A positive diagnosis of EDMD1 is made by emerin analysis. Western blot and immunohistochemistry show an absence of emerin in muscle [73], skin tissue [70], and buccal smears [74] in male patients with X-linked EDMD (EDMD1), and a reduction of the protein content with a mosaic expression pattern in female carriers. Evaluation of emerin expression on skin biopsy and in the exfoliating epithelial cells of oral mucosa are a less invasive though sensitive and more convenient means for diagnosing X-linked EDMD (EDMD1). In particular, these methods can be used to distinguish X-linked EDMD (EDMD1) from the autosomal forms [74]. In the autosomal dominant (EDMD2) and autosomal recessive forms, emerin is normal and genetic analysis is necessary for diagnosis.

Genetics

Most emerin mutations are nonsense, frameshift, or putative splice mutations resulting from base substitutions, small deletions, or insertions [75]. These mutations result in absence of the protein as shown by immunoblotting or immunohistochemistry studies in any tissue studied [70]. However, a few in-frame deletions and missense mutations have been associated with residual or normal expression of the mutant protein [70, 75]. The phenotype in two families with in-frame deletions was similar to that of families with null mutations. In the family with the missense mutation P183, the musculoskeletal phenotype was milder and of later onset, but there was no difference in the age of onset of cardiac involvement [53].

The majority of mutations in EDMD-AD are missense, although nonsense mutations, small deletions, and splice site mutations are reported [76, 77]. Mutations are found throughout the gene and for this phenotype there is, as yet, no apparent correlation with genotype.

Treatment and Management

Achilles tenotomy is recommended for patients with foot deformities in order to allow a wider and more stable stance. No correction for the limited elbow extension is advisable since elbow flexion allows the hand to be closer to the mouth and may compensate for the severe paralysis of the flexor muscles. Neck hyperextension is rarely a problem in EDMD compared to the RSS, where this more often compromises function. A procedure for surgical correction of neck

hyperextension was devised in RSS [78, 79] and applied in one EDMD1 patient [49].

Scoliosis in EDMD patients is usually not so severe to require surgical correction and stabilization. In the exceptional event of severe scoliosis, the benefits of surgery should still be balanced against the peculiar problem its correction poses in EDMD. First, scoliosis in patients with rigid spine is a fixed deformity with limited correction even with surgery. Second, if correction requires lumbosacral fixation, this may precipitate loss of ambulation. Finally, scoliosis surgery stresses cardiac function to its limits, which is a risk in EDMD patients.

Although no complications are reported in EDMD patients receiving general anesthesia, it is advisable to use all the well-established rules for patients with neuromuscular disorders who require general anesthesia [80, 81]. In addition, prophylactic cardiac pacing should be considered before surgery, and facilities for emergency cardiac pacing should be on hand at all times [82].

Arrhythmias are usually more severe during sleep, indicating that continuous 24-h EKG monitoring in the evaluation of patients with EDMD is advisable [32, 54]. A yearly Holter monitor is indicated in all EDMD patients when arrhythmias are detected on routine EKG or after age 17 years. Early recognition of heart involvement is of utmost importance as placement of a pacemaker and/or implantable cardioverter-defibrillator (ICD) may be lifesaving [83–85]. A survey of ICD utilization in 19 subjects with *LMNA* mutations followed over 3 years indicates that about 40 % of these patients had an ICD discharge during the period of observation [86]. The results of this study validate the use of ICDs as prevention for sudden death and indicate that cardiac conduction system disease can precede the development of overt cardiac dilation and arrhythmias. However the treatment of the conduction defect does not prevent intra-atrial thrombus formation and cerebral embolization. Increased awareness of this sequel should lead to successful prophylaxis with anticoagulants [55]. If there is significant ventricular involvement, diuretic therapy and ACE inhibitors may be indicated. Cardiac transplantation should be considered in EDMD patients in whom the dilated cardiomyopathy is not otherwise treatable [55–58, 87–90]. Women carriers of EDMD1 are at risk for cardiac arrhythmias, particularly after age 40, and should be monitored on a yearly basis with EKG or Holter monitoring.

Two inhibitors of ERK and JNK signaling, PD98059 and SP600125, respectively, have been demonstrated to inhibit the expression of RNAs encoding natriuretic peptide precursors and protein involved in sarcomere architecture in $Lmna^{H222P/H222P}$ mice, preventing left ventricular and systolic dilatation [91]. In a near future, drugs that have been entered phase II clinical trials for patients with cancers may be used to treat patients with cardiomyopathy caused by *LMNA* mutations.

Prognosis

Musculoskeletal involvement in EDMD is usually mild and non- or slowly progressive. Loss of ambulation is exceptional. The course of cardiac involvement is the major determinant of the prognosis *quoad vitam*. Initially, the disease was defined as "benign" [1]. However, subsequent surveys suggest that this is not the case, given the high incidence of sudden death [32, 92, 93]. Early recognition of heart involvement, placement of a pacemaker and/or implantable cardioverter-defibrillator [83–85], prophylaxis with anticoagulants [55], diuretic therapy and ACE inhibitors, and cardiac transplantation in patients with nonmedically responsive-dilated cardiomyopathy have changed the cardiac prognosis of EDMD. Hopefully, in the near future EDMD will again be regarded as a benign condition. Furthermore, the heart may be a more reasonable initial target for gene therapy than the skeletal muscles.

Congenital Myopathies

62

John B. Bodensteiner

Introduction

The congenital myopathies are a diverse group of skeletal muscle disorders which are genetic in origin, frequently apparent at birth, usually slowly or not progressive and have overlapping clinical features [1–4]. Until recently, the classification of congenital myopathies into distinct groups was most frequently based on the histopathological features of the muscle [5]. Increasingly, however, the molecular genetic basis of these diseases is being delineated and in the future, the identification of distinct types of congenital myopathies will require the demonstration of the gene abnormality in addition to, or in concert with, the clinical features and the histopathology of the muscle.

The congenital muscular dystrophies are subgroup of the congenital myopathies in which histologic examination of the muscle reveals "dystrophic features." The congenital muscular dystrophies historically were further divided into those conditions with and those without brain involvement, and those which are merosin negative or merosin positive [4, 6]. The delineation of the genetic basis of most of the congenital muscular dystrophies has put the classification schemata in flux and there is currently no universally accepted classification for this uncommon but interesting group of diseases [7].

Most infants affected with a congenital myopathy will have a slowly progressive course. Some infants, however, are severely affected at birth leading to early respiratory failure and death. Occasionally a rapidly progressive course is seen in some patients with congenital myopathy, and rare patients may improve with time [8, 9]. Some individuals with a genetically determined congenital myopathy will not become symptomatic until later in childhood or as an adult.

Nearly four dozen congenital myopathies have been described. The majority of these disorders is rare and considered to be nosologically questionable entities [3]. Because of the limited number of pathological alterations possible in skeletal muscle any classification based on morphologic features will have limitations. Central core disease, nemaline myopathy and centronuclear myopathy are the three most prominent clinical entities, with advances in genetics that have altered our understanding of these diseases (Table 62.1). Less common diseases including multicore disease, congenital fiber-type disproportion, reducing body myopathy, fingerprint myopathy, and cytoplasmic or inclusion body myopathy are not as well delineated, but as the genes responsible for these conditions are identified, the classification is changing and now is perhaps best classified as reducing body myopathies (Table 62.2), myofibrillar myopathies (Table 62.3), and protein aggregate myopathies (Table 62.4) [7]. Also, application of molecular genetics to these conditions has allowed the identification of most of the congenital muscular dystrophies as distinct genetic entities, though the classification is not well-established currently (Table 62.5).

Etiology and Pathogenesis

The well-established congenital myopathies are all genetic in origin. The gene locus and the gene product are known for some for most but for some neither is known. Currently, there are over 20 known genes known to be related to the clinical picture of a congenital myopathy [7]. It is clear that in some of these conditions, the one gene one phenotype axiom is not valid as there are sometimes several genes, dysfunction of which can produce apparently identical clinical (phenotypic) entities. The characteristic histopathologic features of the three well-established conditions are the result of the absence of an intracellular protein necessary for the maintenance of the structural integrity or function of, or the maturation and differentiation of, the myofiber. The characteristic pathological feature of nemaline myopathy, for

example, is the accumulation of disorganized Z disk material which may be seen on histochemical staining of frozen sections and which represents normal Z disk material which has not been held in its proper position in the lattice of the myofibril because of dysfunction of one of three proteins (α-actinin, tropomyosin-3, or nebulin) known to be abnormal in genetically distinct forms of the disease.

The etiology and pathogenesis of the clinical picture in the congenital myopathies is less well established. Hypotonia and weakness are the most common clinical findings. If the weakness is present in utero, the infant may have deformities or contractures as a result. The mechanisms involved in the production of hypotonia are somewhat obscure and may differ with each of the clinical

entities, though more likely they share a common pathophysiology [10, 11].

Clinical Presentation

Floppy Infant: Evaluation and Diagnosis

The clinical presentation of the infant with a congenital myopathy is usually that of a "floppy infant" (see Chapter 77). The affected baby demonstrates decreased tone, weakness, decreased spontaneous movement, and later, delayed acquisition of motor milestones. Most commonly, the floppy infant with these clinical abnormalities will be found to have a non-neuromuscular problem (Table 62.6), and it is frequently worth the physician's effort to spend some time trying to localize the origin of the problem at the beginning of the evaluation [2, 12]. Although the distinction between hypotonia secondary to systemic disease and hypotonia plus/minus weakness due to primary neuromuscular disease would appear to be easy, in actual practice, the localization of the problem to the muscle and the determination of weakness in addition to hypotonia is difficult for most examiners.

In clinical practice, the measurement of muscle tone is subjective. Defined as the resistance to passive movement, tone in the young infant (first month of life) is, normally, dependent on the state of well being and the state of alertness of the infant and can be divided into postural or truncal tone and phasic or appendicular tone:

Postural tone: Postural tone is the tone of the back, hips, and neck muscles and is partially reflected by the posture of the infant at rest. Postural tone is assessed most reliably by four maneuvers (Fig. 62.1):

1. The traction response (pull to a sit)
2. The "scarf sign"
3. Shoulder suspension
4. Ventral suspension (the examiner lifts the prone infant with one hand under the abdomen)

Phasic tone: Phasic tone or axial tone is the tone in the arms shoulders and legs and is more difficult to quantify in the infant. Phasic tone is also very dependent on state of alertness and reflex activity, and for a variety of reasons it can be very difficult to assess strength in the presence of phasic hypotonia. One of the reliable signs of phasic or appendicular hypotonia is the scarf sign [the examiner grasps the hand and pulls the arm across the body to the opposite shoulder as far as the tone in the arm will reasonably allow, in the full-term infant, the elbow does not pass the midline of the thorax (Fig. 62.1b)] [12]. Remember that weak infants are hypotonic, but not all hypotonic infants are weak [2, 9, 10].

Although localizing the cause of the hypotonia is not as easy as it might appear, an attempt to localize the problem before launching into the evaluation may pay dividends in time and effort. Some of the clinical features which may be of help in this localization scheme are the following (Table 62.6):

1. Recent onset, if identifiable, would suggest a more acute systemic condition such as sepsis, meningitis, or congestive heart failure. In the newborn, these conditions should be considered before the evaluation for neuromuscular disease is undertaken.
2. Abnormal texture of the muscle on palpation may indicate the deposition of material in the muscle or an alteration of innervation of the muscle.
3. Absence of myotatic reflexes would suggest motor unit localization of the hypotonia.

Table 62.5 Congenital muscular dystrophies

Disease	Protein/gene	Clinical	Neuroimaging brain MRI	Biopsy feature
CMD with merosin deficiency	Laminin-α2 (LAMA2)	Severe = no merosin Milder = partial deficiency	Abnormal white matter T2 signal, otherwise usually normal	Absent Laminin-α2
CMD partial merosin deficiency	Locus 1q42	Variable	Mild white matter possible gray abnormalities	Variable staining
LARGE-related CMD (MDC1D)	LARGE (like-glycosylated transferase)	Mental retardation blend of MEB/WWS phenotypes	White and gray abn Hypoplastic cerebellum and brainstem	Variable staining…no specific stain
Fukuyama CMD	Fukutin (FKTN)	Frequent in Japanese, do not reach ambulation, MR, overlap with MEB	Lissencephaly type II/pachygyria Hypoplastic cerebellum +/− cysts	Variable staining…no specific stain
Muscle-eye-brain disease (MEB)	POMGnT1 FKRP	Ocular involvement, severe weakness, mental retardation	Lissencephaly II/pachygyria Hypoplastic cerebellum and brainstem	Variable staining…no specific stain
Walker-Warburg syndrome (WWS)	POMT1/POMT2/FKRP/FKTN	Often lethal in first few years, severe brain anomalies	Lissencephaly Lissencephaly II/pachygyria Hypoplastic cerebellum and brainstem Hydrocephalus	Variable staining…no specific stain
CDG1 α-dystroglycan glycosylation defect	Dolichol-phosphate-mannose synthetase 3 (DPM3)	Weakness plus cardiomyopathy, Stroke like episodes, MR	Cerebellar vermis hypoplasia Microcephaly	Reduced glycosylated aDG Variable Laminin-α2
CDG1 (DPM2)	Dolichol-phosphate-mannose synthetase 2 (DPM2)	As above with Severe myoclonus epilepsy	Cerebellar vermis hypoplasia Microcephaly	Reduced glycosylated aDG Variable Laminin-α2
CDG1e (DPM1)	Dolichol-phosphate-mannose synthetase 1 (DPM1)	Usually typical of CDG disease	Cerebellar vermis hypoplasia Microcephaly	Reduced glycosylated aDG Variable Laminin-α2
Collagen VI-related spectrum Ullrich/Bethlem (UCMD)	α1/2 and α3 collagen VI COL6a1, COL6a2 COL6a3	Distal hyperlaxity Proximal contractures Follicular hyperkeratosis Soft palms	None	Variable deficiency of collagen VI staining
Rigid spine muscular dystrophy	Selenoprotein N (SEPN1)	Delayed walking with axial weakness and stiff spine	None	Non-diagnostic
Lamin A/C-related CMD	Lamin A/C LMNA	Dropped head characteristic	None	Non-diagnostic

4. Presence of deformities suggesting weakness in utero such as high palate, club feet, pectus excavatum, long narrow facies with small mandible, and scoliosis would suggest motor unit involvement.
5. Presence of dysmorphic features not resulting from weakness in utero, such as abnormal ear placement, hypo/hypertelorism, abnormalities of nipple position, and anomalies of other systems (heart, genitourinary, gastrointestinal), particularly if the reflexes are present, would suggest a supraspinal localization for the hypotonia.

Table 62.6 Localization in the "floppy infant"

Type of hypotonia	Structural localization	Clinical pathological conditions
Supraspinal hypotonia (preserved DTR)	Brain	Systemic disease (sepsis, HIE, CHF)
	Brainstem	Syndromes (Down, Smith-Lemli-Opitz, Prader-Willi)
		Malformations
	Craniovertebral junction	Cord injury (birth and beyond)
Motor unit hypotonia (DTR decreased or absent)	Anterior horn cell	Spinal muscular atrophy
	Peripheral nerve	HMSN
	Neuromuscular junction	Myasthenia, myasthenic syndromes, botulism
	Muscle	Congenital myopathies, metabolic myopathies
		Neonatal presentation of muscular dystrophy

DTR deep tendon reflexes, *HIE* hypoxic-ischemic encephalopathy, *CHR* congestive heart failure, *HMSN* hereditary motor sensory neuropathy

The severity and distribution of involvement may be variable, and many authors have suggested that the pattern of involvement may be useful in making a diagnosis; however, there is sufficient overlap between the clinical features of the various diseases that specific conditions cannot generally be identified without histopathologic study of the muscle and/or genetic testing.

Routine laboratory investigations are of limited value in the evaluation of the floppy infant. If the examiner localizes the lesion to the supraspinal category and acute systemic disease is not a consideration, a large number of potential investigations become considerations including neuroimaging, genetic and metabolic screens and specific metabolic and genetic tests. Serum CK (creatine kinase) determination may be normal or elevated in any of the congenital myopathies. The CK value in the congenital muscular dystrophies may also be normal but is more likely elevated. On rare occasion, one of the dystrophinopathies will present in infancy as a hypotonic child and a CK 50–100 times normal may be a clue to that diagnosis [13–15]. Imaging of the muscle with ultrasound or magnetic resonance (MR) imaging has revealed a number of identifiable changes in the gross structure of the muscle and is becoming a useful tool in the diagnosis of the congenital myopathies [16, 17]. MR spectroscopy and positron emission tomography have been used to ascertain specific metabolic characteristics of muscle but have not been of use in the diagnostic process.

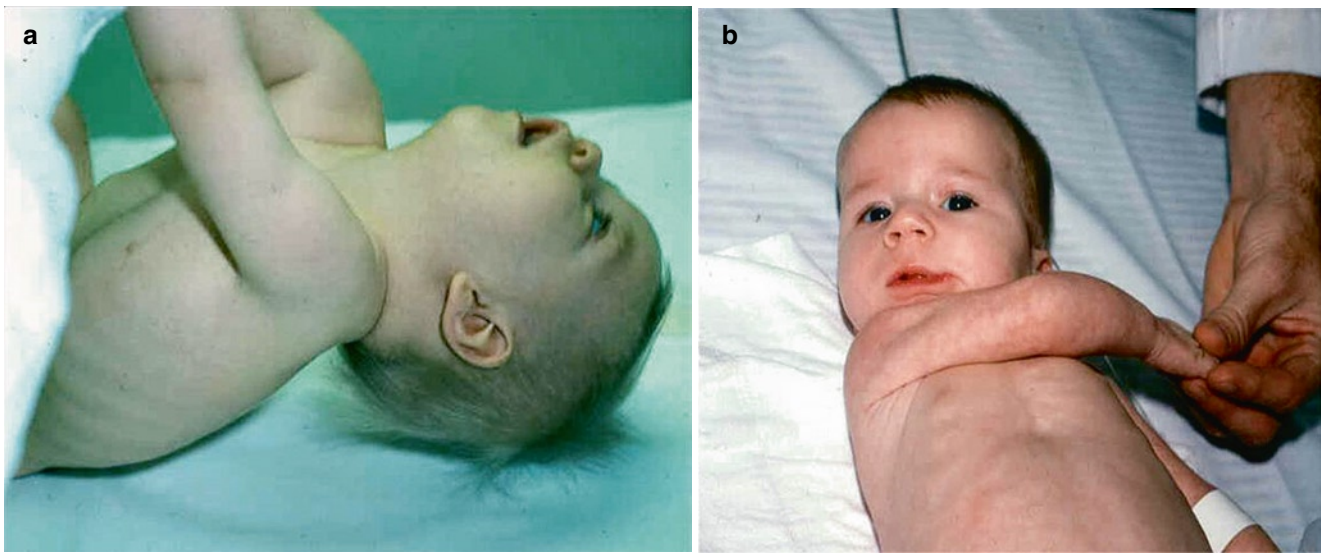

Fig. 62.1 Reliable clinical measures of tone (**a**) "Pull to sit" where the examiner gently pulls the baby from supine to a sitting position, measures axial tone of neck and back and appendicular tone of shoulders and arms. (**b**) "Scarf sign" where the examiner grasps the hand and pulls the arm across the face, normally the elbow will not pass the midline of the chin. This tests appendicular tone. (**c**) "Shoulder suspension" where the examiner picks up the infant under the arms measures appendicular tone unless head control is a problem, then axial tone is also assessed. (**d**) "Ventral suspension" where the examiner holds the infant with one hand placed under the abdomen and thorax measures axial tone mostly, but the arm position may give some information about appendicular tone (Figure from Bodensteiner [12]. With permission)

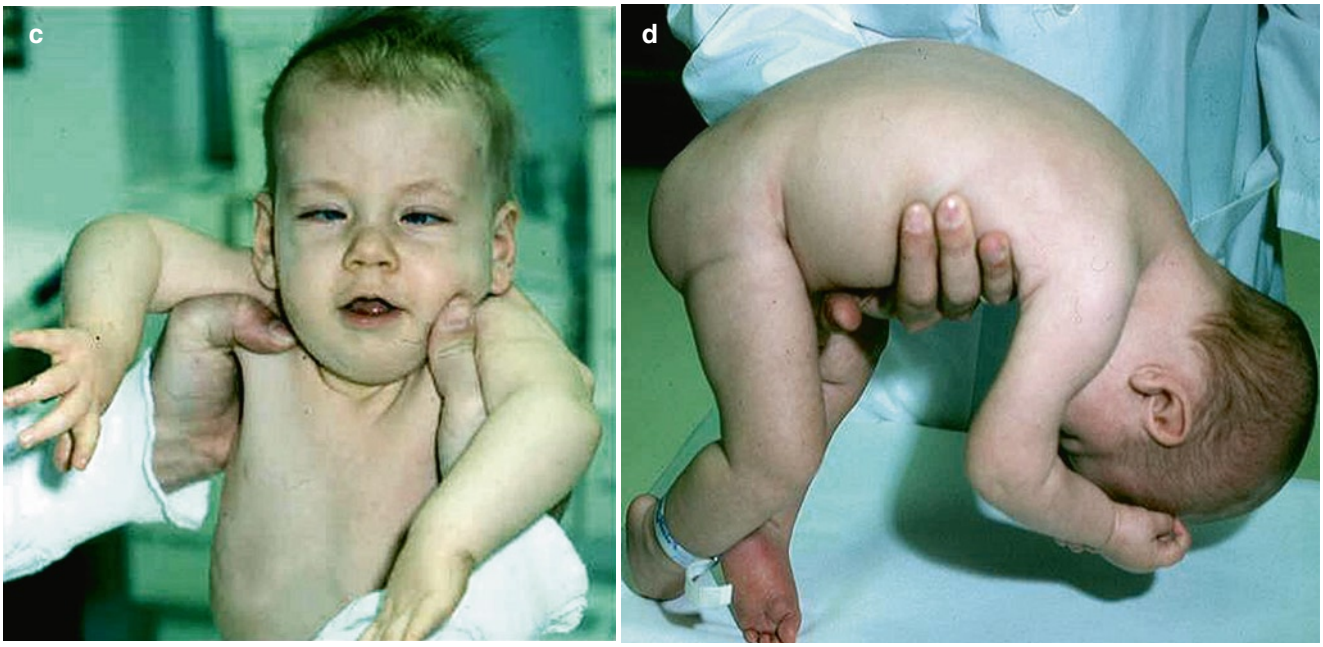

Fig. 62.1 (continued)

Needle electromyography (EMG) is still a useful tool in the diagnostic evaluation of the floppy infant. The finding of small amplitude, short duration, and polyphasic motor units is helpful in localizing the problem to the muscle and choosing an appropriate muscle for histological study. Performing an adequate EMG on a newborn infant, however, is difficult even in the hands of the most experienced examiners, and the findings are sometimes nonspecific. One would hope to be able to distinguish a primary myopathy from anterior horn cell disease by needle EMG, and in the later half of the first year, this is entirely possible and for most experienced electromyographers, this determination can be made in the younger infant. The distinction may not be so easy in the newborn. Thus, the finding of an abnormal EMG may help to localize the lesion and choose the biopsy site but is otherwise unlikely to provide reliable diagnostic information [18].

Because of the number of shared clinical characteristics, it is usually impossible to make a specific diagnosis on the basis of clinical features alone, although some congenital myopathies are more likely to display specific clinical features suggesting a possible diagnosis. The routine laboratory evaluation is equally nonspecific. If the clinical localization of the lesion is the motor unit and the EMG is clearly "myopathic," the next most useful step is muscle biopsy with histochemical study of the muscle and biochemical, electron microscopic and genetic studies available as determined by the biopsy. The needle EMG is also frequently useful in choosing a muscle with an appropriate degree of involvement for biopsy [14]. Open biopsy is preferred in infants in order to get an adequate tissue sample for diagnosis. If the EMG suggests motor unit localization and a "neurogenic" process, the current recommendation is to do the genetic testing for the deletion of the survival motor neuron gene (SMN-1) and copy number determination of SMN-2 for spinal muscular atrophy before undertaking a muscle biopsy. If the expected genetic abnormality is identified, it would obviate the need for direct examination of the muscle tissue.

Congenital Myopathies with Cores (Core Myopathies)

Clinical Features

The congenital myopathies characterized by the presence of "cores" are now generally grouped into the core myopathies which include central core disease and multicore disease, myopathy with minicores, and others, all characterized by focal reductions in oxidative enzyme activity on histochemical staining of frozen sections of muscle tissue. The most commonly used designation for this group of diseases with multiple core structures is now multiminicore disease (MmD) [19]. Mutations in the ryanodine receptor are the most common cause of core myopathies while mutations in the selenoprotein N (SEPN1) are less common [20].

