor neuron signs are notably absent, and muscle stretch reflexes are usually diminished.

Respiratory and bulbar weakness is unusual [3–6, 9, 19–29]. Cranial nerve involvement is rare; however, external ophthalmoplegia and unilateral tongue weakness and atrophy have been described in association with MMN [30, 31]. Although mild sensory complaints may be present, the sensory examination usually remains normal [10].

Differential Diagnosis

The differential diagnosis includes any disorder that presents with slowly progressive primarily distal weakness, especially in the upper extremities, without accompanying upper motor neuron or sensory signs. These include the rare adult-onset forms of spinal muscular atrophy, monomelic amyotrophy (see below), brachial amyotrophic diplegia (see below), and some rare forms of inherited or sporadic distal myopathies. These disorders are distinguished by a careful family history, laboratory testing including creatine kinase (CK) level, and anti-GM1 antibody, as well as EDX testing to look for neurogenic versus myopathic changes. If EDX testing shows evidence of neurogenic changes, a careful search for conduction block or other signs of demyelination is warranted. Genetic testing can be performed if clinically indicated based on the clinical phenotype. In indeterminate cases, muscle biopsy may help distinguish between neurogenic and myopathic etiologies, looking for evidence of chronic denervation-reinnervation, inflammation, or findings suggestive of a metabolic or inherited myopathy.

Evaluation and Diagnosis