Central core disease, the first congenital myopathy to be identified, is characterized by proximal muscle weakness, hypotonia absent reflexes, and delayed acquisition of motor milestones along with skeletal anomalies such as short stature, kyphoscoliosis, pes cavus, and dislocated hips [21]. Affected adults with central core disease may be nearly asymptomatic or may have muscle cramps and myalgias with varying degrees of proximal muscle weakness which is

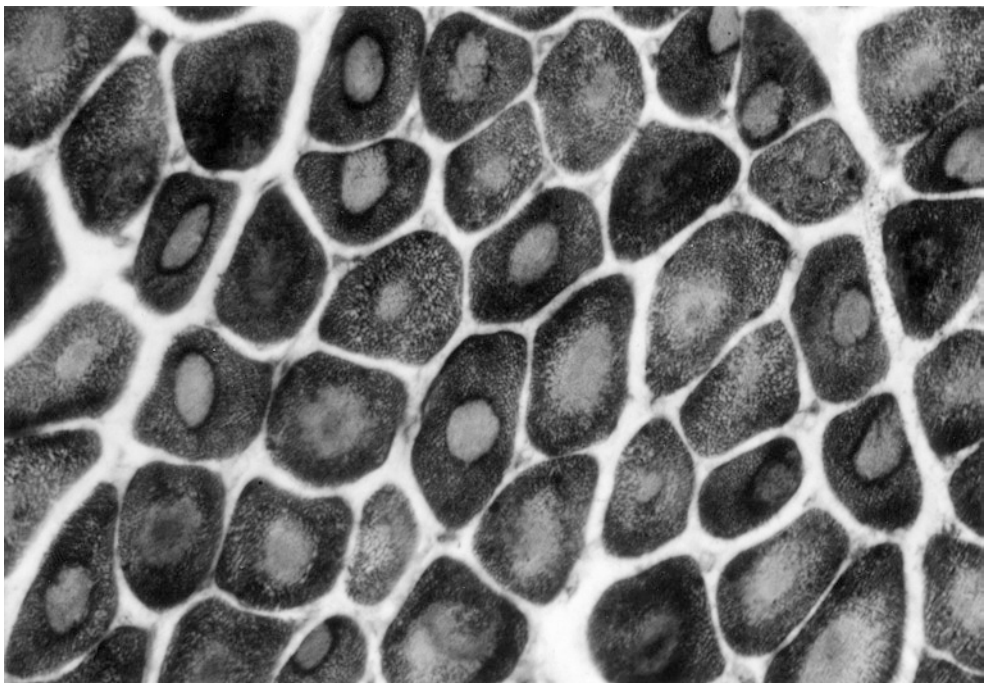

Fig. 62.2 Central core disease. Both this child and her mother had proximal muscle weakness that was more evident in the lower extremities. The central cores are well demarcated with the NADH-TR reaction and probably extend throughout the entire length of the myofibers. Note also the type 1 myofiber predominance. NADH-TR × 350 (original magnification)

typically more pronounced in the lower extremities. Many patients with central core disease have the potential to develop malignant hyperthermia (MHS) with the use of volatile anesthetics and/or muscle relaxants. Patients with truncating mutations in the SEPN1 gene may also be MHS. Magnetic resonance imaging of the muscle in the core myopathies may be useful as the pattern of involvement is one of the more characteristic patterns seen. The gluteus maximus is prominently involved in the pelvis. The thigh shows that the adductor magnus, vastus lateralis, vastus intermedius, semitendinosus, and sartorius muscles are all involved with sparing of the rectus femoris, adductor longus, gracilis, and biceps femoris. In the lower leg, the soleus and peroneal muscles are involved with preservation of the anterior tibial, posterior tibial, and gastrocnemius [17]. Patients with SEPN1 mutations show prominent involvement of the anterior thigh and many will also have rigid spines [22]. Although the precise epidemiological data does not yet exist, the core myopathies are more common than any other congenital myopathies, and RYR1 mutations are the most common identifiable cause with an incidence of 1:250,000 for central core disease in England and perhaps as high as 1:2,000 for the heterozygous state in Japan [23, 24]. The incidence of SEPN1 gene mutations in the population is not known at this time.

Pathological Features

The histology of the muscle from patients with central core disease is characterized by distinctive, well-circumscribed circular regions in the center of most type 1 fibers (Fig. 62.2). These more or less cylindrical structures are seen easily with many stains but are most clearly demonstrated with the NADH-TR technique with which the cores are unstained. The cores extend throughout the length of the myofiber. Most patients with central core disease show type 1 myofiber predominance, though the percentage of fibers containing cores varies considerably. Occasionally one finds nemaline rods in association with cores.

Etiology and Pathogenesis

The pathogenesis of core formation remains undefined [25, 26]. Central cores may result from fusion of myotubes at different stages of maturation during the 24th to 28th week of gestation. Alternatively, the similarity between target fibers and cores suggests possible aberrant innervation. However, targets do not extend throughout the full length of the affected muscle fiber. Studies have failed to show increased extrajunctional acetylcholine receptors in fibers with cores as would be expected with denervation. Structures resembling cores have been produced after tenotomy. Nevertheless, significant differences between experimentally induced lesions and naturally occurring cores and target fibers exist.

Genetics

Most patients with Central core disease inherit the disease as an autosomal dominant. Sporadic cases presumably represent new mutations. The gene for the most common form is located on chromosome 19q13.1, and the gene product is the ryanodine receptor (RYR1) [27, 28]. The ryanodine receptor is one of two genes responsible for malignant hyperthermia, the other being the skeletal muscle dihydropyridine-sensitive L-type voltage-dependent calcium channel gene (CACNA1S) [29–31]. A third gene coding for beta-myosin heavy chain

(MYH7) has been found in patients with a hypertrophic cardiomyopathy and central core like changes in the skeletal muscle [32]. Less frequently, SEPN1 gene mutations cause myopathy with cores/mini cores or multiple cores.

Sequencing of the RYR1 gene has only recently become available and genotype-phenotype correlations are still developing. The dominant RYR1 mutations disrupt excitation contraction coupling and/or disturb intracellular homeostasis, but the mechanisms of the recessive RYR1 mutations are less well understood [20]. The pathogenesis of SEPN1-related core disease (MmD) is not clearly delineated, but there is a close functional and spatial relationship between the ryanodine receptor and the selenoprotein N suggesting a role in calcium homeostasis for the latter [20].

In patients with core structures in the muscle and neither RYR1 or SEPN1 mutations other genetic diseases which may be associated with core structures should be considered. Clinical or pathological features not usually seen in RYR1- or SEPN1-related core myopathies may be helpful in making a diagnosis. For example, cardiomyopathy may be a feature of missense mutations in B-myosin heavy chain gene (MYH7), ACTA1 mutations, or lamin A/C mutations (LMNA gene), all of which may also have core structures [19].

Nemaline Myopathy

Clinical Features

Nemaline myopathy was originally described independently by Shy et al. and Conen et al. in 1963 as a nonprogressive myopathy with a distinctive morphologic abnormality designated myogranules [33] or rods of thread-like fibrous material [34]. The clinical spectrum of nemaline myopathy has expanded considerably since. Infants with nemaline myopathy can have severe weakness and hypotonia, with a rapidly progressive course leading to early death from respiratory failure [35, 36]. The childhood presentation is typically relatively benign with a nonprogressive course characterized by proximal weakness, hypotonia, and delayed motor development. Many afflicted children have a narrow face, high arched palate, kyphoscoliosis, and talipes varus deformity. Many patients also have strikingly diminished muscle bulk. The extraocular muscles tend to be spared in nemaline myopathy, despite the palatal and facial deformities which suggest intrauterine weakness [37].

Adult onset of nemaline myopathy has been reported [38–41]. Adult patients with nemaline myopathy show a wide spectrum of clinical severity; some are asymptomatic, others have mild nonprogressive weakness present since childhood or restricted weakness (such as head drop), and still others manifest progressive weakness [41]. Some adult patients with this condition have severe wasting of distal leg muscles. Fatal cardiomyopathy has been reported in adult patients with nemaline myopathy [42].

Nemaline myopathies are now recognized as a spectrum of disorders resulting from 1 of 7 known genes with the clinical presentation divided into six different categories including severe congenital, intermediate congenital, typical congenital, mild NM of childhood onset, adult onset, and other (unusual) forms [43]. The one feature which is common to the first 4 types at least is the particular involvement of the muscles of respiration. It should be noted that not only are defects in several genes able to produce similar histopathologies but defects in the same gene can result in more than one structural defect such that a single gene mutation may produce nemaline rods, cores, or central nuclear myopathy like changes making any single feature, short of gene identification, less than reliable for diagnosis. Furthermore, the clinical spectrum of nemaline myopathy even associated with a single gene is quite wide making genotype-phenotype correlations difficult [43].

Pathological Features

The diagnosis of nemaline myopathy is still based on the demonstration of the characteristic rods in skeletal muscle. Rods are best demonstrated in frozen sections stained with the modified trichrome technique with which they appear as reddish-purple granules measuring 2–7 μm in length. There commonly are collections of rods which are quite conspicuous and tend to aggregate under the sarcolemma (Fig. 62.3). Rods are found predominantly in type 1 myofibers. Affected fibers are often somewhat smaller than normal and there may be some degree of type 1 myofiber predominance. The number of rods and the number of fibers containing rods varies greatly from patient to patient and from muscle to muscle within patients. There is little correlation between the severity and the number of rods or the number of fibers with rods, but there is a correlation between the severity of the clinical manifestations and the alterations in size and proportion of type 1 myofibers. Type 1 myofiber predominance has been observed in asymptomatic relatives of patients with nemaline myopathy. In one study of patients who underwent repeat biopsy 5–18 years after the diagnosis was made, the second biopsies showed fewer type 2 fibers and increased myofiber size variation with more atrophic fibers [44]. Rods are sometimes found in the nuclei of the myofibers and in the diaphragm muscles in infantile cases with severe clinical manifestations or rapid progression of the clinical course [36, 45]. Nuclear rods, actin accumulation, and the appearance of Zebra bodies are the only histological features which are associated with a specific gene defect that being ACTA1 mutations [43]. Adults with relatively mild clinical manifestations of nemaline myopathy, however, have also been found to have intranuclear rods [38, 46]. Intranuclear rods are not specific to nemaline myopathies as they have been observed in patients with plectin deficiency and ZASP mutations [47, 48].

Ultrastructurally, nemaline rods are elongated osmiophilic structures that are similar in appearance to the Z disks. They

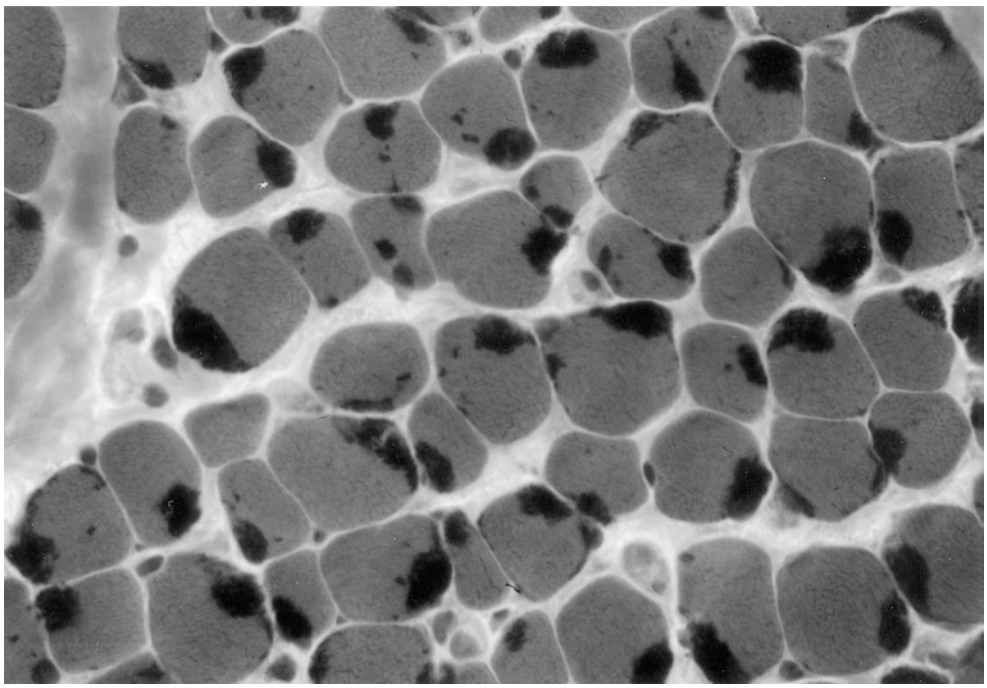

Fig. 62.3 Nemaline myopathy. This biopsy specimen is from a 4-year-old boy with marked weakness and mild skeletal anomalies. The granular nemaline rods stain reddish and tend to accumulate along one side of the myofibers. Modified trichrome × 550 (original magnification)

are composed of compactly aggregated parallel filaments with periodic cross-striations. At their free ends, nemaline rods are in continuity with thin actin filaments. In transverse section, the nemaline rods display a quadratic latticework configuration. Biochemical and immunohistochemical studies have demonstrated the presence of alpha-actinin [49, 50]. A defect in the control mechanisms that normally restrict alpha-actinin to the Z disks may be responsible for the formation of nemaline rods [51]. Rod structures, though characteristic of nemaline myopathy, are not specific for the disease and can be seen in a variety of other situations including other myopathies, normal extraocular muscles, and in normal muscle fibers near myotendinous insertions. Nemaline rods as well as central cores have been seen in tenotomized animals [52].

Genetics

There are currently seven genes known to be associated with nemaline myopathies. Six of the seven genes encode proteins involved with the thin filaments of the sarcomere. The seventh gene is KBTBD13 and the function is not yet known. There are probably more genes to be identified as there are patients with nemaline myopathies who do not have any of the known mutations [43]. Other than the fact that ACTA1 mutations are associated with the intranuclear rods and that the sporadic late-onset nemaline myopathy (SLONM) appears to be an autoimmune disorder, genotype-phenotype correlations are not easily made [41]. The genes associated with nemaline myopathies include:

1. TPM3 Slow alpha-tropomyosin (in first family with NM described) is a dominant mutation. Widely variable clinical presentation, Rods only in type 1 fibers, fiber-type disproportion, may overlap with "cap myopathy" [53].
2. Nebulin (NEB) mutations cause a widely variable NM from severe congenital to milder forms, with and without specific involvement of distal musculature, the knee extensors, neck muscles, and face [54]. These are recessive mutations and can be the cause of rod-core myopathies [55].
3. Muscle alpha actin gene (ACTA1) mutations are often severe sporadic dominant mutations with the severity of the involvement being dependent on the degree of expression of cardiac muscle actin retained in the skeletal muscles of the patient [56].
4. Beta-tropomyosin gene (TPM2) mutations are associated with dominant distal arthrogryposis and recessive Escobar syndrome with NM [57, 58].
5. The last three mutations are uncommon. They include slow skeletal muscle troponin T gene (TNNT1) mutations, KBTBD13 mutations, and CFL2 mutations in the muscle cofilin-2 gene.

It is important to realize that the molecular diagnosis of NM is complicated by the number of genes, the large size of the nebulin gene and the overlapping of the clinical syndromes. This makes the genetic diagnosis expensive and time-consuming at present. It is presumed that the next generation of sequencing and targeted capture should facilitate this process [59].

Centronuclear Myopathy (Myotubular Myopathy)

This condition was originally described in a 12-year-old boy with weakness, including involvement of facial and

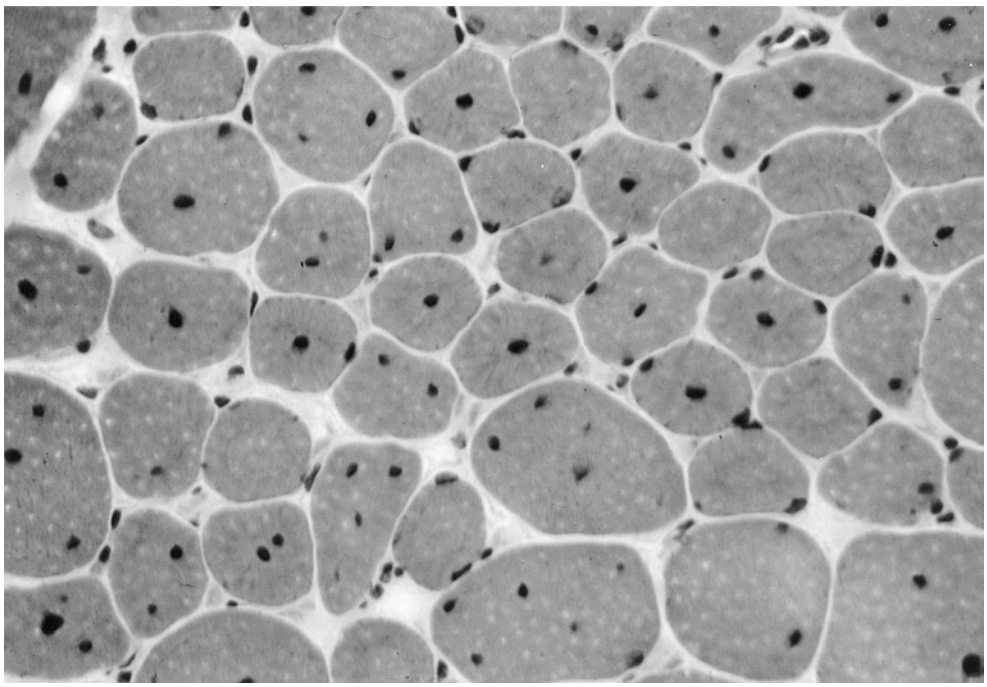

Fig. 62.4 Centronuclear myopathy. This patient and his brother had moderate weakness since infancy. Note the numerous centrally located nuclei and moderate variation in myofiber size. The biopsy specimen also showed type 1 myofiber predominance. H & E × 350 (original magnification)

extraocular muscles and delayed motor development [60]. The authors suggested that the disease resulted from arrested maturation of embryonic muscle and designated the disorder myotubular myopathy. The term centronuclear myopathy (CNM) was soon introduced to describe the disease in two teenage sisters who had weakness, also involving the extraocular muscles, and impaired motor development [61]. The current approach is to label the X-linked infantile form as myotubular myopathy most of which are caused by mutations in the MTM1 (myotubularin 1) gene. The term centronuclear myopathy (CNM) is used for the autosomally inherited later-onset forms, the classical dominant form is caused by mutations in the DNM2 (dynamin 2) gene and the recessive form caused by mutations in the BIN1 (bridging integrator protein) gene [62].

Clinical Features

With subsequent reports the clinical spectrum of the disease has expanded. Three more or less distinct clinical presentations have been delineated [4]. When onset of weakness is in the neonatal period, the clinical course is frequently rapidly progressive, leading to respiratory failure and death [63]. When this presentation occurs, it is usually indicative of the X-linked form of the disease. In the majority of patients, the disease becomes manifest during late infancy or childhood and is characterized by weakness (including extraocular muscles), hypotonia, and delayed motor development. Associated skeletal deformities, such as kyphoscoliosis and pes cavus, may occur. Some patients do not become symptomatic until adulthood. These individuals usually have mild to moderate weakness affecting particularly the lower extremities.

Imaging of the CNMs is most helpful in the MTM1-related cases where there is predominant and prominent involvement of the posterior thigh compartment and anterior medial muscles with preservation of the anterior lateral and gracilis muscles [17]. The imaging features of the dynamin and BNI1-related CNMs are less specific and usually reveal diffuse involvement of the muscle.

Pathological Features

Centronuclear myopathy is histologically characterized by a large but variable number of myofibers that contain rows of centrally placed internal nuclei (Fig. 62.4). The central nuclei are often surrounded by vacuoles that may contain glycogen granules. In some cases, the central nuclei are restricted to the type 1 myofibers; in others, they are found in both fiber types. Centronuclear myopathy often shows type 1 predominance and relatively small type 1 fibers. When viewed in cross section, the affected fibers often show radial striations. This finding may be due to the presence of abnormally small myofibrils in the interior of the myofibers, around and between successive central nuclei [47]. The X-linked form apparent in neonates is characterized by fibers of uncertain type with developing contractile elements around the periphery of the fiber and unstained clear central regions of the fibers resembling myotubes that one might see in developing muscle culture.

Pathogenesis

The gene mutations causing most of the cases of CNM have now been delineated. All are genes that are involved in membrane remodeling and membrane trafficking, perhaps the

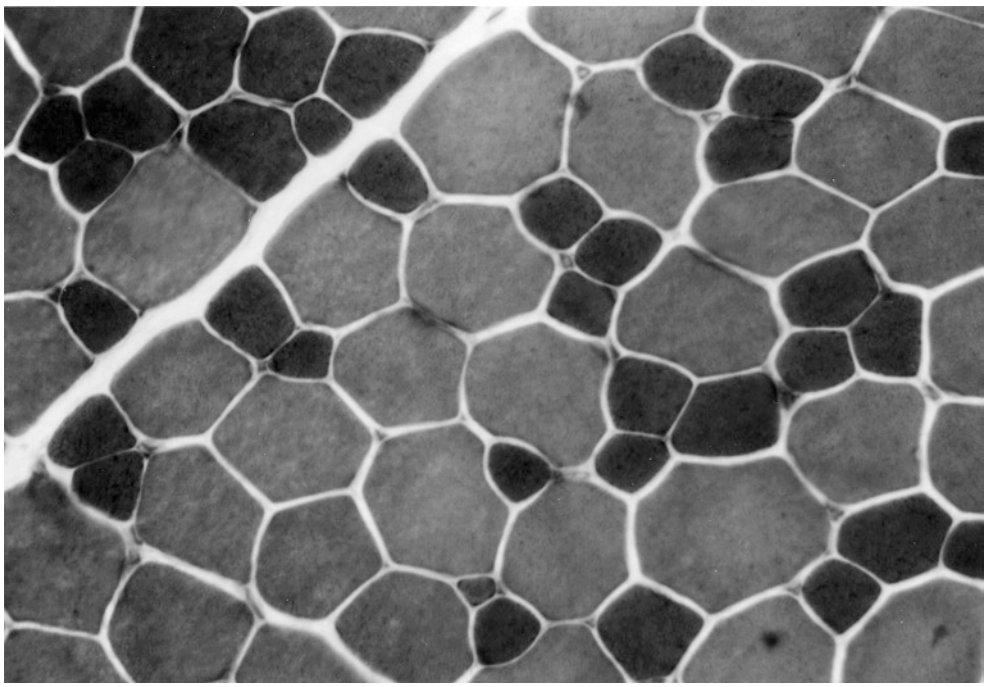

Fig. 62.5 Congenital fiber-type disproportion. This young girl had moderate weakness and hypotonia. The dark staining type 1 myofibers are more than 12 % smaller than the lighter staining type 2 myofibers. Nonspecific esterase × 550 (original magnification)

common pathomechanism involved in the condition although recent data suggests a role for T-tubule dysfunction in the pathogenesis in the X-linked form. The ability to predict the clinical severity based on the gene mutation is not yet well established and mutations in the same gene and similar mutations can be associated with mild or severe phenotypes [64]. Although there is overlap, the triad of pathological features of radial arrangement of sarcoplasmic oxidative enzyme staining, nuclear centralization and internalization, and type 1 fiber predominance and hypotrophy is seen only in the DNM2-related cases of CNM [65].

Congenital Fiber-Type Disproportion

A congenital myopathy in which the chief pathological feature consisted of smallness of type 1 myofibers (where the type 1 fibers are more than 12 % smaller than type 2 fibers) was described and later named by Brooke [66, 67]. Whether congenital fiber-type disproportion (CFTD) is a distinct entity or a part of many other diseases has been controversial, but the term does describe a useful diagnostic category despite the fact that to some degree, fiber size disproportion is a feature of a wide range of conditions [68].

Clinical Features

Infants with CFTD display clinical features that are nonspecific and common to many congenital myopathies. They are hypotonic and weak especially during the first 2 years of life. These children are often short and may have a number of skeletal or morphological abnormalities including high arched palate, kyphoscoliosis, dislocated hips, pes cavus, and contractures of the elbows and knees. CNS abnormalities with mental retardation have been described in some patients with congenital fiber-type disproportion [69, 70]. Congenital fiber-type disproportion has been associated with hyperinsulinemia and peripheral insulin resistance [71]. In those patients with the clinical features of a congenital myopathy and clear-cut fiber-type disproportion on muscle biopsy, the clinical picture is more uniform than is seen in the more common congenital myopathies [2]. There also is a reported association between congenital fiber-type disproportion and rigid spine syndrome [72].

Pathological Features

Histologically the condition is characterized by a disparity in the size of the myofiber types. The type 1 fibers are at least 12–15 % smaller than the type 2 myofibers (Fig. 62.5). Subsequent reports broadened the original definition of the disease and emphasized the occurrence of similar morphologic findings in children with a wide variety of neuromuscular disorders [4]. However, some investigators consider pure fiber-type disproportion to be highly suggestive of a congenital syndrome manifest predominantly by benign hypotonia and nonprogressive weakness [4, 73]. In some cases of congenital fiber-type disproportion, central nuclei have been seen later in the course of the disorder [74]. One of the major unanswered questions with this and some other congenital myopathies is why these patients are weak since their muscle does not show what would ordinarily be considered pathological features or reduction in muscle bulk. In general, the severity of clinical involvement is correlated with the degree

of abnormality of type 1 muscle fibers, though the significance of these findings is still obscure. It has been suggested that this disorder represents a disharmonic maturation of the muscles [70]. If there are rods, cores or central nuclei in the biopsy, the fiber size disproportion is considered secondary and of little importance.

Genetics

Although some cases of CFTD demonstrate autosomal dominant inheritance, most cases are sporadic. There are now several genes which are known to be associated with the finding of CFTD. These include TPM3 (Tropomyosin), RYR1 (ryanodine receptor 1) and ACTA1 (Actin) genes [75–77]. Tropomyosin mutations are the most common gene associated with CFTD and in fact, CFTD is the clinical diagnosis more often in patients with TPM3 mutations than nemaline myopathy. Most of the mutations in which the clinical picture is CFTD are dominant missense mutations and have mild to moderate disease severity [75].

In patients where the gene mutation associated with CFTD is known, there may be specific implications regarding health surveillance such as the need to monitor respiratory function in patients with mutations in the TPM3 gene. In patients with CFTD without known mutations, one can anticipate that the weakness will be only slowly progressive at worst but even here monitoring for scoliosis, joint contractures, cardiac abnormalities, and respiratory muscle weakness is appropriate [78].

Reducing Body Myopathy and FHL1-Related Myopathies

Reducing body myopathy (RBM) as a morphologically distinctive disorder was originally described in 2 weak, hypotonic neonates who died in late infancy [79]. Subsequent reports described similar morphologic features in older individuals with varied clinical manifestations, including a more benign course [80, 81]. Developments in the last few years have delineated several gene defects associated with RBM and a number of related or associated myopathies [82]. We now understand that although several genes can be associated with the presence of reducing bodies as well as other myopathies, the most common gene group is the four and a half Lin-11, Lsl-1, Mac-3 (LIM) domain protein 1 gene (FHL1 gene). The identification of these gene mutations has redefined several clinical phenotypes including at least 4 distinct clinical myopathy conditions including RBM, X-linked myopathy with postural muscle atrophy, Emery-Dreifuss MD (type 6), and scapuloperoneal myopathy. These mutations also have been associated with rigid spine syndrome, and the syndrome of rigid spine, contractures, and cardiomyopathy [82]. MRI study of patients with RBM is distinctive and shows altered density of posterior-medial and soleus muscles with sparing of the glutei muscles which appear hypertrophic in comparison [83].

Pathological Features

Reducing body myopathy is characterized by the presence of a variable number of so-called reducing bodies in the muscle fibers. These structures are round to ovoid masses, measuring 10–70 μm at maximal diameter. Reducing bodies are generally located at the periphery of the myofiber, often near the nucleus. They stain reddish-purple with the modified trichrome technique and are further characterized histochemically by autofluorescence. They also stain for glycogen, nucleic acids, and sulfhydryl groups. Ultrastructurally, reducing bodies are composed of varying proportions of osmiophilic granular and fibrillar material surrounding irregular lacunae. The composition of the reducing bodies is uncertain. They may be derived from ribosomes, viral particles, or myofilaments. Muscle biopsy specimens from these patients also show variation in myofiber size, occasional degenerating myofibers, and type 1 myofiber predominance.

Genetics

There have been at least 26 different mutations in the FHL1 gene. The phenotypes vary considerably; Table 62.2 lists some of the newly discovered genotype-phenotype associations.

Congenital Myopathies with Protein Aggregation

The advances in molecular genetics largely have made the classification of the less well-established congenital myopathies obsolete. As evidenced in the preceding section, mutations in a single gene can cause several distinct phenotypes and conversely, as we will see in this section, a given clinical-pathologic phenotype may be caused by a number of different gene mutations, sometimes affecting the same cellular functions, sometimes the functional relationships are not so clear. A number of congenital myopathies share the aggregation of proteins in the fibers [84]. Among the common proteins accumulated in muscle are AlphaBeta crystallin, desmin, and myotilin which are associated with myofibrillar myopathies including granulofilamentous myopathy, cytoplasmic body myopathy, and spheroid body myopathy, respectively.

Myofibrillar myopathies are known now to be associated with more than a dozen different gene mutations (Table 62.3). The MFM conditions make up the largest group of protein aggregate myopathies to date. These conditions are marked by late onset with a variable progression but including muscle weakness, respiratory failure and cardiomyopathy. The mechanisms of accumulation of protein in these conditions are not established. In some, there may be an abnormal

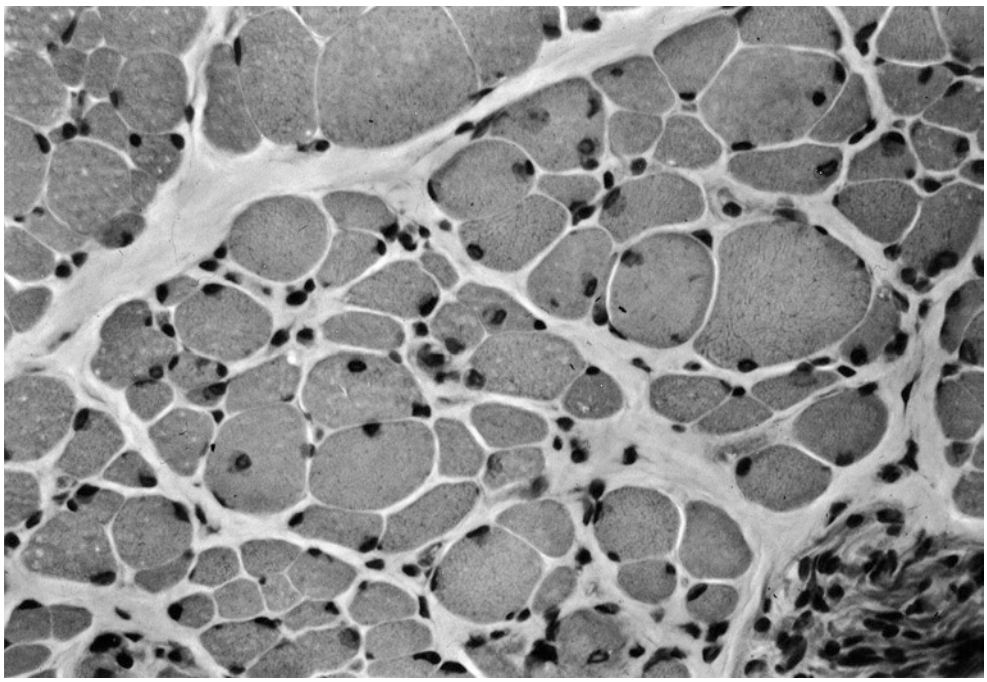

Fig. 62.6 Congenital muscular dystrophy. This biopsy specimen is from a 2-year-old girl with mild weakness and skeletal deformities. Note the variation in myofiber size, increase in internal nuclei, and increased endomysial connective tissue. H & E × 350 (original magnification)

structure of the protein, but it may also represent a defect of muscle protein catabolism [84]. Why the same gene mutation produces protein aggregation in some families and a congenital myopathy in other families is not understood at this time. Table 62.4 gives some examples of known genes that produce both kinds of myopathies.

Congenital Muscular Dystrophy

The term congenital muscular dystrophy refers to a group of congenital myopathies which have what are usually felt to be dystrophic changes on muscle biopsy (Fig. 62.6). These dystrophic changes include muscle fiber necrosis, replacement of muscle tissue by fatty tissue, and fibrosis of muscle. Thus, a congenital muscular dystrophy presents in early life with weakness, hypotonia, and other features of congenital myopathy and is further delineated by the finding of dystrophic changes on biopsy. In the past, the congenital muscular dystrophies were further categorized by the presence or absence of associated cerebral involvement on a clinical basis. While the distinction may be useful on a clinical basis, the classification has now given way to the use of the gene mutation as the primary classification parameter (Table 62.5).

All the congenital muscular dystrophies are associated with muscle weakness, hypotonia, and deformities resulting from intrauterine weakness and decreased movement (arthrogryposis, pes cavus, etc.). Before the deficiency of merosin was identified, two types of congenital muscular dystrophy (CMD) were identified on the basis of clinical severity, mild and severe CMD. The severe form of CMD has now been identified as having a deficiency of merosin (laminin M) as the molecular basis for the myopathy. Current classification would thus identify merosin deficient CMD as a severe form often resulting in extensive disability and not uncommonly leading to respiratory failure and death.

Merosin, or laminin M chain, is a predominantly extracellular protein which forms an essential link between the extracellular matrix and the dystrophin-associated glycoprotein component of the muscle cytoskeleton (see Figure 56.1, chapter 56). The clinical features include hypotonia, weakness, arthrogryposis, and delayed motor milestones. Characteristically, these patients are remarkable for their mental alertness. Although brain involvement has been reported, as these patients get older, it is usually clear that in the majority there is no cognitive impairment [85]. The merosin negative CMDs also have a striking abnormality on cranial MRI scan consisting of diffuse high signal intensity on T-2 weighted images in the cerebral white matter.

The merosin positive form of CMD, or the mild form of CMD, is typically nonprogressive or slowly progressive and usually results in only minor disabilities. There is usually no cognitive impairment and fully 90 % of these patients will be able to ambulate by 4 years of age [86].

The genetic basis of the merosin deficient CMD (MDC1A) is a deletion/mutation of the laminin 2 gene (LAMA2) on 6q22-q23 [87]. The result may be complete deficiency of the merosin in the more severe cases or partial function of the merosin in milder cases [88].

Congenital muscular dystrophy due to abnormal glycosylation of the dystroglycans represents the second group of CMDs. The best known of the CMDs with glycosylation

defects of dystroglycans are Fukuyama CMD (FCMD), Walker-Warburg CMD (WWS), muscle-eye-brain CMD (Santavuori, MEB), congenital muscular dystrophy 1C (FKRP-related or MDC1C), and congenital muscular dystrophy 1D (LARGE-related or MDC1D).

The Fukuyama CMD is most prevalent in Japan and was once thought to be allelic with WWS [89]. The cerebral involvement is characterized by polymicrogyria, lissencephaly, and neuronal heterotopias which result in characteristic MRI features [90]. Seizures are frequently the initial CNS symptom. Affected children are hypotonic at birth, show developmental delay affecting both motor and cognitive developmental milestones and develop progressive muscle weakness and atrophy. Life expectancy is strikingly shortened and most do not survive beyond the first decade. MRI of the brain may be helpful in suggesting the diagnosis in these patients [88].

Another CMD disease which may be distinct from the Fukuyama and Walker-Warburg CMDs was reported as an autosomal recessive disorder by Echenne [89]. These patients had typical CMD with mild intellectual impairment and moderate to severe cerebellar atrophy, strikingly elevated CK in the serum, and normal merosin, dystrophin, and sarcoglycan immunostaining of the skeletal muscle.

Some patients with CMD have a combination of eye and brain anomalies [91]. The cerebral anomalies include disturbances of neuronal migration, hypomyelination, leptomeningeal gliomesodermal proliferation, and pyramidal tract hypoplasia. The ocular anomalies include corneal opacities, severe myopia, congenital glaucoma, pallor of the optic disks, and retinal hypoplasia. Muscle-eye-brain disease has been shown to result from a mutation in POMGnT1 in most cases, but mutations in FKRP and FKTN can also cause this phenotype.

The third group of CMDs is the diseases that result from mutations in the COL6 genes. The spectrum of disease resulting from collagen 6 defects varies from severe (Ullrich CMD) to more mild adult onset (Bethlem Myopathy). These patients are at risk for respiratory failure which may even present prior to the loss of ambulation and requires the physician to be vigilant with regard to the respiratory function. Although there is no diagnostic clinical feature, the MRI of the muscle may show a characteristic "outside-in" pattern of degeneration in which most of the abnormal signal will be at the outer edges of the muscle [88]. These patients also may have contractures of proximal joints with hyperlaxity of the distal joints and often show a characteristic follicular hyperkeratosis of the skin as they get into the second half of the first decade of life.

The fourth category of CMDs is the selenoprotein-related disorders due to recessive mutations of the SEPN1 gene [88]. Clinical characteristics of SEPN1 CMD patients include severe weakness of axial neck and trunk muscles which leads to scoliosis and respiratory failure in the second and thirds decades of life with relatively preserved limb strength. The range of clinical syndromes is large however with the possible phenotypes including rigid spine syndrome, multiminicore disease, desmin-related myopathy with Mallory body-like inclusions and CFTD [92]. Table 62.5 lists some features of the four major groups of congenital muscular dystrophies.

The CK, EMG, and muscle biopsy findings in CMD are similar whether or not there is associated cerebral involvement.

Treatment, Management, and Prognosis

There is no specific treatment for any of the congenital myopathies. Therapeutic interventions consist of symptomatic physical therapy, orthopedic treatment of associated skeletal anomalies, and ventilatory supportive measures (if appropriate) for patients with respiratory muscle weakness. Measures to allow effective sitting or wheel chair fitting are frequently of value in improving the comfort and function of these individuals. There are no established or clinically tested standards of practice for any supportive therapies in the congenital myopathies although the standard of management for muscle disease in general applies to the CMDs generally.

Metabolic Myopathies

63

Salvatore DiMauro, Hasan Orhan Akman,
and Carman Paradas

Introduction

Inborn errors of glycogen and fatty acid metabolism that cause exclusively or predominantly neuromuscular disorders are characterized by dynamic or static symptoms. Dynamic symptoms are acute, recurrent, reversible muscle dysfunctions, manifesting as exercise intolerance, myalgia with or without painful cramps (contractures), and often culminating in muscle breakdown and myoglobinuria. In contrast, static symptoms are manifested by fixed, often progressive weakness, sometimes simulating dystrophic or neurogenic processes (Fig. 63.1).

To understand glycogen and lipid storage disorders, a brief review of muscle metabolism at rest and during exercise is helpful.

The "fuel" utilized by muscle depends on several factors, most importantly the type, intensity, and duration of exercise but also diet and physical conditioning. At rest, muscle utilizes predominantly fatty acids. At the opposite end of the spectrum, the energy for extremely intense exercise (close to one's maximal oxygen uptake, or VO_2max, in dynamic exercise or close to maximal force generation in isometric exercise) derives from anaerobic glycolysis, especially when there is a "burst" of activity with rapid acceleration to maximal exercise. During submaximal exercise, the type of fuel utilized by muscle depends on the relative intensity of exertion. At low intensity (below 50 % VO_2max), blood glucose and free fatty acids (FFA) are the primary sources of energy. At higher intensities, the proportion of energy derived from carbohydrate oxidation increases, and muscle glycogen becomes an important fuel; at 70–80 % VO_2max, aerobic metabolism of glycogen is the crucial source of energy, and fatigue appears to set in when glycogen is exhausted. The type of circulating substrate utilized during mild exercise varies with time, and there is a gradual increase in the utilization of FFA over glucose until, a few hours into

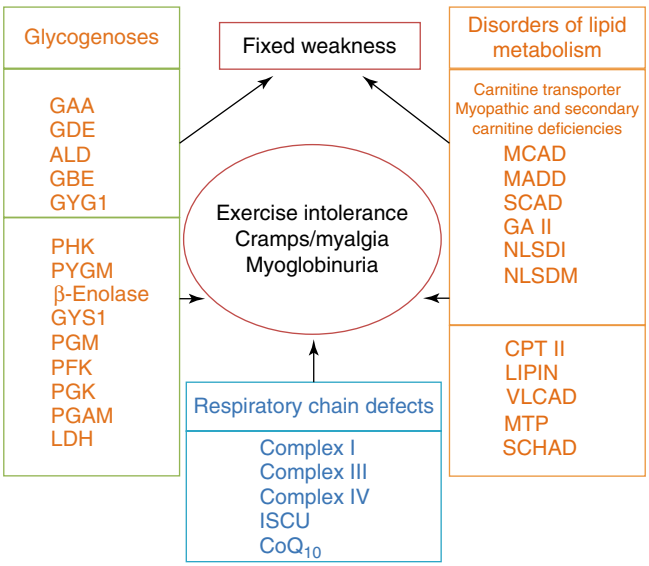

Fig. 63.1 The two major clinical syndromes seen in metabolic myopathies. Deficient enzymes are denoted by abbreviations or gene symbols as follows: *GAA* acid maltase (acid α-glucosidase) (GSD II), *GDE* glycogen debranching (GSD III), *ALD* aldolase (GSD IX), *GBE* glycogen branching (GSD IV), *GYG1* glycogenin (GSD 0), *PHK* phosphorylase kinase (GSD VIII), *PYGM* myophosphorylase (GSD V), *GYS1* glycogen synthetase, *PGM* phosphoglucomutase (GSD IV), *PFK* phosphofructokinase (GSD VII), *PGK* phosphoglycerate kinase (GSD IX), *PGAM* phosphoglycerate mutase (GSD X), *LDH* lactate dehydrogenase (GSD XI), *MTP* mitochondrial trifunctional enzyme, *MCAD* medium-chain acyl-CoA dehydrogenase, *MADD* multiple acyl-CoA dehydrogenase, *SCAD* short-chain acyl-CoA dehydrogenase, *GAII* glutaric aciduria type II, *NLSDI* neutral lipid storage diseases with ichthyosis (Chanarin-Dorfman disease), *NLSDM* neutral storage disease with myopathy, *CPT II* carnitine palmitoyltransferase II, *VLCAD* very-long-chain acyl-CoA dehydrogenase, *SCHAD* short-chain 3-hydroxyacyl-CoA dehydrogenase, *ISCU* nonheme iron-sulfur (Fe-S) protein, *CoQ_{10}* coenzyme Q_{10}

exercise, lipid oxidation becomes the major source of energy. Because the availability of FFA from adipose tissue is virtually unlimited, a normal person can perform moderate dynamic exercise for many hours.

Figure 63.2 illustrates schematically mitochondrial energy metabolism, including the "points of entry" of carbohydrate and lipid fuel. Pyruvate, the terminal product of aerobic glycolysis, is carried across the inner mitochondrial membrane by an incompletely known transporter system. Transport of FFA requires a more complex system, which includes two enzymes (carnitine palmitoyltransferase [CPT] I and CPT II), a carrier molecule (L-carnitine), and a translocase (carnitine-acylcarnitine translocase, CACT). After oxidation of pyruvate through the pyruvate dehydrogenase complex (PDHC) and of fatty acyl-CoAs through ß-oxidation, both carbohydrate and lipid fuels converge into a common central metabolite, acetyl-CoA, which is further oxidized in the Krebs cycle. The reducing equivalents produced in the Krebs cycle and in the ß-oxidation spirals are passed along a chain of proteins embedded in the inner

mitochondrial membrane (the electron transport chain) to molecular oxygen with production of water. The *electron transport chain* consists of four multimeric complexes (I to IV) plus two small electron carriers, coenzyme Q (or ubiquinone) and cytochrome *c*. The energy generated by these reactions is used to pump protons from the mitochondrial matrix into the space between inner and outer mitochondrial membranes. This creates an electrochemical proton gradient across the inner membrane. A fifth multimeric complex (complex V or adenosine triphosphate [ATP] synthase), a tiny rotary engine, converts the energy of the electrochemical proton gradient into ATP, in a process known as oxidation/phosphorylation coupling. The terminal pathway of oxidative metabolism, comprising the electron transport chain and complex V, is known as the *respiratory chain*.

Disorders Causing Exercise Intolerance and Myoglobinuria

In general, there is a good correlation between the circumstances leading to clinical problems and the different roles of glycogen and lipid metabolism in the provision of energy. Thus, the complaints of patients with glycogenoses are almost invariably related to an identifiable, and usually strenuous, bout of exertion, and the muscles that hurt, swell, or cramp up are those that have been engaged in that particular type of exercise.

In contrast, patients with disorders of lipid metabolism, such as CPT II or very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency, often have no warning of an impending episode of myoglobinuria, which usually follows prolonged moderate exercise and may be heralded by myalgia of exercising muscles but is never accompanied by painful cramps. In addition, prolonged fasting in and by itself may cause myoglobinuria, in which case any muscle group may be affected, including respiratory muscles; a few patients with CPT II deficiency have been taken to the emergency room in respiratory distress during an episode of myoglobinuria [1]. The deleterious effect of fasting in CPT II deficiency is easily explained by the increased dependence of muscle on FFA oxidation, which is partially blocked. Conversely, some patients with myophosphorylase deficiency, a glycogen storage disease, note a beneficial effect of fasting on their exercise ability. This is explained by the mobilization of FFA, which facilitates the physiological switch from carbohydrate to lipid utilization.

The *respiratory chain* is indeed the "business end" of mitochondrial metabolism, where the energy generated by carbohydrate and lipid oxidation is released as ATP. This raises an interesting question: if disturbances of glycogen and lipid metabolism cause exercise intolerance, cramps, and myoglobinuria by impairing ATP production, why did it take so long to associate this syndrome with defects in the respiratory chain, the energetic pathway "par excellence"? The answer is that these patients often stay below the clinical radar because they contradict the rules of mitochondrial genetics (see below) [2].

Glycogenoses

In reviewing the glycogenoses causing exercise intolerance and myoglobinuria, we follow the metabolic "flow" in the glycogenolytic and glycolytic pathways rather than the historical numeration (Fig. 63.3).

Phosphorylase Kinase (PhK) Deficiency (Glycogenosis Type VIII)

PhK is a key regulatory enzyme in glycogen metabolism because it activates glycogen phosphorylase by phosphorylating a specific serine in response to neuronal or hormonal stimuli. PhK deficiency is associated with four distinct clinical presentations, which are distinguished on the basis of tissue involvement (liver, muscle, heart, or liver and muscle) and mode of inheritance (autosomal or X-linked). This clinical and genetic heterogeneity is explained by the complexity of the enzyme, a decahexameric protein composed of four subunits $(\alpha\beta\gamma\delta)4$: the α and β subunits are regulatory, the γ is catalytic, and the δ- is bound to calmodulin and confers calcium sensitivity to the enzyme. In addition, there are two isoforms for the α subunit (muscle and liver, A1 and A2), both encoded by genes on the X-chromosome, and two isoforms for the γ subunit (muscle and testis, G1 and liver, G2). Both G isozymes and the B-subunit are encoded by autosomal genes.

The purely myopathic variant of PhK deficiency usually manifests as a milder form of myophosphorylase deficiency (McArdle's disease), with exercise intolerance, cramps, and, infrequently, myoglobinuria. One distinguishing laboratory feature is the lactate response to the ischemic forearm exercise test (see Chap. 6), which is usually flat in patients with McArdle's disease, while it is normal or blunted in patients with PhK deficiency. Only about 15 patients with myopathic PhK deficiency have been reported, most of whom were men, suggesting X-linked inheritance. In agreement with this concept, all molecular defects identified thus far were in the *PHKA1* gene [3].

The liver and muscle variant of PhK is an autosomal recessive disorder dominated by hepatomegaly and fasting hypoglycemia with minimal muscle involvement: in one female and four male patients, five distinct nonsense mutations have been identified in the *PHKB* gene [4].

The cardiac phenotype of PhK deficiency is secondary to mutations in the gene (*PRKAG2*) encoding the γ2 subunit of AMP-activated protein kinase (AMPK) [5]. The mechanism of this AMPK-mediated PhK inhibition is unknown.

Myophosphorylase Deficiency (Glycogenosis Type V; McArdle's Disease)

Introduction

Although McArdle did not identify the biochemical defect, never was an eponym more appropriate than in this case. In 1951, on the basis of clinical observations and a few critical lab tests, Brian McArdle gave a remarkably precise description of the metabolic problem. He noted that ischemic exercise resulted in painful cramps of forearm muscles and that no electrical activity was recorded from the shortened muscles, indicating that they were in a state of contracture. He also noted that oxygen consumption and ventilation were normal at rest but increased more than normal with exercise. The astute observation that venous lactate and pyruvate did not increase after exercise led McArdle to conclude that his patient's disorder was "characterized by a gross failure of the breakdown of glycogen to lactic acid." Nor was the specific involvement of muscle lost to McArdle, who noted that epinephrine elicited a normal rise of blood glucose and "shed blood" in vitro accumulated lactate normally, leading him to conclude that "the disorder of carbohydrate metabolism affected chiefly, if not entirely, the skeletal muscles."

Etiology and Pathogenesis

Myophosphorylase deficiency is transmitted as an autosomal recessive trait, and the gene for the muscle isoenzyme of phosphorylase has been localized to chromosome 11 [7]. The apparently autosomal dominant transmission in a few families may be explained by at least two mechanisms: (1) the presence in subsequent generations of homozygous and manifesting heterozygous individuals [8–10] or (2) the presence of one homozygous and one heterozygous parent [11].

The molecular heterogeneity of myophosphorylase deficiency is striking: in the 19 years from the description of the first molecular defects [11, 12], more than 100 different mutations have been reported [13]. The most common mutation in North America and Northern Europe appears to be a cytosine-to-thymine substitution in codon 50 of exon 1, converting an arginine to a stop codon (R50X). This has allowed the use of molecular genetic analysis in leukocytes for diagnostic purposes, thus avoiding the obligatory need of a muscle biopsy [14]. However, as more and more mutations in the myophosphorylase gene are described and leukocytes are increasingly used for diagnosis, it becomes important to establish the relative frequency of the different mutations in ethnic groups. For example, the R50X mutation has never been observed in Japan, where the most common mutation appears to be a 3-bp deletion, TTC at codon 708/709 [15].

The genotype/phenotype relationship in McArdle's disease remains unclear: the most common genetic defect in typical McArdle patients, R50X, was also found in an infant who had the fatal myopathic variant [11] and in a child who died of sudden infant death syndrome (SIDS) [16]. Of course, one cannot exclude that these unusual presentations may be due to additional gene defects. Unlikely as this situation may appear, it has been verified in two children with McArdle's disease (both homozygous for the common mutation), who were also homozygous for the most common mutation associated with adenylate deaminase (AMPD) deficiency [17, 18]. One patient had myoglobinuria at the unusually early age of 2 years; the other was a young man with multiple episodes of myoglobinuria and early onset of weakness. Although AMPD deficiency per se is an inconsistent cause of myopathy, it might have worsened the phenotypic expression of myophosphorylase deficiency.

Phosphorylase activity is virtually absent in muscle biopsies when determined either histochemically or biochemically. Biochemical studies show that the enzyme is lacking in most patients, which is consistent with the most common genetic error, a nonsense mutation (see above). As a consequence, glycogen of normal structure accumulates in muscle, reaching concentrations two or three times higher than normal. Morphologically, the stored glycogen is mostly visible at the periphery of muscle fibers, where it forms subsarcolemmal "blebs." However, glycogen accumulation may be mild enough to escape morphological detection.

Phosphorylase catalyzes the first step in glycogen breakdown by removing 1,4-glucosyl residues phosphorolytically with liberation of glucose-1-phosphate. Hence, lack of phosphorylase impedes glycolysis, as shown by the flat venous lactate response to the ischemic forearm exercise test. Similarly, 31P-nuclear magnetic resonance spectroscopy (MRS) shows lack of acidification during aerobic or ischemic exercise and a greater than normal drop of the phosphocreatine/inorganic phosphate ratio [19].

Two main pathophysiological mechanisms underlie the exercise intolerance of myophosphorylase deficiency: (1) block of anaerobic glycolysis deprives muscle of the energy needed for isometric exercise and (2) block of aerobic glycogen utilization, with the attending shortage of pyruvate and acetyl-CoA, impairs dynamic exercise above certain intensity (approximately 50 % VO_2max). In agreement with the concept that oxidative phosphorylation is curtailed by decreased substrate availability, oxygen extraction and maximal oxygen uptake are decreased in myophosphorylase deficiency but may be at least partially restored by intravenous glucose infusion [20]. Haller et al. have also documented lower concentrations of Na+/K+ pumps in needle muscle biopsies from patients with McArdle's disease than in controls [21]. This finding explains several previous observations in McArdle patients, including the excessive rise of plasma potassium with exercise, the decline in the compound muscle action potential with repetitive stimulation (probably due to extracellular potassium-mediated membrane inexcitability), and the exaggerated increase in heart rate during exercise.

The pathogenesis of contracture and myoglobinuria remains unknown: depletion of high-energy phosphate compounds, especially ATP, has long been postulated to occur, but experimental evidence is lacking.

Resting serum creatine kinase (CK) is consistently elevated in patients with McArdle's disease, indicating that individual fiber necrosis probably occurs even with daily activities, a concept supported by morphological observations. The cumulative effect of this focal muscle damage along the years may explain the appearance of fixed weakness in older individuals; we found that 28 of 52 patients had fixed weakness, with a mean age of 41.5 years, while the mean age of patients without fixed weakness was 28.1 years [22].

Clinical Presentation

The clinical picture of McArdle's disease is rather stereotypical, dominated by exercise intolerance manifested by myalgia, premature fatigue, and stiffness or weakness of exercising muscles, which is relieved by rest. The type and amount of exercise needed to precipitate these symptoms vary considerably from patient to patient, possibly in relation to training and diet, but two types of exertion are likely to cause problems: brief intense isometric exercise, such as lifting heavy weights, or less intense but sustained dynamic exercise, such as walking uphill. Moderate exercise, such as walking on level ground, is usually well tolerated. On the other hand, strenuous exercise often results in painful cramps and muscle swelling, which can last for hours. Myoglobinuria is seen in about half of the patients. In fact, McArdle's disease is the second most common metabolic cause of recurrent myoglobinuria after CPT II deficiency [23]. An interesting phenomenon, almost invariably described by McArdle patients, is the "second wind" that they experience when, at the first appearance of exercise-induced myalgia, they slow down or rest briefly before resuming their activity.

The severity of symptoms may vary markedly in different patients, some of whom have neither cramps nor myoglobinuria but complain only of excessive fatigue and poor stamina, symptoms that are likely to be dismissed as "psychogenic." On the other hand, about 20 % of patients have progressive weakness, usually starting late in life [24]. A distinct clinical variant reported in four children is characterized by severe generalized weakness at or soon after birth, respiratory insufficiency, and death in infancy [25, 26].

Differential Diagnosis

Differential diagnosis includes other metabolic myopathies, especially glycogenoses and disorders of lipid metabolism.

On purely clinical grounds, myophosphorylase deficiency is indistinguishable from defects of glycolytic enzymes, such as phosphoglucomutase (PGM), phosphofructokinase (PFK), phosphoglycerate kinase (PGK), phosphoglycerate mutase (PGAM), β-enolase (EN), and lactate dehydrogenase (LDH). Laboratory data may offer useful clues. Patients with PFK deficiency have a compensated hemolytic trait, with hyperbilirubinemia and increased reticulocyte count. With the ischemic forearm exercise test, patients with defects of terminal glycolysis (PGK, PGAM, and LDH deficiencies) have an abnormally low but not absent venous lactate response, and patients with LDH deficiency show a low lactate but excessive pyruvate response.

McArdle's disease should be distinguished from the most common metabolic cause of recurrent myoglobinuria in adults, i.e., CPT II deficiency. In patients with myophospho-

rylase deficiency, myoglobinuria is invariably triggered by exercise, usually of high intensity. Patients with CPT II deficiency, however, have episodes of myoglobinuria not only after exercise (which can be of moderate intensity but is usually prolonged) but also after prolonged fasting without exertion or after a combination of exercise and fasting. Furthermore, the ischemic forearm exercise test is normal in patients with CPT II deficiency.

Exercise-related myoglobinuria may occur in dystrophinopathies and in malignant hyperthermia. In patients with dystrophinopathies, serum CK levels between attacks are usually much higher than in patients with myophosphorylase deficiency, and transmission is X-linked recessive. In patients with malignant hyperthermia, there is usually a family history of characteristic attacks related to the administration of volatile anesthetics, and inheritance is autosomal dominant.

Intolerance to exercise without myoglobinuria can be due to adenylate deaminase (AMPD) deficiency. In patients with AMPD deficiency, the ischemic forearm exercise test causes a normal rise of venous lactate, in contrast with a lack in the rise of ammonia. Because of the high frequency of the adenylate deaminase deficiency trait, its association with myophosphorylase deficiency may occur and this "double trouble" may aggravate the clinical phenotype [17, 18].

Exercise intolerance without myoglobinuria is a common complaint of malingering and hysterical patients and is the cardinal symptom of the "chronic fatigue syndrome." However, these diagnoses should be used prudently and only after finding normal serum CK and lactate levels and a normal ischemic forearm exercise test.

Evaluation and Diagnosis

The ischemic forearm exercise test is a valuable but not specific diagnostic test, because absent or abnormally low rise of venous lactate is seen in all defects of muscle glycogenolysis or glycolysis.

Until recently, definitive diagnosis required muscle biopsy showing lack of myophosphorylase immunostaining. Our present knowledge of multiple genetic defects allows us to identify many suspected patients using genomic DNA from white blood cells. However, it is important to keep in mind the ethnic origin of the patient in order to screen for the most likely mutations.

Treatment and Management

Most patients learn to adapt their lifestyles to their limited exercise tolerance, and, within this framework, they can lead nearly normal lives. Late in the course of the disease, fixed weakness, usually moderate and affecting proximal more than distal muscles, may become a problem.

Acute renal insufficiency is the most important complication, occurring in about 50 % of patients with myoglobinuria. In those cases, abundant fluid intake to induce diuresis may suffice, but renal dialysis is often necessary. Uncomplicated episodes of myoglobinuria are followed by complete functional recovery.

There is no specific therapy for McArdle's disease. Regular moderate aerobic training (resulting in a heart rate of no more than 60–70 % of maximal) is effective because it optimizes alternate fuel delivery and utilization [27]. Another promising therapeutic agent, at least in cases with residual phosphorylase activity, is vitamin B6, because the overall body stores of pyridoxal phosphate (PLP) are depleted in McArdle's disease due to the frequent lack of enzyme protein (to which PLP is bound) [28–30]. Naturally, patients should be warned about the risks of strenuous exercise and advised to seek medical attention at the first appearance of pigmenturia, especially if accompanied by oliguria. Sucrose ingestion shortly before exercise is beneficial but must be used sparingly to avoid weight gain [31]. The ketogenic diet improved exercise tolerance in one patient but has not been subjected to a formal therapeutic trial [32].

There are two spontaneous animal models of McArdle's disease, Charolais cattle and Merino sheep. Recently, a knock-in mouse model of the R50X mutation has been obtained that recapitulates faithfully the human disease [33]. This model will provide valuable information on the pathophysiology and allow therapeutic experimentation.

Phosphoglucomutase (PGM) Deficiency (Glycogenosis Type XIV)

A single patient with biochemically and genetically proven PGM deficiency had two exercise-induced episodes of myoglobinuria [34]. Nonischemic forearm exercise caused normal rise of venous lactate but excessive rise of ammonia. Muscle biopsy showed moderate increase of normal-looking glycogen.

Phosphofructokinase (PFK) Deficiency (Glycogenosis Type VII; Tarui Disease)

Introduction

In its typical presentation, this disorder, first described by Tarui et al. in a Japanese family [35] and soon thereafter by Layzer et al. in an Ashkenazi Jewish American patient [36], is clinically indistinguishable from McArdle's disease. Minor clinical differences include lack of a typical "second wind" phenomenon; more common report of nausea and vomiting accompanying the exercise-induced crises of myalgia, cramps, and weakness; and lower frequency of myoglobinuria attacks. Much more useful in distinguishing PFK deficiency from McArdle's disease are a few simple laboratory tests, such as increased bilirubin concentration and reticulocyte count (reflecting compensated hemolytic anemia).

Etiology and Pathogenesis

The reason for the hemolytic trait in PFK deficiency is that PFK is a tetrameric enzyme under the control of three autosomal loci: a locus on chromosome 1 encodes the muscle (M) subunit; a locus on chromosome 21 encodes the liver (L) subunit; and a locus on chromosome 10 encodes the platelet (P) isozyme [37]. The three subunits are variably expressed in different tissues. Mature human muscle expresses only the M subunit and contains only the homotetramer M4, while erythrocytes express both the M and L subunits and contain five isozymes, the two homotetramers M4 and L4, and three hybrid isoforms. In patients with typical PFK deficiency, genetic defects of the M subunit cause total lack of activity in muscle but only partial PFK deficiency in red blood cells, where the residual activity (approximately 50 % of normal) is accounted for by the L4 isozyme.

The first molecular defect in PFK deficiency (a splice junction mutation resulting in a large deletion) was identified in the Japanese family originally described by Tarui and coworkers [38]. Soon thereafter Raben and her coworkers described two mutations, a splicing defect and a nucleotide deletion, which are common among Ashkenazi Jewish patients [39, 40]. About 20 distinct mutations have been identified in patients of different ethnic origins. The molecular basis of PFK deficiency in patients with infantile or childhood onset remains unknown.

Genetic defects of PFK-M cause virtual absence of PFK in muscle biopsies, when the activity is determined either histochemically [41] or biochemically. The same defects cause partial enzyme deficiencies in erythrocytes, where the L4 homotetramer accounts for the residual activity (about 50 % of the total). Tissues such as liver and platelets express predominantly or exclusively the non-M PFK subunits and are not affected. The lack of clinical cardiomyopathy or encephalopathy, however, is more difficult to explain, because PFK-M accounts for over 90 % of heart PFK and over 50 % of brain PFK [42].

As a consequence of PFK deficiency, glycogen accumulates in muscle, reaching concentrations two to three times greater than normal. Morphologically, the stored glycogen is mostly seen at the periphery of the fibers, where it is revealed by the periodic acid-Schiff (PAS) histochemical reaction and is normally digested by preincubation with diastase. However, a peculiarity of PFK deficiency is the finding, in muscle fibers of some, usually older, patients, of an abnormal polysaccharide, which stains intensely with PAS but is not digested by diastase (*polyglucosan*, PG). Ultrastructurally, PG is composed of finely granular and filamentous material, similar to the amylopectin-like polysaccharide that accumulates in branching enzyme deficiency. The presence of this material has been attributed to the accumulation in muscle of glucose-6-phosphate, an activator of the enzyme glycogen synthetase, which alters the delicate ratio between the two main glycogenosynthetic enzymes, synthetase and branching enzyme [43, 44].

PFK is the rate-limiting enzyme of glycolysis and PFK deficiency blocks glycolysis, thus explaining the flat venous lactate response to forearm ischemic exercise. The accumulation in muscle of phosphorylated monoesters, observed by 31P-nuclear MRS in PFK but not in myophosphorylase deficiency, is easily explained by the sites of the two metabolic blocks: midway in the glycolytic pathway for PFK deficiency and preceding glycolysis for myophosphorylase deficiency.

As in myophosphorylase deficiency, PFK deficiency also impairs both anaerobic and aerobic glycogen metabolism and blocks the fall in muscle pH that normally accompanies heavy exercise. It also results in high levels of adenosine diphosphate (ADP) and increased adenine nucleotide degradation with exaggerated production of ammonia and myogenic hyperuricemia during exercise [45]. It causes substrate-limited oxidative metabolism with fluctuations in exercise and oxidative capacity related to the availability of blood-borne fuels [46]. Finally, PFK deficiency causes exaggerated sympathetic neural responses to exercise associated with enhanced mobilization of extramuscular fuels [47] and exaggerated heart rate, cardiac output, and blood flow relative to the muscle capacity to use oxygen [48].

The negative effect of high-carbohydrate meals on exercise tolerance is attributed to the fact that glucose lowers the blood concentration of free fatty acids and ketones, which are alternative fuels in PFK-deficient patients. Thus, not only is glucose ineffective in alleviating exercise intolerance (in contrast to myophosphorylase deficiency), but it is actually harmful, a situation dubbed "out-of-wind" phenomenon [46].

The pathogenesis of contracture and myoglobinuria in PFK remains unknown: depletion of high-energy phosphate compounds, especially adenosine triphosphate, has long been postulated to occur, but experimental evidence is lacking. Abnormal accumulation of metabolites such as adenosine diphosphate may be an important trigger of premature fatigue.

Clinical Presentation

Typically, there is intolerance to intense exercise, often accompanied by cramps of exercising muscles, which is relieved by rest [37]. Although careful history reveals that exercise intolerance is present since childhood, patients usually do not come to medical attention until adolescence, and the diagnosis is most commonly established in young people. Symptoms are more likely to occur with isometric exercise (such as pushing a stalled car) or intense dynamic exercise (such as walking uphill). The exercise intolerance appears to worsen with high-carbohydrate intake [46]. In contrast to patients with McArdle's disease, patients with PFK deficiency do not experience a "second wind" [49].

A few patients may be jaundiced as a consequence of the hemolytic trait that accompanies PFK-M deficiency, and a few may suffer from gouty arthritis due to hyperuricemia.

Fixed weakness of late onset has been described in a few patients who suffered from exercise intolerance earlier in life [50–54]. A strikingly different clinical presentation consists of severe myopathy in infancy or early childhood, with respiratory failure and death before 2 years of age. This variant has been reported in several children [37]. Although they all had severe myopathy with muscle PFK deficiency, clinical and biochemical data were rather heterogeneous, possibly reflecting different molecular etiologies.

In patients with typical muscle disease, serum CK is usually increased. There is moderate reticulocytosis and increased serum bilirubin, reflecting the hemolytic trait. Uric acid is increased in most patients.

The ischemic forearm exercise test is a useful but not specific test. In patients with PFK-M deficiency (but also in patients with myophosphorylase deficiency or other defects of muscle glycolysis), the increase of venous lactate is absent or inadequate. It is important to keep in mind that the test depends on the patient's ability and willingness to exercise vigorously.

Needle electromyography (EMG) may be normal or show "myopathic" abnormalities (small and short-duration motor unit action potentials). Furthermore, no electrical activity is recorded from maximally shortened muscles during contractures induced by ischemic exercise.

Studies of ^{31}P-nuclear MRS show the accumulation, even with mild exercise, of glycolytic intermediates in the form of phosphorylated monoesters, which occurs also in other defects of glycolysis but not in myophosphorylase deficiency [55].

Differential Diagnosis

The differential diagnosis is similar to that outlined above for McArdle's disease. Few laboratory data may offer useful clues because of the compensated hemolytic anemia that accompanies PFK and aldolase deficiency, with consequent hyperbilirubinemia and increased reticulocyte count. Of all the other glycogenoses, only PGK and aldolase deficiency causes a hemolytic trait [56].

Muscle PFK deficiency should be included in the differential diagnosis of late-onset proximal limb weakness. Usually these patients have a history of lifelong exercise intolerance and cramps. Laboratory signs of a hemolytic trait, an abnormal ischemic forearm exercise test, and abundant polyglucosan in the muscle biopsy are clues to the correct diagnosis.

Evaluation and Diagnosis

The ischemic forearm exercise test is a valuable but not specific diagnostic test. In patients with an abnormal ischemic forearm exercise test (i.e., no rise of venous lactate), laboratory evidence of hemolytic anemia suggests PFK deficiency. Documentation of partial PFK deficiency in erythrocytes bolsters this conclusion, but, until recently, definitive diagnosis required biochemical documentation of the enzyme defect in muscle (keeping in mind that PFK is notoriously labile and PFK deficiency is often a spurious finding if muscle is not flash frozen at the time of biopsy). Present knowledge of multiple molecular defects in the PFK-M gene allows identification of many suspected patients using genomic DNA isolated from white blood cells.

Treatment and Management

Most patients learn to adapt their lifestyles to the limited exercise, and, within this framework, they may lead nearly normal lives. In the fifth or sixth decade, some patients develop proximal limb weakness, which can limit their functional independence but is rarely disabling.

Although myoglobinuria is rare in this condition, acute renal insufficiency may occur in patients with myoglobinuria, requiring forced diuresis or renal dialysis. Uncomplicated episodes of myoglobinuria are followed by complete functional recovery.

There is no specific therapy. Glucose administration is not only useless because the metabolic block is halfway in the glycolytic pathway but is in fact detrimental because glucose lowers the blood concentration of alternative fuels, such as free fatty acids and ketone bodies [46].

High-protein diet and aerobic training [57] have proved beneficial in patients with myophosphorylase deficiency and should be tried in patients with PFK deficiency.

A 2-year-old boy with the infantile form of PFK deficiency benefited remarkably – as had a patient with McArdle's disease [32] – from a ketogenic diet, which was instituted to provide muscle and brain with ketone bodies as alternative fuels [58]. There was clear improvement in strength, EMG features, and electroencephalogram (EEG) pattern. Unfortunately, the child worsened suddenly at 35 months of age and died of complications of pneumonia. Still, a ketogenic diet should be considered in children with the more severe infantile variant of PFK deficiency.

Aldolase (ALD) Deficiency (Glycogenosis Type XII)

Two children with muscle and erythrocyte aldolase deficiency have been reported [59, 60]. Both had transfusion-requiring nonspherocytic hemolytic anemia, muscle weakness, exercise-induced myalgia, and increased serum CK, especially during febrile illnesses (2,620 U/L in one patient and 13,800 U/L in the other). One patient was alive at 4 and ½ years [59], the other died at 4 years during an episode of myoglobinuria and hyperkalemia [60]. Both children were compound heterozygous for mutations in *ALDOA*, the gene that encodes

aldolase A, the only aldolase isozyme present in muscle and erythrocytes. The mutant enzyme is more thermolabile than normal, thus probably explaining the vulnerability of patients to febrile illnesses.

Phosphoglycerate Kinase (PGK) Deficiency (Glycogenosis Type IX)

Primary myopathy is not a common presentation of PGK deficiency, an X-linked recessive disorder most commonly (11 of 33 reported patients) presenting as nonspherocytic hemolytic anemia and central nervous system (CNS) dysfunction. However, purely myopathic presentation is a close second (9 of 33 patients), while isolated blood dyscrasia was reported in 6 patients and the association of myopathy and CNS dysfunction in 4 patients [56]. All myopathic patients complained of exercise intolerance, with cramps and myoglobinuria. Molecular defects were documented in several recent patients, and one, T378P (PGK Afula), caused the peculiar association of myopathy and severe juvenile Parkinsonism [61, 62].

The wide spectrum of clinical phenotypes in PGK deficiency is difficult to explain because PGK is a monomeric enzyme encoded by a single gene on Xq13 and expressed in all tissues except the testis (a testicular isozyme, PGK2, is encoded by a gene on chromosome 19). Different amounts of residual activities in different tissues do not fully explain the clinical heterogeneity [56]. While lack of myoglobinuria in patients with severe hemolytic anemia and brain dysfunction may be attributed to their inability to exercise, it is more difficult to explain the converse situation, lack of blood dyscrasia, or brain disease in patients with myopathy.

Phosphoglycerate Mutase (PGAM) Deficiency (Glycogenosis Type X)

In contrast to PGK deficiency, PGAM deficiency affects only muscle, causing exercise intolerance, cramps, and recurrent myoglobinuria [63]. This is because PGAM is a dimeric enzyme composed of a muscle-specific (M) and a brain-specific (B) subunit, and normal muscle contains predominantly the MM homodimer, which accounts for 95 % of the total activity. The only other tissues containing substantial amounts of the M subunit are heart and sperm, but there is no evidence of cardiomyopathy or male infertility in patients with PGAM deficiency. A dozen patients have been reported, most of them from the United States [64]. All US patients have been black and they harbor one common mutation (W78X) in the *PGAM-M* gene (encoded by a gene on chromosome 7), suggesting a founder effect [64]. Different mutations were found in two Italian families [65, 66], in a Japanese family [67], and in a Pakistani patient [64, 68].

Despite the abundance of PGAM in muscle, we have observed exercise intolerance in heterozygous relatives of PGAM-deficient patients [64, 67]. A second unusual feature of PGAM deficiency is the frequent (33 % of patients) occurrence of tubular aggregates, which have never been associated with other, more common glycogen storage diseases: the relationship between this morphological abnormality and the enzyme defect remains unexplained.

Cycle exercise responses in two patients were markedly different from those of patients with clinically similar McArdle's disease: the PGAM-deficient patients had virtually normal cycle exercise and oxidative capacity, no second wind, and no improvement of their exercise capacity with lipid or lactate supplements [69].

The first mutation in the PGAM-B subunit of PGAM has been reported in a patient with hereditary spherocytosis [70].

Beta-Enolase Deficiency (Glycogenosis Type XIII)

A single patient with adult-onset exercise intolerance and generalized weakness but without episodes of myoglobinuria had a flat lactate response to forearm ischemic exercise. Muscle ultrastructure showed subsarcolemmal accumulations of glycogen, and muscle biochemistry revealed an isolated severe deficiency of enolase activity (5 % of the normal mean). Over 90 % of the muscle enzyme is accounted for by the β-enolase form, which is encoded by the *ENO3* gene. The patient was compound heterozygous for two missense mutations, probably reducing the stability of the mutant enzyme [71].

Lactate Dehydrogenase (LDH) Deficiency (Glycogenosis Type XI)

The discovery of this glycogenosis was due to the astute observation that a patient with myoglobinuria had predictably sky-high values of serum CK but extremely low values of LDH [72]. LDH is a tetrameric enzyme composed of various proportions of a muscle-specific subunit (LDH-A) and a cardiac subunit (LDH-B). LDH-A is encoded by a gene on chromosome 11, and three different mutations have been identified in Japanese patients [73–75], while the only two described white patients had two distinct mutations [76]. In addition to muscle symptoms, three affected Japanese women suffered from dystocia necessitating cesarian sections, and a few patients had dermatologic problems [77].

Muscle Glycogen Synthetase (GS) Deficiency (Glycogenosis Type 0)

Although glycogen synthetase (GS) deficiency of the liver was described almost 50 years ago and aptly called "glycogenosis" (i.e., lack of glycogen), the first cases of muscle glycogenosis were reported only 5 years ago in a Swedish family, and the condition was dubbed glycogenosis type 0 [78]. Of three siblings, a boy died of sudden cardiac arrest at 10 years of age, his brother suffered from exercise intoler-

ance and hypertrophic cardiomyopathy, and his sister was asymptomatic. Muscle biopsies from the younger siblings showed conspicuous lack of glycogen by periodic acid-Schiff histochemistry and by electron microscopy, as well as increased numbers of mitochondria. All three children harbored a homozygous nonsense mutation in the muscle GS gene (*GYS1*), which encodes the muscle and heart isoform of the enzyme.

The fourth patient was an 8-year-old previously asymptomatic boy who unexpectedly collapsed and died while climbing up and down the stairs at school [79]. A sister had died at 6 days of age from unknown cause. Muscle morphology showed mitochondrial proliferation and – in retrospect – lack of glycogen by EM. The diagnosis of glycogenosis type 0 is complicated by the mild muscle symptoms (exercise intolerance), the scarce attention paid by morphologists to lack of glycogen (as opposed to glycogen storage), and the misleading clue of the reactive mitochondrial proliferation.

The fifth patient was a Japanese girl who died at age 12 of cardiac arrest [80]. She had had normal early development but suffered from two generalized tonic-clonic seizures at 2 and 4 years. Since age 5, she had recurrent rather stereotypical syncopal episodes after brief exercise. Loss of consciousness lasted a few hours and was followed by muscle weakness and pain. Muscle biopsy showed lack of glycogen by PAS and negative histochemical stain for myophosphorylase, which depends on the presence of endogenous glycogen. Glycogen synthetase activity was 2 % of normal, and glycogen concentration was barely detectable. The modified Gomori trichrome stain showed abundant subsarcolemmal mitochondria. Molecular genetic analysis revealed a compound heterozygous mutation in *GYS1*.

Glycogenin Deficiency (Glycogenosis Type XV)

The primer of glycogen synthesis is a glycosyltransferase that uses uridine diphosphate glucose as a substrate in an autoglycosylation reaction to generate a short (about 10 glucosyl units) glucose polymer, the kernel of the new glycogen molecule. There are two isoforms of glycogenin, the muscle isozyme glycogenin-1 and the liver isozyme glycogenin-2, which are also expressed partially in the heart.

The first pathogenic mutation in the gene encoding glycogenin-1 (*GYG1*) was described 2 years ago in a young man who was slower than his peers as a child, suffered from exertional dyspnea, and at age 27 had a life-threatening episode of ventricular fibrillation and was equipped with a permanent defibrillator [81]. Skeletal muscle was devoid of glycogen, whereas the heart showed large accumulation of a poorly structured PAS-positive material, presumably a novel form of abnormal polysaccharide due to the presence in the heart of some glycogenin.

Disorders of Lipid Metabolism

Carnitine Palmitoyltransferase II (CPT II) Deficiency

Introduction

CPT II deficiency (rather, CPT deficiency, because at the time we could not distinguish CPT I and CPT II activities) was identified in 1973 in two brothers with recurrent exercise-induced myoglobinuria whose muscle biopsies had shown no glycogen storage and normal phosphorylase and PFK activities [82, 83]. A hindsight reevaluation of their clinical histories revealed interesting differences from patients with glycogenoses: (1) neither brother had any weakness nor any problem with brief intense exercise; (2) neither complained of cramps but described muscle tenderness preceding myoglobinuria; (3) both had problems with prolonged and not necessarily strenuous exercise; (4) both identified fasting as a precipitating factor, usually in combination with exercise. Their histories summarize the main clinical features of CPT II deficiency, except that additional precipitating factors may also include emotional stress, lack of sleep, and cold exposure.

Etiology and Pathogenesis

CPT II is a key enzyme in the *carnitine cycle*, needed for the transport of long-chain fatty acids from the cytosol into the mitochondrion. The carnitine cycle is comprised of four elements: (1) carnitine palmitoyltransferase I (CPT I), on the inner aspect of the outer mitochondrial membrane, which catalyzes the esterification of palmitoyl-CoA to palmitoylcarnitine; (2) the carrier molecule L-carnitine; (3) carnitine palmitoyltransferase II (CPT II), on the inner aspect of the inner mitochondrial membrane, which catalyzes the reverse reaction of CPT I, regenerating palmitoyl-CoA and liberating carnitine; and (4) a carnitine-acylcarnitine translocase (CACT), capable of exchanging acylcarnitine and carnitine across the inner mitochondrial membrane (Fig. 63.2).

Although the existence of two CPT enzymes, one outside and the other inside the inner mitochondrial membrane, was never questioned, for many years it was uncertain whether the two enzymes were distinct proteins under separate genetic control or a single protein with different milieus. It is now known that CPT I and CPT II are different proteins: CPT I is encoded by a gene on chromosome 11q [84], while CPT II is encoded by a gene on chromosome 1p32 [85].

Although by 1990 it was apparent that CPT deficiency was an important cause of recurrent myoglobinuria [23], a vexing question was why the defect of such a key enzyme in lipid metabolism should affect skeletal muscle selectively, especially since there was no evidence for the existence of tissue-specific CPT isozymes. The situation is now clearer. CPT I deficiency does, in fact, cause life-threatening hypoketotic hypoglycemia of infancy induced by fasting and often accompanied by lethargy, coma, and seizures [86]. CPT II

deficiency can also cause two different and severe infantile phenotypes: (1) a rapidly lethal neonatal form with hypoketotic hypoglycemia, generalized steatosis, and multiple malformations and (2) an infantile hepatomuscular form characterized by episodes of hypoketotic hypoglycemia, lethargy, seizures, hepatomegaly, cardiomegaly, and cardiac arrhythmias [86]. However, these variants are rare compared to the adult myopathic phenotype. Molecular genetic analysis has revealed more than 30 pathogenic mutations in patients with myopathic CPT II deficiency. Of these, the S113L mutation is common in American patients [87], and screening genomic DNA from white blood cells in suspected patients may eliminate the need for a muscle biopsy. The large predominance of affected men in CPT II deficiency has been perplexing and has suggested a hormonal influence; it is, therefore, interesting that studies of the CPT II promoter region do, in fact, suggest that gene expression may be hormonally regulated [88].

Clinical Presentation

The more common, myopathic form of CPT II deficiency usually presents in adolescents or young adults, predominantly males, with recurrent myoglobinuria following prolonged, though not necessarily strenuous, exercise, prolonged fasting, or a combination of the two conditions. Other precipitating factors include cold exposure, lack of sleep, and, especially in children, intercurrent illnesses with high fever. Between attacks, these patients have normal physical and neurological exams. At difference from the glycogenoses, the attacks of myoglobinuria are not heralded by painful cramps. In addition, exercising muscles are not necessarily the only ones undergoing acute necrosis, and a few patients have been admitted to the hospital in respiratory distress. Another distinguishing feature from the glycogenoses is the normal level of serum CK between attacks of myoglobinuria. Muscle biopsy is usually normal.

Differential Diagnosis

The differential diagnosis includes other inborn errors of metabolism characterized by recurrent myoglobinuria, especially glycogenoses and defects of the mitochondrial respiratory chain. Several features distinguish CPT II deficiency from the glycogenoses: (1) whereas in the glycogenoses, myoglobinuria is always triggered by exercise, in CPT II deficiency, myoglobinuria may follow prolonged fasting or, less frequently, cold exposure, lack of sleep, emotional stress, or intercurrent illness; (2) painful cramps of exercising muscles are not described by patients with CPT II deficiency, who, therefore, lack a useful warning sign of impending myoglobinuria; (3) fixed weakness is much less common in CPT II deficiency than in the glycogenoses; (4) between episodes of myoglobinuria, serum CK is usually normal in CPT II deficiency while it is variably but consistently increased in the glycogenoses. Patients with defects in the mitochondrial respiratory chain typically complain of exercise intolerance and premature fatigue, whereas patients with CPT II deficiency have no problem with brief exercise, even when this is strenuous, and their everyday life is usually normal. CPT II deficiency is a "silent disease" that manifests itself only in extreme situations because the presence of 15–20 % residual enzyme activity in muscle is sufficient to support fat oxidation at rest but does not allow the increase in fat oxidation needed to supply muscle energy during dynamic exercise [89]. Also, patients with CPT II deficiency have no central nervous system involvement, unlike patients with CoQ10 deficiency, in whom recurrent myoglobinuria is usually associated with seizures, ataxia, or mental retardation [90].

Therapy is based on a low-fat, high-carbohydrate dietary regimen, medium-chain triglyceride (MCT) instead of long-chain oil, or triheptanoin as an anaplerotic compound [91]. Another therapeutic approach is based on the upregulation of mitochondrial biogenesis by bezafibrate [92].

Very Long-Chain Acyl-CoA Dehydrogenase (VLCAD) Deficiency

The clinical picture of CPT II deficiency may be indistinguishable from that of some defects in the first step of ß-oxidation, including very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency and trifunctional protein deficiency.

VLCAD is associated with the inner mitochondrial membrane and is specific for C14–C24 fatty acyl-CoAs. Age at onset and clinical severity of VLCAD deficiency depend on the amount of residual enzyme activity. A severe infantile form is characterized by cardiomyopathy and high mortality. A milder childhood form with hypoketotic hypoglycemia and rare cardiac involvement has a more benign outcome. The adult myopathic form causes recurrent myoglobinuria triggered by prolonged exercise or fasting, thus closely simulating CPT II deficiency [86, 93]. The diagnosis can be made by tandem mass spectroscopy detecting long-chain acylcarnitines (especially C14) in blood or in fibroblasts incubated with long-chain acylcarnitines [94].

The muscle biopsy is usually normal or nonspecifically altered as in patients with CPT II deficiency, but the diagnosis can be established by immunohistochemistry [93].

Mitochondrial Trifunctional Protein (MTP) Deficiency

Mitochondrial trifunctional protein (MTP) comprises three enzyme reactions, enoyl-CoA hydratase, long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD), and acyl thiolase, and generates acetyl-CoA and an acyl-CoA shortened by two carbon atoms, which is ready to enter a new β-oxidation cycle. Most patients with MTP have isolated LCHAD

deficiency, usually due to one mutation (E510Q) in the *HDHA* gene encoding the α subunit of the enzyme [95]. A fatal infantile presentation is dominated by encephalopathy and hepatopathy. The childhood presentation is characterized by recurrent myoglobinuria, often accompanied by cardiomyopathy, pigmentary retinopathy, and sensorimotor axonal neuropathy. The episodes of myoglobinuria may be precipitated by exercise, fasting, or intercurrent illnesses and are often accompanied by life-threatening respiratory distress. Because of the concurrent neuropathy, the muscle biopsy shows features of denervation but only rarely lipid storage.

Phosphatidic Acid Phosphatase (LIPIN) Deficiency

It has long been known that many cases of recurrent myoglobinuria, especially in children, go undiagnosed at the molecular level [96]. It is, therefore, important that a new cause of childhood myoglobinuria has now been added, mutations in the *LPIN1* gene that encodes the muscle-specific phosphatidic acid phosphatase: this enzyme converts phosphatidate to diacylglycerol in the triacylglycerol pathway [97]. Affected children had episodes of myoglobinuria between 15 months and 7 years of age, usually precipitated by febrile illnesses. Muscle biopsy was essentially normal. It has been proposed that the enzyme defect during stress periods causes accumulation of lysophospholipids, which act as detergents, thus favoring muscle breakdown.

Respiratory Chain Defects

While exercise intolerance is a common complaint in patients with mitochondrial encephalomyopathies, it is often overshadowed by other symptoms and signs [98]. Only relatively recently we have come to appreciate that exercise intolerance, myalgia, and myoglobinuria may be the sole presentation of respiratory chain defects. These may affect complex I, complex III, or complex IV, although they seem to be more commonly associated with complex III deficiency [2, 99].

Complex I Deficiency

Increased blood lactic acid at rest (5.2 mEq/L; normal, less than 2.2) was the only objective indication for a muscle biopsy in a 38-year-old man who complained of severe lifelong exercise intolerance [100]. He was otherwise completely normal, including muscle strength and bulk, resting serum CK, and EMG. He had never noticed pigmenturia, and his mother and siblings had no muscle problems. The muscle biopsy showed intensely cytochrome *c* oxidase (COX)-positive ragged-red fibers (RRF) and an isolated moderately severe defect of complex I activity. Molecular analysis identified a heteroplasmic (54 % of muscle mitochondrial DNA) nonsense mutation (G11832A) in the gene encoding subunit 4 of complex I (ND4). Single-fiber polymerase chain reaction (PCR) showed that the mutation was much more abundant in RRF than in normal fibers, thus confirming the pathogenicity of this base change.

In 1990, Bet et al. [101] had reported a similar case: a 43-year-old man with lifelong exercise intolerance, myalgia, mild proximal limb weakness, and negative family history. His muscle biopsy also showed abundant RRF and an isolated defect of complex I activity (40 % of normal). Molecular analysis of his muscle revealed a novel pathogenic mutation in the ND1 gene of mtDNA, a seven nucleotide intragenic inversion that alters three highly conserved amino acids [102].

Complex III Deficiency

In 1993, Bouzidi et al. [99] found low complex III activity in the muscle of a 25-year-old man with exercise intolerance in whom they later identified a missense mutation (G15615A) in the cytochrome *b* gene (the only mtDNA-encoded subunit of complex III) [100]. In the years that followed, 14 more patients were reported with different mutations in the cytochrome *b* gene of mtDNA (*MTCYB*) but with the same clinical picture: isolated myopathy with exercise intolerance and sometimes myoglobinuria [99]. The muscle biopsy in all patients showed complex III deficiency and "ragged-blue" fibers with the SDH stain, which were also COX positive. The lack of maternal inheritance and of multisystem involvement keeps these patients under the radar for the diagnosis of mtDNA-related disorders.

Complex IV (COX) Deficiency

Starting at age 15, a 16-year-old woman had four episodes of muscle cramps and myoglobinuria precipitated by prolonged exercise or viral illness [103]. Rather surprisingly, she had only "mildly reduced endurance." Between attacks, both physical and neurological exams were normal, as were routine laboratory tests, including serum CK and lactate. Interestingly, no tissue other than muscle was clinically affected, and family history was entirely negative. A muscle biopsy at age 16 showed numerous ragged-red fibers, which stained intensely for the succinate dehydrogenase (SDH) reaction but not at all for the cytochrome *c* oxidase reaction. Biochemical analysis showed a marked and isolated defect of COX activity (14 % of normal), and molecular genetic analysis identified a 15-bp microdeletion in the mtDNA gene encoding subunit III of COX (*COX III*). The deletion affected 92 % of the mtDNA in muscle and 0.7 % in leukocytes but was not detected in the patient's fibroblasts or in her mother's leukocytes.

We studied a very similar case [104], except that our patient was a 34-year-old man who had suffered from exercise intolerance since childhood. He also had an isolated myopathy with recurrent episodes of exercise-induced myoglobinuria, normal neurological exam between attacks, and

negative family history. Muscle biopsy showed scattered RRF but numerous COX-negative fibers severely reduced COX activity (13 % of normal), and molecular studies revealed a heteroplasmic nonsense mutation (G5920A) in the *COX I* gene of mtDNA.

A third case of isolated myopathy due to a mutation in *COX II* was described in a 14-year-old boy with mild weakness of shoulder and pelvic girdle muscle and exercise intolerance without myoglobinuria [105]. Family history was negative, and although lactate in the CSF was mildly elevated, there was no evidence of brain dysfunction and brain MRI was negative.

A fourth case of isolated mitochondrial myopathy with weakness, myalgia, and one episode of myoglobinuria regarded a 34-year-old woman with no family history of similar disorders. Muscle histochemistry showed over 90 % COX-deficient fibers, and molecular genetic analysis identified a heteroplasmic nonsense mutation in *COX I* [106].

Reevaluation of a 30-year-old man with exercise-related recurrent myoglobinuria and no family history revealed a mutation (m.7989T>C) in subunit II of COX. Single-fiber PCR showed that COX-negative fibers contained >90 % mutant mtDNAs compared to 52 % in COX-positive fibers [107].

The clinical and molecular characteristics of all reported patients with exercise intolerance and mutations in mtDNA protein-coding genes are summarized in Table 63.1. All patients had pure myopathy, with no evidence of multisystem involvement. The myopathy was dominated by exercise intolerance with premature fatigue and myalgia. Myoglobinuria occurred in a few patients. Fixed weakness was also rare and appeared nonprogressive. All patients were sporadic cases with no family history of similar disorders.

Iron-Sulfur Cluster Scaffold Protein (ISCU) Deficiency

In 1991 and 1993, Haller and coworkers described a young man with lifelong exercise intolerance, dyspnea, cardiac palpitations, and episodes of myoglobinuria [108, 109]. The syndrome, which is common in northern Sweden, was dubbed "mitochondrial myopathy with succinate dehydrogenase and aconitase deficiency" and correctly attributed to altered metabolism of iron-sulfur (Fe-S) cluster proteins, which are prosthetic groups present in complexes I, II, and III and in the Krebs cycle enzyme aconitase. Accordingly, histochemical analysis of muscle showed SDH deficiency, and biochemical analysis showed deficiencies of complex II, complex III, and aconitase. In 2008, homozygosity mapping revealed a single pathogenic mutation in the *ISCU* gene in three Swedish families [110]. Two years later, Kollberg et al. [111] defined SDH deficiency and accumulation of iron in muscle as the morphological hallmarks of the disease. They also observed that these features transiently disappeared after rhabdomyolysis, warning that false-negative histochemical results may be obtained if muscle biopsies are taken soon after episodes of myoglobinuria.

Coenzyme Q10 (CoQ10) Deficiency

CoQ10, which is encoded by the nuclear genome, transfers electrons from complex I and complex II to complex III (Fig. 63.2). CoQ10 is also the final acceptor of electrons

derived from ß-oxidation via the electron transfer flavoprotein (ETF) and the ETF dehydrogenase (Fig. 63.2), and, in this sense, it is part of lipid metabolism. The coexistence of ragged-red fibers and lipid storage in muscle biopsies of patients with the myopathic variant of CoQ10 deficiency underscores the dual metabolic nature of this disorder. Also, CoQ10 deficiency, though first described in 1989 [112], was "rediscovered" in recent years and may have been underestimated as a cause of recurrent myoglobinuria [113, 114]. In the five patients described thus far, primary CoQ10 deficiency in muscle was characterized by the triad: (1) exercise intolerance and recurrent myoglobinuria; (2) central nervous system dysfunction, with seizures or mental retardation; and (3) RRF and markedly increased lipid droplets in the muscle biopsy. Biochemical analysis of muscle shows a partial block at the level of complex III and variably severe deficiency of CoQ10.

Isolated lipid storage myopathy without myoglobinuria has been described in a few patients [115–118]. The report by Gempel et al. [118] implied that myopathic CoQ10 deficiency could be secondary to multiple acyl-CoA dehydrogenase deficiency (MADD) due to mutations in the gene encoding the electron-transferring-flavoprotein dehydrogenase (*ETFDH*), but this generalization has been contradicted [119, 120].

More common and severe presentations of primary CoQ10 deficiency include infantile encephalomyopathy, childhood-onset cerebellar atrophy and ataxia, and glomerulopathy [90].

Miscellaneous

Adenylate Deaminase Deficiency

Adenylate deaminase (AMPD) deficiency is a muscle disease with variable manifestations [121]. Some patients have no symptoms. The most common complaints are muscle cramping, stiffness, or pain after exercise. In others, fixed weakness, hyporeflexia, paresthesias, periodic paralysis, and repeated infections in childhood have been reported. The serum CK concentration may be increased, but myoglobinuria is extremely rare. Muscle biopsy is usually normal, but a specific histochemical stain facilitates the diagnosis and shows that the enzyme defect is often encountered in virtually asymptomatic subjects. In keeping with this observation, molecular genetic analysis has shown that a common mutation (Q12X) in the *AMPD-1* gene, which encodes the muscle isozyme, can explain the 2 % incidence of myoadenylate deficiency encountered in the general population. As mentioned above, two children, who were homozygous for pathogenic mutations in the myophosphorylase gene (glycogenosis type V, McArdle's disease) or in the muscle phosphofructokinase gene (glycogenosis type VII, Tarui disease), were also homozygous for the *AMPD-1* mutation. Interestingly, both children had unusually severe phenotypes, with early episodes of myoglobinuria. This suggests that the per se mild AMPD-1 mutation may have worsened the clinical expression of the two glycogenoses. Thus, it is important to keep in mind the possibility of genetic "double trouble" between adenylate deaminase deficiency and other metabolic errors.

Disorders Causing Fixed Weakness

All but one of the glycogenoses causing exercise intolerance and myoglobinuria are due to muscle-specific enzyme defects, whereas all but one of those causing fixed weakness are due to generalized enzyme defects (Fig. 63.3). This suggests the possibility that factors other than defective substrate utilization may play a role in the etiology of weakness. One such obvious factor is the severe involvement of spinal motor neurons in the infantile form of acid maltase deficiency (Pompe disease) [122, 123]. A more subtle neurogenic involvement may occur in debrancher deficiency, where glycogen storage has been documented in intramuscular nerves [124] and in both Schwann cells and axons of sural nerve biopsies [125, 126]. Subclinical cardiomyopathy may contribute to weakness in both debrancher [127] and, possibly, brancher deficiencies. Similarly, liver dysfunction with hypoglycemia in debrancher deficiency, and with chronic hepatic failure in brancher deficiency, will undoubtedly contribute to the lack of stamina of these patients.

Whereas glycogen storage is mild (sometimes hardly detectable) in the glycogenoses associated with exercise intolerance, it tends to be more severe in the glycogenoses associated with weakness, especially in the infantile and juvenile forms of acid maltase deficiency and in debrancher deficiency.

Glycogenoses

Acid Maltase (α-Glucosidase, GAA deficiency), Glycogenosis Type II

Introduction The fatal infantile form of acid maltase (acid α-glucosidase, GAA) deficiency was first described in 1932 in separate papers by Pompe and Putschar, who called attention to the severe glycogen storage in the heart [128, 129]. In 1963, Hers documented the defect of GAA in liver, heart, and skeletal muscle of children with "cardiomegaly glycogenosis" [130] and, together with Lejeune and Tines-Sempoux, showed that GAA was a lysosomal enzyme [131]. Thus, GAA deficiency became the prototype of inborn lysosomal diseases [132]. In the years that followed, GAA deficiency was recognized in both children and adults with myopathy but without cardiac involvement, and, by 1973, the three main clinical variants of GAA deficiency were clearly defined [133]. The eponym *Pompe disease* should be limited to the infantile form, but it is now used to indicate the disease as a whole.

Etiology and Pathogenesis Acid maltase deficiency is a hereditary condition transmitted as an autosomal recessive trait. The gene encoding GAA is localized on the long arm of chromosome 17, and a variety of molecular defects have been described in both infants and adults [134].

The genotype/phenotype correlation is hard to establish, partly because of the frequency of compound heterozygotes. In general, there is good correlation between the severity of the mutation and the severity of the clinical phenotype. Thus, deletions and nonsense mutations are usually associated with infantile GAA deficiency, whereas "leaky" mutations, such as the common IVS1(−13T->G) splice site mutation, are associated with the adult-onset variant of the disease.

GAA has both α-1,4-glucosidase and α-1,6-glucosidase activity and is, therefore, capable of digesting glycogen completely to glucose. Like other lysosomal enzymes, GAA, a glycoprotein, is synthesized as a high-molecular-weight precursor, which is extensively modified posttranslationally as the protein travels from ribosomes to primary lysosomes through endoplasmic reticulum and Golgi apparatus. Posttranslational processing includes glycosylation, acquisition of a mannose-6-phosphate recognition marker, phosphorylation, and proteolytic trimming. Through these steps, in cultured fibroblasts, a 95-kd precursor is converted into two enzymatically active 76- and 70-kDa glycoproteins [135, 136].

One intriguing question is: why non-muscle tissues in childhood and adult acid maltase deficiency are spared? In agreement with the concept that there are no tissue-specific isozymes of acid maltase, GAA activity is markedly decreased in all tissues not only in infantile acid maltase deficiency but also in the adult form [137]. The difference in clinical expression and pathology between infantile and later-onset forms of GAA deficiency has been attributed to the presence of a small but crucial amount of residual GAA activity in childhood and adult cases but not in infantile cases. The difference in residual activity, first observed in muscle specimens [138], is more evident in fibroblast and muscle cultures from patients with the different variants [139].

A second question concerns the pathogenesis of weakness. Muscle biopsy shows a vacuolar myopathy in all three forms of AMD. In the infantile form, all muscles and all fibers contain many, often confluent vacuoles, resulting in a "lacework" appearance. In childhood and adult GAA deficiency, vacuoles are less numerous and tend to be smaller. Furthermore, in the adult variant, biopsies from clinically unaffected muscles may appear normal, despite the marked decrease of GAA activity. The vacuoles contain PAS-positive material and stain intensely for acid phosphatase, another lysosomal enzyme. The positive acid phosphatase stain is a useful diagnostic clue in otherwise normal biopsy specimens. In agreement with morphological appearance, glycogen content is massively increased in muscle from patients with infantile GAA deficiency, often reaching a level ten times higher than normal. Muscle glycogen concentrations are generally lower in the childhood form and may be normal in the adult variant.

A central riddle regards the pathogenesis of weakness: is it simply due to the mechanical disarray of the contractile system caused by the glycogen-laden lysosomes or rather to an energy defect? The energetic hypothesis is supported by the notion that GAA activity normally releases glucose into the cytoplasm. A compelling scenario for the pathogenesis of acid maltase deficiency, as well as other lysosomal diseases [140], involves a disruption of the vital autophagic process, with accumulation of autophagosomes resulting from defective autophagosome-lysosome fusion [140, 141]. In fact, Nishino and colleagues went as far as stating that "Pompe disease can no longer be viewed simply as a glycogen storage disease," but rather as a problem in handling excessive numbers of autophagosomes [142].

In infantile GAA deficiency, accumulation of free and intralysosomal glycogen occurs in all tissues and is especially severe in the heart. In the CNS, anterior horn cells of the spinal cord and neurons of brainstem nuclei are more severely affected than neurons of the cerebral cortex [122, 123, 143]. This probably contributes to the flaccid quadriplegia of these infants and may explain why mental retardation does not become apparent within their short life span.

Clinical Presentation *Infantile Pompe disease* manifests in the first weeks or months of life with diffuse hypotonia and weakness, giving these infants a "rag doll" appearance (floppy infant syndrome). However, muscle bulk may be increased, and macroglossia is common. There is massive cardiomegaly and less severe hepatomegaly. Despite their extreme weakness, these infants are usually alert and interested in their environment. Respiratory muscle weakness increases susceptibility to pulmonary infections, and death due to cardiac or respiratory failure occurs invariably before 2 years of age and usually within the first year.

Glycemia and the response of blood glucose to epinephrine or glucagon administration are normal. Serum CK is markedly increased. Needle EMG shows myopathic motor unit action potentials (MUAPs) associated with fibrillation potentials, positive waves, complex repetitive discharges, and myotonic discharges. Electrocardiography shows a short P-R interval, giant QRS complexes, and signs of left ventricular or biventricular hypertrophy. Chest radiography shows massive cardiac enlargement.

In *childhood GAA deficiency*, weakness starts in infancy or early childhood but is less severe than in the infantile form, and progression is slower. Motor milestones may be delayed. Some patients have calf enlargement and, in boys, the clinical picture may suggest the diagnosis of Duchenne

muscular dystrophy. Respiratory muscles are affected early and respiratory failure is the usual cause of death within the second or third decade. There is no cardiomegaly, and both hepatomegaly and tongue enlargement are much less frequent than in infantile AMD.

Serum CK is variably but consistently increased. On needle EMG, the association of myopathic MUAPs with signs of abnormal irritability and myotonic discharges should raise the suspicion of acid maltase deficiency.

The clinical hallmark of *adult-onset GAA deficiency* is a slowly progressive myopathy, starting in the third or fourth decade, but occasionally later, including a few patients with onset in the sixth or seventh decade. Weakness predominates in truncal and proximal muscles, sometimes involving bulbar muscles and causing dysphagia. Respiratory muscles are selectively affected, and respiratory insufficiency may be the presenting complaint, with morning headache or exertional dyspnea [144, 145]. The initial diagnosis in most cases is limb-girdle dystrophy or polymyositis. There is no visceromegaly. Glycogen accumulation in the smooth muscle of cerebral arteries may lead to the formation of intracranial aneurysms, which have been described in a few families [146].

Serum CK is variably increased in most patients. The ischemic forearm exercise test causes a normal rise of venous lactate, indicating that phosphorolytic glycogen breakdown and glycolysis are normal. On needle EMG, fibrillation potentials, positive waves, and myotonic discharges are useful clues to the diagnosis and may be more evident in paraspinal muscles. Studies of pulmonary function show restrictive ventilatory insufficiency, with reduced maximal static inspiratory and expiratory pressures, and early diaphragmatic fatigue. Whole-body muscle MRI can provide an accurate picture of the muscles involved in the course of the disease [147].

Differential Diagnosis Infantile GAA deficiency has to be distinguished from other causes of the floppy infant syndrome, including spinal muscular atrophy type I (Werdnig-Hoffmann disease) and other metabolic or congenital myopathies. The massive cardiomegaly distinguishes acid maltase deficiency from most of these disorders. Some infants with cytochrome *c* oxidase deficiency have both myopathy and cardiomyopathy, but cardiomegaly is usually less marked and there is lactic acidosis. Muscle biopsy is virtually pathognomonic for acid maltase deficiency.

AMP-dependent protein kinase (AMP) deficiency can present with massive glycogen storage and cardiomegaly in infancy, but muscle weakness is modest and muscle biopsy shows only minor glycogen storage [5].

Childhood GAA deficiency may simulate Duchenne muscular dystrophy in boys with calf pseudohypertrophy. In Duchenne muscular dystrophy, however, family history may suggest X-linked transmission, serum CK tends to be higher, and needle EMG does not show myotonic discharges. Muscle biopsy clearly differentiates the two conditions.

Other metabolic myopathies of childhood include debrancher deficiency, phosphorylase *b* kinase deficiency, and carnitine deficiency. Debrancher deficiency myopathy is often accompanied by hepatomegaly and fasting hypoglycemia; there is no response of blood glucose to epinephrine or glucagon administration, and if feasible to do, the ischemic forearm exercise test shows no rise of venous lactate. Differential diagnosis from phosphorylase *b* kinase deficiency and from carnitine deficiency requires morphological and biochemical studies of muscle.

Muscle biopsy is also required to distinguish childhood GAA deficiency from congenital myopathies, because several patients with Pompe disease have a thin body habitus, elongated facies, and high-arched palate that are commonly seen in congenital myopathies, such as myotubular myopathy, nemaline myopathy, and central core disease.

Adult GAA deficiency is an important consideration in patients thought to have limb-girdle dystrophy or polymyositis. The early and often selective involvement of respiratory muscles and the EMG features, especially in paraspinal muscles (fibrillation potentials, positive waves, complex repetitive discharges, and myotonic discharges), are useful clues to acid maltase deficiency [145].

A disorder resembling acid maltase deficiency but not due to acid maltase deficiency is characterized by X-linked dominant "cardiomyopathy, mental retardation, and autophagic vacuolar myopathy" [148]. The molecular defects in this disorder involve the *LAMP-2* gene, which encodes a major lysosomal membrane protein [149].

Evaluation and Diagnosis Diagnostic workup includes serum CK (variably increased in all three forms of GAA deficiency), electrocardiogram (EKG) and chest radiogram in the infantile form, pulmonary function tests in childhood and adult acid maltase deficiency, MRI of spine/paraspinal muscles and needle EMG of paraspinal muscles in the adult variant (looking for fibrillation potentials and myotonic discharges), ischemic forearm exercise test (to exclude other glycogenolytic or glycolytic defects), and muscle biopsy.

In all three forms of acid maltase deficiency, short of a muscle biopsy, the diagnosis may be aided by determination of acid and neutral maltase activities (and calculation of the acid/neutral activity ratio) in lymphocytes [150].

Treatment and Management A generally effective enzyme replacement therapy (ERT) with recombinant human GAA (rhGAA) is now available and widely utilized. There is already a vast literature on the subject particularly in the infantile form of the disease [151]. A few problems have emerged recently, such as the immune reaction to rhGAA in

infants with null mutations and no GAA protein (i.e., no cross-reactive immunological material, CRIM) [152]. A multicentric, randomized, placebo-controlled trial of alglucosidase alfa, a recombinant human GAA, was conducted in 90 patients (8 years of age or older) with the late-onset form of Pompe disease [153]. The two primary end points were motor (6-min walk test) and respiratory (percentage of predicted forced vital capacity). Secondary and tertiary end points were quantitative muscle testing and maximum inspiratory and expiratory pressures. Treatment with rhGAA for 78 weeks was associated with improved walking distance and stabilization of pulmonary function over a period of 18 months. The results were modest but important considering the slow but inexorable progression of the disease [154]. One question remains unanswered: whether to start ERT in presymptomatic late-onset patients [155].

The response of patients with infantile Pompe disease has been much more patchy, as illustrated by the first four children treated [156, 157]. All four children survived until 4 years or longer, thus meeting the provisional end point of the trial. Three of the children are still alive more than 11 years later, but the two who started therapy late (7 and 8 months of age) are paralytic and ventilator dependent. The child who started therapy at 3 months is still able to walk at age 11 and goes to school, although he has some weakness [151]. The UK experience with 20 infants treated between 2000 and 2009 is equally tattered: overall ventilator-free survival was 35 %; 35 % died at a median age of 10 months; 30 % were alive but ventilator dependent. Again, age and clinical severity at the beginning of treatment were of paramount importance. The authors wisely conclude that ERT for infants with Pompe disease has to be pondered carefully [158].

Patients with childhood or adult AMD and respiratory insufficiency may need intermittent or permanent mechanically assisted ventilation [159]. Controversial results have been obtained with high-protein diet and aerobic exercise, which appears to improve strength and respiratory function in some, but not all patients [160].

Debrancher Deficiency (Glycogenosis Type III)

This is usually a benign disease of childhood characterized by hepatomegaly, growth retardation, and fasting hypoglycemia, which tend to resolve around puberty [161]. However, later in life (third or fourth decade), a small proportion of patients develops a myopathy, which is often more distal than proximal. Wasting of leg muscles and intrinsic hand muscles often leads to the diagnosis of motor neuron disease or peripheral neuropathy. This clinical picture, the "mixed" myopathic and neurogenic EMG pattern, and the often slowed nerve conduction velocity reinforce the impression that weakness in these patients may have a neurogenic component [162, 163]. It is, however, surprising that an enzyme that acts "hand in hand" with muscle phosphorylase in the degradation of glycogen should not cause exercise intolerance and myoglobinuria, at least in those patients that are not severely weak.

The debranching enzyme is a single protein that catalyzes two enzymatic reactions, an oligo-1,4-1,4-glucantransferase and an amylo-1,6-glucosidase, and is encoded by a gene on chromosome 1p21. There are three biochemical variants: a rare deficiency of the transferase activity alone (type IIId), a common deficiency of both enzyme activities in both muscle and liver (type IIIa), and a less frequent deficiency of both enzyme activities in liver but not in muscle (type IIIb) [37]. Numerous mutations have been identified: although the molecular basis for the differential tissue involvement in patients with the IIIa and IIIb variants remains unclear, it is interesting that most patients with the IIIb variant (but none with the IIIa variant) have mutations in exon 3 of the debrancher gene, which are expected to result in truncated proteins [164].

Glycogen Branching Enzyme (GBE) Deficiency (Glycogenosis Type IV)

This glycogenosis has a surprising spectrum of clinical phenotypes, considering that GBE is a single polypeptide (encoded by a gene on chromosome 3). The enzyme defect can be silent or affect predominantly the liver, the heart, skeletal muscle, or the brain [37]. GBE deficiency results in the deposition of an amylopectin-like polysaccharide that has fewer branching points and longer outer chains than normal glycogen and is known as polyglucosan (PG). PG is PAS positive and only partially digested by diastase, which makes it easily recognizable in various tissues and offers an important clue to the correct diagnosis.

The "typical" presentation described by most authors is in infancy with hepatosplenomegaly, progressive cirrhosis, and chronic hepatic failure. Cardiomyopathy dominates the clinical picture in a few older children. We now realize that we have vastly underestimated the infantile neuromuscular presentation.

As recognized in a seminal paper published in 2004 [165], there are two main infantile presentations. The first is a perinatal disorder dubbed "fetal akinesia deformation sequence" (FADS), characterized by multiple congenital contractures (arthrogryposis multiplex congenita), hydrops fetalis, pulmonary hypoplasia, craniofacial abnormalities, intrauterine growth retardation, abnormal amniotic fluid volume, and perinatal death. The second form, labeled "congenital," should probably be called "fatal infantile" because it presents at or soon after birth with hypotonia, muscle wasting, neuronal involvement, inconsistent cardiomyopathy, and early death. Of the eight patients reported by Bruno et al. [165], three had FADS, three had the congenital form, and two had childhood myopathy. Interestingly, there was a good correlation between molecular severity and clin-

ical severity, which has been confirmed in several subsequent patients.

It is becoming increasingly clear that patients with congenital GBE deficiency present a clinical continuum from FADS to a rapidly fatal congenital multisystem disorder dominated by profound hypotonia, respiratory failure, and inconsistent cardiomyopathy [165–172]. Detailed neuropathology in a few infants showed PG inclusions in neurons of the basal ganglia and thalamus, oculomotor and pontine nuclei, and periaqueductal neurons [169]. In the medulla, PG deposits were found in the hypoglossal nucleus, the dorsal motor nucleus of the vagus, and the nucleus ambiguous [166, 168]. The motor neurons of the spinal cord are also severely affected [173], thus explaining how one of the patients we studied was initially diagnosed as spinal muscular atrophy type I until mutations in the *SMN1* gene were ruled out [166].

Brain involvement dominates the clinical picture also in a characteristic late-onset (fifth or sixth decade) form of GBE deficiency known as "adult polyglucosan body disease" (*APBD*) manifested by progressive upper and lower motor neuron involvement, sensory loss, sphincter problems, and dementia (see Chap. 22). Although APBD is seen in various ethnic groups, this disorder predominates among Ashkenazi Jews, in whom one common mutation (Y329S) probably reflects a founder effect [174].

There is no specific therapy for GBE deficiency, but the recent creation of transgenic mice models that faithfully recapitulate both the fatal infantile form and APBD will facilitate the development of therapeutic modalities [175].

Disorders of Lipid Metabolism

Primary Systemic Carnitine Deficiency (PCD)

The mean age at onset of this autosomal recessive condition ranges from 1 month and 7 years. Progressive cardiomyopathy is the most common presentation: echocardiography and EKG show dilated cardiomyopathy, peaked T waves, and signs of ventricular hypertrophy. Endomyocardial biopsies or postmortem studies show massive lipid storage, and, when measured, carnitine concentration in the myocardium is less than 5 % of normal. Cardiac function responds poorly to inotropics and diuretics but responds dramatically to carnitine supplementation, with progressive normalization of cardiac function indices within a few months. Some infants may present with acute encephalopathy together with hypoketotic hypoglycemia and hepatomegaly with liver steatosis. Myopathy is usually associated with cardiomyopathy or encephalopathy and is manifested by mild motor delay, hypotonia, or slowly progressive proximal weakness. Serum CK is normal or slightly elevated. Muscle biopsy shows lipid storage myopathy and very low levels of total and free carnitine (below 10 % of normal).

Defective carnitine transport in kidney causes defective carnitine reabsorption and excessive carnitine excretion. Deficient intestinal transport results in poor and delayed carnitine absorption. The combination of defective renal and intestinal carnitine handling causes carnitine levels to fall in blood. Hence, it is important to measure blood carnitine concentrations in all infants and young children with unexplained cardiomyopathy. In vitro, deficient carnitine transport has been documented in cultured skin fibroblasts [176] and in cultured muscle cells [177].

PCD is due to mutations in the *SLC22A5* gene that encodes the high-affinity, sodium-dependent plasma membrane carnitine transporter (organic cation transporter, OCTN2) [178].

Primary Myopathic Carnitine Deficiency

This disorder, characterized by decreased muscle carnitine with normal serum carnitine, was the first example of carnitine deficiency described by A.G. Engel and Angelini in 1973 in a young woman with progressive proximal weakness and lipid storage myopathy responsive to corticosteroids [179]. The existence of this entity, however, is controversial because there is no definitive documentation of an isolated defect of carnitine uptake in muscle. It is possible that patients with the myopathic form of carnitine deficiency have other fatty acid oxidation defects, either generalized or muscle specific. In some of the patients described, symptoms appeared in the first years of life, but in most the onset was between the second and third decade. There was progressive and sometimes fluctuating weakness of proximal limb and axial muscles of variable severity. A few of these patients had associated cardiomyopathy. Muscle biopsy showed accumulation of triglycerides, especially in type I fibers. Muscle carnitine levels were 20 % of normal or less, while plasma carnitine levels were normal or slightly reduced. Some of the patients improved with carnitine administration.

Secondary Carnitine Deficiency

This condition, characterized by decreased levels of carnitine in blood and, often, in tissues, can accompany diverse disorders, including inborn errors of metabolism, acquired medical disorders, and iatrogenic states.

Examples of inborn errors of metabolism include numerous defects of fatty acid metabolism affecting both the carnitine cycle and β-oxidation, disorders of branched-chain amino acid metabolism, and defects of the mitochondrial respiratory chain.

Examples of acquired medical conditions include those causing decreased carnitine biosynthesis (e.g., hepatic cirrhosis or extreme prematurity), those causing decreased carnitine intake (e.g., malnutrition, chronic total parenteral nutrition, strict vegetarian diet, soy protein infant formula,

malabsorption), those causing decreased body stores of carnitine in the face of increased requirements (e.g., pregnancy and lactation, extreme prematurity, infant of carnitine-deficient mother), and those causing increased carnitine loss, such as Fanconi syndrome.

Examples of iatrogenic factors include valproate therapy [180], hemodialysis, and zidovudine administration [181]. It is important to keep in mind these diverse causes of carnitine deficiency because carnitine replacement often results in marked improvement.

Medium-Chain Acyl-CoA Dehydrogenase (MCAD) Deficiency

This relatively common condition presents in childhood as an episodic acute illness with hypoketotic hypoglycemia following intercurrent infection and fasting. The presenting symptoms and signs, in order of decreasing frequency, include lethargy, vomiting, encephalopathy, respiratory arrest, hepatomegaly, seizures, apnea, cardiac arrest, and sudden death. Once the correct diagnosis is established, subsequent crises can generally be prevented, but survivors are at risk for developmental disabilities. In a large retrospective analysis of 120 MCAD patients, weakness was present in 16 % of the survivors [182]. The most effective laboratory test in this, as in other β-oxidation disorders, is the profile of acylcarnitines in plasma as determined by tandem mass spectrometry. The profile is characteristically abnormal both in sick and in well children with MCAD deficiency.

The gene for MCAD has been cloned and assigned to chromosome 1p31. A single mutation (K304E) is present in over 90 % of patients.

Multiple Acyl-CoA Dehydrogenase Deficiency (MADD)

MADD can be due to mutations in either one of two enzymes: electron-transfer flavoprotein (ETF) or ETF/CoQ10 oxidoreductase (ETFDH). Another name for MADD is glutaric aciduria type II. The clinical spectrum ranges from a fatal multisystem disorder of infancy to a less severe disorder of adolescence or adult life. Late-onset MADD often causes severe lipid storage myopathy with proximal and axial weakness. Of considerable practical importance is the riboflavin-responsive form of MADD, which is predominantly associated with ETFDH deficiency [120, 183]. Some of these patients had CoQ10 deficiency in muscle and responded to CoQ10 supplementation alone or together with riboflavin [118], but secondary CoQ10 deficiency is not a consistent finding [120].

Neutral Lipid Storage Disease with Ichthyosis (NLSDI, Chanarin-Dorfman Syndrome)

This disorder was first reported by Chanarin in a Ugandan woman [184], then recognized in several patients from the Mediterranean area [185]. Patients suffer from ichthyosis, steatorrhea, and a neurological syndrome that includes ataxia, nystagmus, neurosensory hearing loss, and slowly progressive proximal limb weakness. The pathological hallmark is massive triglyceride storage in all tissues, including muscle, liver, gastrointestinal epithelium, endometrium, skin, bone marrow, and both fibroblast and muscle cells in culture [186]. The presence of lipid droplets in granulocytes of a blood smear (Jordan anomaly) facilitates diagnosis. The biochemical basis of this condition is a deficiency of the protein (CGI-58) that activates the adipocyte triglyceride lipase (ATGL), which catalyzes the first step in triglyceride hydrolysis, thus liberating fatty acids from triglyceride stores in skeletal muscle and all other tissues. Several mutations in the *CGI-58* gene have been identified [185].

Neutral Lipid Storage Disease with Myopathy (NLSDM)

This generalized lipid storage disease is due to mutations in the gene (*PNPLA2*) encoding the ubiquitous adipocyte triglyceride lipase (ATGL). Although all tissues can be affected, some patients present with "triglyceride deposit cardiomyovasculopathy (TGCV)" or "obesity of the heart" [187], but many patients present with a myopathy that does not start until adulthood and progresses slowly but steadily, such that many patients are confined to a wheelchair late in life. Some patients may also develop severe cardiomyopathy. There is no ichthyosis, but the Jordan anomaly is present in blood smears [120, 188]. Serum CK is increased and was the only consistent abnormality in a young preclinical woman with severe lipid myopathy and a retrotransposal mutation in *PNPLA2* [189].

and Michio Hirano

Introduction

The concept of mitochondrial diseases originated in 1962 with the report by Luft and colleagues of a patient with nonthyroidal hypermetabolism due to loose coupling of oxidation (the breakdown of biomolecules such as carbohydrates and fatty acids) and phosphorylation (the production of ATP) in muscle mitochondria [1]. Over the following quarter of a century, numerous clinical and morphological reports described patients with abnormalities of muscle mitochondria. In 1988, the discovery of mutations in the mitochondrial DNA (mtDNA) led to an explosive expansion of research on mitochondrial myopathies. Over the past two decades, the rapid pace of identification of these clinically diverse disorders and their associated gene defects has left many physicians bewildered about these heterogeneous and complex syndromes.

Etiology and Pathogenesis

Structural Considerations

Each mitochondrion is about the size of a bacterium (1–2 μm by 0.5–1 μm) and has two membranes: an external or outer mitochondrial membrane (OMM) and an internal or inner mitochondrial membrane (IMM). The OMM separates the organelle from the cytoplasm. The IMM serves as a barrier to most molecules and contains vital enzymes required for import of molecules and for ATP synthesis. Within the IMM resides the mitochondrial matrix, which harbors mtDNA (actually, mtDNA molecules are organized into discrete assemblies called nucleoids, which are probably tethered to the IMM [2, 3]), as well as many enzymes responsible for housekeeping and metabolic processes.

Biochemical Properties

The mitochondria are essential to the cell because they harbor the enzymatic machinery necessary for aerobic metabolism, by which fatty acids, carbohydrates, and amino acids are broken down to form CO_2 and H_2O and, most importantly, to convert adenosine diphosphate (ADP) to adenosine triphosphate (ATP), the energy currency of the cell. The biochemical processes of aerobic metabolism may be classified into five major steps: (1) transport; (2) substrate utilization; (3) Krebs, citric acid, or tricarboxylic acid (TCA) cycle; (4) electron transport chain; and (5) oxidation-phosphorylation coupling (Fig. 64.1).

Transport refers to the importation of molecules, including polypeptides and substrates for the TCA cycle, that are necessary for mitochondrial structure and function. Carnitine palmitoyltransferase (CPT) II deficiency is a prototypical example of a substrate transport defect and is described in the chapter on metabolic myopathies (Chap. 63) [4].

Substrate utilization refers to the oxidation of metabolites within the mitochondrial matrix to form acetyl-coenzyme A (acetyl-CoA), which enters the TCA cycle. Specifically, acetyl-CoA is produced through the metabolism of pyruvate by the pyruvate dehydrogenase enzyme complex (PDHC) [5] and through the catabolism of fatty acids in the ß-oxidation pathway.

Krebs cycle enzymes convert the energy stored in the acetyl-CoA to high-energy electrons in the form of NADH and $FADH_2$. Defects in fumarase, aconitase, and

beta-ketoglutarate dehydrogenase are associated with human diseases [5].

The *electron transport chain* is composed of four enzyme complexes (complexes I–IV) and two small electron carriers, coenzyme Q_{10} (CoQ_{10}) and cytochrome *c*. Reducing equivalents (electrons) are carried along these enzymes to sustain an efflux of protons from the mitochondrial matrix across the IMM, thus generating a transmembrane proton gradient.

Oxidative phosphorylation is the process by which the proton gradient across the IMM is converted into ATP when protons flow back into the mitochondrial matrix through the world's tiniest rotary motor, ATP synthase (complex V). Luft's disease with loose coupling of mitochondrial oxidation to phosphorylation is a classic example of an oxidative-phosphorylation defect. Although the molecular etiology of this exceedingly rare disorder has not been elucidated, defects of complex V have been identified in patients with other forms of mitochondrial encephalomyopathies [6].

While the biochemical features of human mitochondrial disorders are vitally important in understanding the diseases, the identification of mutations in the mitochondrial and nuclear genomes has revolutionized the conceptual framework of mitochondrial myopathies.

Genetic Concepts

Mitochondria originated from aerobic bacteria that formed symbiotic relationships with eukaryotic cells, which benefited from their newly acquired capacity to utilize oxygen. This

relationship is unique because mitochondria are the only mammalian subcellular organelles – aside from the nucleus – that contain genetic material (mtDNA). However, during evolution most of the genes necessary for mitochondrial functions were transferred to the nuclear DNA (nDNA) so that mitochondria are the products of two genomes.

Human mtDNA is a small circular, double-stranded molecule composed of 16,569 base pairs. It contains 37 genes: 13 encode polypeptides; 22 encode transfer ribonucleic acids (tRNA) molecules, and 2 encode ribosomal RNAs (RRNAs) [7]. All 13 mtDNA-encoded polypeptides are subunits of the respiratory chain (seven in complex I, one in complex III, three in complex IV, and two in complex V). The mitochondrial genome differs from nDNA in several aspects. First, there are no introns in the mtDNA, which is therefore tightly packed with information. Second, mtDNA is maternally inherited. Third, each cell contains hundreds to thousands of copies of mtDNA whereas nDNA contains two copies of each autosome and, in the case of normal males, single copies of X and Y chromosomes. Fourth, mtDNA undergoes spontaneous mutations more rapidly than nDNA. These properties of mtDNA are responsible for the unusual genetic features of mitochondrial myopathies.

An important principle of mtDNA genetics is *heteroplasmy*. As each mitochondrion contains two to ten copies of mtDNA and each cell contains multiple mitochondria, there are thousands of copies of mtDNA in each cell. Alterations of mtDNA may be present in some (heteroplasmy) or in all (homoplasmy) of the mtDNA molecules. As a consequence of heteroplasmy, the proportion of a deleterious mtDNA mutation can vary widely. An individual who harbors a large proportion of mutant mtDNA will be more severely afflicted by the mitochondrial dysfunction than a person with a low percentage of the same mutation; therefore, there is a spectrum of clinical severity among patients with a given mitochondrial mutation.

A second factor that may influence the expression of the same mtDNA mutation in different individuals is *the tissue distribution of that mutation*. The best example of different clinical phenotypes due to diverse tissue distribution comes from large-scale single mtDNA deletions. Infants with a high proportion of deleted mtDNA in the blood develop Pearson syndrome (PS, sideroblastic anemia often accompanied by exocrine pancreatic dysfunction) [8]. Presumably, these infants have a high proportion of deleted mtDNA in the bone marrow stem cells. With blood transfusions, some children survive the anemia and subsequently recover because the stem cells with a high proportion of deleted mtDNA are under a negative selection bias. Later in life, however, as mtDNA deletions accumulate in postmitotic tissues, such as brain, heart, and muscle, these same children may develop the multisystem mitochondrial disorder Kearns-Sayre syndrome (KSS) characterized by ophthalmoplegia, pigmentary retinopathy, and cardiac conduction block [9]. Thus, variable tissue distribution broadens the clinical spectrum of pathogenic mtDNA mutations.

The third factor that determines the clinical spectrum of an mtDNA mutation is the *tissue threshold effect*. Cells with high metabolic activities are severely and adversely affected by mtDNA mutations; therefore, these disorders tend to affect disproportionately the brain and muscle (encephalomyopathies).

A fourth characteristic of mtDNA is *maternal inheritance* [10]. During the formation of the zygote, mtDNA derives exclusively from the oocyte. Thus, mtDNA is transmitted vertically in a non-mendelian fashion from the mother to both the male and female progeny. This inheritance pattern is important in determining whether a family is likely to harbor an mtDNA mutation. A caveat to this principle is that maternal relatives harboring lower percentages of an mtDNA mutation may have fewer symptoms (oligosymptomatic) than the proband or may even be asymptomatic. Therefore, in taking the family history, it is important to ask about "soft" symptoms or signs in maternally related family members who might be oligosymptomatic.

These peculiar features of "mitochondrial genetics" contribute to the clinical complexity of mitochondrial disorders. Variable heteroplasmy of mtDNA mutations produces an extensive range of disease severity while tissue distribution and tissue threshold of mtDNA mutations explain the frequent but variable involvement of multiple organ systems. In addition to mtDNA mutations, nuclear DNA (nDNA) defects may also cause mitochondrial dysfunction. In fact, nDNA encodes the following: (1) most electron transport chain subunits and all ancillary proteins needed for proper subunit assembly; (2) factors needed for mitochondrial protein importation; (3) factors needed for mtDNA replication, transcription, and translation ("mtDNA maintenance"); (4) factors controlling the synthesis and assembly of phospholipids in the OMM and IMM; and (5) factors controlling mitochondrial dynamics, i.e., mitochondrial motility, fusion, fission, and mitophagy.

Clinical Presentations

Primary Mitochondrial DNA Mutations

In 1988, the first mtDNA point mutation and large-scale single deletions were described [11, 12]. Since then, there has been an outburst of information relating mtDNA mutations to human mitochondrial disorders. Numerous mtDNA mutations were identified including: single or multiple deletions, and over 250 pathogenic point mutations. Most mtDNA point mutations are in transfer RNA (tRNA) genes. Here, we describe only the most common mtDNA mutations associated with mitochondrial myopathies to illustrate some of the principal features of mtDNA genetics.

Holt and colleagues first identified large-scale single mtDNA deletions ("single" because all mutated mtDNAs in the patient are identical) in patients with mitochondrial myopathy, and soon thereafter, Lestienne and Ponsot [13] and Zeviani and colleagues [14, 15] pointed out the specific association with KSS or chronic progressive external opthalmoplegia (CPEO). Approximately 90 % of KSS patients have large-scale mtDNA deletions, duplications, or both. The mtDNA deletions range from about 2.0 to 10.4 kilobases (kb) in length and are mainly confined to an 11-kb region that does not include the origins of mtDNA replication or mtDNA promoter regions. About one-third of the mtDNA deletions involve an identical 4,977 base pair (bp) segment: this is often referred to as the "common deletion" [16]. Most mtDNA deletions are flanked by direct sequence repeats, suggesting that they may arise from homologous recombination events. Most patients with single deletions of mtDNA are sporadic cases suggesting that the recombination events occur in the oocytes or early in embryogenesis. Large-scale mtDNA deletions are often undetectable in leukocytes; therefore, molecular diagnosis requires muscle biopsy.

The first point mutation in human mtDNA was identified by Wallace and colleagues in patients with Leber's hereditary optic neuropathy (LHON) [11]. This mutation was a guanine-to-adenine (G-to-A) transition at nucleotide (nt) 11778 (m.11778G>A) in subunit 4 of complex I (ND4). We now know that almost all cases of LHON are due to one of three mutations in complex I: m.11778G>A in ND4, m.3460C>A in ND1, or m.144484T>C in ND6 [17].

Myoclonus epilepsy with ragged-red fibers (MERRF) was the first multisystemic disorder to be associated with an mtDNA point mutation, specifically m.8344A>G in the $tRNA^{Lys}$ gene [18]. A second $tRNA^{Lys}$ mutation at nt 8356 (m.8356T>C) was associated with both the MERRF phenotype and a clinical overlap syndrome with features of MERRF and mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS) [19, 20]. Two additional mutations in the $tRNA^{Lys}$ have been identified in MERRF patients, one at nucleotide 8363 in two Japanese families [21] and the other at nucleotide 8361 [22]. While the mitochondrial $tRNA^{Lys}$ gene is clearly a hot spot for mutations causing MERRF, a mutation in the $tRNA^{Phe}$ was also identified in a family with MERRF [23]. Overlap syndromes between MERRF and MELAS have also been attributed to point mutations in $tRNA^{Ser(UCN)}$ [24], in $tRNA^{His}$ [25], and in subunit 5 of complex I [26]. Overlap syndromes between MERRF and KSS have been associated with two point mutations in $tRNA^{Leu(UUR)}$ [27, 28].

MELAS was first associated with a specific mtDNA point mutation, m.3243A>G, in the $tRNA^{Leu(UUR)}$ gene [29], and about 80 % of MELAS patients harbor this mutation. However, mutations in at least ten mtDNA genes have been identified in patients with MELAS [30]. These data illustrate how in mitochondrial genetics one phenotype may have multiple genotypes and, conversely, one genotype can cause multiple phenotypes. In addition to MELAS, the m.3243A>G mutation is associated with maternally inherited progressive external ophthalmoplegia (PEO) [31] and with maternally inherited diabetes and deafness (DAD) [32].

The syndrome of neuropathy, ataxia, and retinitis pigmentosa (NARP) is due to the m.8993T>G mutation in subunit 6 of complex V (ATPase subunit 6) [33]. The mutation changes a leucine to arginine and is associated with in vitro decreased ATP synthase activity. In the original NARP patients, the proportion of mutant mtDNA in leukocytes was 82–88 % [33]. When individuals inherit higher proportions of the mutation (around 90 %), they develop a more devastating and earlier-onset disease, maternally inherited Leigh syndrome (MILS) [34]. The relationship between mutational load and clinical phenotypes reinforces the significance of heteroplasmy in mitochondrial genetics. Interestingly, a clinically milder form of NARP/MILS can be caused by a T>C mutation at the very same site (m.8993T>C) [35].

In addition to the mtDNA mutations described above, the already long list of pathogenic point mutations continues to expand [36, 37]. There are recurrent themes in these mutations, which have become widely accepted criteria for pathogenicity. First, most pathogenic mtDNA mutations are heteroplasmic, presumably because the homoplasmic mutant state would be incompatible with life. Second, there are general correlations between levels of heteroplasmy and clinical severity and between tissue distribution of the mutations and syndromic phenotypes. Third, pathogenic mutations generally affect evolutionarily conserved and presumably functionally important sites. Fourth, when the muscle biopsy shows ragged-red or COX-negative fibers, these can be literally "plucked" and used for PCR analysis ("single-fiber PCR") [38]: pathogenic mutations ought to be present in higher proportion in these abnormal fibers (or fiber segments) than in histologically normal segments. A disproportionate number of mutations have been identified in the tRNA genes, and the $tRNA^{Leu(UUR)}$ gene appears to be a hot spot for mutations [36]. Finally, mutations in polypeptide-encoding genes in the mtDNA are emerging as important and not uncommon causes of human diseases [37]. Interestingly, sporadic somatic mutations of polypeptide-encoding genes, particularly in the cytochrome *b* gene, are not uncommon in patients with isolated exercise intolerance [39]. The absence of maternal inheritance and lack of multisystem involvement are strikingly different from our experience with tRNA gene mutations. A full discussion of mitochondrial myopathies due to mutations of mtDNA genes presenting with exercise intolerance, myalgia, or myoglobinuria may be found in Chap. 63 discussing metabolic myopathies.

While much effort was placed on the identification of mtDNA mutations, their pathogenic mechanisms are not

Table 64.1 Overview of the mitochondrial diseases

Genome	Genetic defect	Clinical examples
mtDNA	Single deletions	KSS, sporadic PEO, PS
	Mutations affecting protein synthesis	MELAS, MERRF, LHON
	Mutations in protein-coding genes	NARP/MILS, myopathy
nDNA	Mutations in RC subunits ("direct hits")	LS
	Mutations in RC ancillary proteins ("indirect hits")	LS-plus, GRACILE, leukoencephalopathy, CM
	Defects in intergenomic communication	mtDNA depletion syndromes (myopathy, hepatocerebral syndrome, Alpers syndrome, encephalomyopathy)
		Multiple mtDNA deletion syndromes (AD/AR PEO, SANDO)
		Defects of mtDNA translation (hepatocerebral syndrome, encephalomyopathy, MLASA)
	Defects of the lipid milieu	Barth syndrome
		Megaconial encephalomyopathy
		Sengers syndrome
		Childhood myoglobinuria
		MEGDEL
	Defects of mitochondrial dynamics	DOA, DOA-plus, CMT 2A

Abbreviations: *KSS* Kearns-Sayre syndrome, *PEO* progressive external ophthalmoplegia, *LHON* Leber's hereditary optic neuropathy, *NARP/MILS* neuropathy, ataxia, retinitis pigmentosa/maternally inherited Leigh syndrome, *RC* respiratory chain, *LS* Leigh syndrome, *GRACILE* growth retardation, aminoaciduria, cholestasis, iron overload, and early death, *CM* cardiomyopathy, *SANDO* sensory ataxic neuropathy, dysarthria, and ophthalmoparesis, *MLASA* mitochondrial myopathy, lactic acidosis, and sideroblastic anemia, *MEGDEL* refers to 3-merthylglutaconic aciduria type IV, deafness, and Leigh-like encephalopathy, *DOA* dominant optic atrophy, *CMT* Charcot-Marie Tooth

fully elucidated and questions remain unanswered. For example, why do different tRNA mutations produce different clinical syndromes? All tRNA mutations should decrease mitochondrial protein synthesis, reduce respiratory enzyme activities, and impair ATP synthesis, yet the phenotypic consequences vary considerably. How does one mutation produce multiple genotypes? The m.3243A>G mutation is associated with MELAS, maternally inherited PEO, and diabetes and deafness, but the reasons for this heterogeneity remain unclear.

Defects of Nuclear DNA

The vast majority of polypeptides in the mitochondria are encoded in nDNA; therefore, nuclear mutations are the cause of many, in fact most, mitochondrial myopathies. These mutations have been more difficult to identify, but both traditional sequencing techniques and novel genome-wide or more targeted (mito-exome) "next-generation" sequencing technologies have revealed a bewildering number of mutant mitochondrial genes, most of them responsible for encephalomyopathies but some for myopathies [40, 41].

Historically, Bougeron and colleagues provided the first description of a nDNA gene defect causing a human mitochondrial disease when they identified a mutation in the flavoprotein subunit gene of succinate dehydrogenase (complex II) in two siblings with Leigh syndrome [42].

Table 64.1 shows one rational way to classify nDNA-related mitochondrial disorders into five groups. First, "direct hits" comprise disorders due to mutations in genes encoding subunits of respiratory chain complexes. Second, "indirect hits" refer to those disorders that are due to mutations in genes encoding not respiratory chain subunits but ancillary proteins needed for assembly, stability, or function of individual complexes. Third, defects of intergenomic communication scramble the dialogue between the nuclear genome and the mitochondrial DNA: although transmitted as mendelian traits, these disorders have features of both mendelian and mitochondrial genetics. Fourth, mutations in nuclear genes may alter the lipid milieu of the inner mitochondrial membrane, which is not merely a scaffold for respiratory chain complexes but contributes to their function. Fifth, alterations of mitochondrial dynamics (motility, fusion, and fission) are associated with disease, although the pathogenesis of respiratory chain dysfunction remains unclear.

Mutations in Respiratory Chain Subunits ("Direct Hits")

Complex I

Complex I (NADH-ubiquinone oxidoreductase) comprises 45 subunits, of which 38 are encoded by nDNA, and it generates about 40 % of the proton motive force eventually harnessed by ATP synthetase (complex V). Given its size, it is not too surprising that isolated complex I deficiency is the most frequently encountered RC defect [43].

Pathogenic mutations have been identified in all evolutionarily conserved subunits that comprise the catalytic core and generally result in Leigh syndrome (LS). LS, which reflects the ravages of energy shortage on the developing nervous

system, is defined neuropathologically (or neuroradiologically) by bilateral symmetrical lesions all along the nervous system, but especially in the basal ganglia, thalamus, brainstem, and cerebellar roof nuclei. Microscopically, there is neuronal loss, proportionate loss of myelin, reactive astrocytosis, and proliferation of cerebral microvessels.

Clinically, these children have psychomotor retardation or regression, respiratory abnormalities, hypotonia, failure to thrive, seizures, dystonia, and blindness. Although hypotonia is usually severe, isolated myopathy is not seen in mutations of nuclear genes for complex I whereas it has been reported in several patients with mutations in mtDNA-encoded complex I (ND) genes (see Chap. 63).

Besides LS, four distinct presentations had been attributed to mendelian complex I deficiency: fatal infantile lactic acidosis (FILA), neonatal cardiomyopathy with lactic acidosis, leukodystrophy with macrocephaly, and hepatopathy with renal tubulopathy [43]. It is likely that they represent variations on a common LS theme rather than separate clinical entities, and differences in residual activity may account for the apparent differential tissue involvement.

One important clinical feature common to these disorders is that onset is invariably in infancy or childhood. Usually, these children are fine at birth and early in life, but disease progression is rapid and relentless, leading to death often before 1 year of age. Lactic acid is consistently and markedly elevated both in the blood and in the cerebrospinal fluid (CSF). From a genetic point of view, it is noteworthy that mutations in NDUFA1 cause X-linked LS [44], a most unusual hereditary pattern for RC defects.

Complex II

Complex II (succinate-ubiquinone oxidoreductase) is the smallest multimeric component of the RC, comprising only four subunits. Complex II deficiency is also probably the least common RC defect [45].

Four reported patients had typical LS [46, 47] whereas one child at 5 months developed hypotonia, respiratory distress, hepatosplenomegaly, and cardiomegaly [48]. Two children with psychomotor regression and spastic quadriparesis showed diffuse leukodystrophy by MRI, and a third child presented in the first year of life with stunted growth and lactic acidosis without neurological symptoms. Interestingly, all three children stabilized or improved after riboflavin administration [49]. Two sisters were heterozygous for a mutation in the gene encoding the flavoprotein subunit and showed late-onset optic atrophy, ataxia, and myopathy with a partial defect of succinate dehydrogenase (SDH) [50].

Coenzyme Q_{10} Deficiency

Enzyme defects that impair the biosynthesis of the small electron carrier CoQ_{10} can be considered "direct hits" because they drastically reduce the concentration of CoQ_{10}, thus blocking the flux of electrons in the RC between complexes I and II and complex III (see Fig. 64.1).

CoQ_{10} is a lipophilic molecule composed of a benzoquinone ring and an isoprenoid chain, which in humans contains 10 isoprenyl units. The quinone group is synthesized in mitochondria from para-hydroxy-benzoate, a catabolite of tyrosine, whereas the polyisoprene tail is synthesized in the cytoplasm starting from acetyl-CoA through the mevalonate pathway [51, 52]. CoQ_{10} biosynthesis is carried out by a set of at least eight enzymes encoded by nuclear genes named *COQ*. Pathogenic mutations have been identified in six genes and cause heterogeneous clinical conditions. Five main clinical syndromes have been associated with CoQ_{10} deficiency in skeletal muscle.

The first syndrome is an encephalomyopathy described in 1989 by Ogasahara et al. [53] in two sisters with mitochondrial myopathy and recurrent myoglobinuria, seizures, mental retardation, and ataxia. The triad of mitochondrial myopathy, myoglobinuria, and encephalopathy was then reported in a few other patients [54–57], but responsible genes remain elusive.

The second syndrome is childhood-onset cerebellar ataxia and atrophy, with variable additional symptoms, including neuropathy, seizures, mental retardation, and muscle weakness [58–61]. The molecular basis of this syndrome was identified in some but not all patients, and the mutated gene was *ADCK3*/*CABC1* (*COQ8*) [62–64].

The third syndrome is an infantile encephalomyopathy, first described by Rötig et al. [65] in three siblings with nystagmus, optic atrophy, sensorineural hearing loss, ataxia, dystonia, weakness, and nephropathy. Quinzii et al. found a homozygous missense mutation in the *COQ2* gene in an infant boy who presented with nystagmus at 2 months and, at 12 months, had hypotonia, psychomotor delay, and severe nephrotic syndrome requiring renal transplantation [66]. His neurological condition deteriorated and he developed psychomotor regression, tremor, weakness, and status epilepticus. Brain MRI showed cerebral and cerebellar atrophy and stroke-like lesions. His younger sister had severe nephrosis at 12 months but never developed neurological symptoms. Oral CoQ_{10} administration improved the boy's condition dramatically and presumably protected his sister from developing neurological problems [67].

A similar but rapidly fatal condition was associated with *COQ2* mutations in two siblings. One was a girl with neonatal neurological distress, nephrosis, hepatopathy, pancytopenia, diabetes, seizures, and lactic acidosis, leading to death at 12 days [68]. Her older brother had anemia, liver failure, and nephropathy and survived only 1 day.

COQ1 is composed of two subunits, PDSS1 and PDSS2. Mutations in *PDSS2* were responsible for typical Leigh syndrome and nephrotic syndrome in an infant boy who died at age 8 months of intractable status epilepticus despite CoQ_{10}

supplementation [69]. Mutations in *PDSS1* were associated with early deafness, encephaloneuropathy, obesity, valvulopathy, livedo reticularis, and mental retardation in two siblings, who were 14 and 22 years old at the time of publication [68], and in two much more severely affected siblings, who died at 1 and 12 days with neonatal neurologic distress, liver failure, nephrotic syndrome, diabetes, seizures, and pancytopenia [68].

The fourth syndrome is dominated by severe nephrotic syndrome and is outside the scope of this book. Two patients had mutations in *COQ2* [70] and 13 patients from 7 families had mutations in *COQ6* [71].

The fifth syndrome, characterized by isolated myopathy, was described by two groups [72–74]. Patients have progressive weakness, lipid storage in the muscle biopsy, and respiratory chain dysfunction. Gempel et al. [72] attributed this myopathic presentation to mutations in the gene encoding the electron-transferring flavoprotein dehydrogenase (*EFTDH*) also associated with glutaric aciduria type II (multiple acyl-CoA dehydrogenase deficiency [MADD]) and described a beneficial effect not only of CoQ_{10} but also of riboflavin supplementation. However, this entity is controversial because in some studies patients with MADD and ETFDH mutations had normal CoQ_{10} levels in muscle [75, 76].

Complex III

Two distinct direct hits for complex III (ubiquinol-cytochrome *c* reductase) have been described, one in a single patient and the other in a large consanguineous family. A deletion in the *UQCRB* gene encoding the ubiquinone-binding protein (QP subunit or subunit VII) was identified in an 8-month-old girl with moderate hepatomegaly, hypoglycemia, metabolic acidosis, and lactic acidosis [77]. During a fasting test, she developed hypoglycemia after 19 h, which became symptomatic after 21 h. Lactic acid was also markedly increased (4.16 mmol/L, normal 0.5–2.2), and ketogenesis was impaired, suggesting a functional defect of fatty acid oxidation. At age 4 years, the child was normal and the hepatomegaly had regressed. Complex III activity was decreased in the liver, lymphocytes, and fibroblasts.

Twenty members of a Bedouin family in Israel presented with a uniform encephalomyopathy that was severe but compatible with long survival. These patients were normal at birth and for the first few months, then showed psychomotor retardation and developed extrapyramidal signs, including dystonia, athetoid movements, ataxia, and dementia [78]. There was a homozygous mutation in *UQCRQ*.

Complex IV

It is likely that most "direct hits" in nuclear-encoded subunits of complex IV (cytochrome *c* oxidase) are incompatible with life because years of research have revealed mutations in only one of the 10 nDNA-encoded subunits, COX6B1 [79]. Both siblings with mutations in this gene had had failure to thrive but normal psychomotor development until late childhood, when they developed muscle weakness, cognitive deterioration, visual problems, and lactic acidosis. MRI showed severe cavitating leukodystrophy in both.

Complex V

As for complex IV, "direct hits" of complex V appear to be very rare, having been reported only in one patient, who harbored a homozygous mutation in the *ATP5E* gene and – paradoxically – had a more benign course than patients with "indirect hits" (see below) [80]. This girl was small at birth and had a poor suck, respiratory distress, lactic acidosis, and 3-methylglutaconic aciduria. Although she had recurrent metabolic crises, her clinical course stabilized at 5–6 years, and she completed school and was gainfully employed. At the age of 17 years, she had mild ataxia, horizontal nystagmus, exercise intolerance, mixed axonal and demyelinating polyneuropathy, and mild left ventricular hypertrophy.

Mutations in Genes Encoding Ancillary Proteins ("Indirect Hits")

Pathogenic mutations in proteins needed for the assembly, stabilization, and functional regulation have been identified for all five complexes of the RC.

Complex I

Pathogenic mutations have been reported in 6 assembly subunits [81–86] and in 5 chaperone factors [87–93], and many more mutated genes in both groups will be identified through the increased use of exome sequencing [41, 94].

The clinical manifestations tend to be more heterogeneous than those associated with "direct hits" in complex I, but, again, isolated myopathy is exceedingly rare. Three siblings in a doubly consanguineous Dutch family and an unrelated patient, who harbored mutations in the *ACAD9* gene, had isolated myopathy with exercise intolerance and lactic acidosis responsive to riboflavin [91].

Complex II

Even the tiny complex II requires assembly factors, and mutations have been described in one of them (SDHAF1), which contains a LYR motif and is presumably involved in Fe-S metabolism [95]. The clinical picture was dominated by psychomotor regression, impaired growth, spastic quadriplegia, and moderate cognitive decline. Weakness was not related to a primary myopathy.

Complex III

The first assembly defect in complex III was identified in 2002 in Finnish infants with an extremely severe syndrome named GRACILE, which summarizes the main symptoms

and signs: *g*rowth *r*etardation, *a*minoaciduria, *c*holestasis, *i*ron over*l*oad, and *e*arly death (before 5 months of age). The mutated protein BCS1L is a member of the AAA family of ATPases needed for insertion of the Rieske FeS subunit into the complex [96]. This syndrome was also recognized in British and Turkish children: although symptoms vary somewhat in different ethnic groups, myopathy is not a prominent feature.

In addition, *BCS1L* mutations cause the milder Björnstad syndrome characterized by sensorineural hearing loss and pili torti (flattened and twisted hair shafts) [97]. One patient with a novel homozygous *BCS1IL* mutation had an intermediate presentation with infantile onset of hypotonia, psychomotor retardation, coarse facial features, and hirsutism [98].

A second assembly factor for complex III is tetratricopeptide repeat 19 (TTC19), a protein of the inner mitochondrial membrane, where it interacts with complex III [99]. Four Italian patients with homozygous mutations in *TTC19* had severe encephalopathy, which, although incapacitating, was compatible with life into the second and even fourth decade.

Complex IV

It has long been known that cytochrome *c* oxidase (COX, complex IV) deficiency is a common cause of LS [100, 101]. Yet, years went by before a mutated gene was associated with LS: the gene (*SURF1*) is essential for correct COX assembly, and this was the first example of an "indirect hit" to affect the RC [102, 103].

Mutations in the COX assembly gene *SCO2*, which encodes a metallochaperone involved in mitochondrial copper delivery, cause a severe clinical phenotype that combines neonatal hypertrophic cardiomyopathy with encephalopathy and is fatal in the first weeks or months of life [104].

Importantly, *SCO2* mutations (both in compound heterozygosity and in homozygosity) can simulate spinal muscular atrophy (SMA), and the neurogenic, often SMA-like, histological pattern of the muscle biopsy further complicates the differential diagnosis [105–107]. One postmortem study of the spinal cord showed severe neuronal loss and astrocytosis in the anterior horns [106]. Two distinctive features orient towards the correct diagnosis: clinically, the severe cardiomyopathy and, morphologically, the lack of COX stain in the muscle biopsy. However, in patients with the clinical picture of SMA but without mutations in the *SMN* gene, it is important to consider *SCO2* mutations.

Mutations in several other genes encoding COX assembly proteins have been associated with encephalopathy resembling Leigh syndrome together with involvement of one other tissue, although the reason for this additional tissue vulnerability is not clear. Thus, mutations in *SCO1*, another copper chaperone, cause encephalohepatopathy; mutations in *COX10* cause encephalonephropathy; and mutations in *COX15* cause encephalocardiopathy as do mutations in *C2orf64* [104]. Additional disorders due to "indirect hits" and resulting in generalized COX deficiency, including an unusual "toxic" mechanism of COX inhibition, have been reported (for review, see [104]), but myopathy, if present, is overshadowed by brain and visceral involvement.

Complex V

Mutations in two ancillary proteins, *ATP12* (now known as *ATPAF2*) and *TMEM70*, cause severe infantile disorders involving multiple organs, but myopathy is not a prominent feature [6].

Iron-Sulfur (Fe-S) Cluster Scaffold Protein (ISCU) Deficiency

In 1991 and 1993, Haller and coworkers described a young Swedish man with lifelong exercise intolerance, dyspnea, cardiac palpitations, and episodes of myoglobinuria [108, 109]. The syndrome was called "mitochondrial myopathy with succinate dehydrogenase and aconitase deficiency" and attributed to altered metabolism of iron-sulfur (Fe-S) cluster proteins, which are prosthetic groups present in complexes I, II, and III, and in the Krebs cycle enzyme aconitase. Accordingly, histochemical analysis of muscle showed SDH deficiency, and biochemical analysis showed deficiencies of complex II, complex III, and aconitase. In 2008, homozygosity mapping revealed a single pathogenic mutation in the *ISCU* gene in three Swedish families [110], and 2 years later, Kollberg et al. [111] described SDH deficiency and accumulation of iron in muscle as the morphological hallmarks of the disease.

Defects of Intergenomic Communication

As noted above, the mtDNA is highly dependent for its proper synthesis and replication on numerous factors encoded by nuclear genes. Mutations in these genes cause disorders characterized by qualitative or quantitative alterations of mtDNA. Although these disorders are mendelian, it is important to keep in mind that they show overlap features with mitochondrial genetics because mtDNA is unevenly affected and clinical phenotypes depend on the degree of heteroplasmy. Most of these disorders are generalized, but myopathy is a frequent symptom and extraocular muscles are almost always involved, causing progressive external ophthalmoplegia (PEO) and droopy eyelids (ptosis).

Initially, qualitative mtDNA alterations (multiple mtDNA deletions) and quantitative alterations (mtDNA depletion) were considered separate entities due to distinct molecular defects. However, in the past few years, and especially after the introduction of exome sequencing, it has become apparent that multiple mtDNA deletions and mtDNA depletion often coexist in the same patient and that syndromes

Table 64.2 Main clinical presentations associated with mtDNA depletion or multiple mtDNA deletions (Δ)

Gene	mtDNA depletion	Multiple mtDNA Δ
TK2	Infantile or adult myopathy, SMA phenocopy	Adult AD PEO
DGUOK	Infantile hepatocerebral syndrome	Adult myopathy ± PEO
PEO1	IOSCA, hepatocerebral syndrome	Adult AD PEO-plus
SUCLA2	Infantile encephalomyopathy	
SUCLG1	Infantile encephalomyopathy, MMA	
RRM2B	Infantile encephalomyopathy	Adult AD/AR PEO-plus
MPV17	Infantile hepatocerebral syndrome, NNH	Adult AR PEO-plus
TYMP	MNGIE	MNGIE
POLG	Hepatocerebral syndrome (Alpers syndrome)	Adult AD/AR PEO-plus, SANDO, MIRAS
POLG2		Adult AD PEO
ANT1		Adult AD PEO-plus
OPA1		DOA, adult PEO-plus
MFN2		DOA-plus
GFER		Congenital cataract, encephalomyopathy

Note how mutations in the same gene can cause mtDNA depletion, multiple mtDNA deletions, or both. The proteins encoded by genes are described in the text

Abbreviations: *AR* autosomal recessive, *AD* autosomal dominant, *PEO* progressive external ophthalmoplegia, *IOSCA* infantile-onset spinocerebellar ataxia, *MMA* methylmalonic aciduria, *NNH* Navajo neurohepatopathy, *MNGIE* mitochondrial neurogastrointestinal encephalomyopathy, *SANDO* sensory ataxic neuropathy, dysarthria, and ophthalmoparesis, *MIRAS* mitochondrial recessive ataxia syndrome, *DOA* dominant optic atrophy

considered typical of multiple mtDNA deletions can be caused by mtDNA depletion and vice versa. This is illustrated in Table 64.2.

For the sake of clarity, we will still consider separately the two entities but we will alert the reader about overlap situations.

Disorders Characterized by Multiple mtDNA Deletions

Mitochondrial Neurogastrointestinal Encephalomyopathy (MNGIE)

One of the disorders in which the coexistence of multiple mtDNA deletions and mtDNA depletion was first recognized is MNGIE (mitochondrial neurogastrointestinal encephalomyopathy). This autosomal recessive multisystemic syndrome is characterized by mitochondrial myopathy with ptosis and PEO, peripheral neuropathy, gastrointestinal dysmotility causing severe cachexia, and leukoencephalopathy without cognitive impairment. MNGIE is due to mutations in the gene (*TYMP*) encoding thymidine phosphorylase (TP), resulting in elevated levels of thymidine and deoxyuridine in plasma and tissues [112]. In fact, measurement of these metabolites in plasma and measurement of TP activity in buffy coat are valuable diagnostic tools. The disease starts in young adults and is relentlessly progressive, with an average age of death of 37 years [112]. Muscle biopsy shows COX-negative RRF and combined deficiencies of respiratory chain complexes. Molecular analysis has shown over 50 *TYMP* mutations resulting in mtDNA multiple deletions, depletion, and site-specific somatic mtDNA point mutations in multiple tissues. It has been suggested that the increased levels of thymidine and deoxyuridine imbalance the mitochondrial deoxynucleotide triphosphate pool, resulting in mtDNA instability.

This devastating mitochondrial disorder is amenable to therapy. Transient biochemical benefit is obtained with hemodialysis, which eliminates the offending nucleosides from the blood. Permanent benefit derives from allogeneic hematopoietic stem cell transplantation (AHSCT). Bone marrow transplantation in a few MNGIE patients has raised blood levels of TP activity to heterozygous levels and normalized plasma thymidine and deoxyuridine. Seven years after AHSCT, one patient had markedly improved gastrointestinal function and improved exercise tolerance and nerve function (assessed clinically and electrophysiologically) [112].

Mutations in ANT1

Mutations in the gene for one isoform of the adenine nucleotide translocator (*ANT1*) have been identified in patients with autosomal dominant PEO, sometime associated with psychiatric disorders [113–115]. In the seminal paper by Suomalainen et al., multiple mtDNA deletions were most abundant in the brain, followed by cardiac and skeletal muscle [114]. Sporadic PEO may also infrequently be due to mutations in *ANT1* [116], and the association of mitochondrial myopathy and cardiomyopathy, even in patients with recessive inheritance and without PEO, should raise the question of *ANT1* mutations [117].

Mutations in PEO1

In 2001, autosomal dominant PEO with multiple mtDNA deletions was associated with mutations in the gene (*PEO1*), encoding a mitochondrial helicase called Twinkle [118], an essential factor for mtDNA maintenance and for the regulation of mtDNA copy number [119]. A review of 33 patients from 26 families showed that the most common symptoms were ptosis (97 %) and ophthalmoparesis (94 %), followed by exercise intolerance (52 %) and mild proximal weakness (33 %) [120]. Central nervous system involvement was infrequent and included visual impairment, migraine, lethargy, hearing loss, and epilepsy. Cardiac problems were noted in 24 % of the patients. It was

also noted by several investigators that multiple mtDNA deletions are often not revealed by Southern blot and require long-range or real-time PCR. When 67 patients with multiple mtDNA deletions in muscle (with mitochondrial myopathy but with or without PEO) were screened for mutations in *ANT1*, *PEO1*, *POLG1*, and *POLG2*, it was found that mutations in *PEO1* accounted for 27 %, mutations in *ANT1* for 15 %, and mutations in *POLG* for 10 % of familial cases [121]. However no mutations in known genes were found in 54 % of cases (this study preceded mitoexome screening).

Infantile-onset spinocerebellar ataxia (IOSCA) was described in the 1970s in Finland (reviewed in reference [122]): between 9 and 18 months, children develop acutely or subacutely ataxia, hypotonia, athetosis, and areflexia, and by teenage years they lose independent ambulation. Additional symptoms include PEO, optic atrophy, sensorineural hearing loss, cognitive impairment, sensory neuropathy, and autonomic nervous system dysfunction. Neuroradiology shows cerebellar atrophy. In 2005, this autosomal recessive disorder was attributed to mutations in *PEO1* [123]. Although no mtDNA alteration was initially identified [123], it was later found that both the brain and the liver showed mtDNA depletion [124]. In fact, an early-onset hepatocerebral presentation similar to Alpers-Huttenlocher syndrome has also been associated in two siblings with recessive *PEO1* mutations and mtDNA depletion in the liver [125]. Although muscle showed only mild mtDNA depletion, these children had hypotonia and PEO.

Mutations in POLG

Mutations in the gene encoding the only mitochondrial polymerase, polymerase γ (*POLG*), have emerged as major causes of a vast array of mitochondrial disorders [126]. Over 150 mutations have been described in all three domains of the gene, exonuclease, linker, and polymerase, and may cause either autosomal dominant or autosomal recessive PEO, a syndrome comprising autosomal recessive sensory ataxic neuropathy, dysarthria, and ophthalmoparesis (SANDO) [127, 128], mitochondrial recessive ataxia syndrome (MIRAS) [129], or parkinsonism with or without PEO [130–134].

Mutations in *POLG* can cause multiple mtDNA deletions – as in the diseases mentioned above – or mtDNA depletion as in Alpers-Huttenlocher syndrome (AHS), a severe autosomal recessive hepatocerebral disorder of childhood defined by the tetrad of refractory seizures, episodic psychomotor regression, cortical blindness, and hepatopathy with micronodular cirrhosis [135]. It is crucially important not to expose these children to valproate, which often precipitates fulminant hepatic failure. This interaction of gene and environment contributes to the extreme clinical heterogeneity of POLG mutations [127]. As if the many syndromes listed above were not enough, *POLG* mutations can mimic other mitochondrial disorders, including MNGIE [136, 137] and MERRF [138].

From the neuromuscular point of view, *POLG* mutations have to be considered in the differential diagnosis of autosomal dominant and autosomal recessive PEO and SANDO, but also isolated myopathies [139]. The extraordinary clinical spectrum of *POLG* mutations, the relationship of the different phenotypes to the three functional domains of the gene, and the vulnerability of the gene to environmental factors are discussed in several reviews [140, 141].

In human mitochondria, polymerase γ is part of an enzyme complex containing an accessory subunit of 55 kDa, p55, which is encoded by the *POLG2* gene. A dimer of p55 binds to polymerase γ and stimulates its catalytic activity. Heterozygous mutations in *POLG2* have been reported in two patients with remarkably similar clinical histories: both women were in their 60s and had developed bilateral ptosis in midlife, followed by PEO and facial weakness in one patient [142] but not in the other [143]. Both patients had proximal muscle weakness, COX-negative fibers in the muscle biopsy, and multiple mtDNA deletions by long-range PCR.

Mutations in OPA1

One unexpected gene was recently added to those described above and associated with myopathy and PEO, *OPA1*. Why unexpected? Because mutations in *OPA1* were initially associated with a purely ophthalmological condition, dominant optic atrophy (DOA) or Kjer disease [144, 145], and because the gene product was a mechanoenzyme associated with mitochondrial fusion rather than with mitochondrial maintenance.

However, a syndromic disorder, often dubbed DOA-plus, has emerged, which is characterized more or less sequentially [146] by optic atrophy with visual failure, sensorineural deafness, ataxia, myopathy, axonal sensory-motor polyneuropathy, and PEO [147–150]. Muscle biopsy in these patients shows scattered ragged-blue, COX-negative fibers, and multiple mtDNA deletions are demonstrable by long-range PCR. Interestingly, the proportion of COX-negative fibers is much higher in patients with DOA-plus than in those with non-syndromic DOA. The relationship between this defect of mitochondrial dynamics and altered mitochondrial maintenance is intriguing. Two explanations have been proposed, decreased ability by the organelles to repair stress-induced mtDNA damage or accelerated accumulation of pre-existing age-associated somatic mtDNA mutations [151].

Mutations in RRM2B

An identical mutation in a gene (*RRM2B*, encoding the small subunit, p53R2, of the p53-inducible ribonucleotide reductase protein), which had been typically associated with autosomal recessive mtDNA depletion syndromes (see

below), was recently reported in two unrelated families with autosomal dominant PEO [152]. The patients in the first family had only PEO with or without ptosis manifesting in adulthood. Muscle biopsies showed COX-negative fibers and multiple mtDNA deletions by long-range PCR. The propositus from the second family was more severely affected: besides PEO, he also had hearing loss, gait ataxia, depression, and moderate cognitive impairment. Mutations in *RRM2B* are not a rare cause of PEO because screening this gene in 75 patients with molecularly unexplained PEO, COX-negative fibers, and multiple mtDNA deletions showed that 12 of them (16 %) were either compound heterozygous (2 patients with autosomal recessive PEO) or heterozygous (10 patients with autosomal dominant PEO) for pathogenic mutations [153]. A single patient with PEO, the child of first cousins, had a homozygous missense mutation in RRM2B [154].

Mutations in TK2

Whole exome sequencing also revealed that two sisters with late-onset PEO, ptosis, proximal weakness, dysarthria, and dysphagia were compound heterozygous for two pathogenic mutations in the *TK2* gene, which is typically associated with infantile myopathy and mtDNA depletion (see below). Muscle biopsy showed mosaic distribution of COX-negative fibers, and multiple mtDNA deletions were seen by Southern blot [155].

Mutations in MPV17

Although mutations in this gene are typically associated with multisystemic infantile mtDNA depletion, they have also been described in two adult patients with peripheral neuropathy (both patients), steatohepatopathy (both patients), leukoencephalopathy (one patient), ptosis, PEO, diabetes mellitus, depression, parkinsonism, and gastrointestinal dysmotililty (one patient) [156, 157]. Both patients had ragged-blue COX-negative fibers and multiple mtDNA deletions but no evidence of mtDNA depletion.

Mutations in GFER

The *GFER* gene encodes a sulfhydryl oxidase (DRS) of the mitochondrial intermembrane space, which is involved in mitochondrial protein import. A homozygous mutation of GFER caused congenital cataract, progressive muscle hypotonia, sensorineural hearing loss, and developmental delay in three siblings of a consanguineous family [158]. The pathogenic relationship between this gene and the multiple mtDNA deletions observed in muscle biopsies is not clear.

Disorders Characterized by mtDNA Depletion

These disorders are characterized by paucity of mtDNA, but the residual molecules are normal. mtDNA depletion syndromes (MDS) are phenotypically and genotypically heterogeneous. Transmission, however, is autosomal recessive in all forms. From the very first documentation of mtDNA depletion [159], it looked like myopathy or hepatopathy were the predominant presentations, but some children have multisystem involvement.

Myopathic MDS

Patients usually present in the first year of life with failure to thrive, hypotonia, weakness, and sometimes PEO. They usually die in childhood from pulmonary insufficiency, but severity of weakness and survival vary considerably [160]. The myopathic MDS is most commonly due to mutations in the gene (*TK2*) encoding mitochondrial thymidine kinase. About 20 mutations have been reported in as many patients. Notably, mutations in *TK2* can also cause a phenocopy of spinal muscular atrophy (SMA) [160–162]. It is notable, in this respect, that a *TK2* knockin mouse has more severe involvement of the central nervous system than of muscle [161]. It is also of practical importance to sequence the *TK2* gene in patients with SMA but without mutations in the *SMN1* gene.

Muscle biopsies in early-onset patients are uniformly COX-negative and do not react to DNA antibodies [162], whereas in later-onset patients some fibers appear normal and others lack both COX activity and mtDNA. Ragged-red fibers are not always present in early biopsies but may appear later. Biochemical analyses show combined defects of respiratory chain complexes containing mtDNA-encoded subunits. Of practical importance, serum CK levels tend to be elevated (2–30 times normal) in patients with myopathic MDS: this is an important diagnostic clue because CK levels are normal or only mildly elevated in other mitochondrial myopathies.

However, mutations in *TK2* can also cause adult-onset myopathy with mtDNA depletion [163] and even – as mentioned above – late-onset PEO with multiple mtDNA deletions rather than mtDNA depletion [155].

Muscle is almost invariably involved – though not in isolation – in patients with mtDNA depletion due to mutations in *RRM2B* (see above). Infants are hypotonic and children are weak, but there is usually also renal involvement [164–166] and central nervous system involvement with microcephaly, seizures, and developmental delay. As mentioned above, mutations in *RRM2B* can also be associated with autosomal dominant or recessive PEO and multiple mtDNA deletions [152–154]. One such case had multisystem involvement mimicking KSS [167].

Encephalomyopathic MDS

Two variants of this condition are both due to a defect of succinyl-CoA lyase activity in the Krebs cycle. Mutations in the gene (*SUCLA2*) encoding the ATP-dependent succinyl-CoA lyase SUCLA2 cause severe psychomotor retardation,

muscle hypotonia, hearing loss, generalized seizures, knee and hip contractures, mild ptosis, lactic acidosis, and methylmalonic aciduria. There is moderate mtDNA depletion (about 30 %) in muscle, and MRI of the brain is suggestive of Leigh syndrome [168–171].

Mutations in the gene (*SUCLG1*) encoding the GTP-dependent isoform SUCG1 cause a much more severe and rapidly fatal phenotype with mtDNA depletion in both muscle and the liver, characterized clinically by dysmorphic features, congenital lactic acidosis, and methylmalonic aciduria [172–174]. A less dismal course, more like the SUCLA2 phenotype, is correlated to the degree of residual activity [175, 176].

Hepatocerebral MDS

Alpers syndrome is the most important form of hepatocerebral MDS, and it has been described above. Mutations in two other genes, *DGUOK* and *MPV17*, also cause liver and brain involvement. Mutations in *DGUOK*, encoding the mitochondrial deoxyguanosine kinase (dGK), were first reported in 2001 [177], and by 2007 15 different mutations had been identified in 12 kindreds [178]. Severe mutations cause fatal infantile hepatopathy and brain involvement whereas milder mutations cause isolated liver disease and are compatible with longer survival, suggesting that the encephalopathy is largely secondary to the liver dysfunction.

Skeletal muscle is not directly affected in infants, and the only reported myopathy was due to a most unusual "double trouble," the association of McArdle disease and *DGUOK* mutations in an infant with hepatopathy and muscle glycogenosis [179]. However, exome sequencing has revealed *DGUOK* mutations in five adult patients with PEO and mitochondrial myopathy with multiple mtDNA deletions: only one of these patients had had liver problems in childhood [180].

Mutations in *MPV17*, which encodes a small mitochondrial membrane protein of unknown function, cause a rather typical hepatocerebral syndrome in Caucasian children [181] but is associated with a peculiar neurohepatopathy in the Navajo population. Navajo neurohepatopathy (NNH), which has a prevalence of 1 in 1,600 live births, was attributed to mtDNA depletion [182] and is due to a homozygous *MPV17* mutation [183]. The clinical features of NNH include peripheral and central nervous system involvement, acral mutilation, corneal scarring or ulceration, liver failure, and immunologic derangement [184]. As mentioned above, *MPV17* mutations can also impair mtDNA maintenance and cause mtDNA multiple deletions in adults [156, 157].

Defects of mtDNA Translation

Clinically, these disorders came to the attention of pediatricians because they cause severe infantile syndromes, often similar to those associated with mtDNA depletion even though mtDNA is normal both qualitatively and quantitatively.

A thorough update on this rapidly expanding group of diseases can be found in a recent Workshop Report [185], in which the authors classify the mutated proteins into six types according to the translational step affected and list the most common clinical features. Onset is usually in infancy or early childhood, and the course is rapidly fatal. Encephalomyopathy is the most common presentation, although cardiomyopathy and hepatopathy are occasionally seen. Lactic acidosis is almost invariably present.

Skeletal muscle is not a target organ, except in the disorder known as MLASA (mitochondrial myopathy, lactic acidosis, and sideroblastic anemia). MLASA is an autosomal recessive condition due to mutations in the gene (*PUS1*) encoding pseudouridine synthase 1 [186]. PUS1 is an enzyme located both in the nucleus and in the mitochondria: it converts uridine to pseudouridine in cytosolic and mitochondrial tRNAs, thus increasing the efficiency of protein synthesis in both compartments [187]. Detailed clinical descriptions of two affected brothers showed similar features but different severity. The older brother had severe hypotonia at 6 months and at 5 years developed sideroblastic anemia unresponsive to vitamin B6 administration. At 10 years, he had marked growth retardation despite growth hormone supplementation, generalized muscle weakness and wasting, winged scapulae, waddling gait, and Gowers sign. Blood lactate was markedly increased but CK was normal. He developed severe restrictive ventilatory syndrome and died at the age of 12 years. A muscle biopsy showed ragged-blue COX-negative fibers and a combined defect of complexes I and IV. His younger brother had cognitive impairment but milder myopathic involvement and was still alive at age 13, although he complained of exercise intolerance and had incipient ventilatory insufficiency [187].

Defects of Lipid Milieu Composition

The phospholipid components of the inner mitochondrial membrane (IMM) do not simply act as a scaffold for the respiratory chain, but participate in its structural and functional integrity. Phospholipid metabolism and the lipid composition of the IMM have been relatively neglected in the study of mitochondrial diseases, but there has been a recent awakening to this subject, and several new disorders have been discovered, thanks in part to exome sequencing (Table 64.2).

Barth Syndrome

Cardiolipin is the most abundant phospholipid component of the IMM. Alterations in cardiolipin biosynthesis resulting in

loss of tetralinoleoyl-cardiolipin [188] have been associated with Barth syndrome, due to mutations in the *TAZ1* gene that encodes the monolysocardiolipin transacylase [189]. Barth syndrome is an X-linked disorder characterized by mitochondrial cardiac and skeletal myopathy, cyclic neutropenia, and growth retardation [190]. Two commonly associated laboratory abnormalities are urinary excretion of 3-methylglutaconic acid and hypocholesterolemia.

A second disorder of the mitochondrial lipid milieu was recently identified in 15 patients with a congenital myopathy characterized clinically by early-onset muscle weakness and mental retardation with protracted course (most patients were alive at the time of publication and only four had died between the ages of 2½ and 28 years). The hallmark of the disease was the presence in muscle of greatly enlarged mitochondria displaced to the periphery of the fibers [191, 192].

Ten of the patients were Turkish, 4 Japanese, and 1 British, and they all harbored various mutations in the gene (*CHKB*) encoding choline kinase beta, the enzyme that catalyzes the first step in the *de novo* biosynthesis of phosphatidyl choline (PtdCho) and phosphatidylethanolamine (PtdEtn) via the Kennedy pathway.

A new homozygous *CHKB* mutation was found in an American patient, who also had weakness and psychomotor delay and was alive at 2 years [193]. The American patient had COX deficiency in muscle, and impaired RC enzyme activities were documented in muscle from mice harboring a loss-of-function mutation in the ortholog gene *Chkb* and which were affected with retrocaudal muscular dystrophy (rmd) [194].

Sengers syndrome, an autosomal recessive disorder described in 1975 [195] and consisting of congenital cataracts, hypertrophic cardiomyopathy, skeletal myopathy, exercise intolerance, and lactic acidosis, has now been attributed to mutations in the gene (*AGK*) encoding acylglycerol kinase. AGK phosphorylates diacylglycerol and monoacylglycerol to produce phosphatidic acid and lysophosphatidic acid, which are deficient in Sengers syndrome and result in a secondary decrease of the adenine nucleotide translocator (ANT1) in the IMM [196].

A fourth genetic alteration of phospholipid metabolism helped explain many cases of recurrent myoglobinuria in children, which are often not due to known metabolic myopathies [197]. Mutations in the gene (*LPIN1*) encoding the muscle-specific phosphatidic acid phosphatase cause accumulation of phosphatidic acid and lysophospholipids in muscle. Interestingly, carriers of *LPIN1* mutations are prone to develop myoglobinuria upon statin administration [197].

The most recent – but certainly not the last – defect of lipid milieu is associated with a syndrome characterized by 3-methyglutaconic aciduria (3-methylglutaconic aciduria type IV [198], deafness, and Leigh-like encephalopathy, which was dubbed MEGDEL). This syndrome is caused by mutations in the phospholipids remodeling gene *SERAC1*, a key player in intracellular cholesterol trafficking and a member of the mitochondria-associated ER membranes (MAM) [199]. The differences in cardiolipin species composition found in fibroblasts from patients are reminiscent of Barth syndrome and probably explain the respiratory chain dysfunction observed in MEGDEL patients.

Defects of Mitochondrial Dynamics

In keeping with their bacterial origin, mitochondria move, fuse, and divide, often forming tubular networks that may favor a balanced distribution of energy throughout the cell [200]. In fact, mitochondria fuse and split constantly, such as – to quote David Chan – "the identity of any individual mitochondrion is transient" [201]. Any interference with mitochondrial motility, fusion, or fission results in disease, and especially neurological disease, both because the nervous system is highly dependent on oxidative energy and because neurons have long processes and mitochondria have to travel long distances along central axons and peripheral nerves.

In agreement with this concept, most disorders of mitochondrial dynamics involve either the central or the peripheral nervous system. Under "Disorders Characterized by Multiple mtDNA Deletions," we have already discussed the wide phenotypic expression of mutations in *OPA1*, encoding a mitochondrial guanosine triphosphatase (GTPase) involved in mitochondrial fusion and first associated with dominant optic atrophy (DOA) [144, 145]. Mutations in a second gene (*MFN2*) also encoding a mitochondrial fusion protein, mitofusin 2, result in Charcot-Marie-Tooth (CMT) type 2A neuropathy [202], but mutations in *MFN2* have also been associated with a multisystem disorder that includes mitochondrial myopathy with multiple mtDNA deletions [203].

Mutations in KIF5A, whose product, a kinesin, moves mitochondria along microtubules, were associated with a long-tract disorder, autosomal dominant hereditary spastic paraplegia (HSP) type 10 (SPG10) [204].

Mutations in the gene (GDAP1) encoding the ganglioside-induced differentiation-associated protein 1 (GDAP1), a regulator of mitochondrial fission, are responsible for CMT4A, the most common recessive type of CMT [205, 206].

Interestingly for myologists, a form of centronuclear myopathy (CNM) has been associated to mutations in the gene encoding dynamin 2 (*DNM2*) and shows – besides the typical features of CNM – mitochondrial changes with ragged-blue COX-negative fibers [207, 208]. Curiously, DNM2 mutations also cause CMT that may be axonal (CMT2M) or dominant intermediate (CMTDIB) [202, 209]. Dynamin 2 is a GTPase involved in plasma membrane endocytosis, intracellular membrane trafficking, actin assembly, and centrosome cohesion.

The increasing role of altered mitochondrial dynamics in neurological diseases has been reviewed in several recent articles [210–212].

Zidovudine Myopathy

Zidovudine or azidothymidine (AZT) administration is associated with a ragged-red-fiber (RRF) myopathy [213]. This nucleoside analogue lacks a 3′-hydroxyl group and inhibits infectivity of retroviruses (e.g., HIV-I) by incorporating into the replicating viral DNA and causing premature termination of the elongating DNA chain. Patients on AZT with RRF myopathy have reduced amounts of mtDNA in muscle, an iatrogenic form of mtDNA depletion [214]. It was shown that the drug is incorporated into mtDNA in vitro by the DNA polymerase gamma, one of the enzymes responsible for mtDNA replication [215].

Therapeutic Considerations and Conclusions

Therapy for mitochondrial diseases is woefully inadequate. A trite but true statement is that incurable diseases are not untreatable diseases. Two eminently treatable mitochondrial conditions are some of the CoQ_{10} deficiencies and MNGIE [112]. Palliative therapy for other mitochondrial disorders includes pharmacology (i.e., antiepileptic drugs), surgery (i.e., blepharoplasty for ptosis), and physical therapy (i.e., aerobic exercise) [216, 217]. "Cocktails" of vitamins and antioxidants are commonly used, and the pervasive administration of CoQ_{10} in high doses is justified by its safety, by evidence that CoQ_{10} levels are decreased in patients with mitochondrial diseases [218], and by a small randomized therapeutic trial [219]. However, a Cochrane Review concluded that no therapy had shown convincing beneficial results [220].

The history of mitochondrial diseases after the opening of the molecular era in 1988 has been a succession of exciting discoveries [221]. After most of the mtDNA-related disorders had been described, the mitochondrial disorders due to mutations in nuclear DNA have revealed surprising numbers of disease paradigms, from mutations affecting the respiratory chain directly and indirectly to defects of the crucial interaction between the two genomes, to alterations in the phospholipid composition of mitochondrial membranes, and to disorders of mitochondrial dynamics and quality control. The sheer number of nuclear genes controlling mitochondrial structure and function has made progress rather slow, but the advent of exome sequencing is propelling our knowledge of new diseases by leaps and bounces.

Despite recent progress, our knowledge of pathogenesis remains limited; we have not yet tackled the new field of epigenetics [222], and therapy remains our greatest challenge.

Inflammatory Myopathies

65

Namita Goyal and David A. Chad

Introduction

The inflammatory myopathies comprise three major categories of muscle disease: polymyositis (PM), dermatomyositis (DM), and inclusion body myositis (IBM), conditions that are pathogenetically, histologically, and clinically distinct [1]. Although the inflammatory myopathies are uncommon diseases, they demand attention for several reasons. First, PM and DM are eminently treatable, but improvement and ultimate favorable outcome depend on early diagnosis and prompt initiation of immunotherapy. Although IBM is therapy resistant, accurate diagnosis is critical so that side effects from long-term therapy with potent immunosuppressive drugs are avoided. Second, DM and PM may be associated with disorders of the lungs and heart, as well as with specific connective tissue diseases or neoplasms. Thus, accurate diagnosis of the myopathy should lead the physician to a careful exploration and systematic search for these potentially treatable illnesses before onset of irreversible morbidity. Third, a number of different myopathic and some neurogenic disorders may cause weakness resembling these myositides, particularly PM and IBM. Thus, familiarity with the clinical nuances that characterize PM, DM, and IBM allows the physician to establish an early and accurate diagnosis.

Clinical Features

PM and DM are characterized by subacute (over several weeks to months), progressive, proximal muscle weakness (Table 65.1). There is a bimodal age distribution: one peak occurs in children 5–14 years of age, and a second, larger peak occurs between 45 and 64 years of age [2]. The annual incidence is 5–10 new cases per million per year in the United States. Women outnumber men by 2 to l; moreover, black women have a greater risk for developing this disease than do white women, with the former group showing a higher mortality [2, 3]. IBM progresses more slowly than either PM or DM, on average 6 years from the onset of symptoms to diagnosis. It shows a male predominance, is more common in the white than black population, and is the most common acquired inflammatory muscle disease in patients over the age of 50 years [1, 2, 4–6]. It represents 30 % of inflammatory myopathies referred to a tertiary care center [7].

Table 65.1 Clinical features of polymyositis (PM) and dermatomyositis (DM)

Clinical characteristic	Description
Time course	Weeks to months
Distribution of weakness	Proximal muscles and neck flexors, dysphagia in 30 %, weakness may not be obvious in DM (amyopathic form)
Rash	In DM: heliotrope, V sign, shawl sign, Gottron's sign (all may be subtle)
Childhood form	Yes, primarily DM
Other organ involvement	Interstitial lung disease and cardiac conduction defects most commonly
Associated diseases	Malignancy (especially in DM), connective tissue disease (especially scleroderma)
Diagnostic process	Straightforward for DM, complex for PM with broad differential diagnosis
Response to immunosuppressive treatment	Usually good

In all three forms, weakness of the neck flexors, limb girdle, and proximal muscles is common; in IBM, there is also a predilection for distal muscle involvement (Table 65.2). Dysphagia from involvement of the striated muscle of the upper esophagus and pharynx occurs in 30 % of patients with PM and DM and up to 60 % of patients with IBM [1]. Respiratory muscle involvement is rare but is occasionally seen in the most advanced cases of PM and DM and may occur with an acute form of DM. Although mild facial weakness is occasionally encountered, pronounced facial

Table 65.2 Clinical features of inclusion body myositis

Clinical characteristic	Description
Time course	Months to years
Distribution of weakness	Proximal muscles and neck flexors; dysphagia in up to 60 %; weakness and wasting tend to be distal, asymmetric, predilection for volar forearm and quadriceps
Rash	None
Childhood form	Very rare
Other organ involvement	Not typically described
Associated diseases	No increase risk of malignancy; connective tissue diseases do occur
Diagnostic process	Often difficult with delay in diagnosis, simulates amyotrophic lateral sclerosis
Response to immunosuppressive treatment	Poor

weakness is not a part of the clinical picture, and extraocular muscles are unaffected; indeed, prominent involvement of cranial muscles should raise the suspicion of another diagnosis. IBM is further distinguished from the other inflammatory myopathies by early and asymmetrical involvement of the finger flexors, wrist flexors, knee extensors, and ankle dorsiflexors [7, 8]. In contrast to PM and DM, where proximal muscles tend to be more affected than more distal groups, in IBM, the shoulder abductors are stronger than the forearm muscles, and the hip flexors perform better than the quadriceps [8]. Indeed, frequent and unexpected falls, a result of pronounced weakness involving the quadriceps, are common complaints in IBM. For reasons not entirely clear, there appears to be a higher incidence of peripheral neuropathy (as indicated by distal sensory loss, attenuated ankle reflexes, and low-amplitude sural nerve action potentials) in IBM compared to PM and DM [8].

A wide range of myopathic disorders may simulate PM and include endocrine myopathy, toxic myopathy, Becker and some limb-girdle dystrophy, late-appearing congenital myopathy, and some metabolic myopathies [9]. The main differential diagnostic consideration for IBM is usually (amyotrophic lateral sclerosis), given the propensity for the former to present with asymmetrical, distal weakness. Distinguishing these two diseases may at times be especially challenging because the electromyographic (EMG) signature of a chronic denervating disease like ALS may be found in some patients with long-standing IBM [10] (see below).

Dermatomyositis is characterized by proximal muscle weakness with a skin rash. The rash often precedes the onset of weakness by weeks to months. Early in its course, rash and muscle enzyme elevations may be the sole manifestations of DM [11]. The rash occurs in light-sensitive areas and is erythematous, edematous, and sometimes pruritic; in the later, healed stages of DM, there may be atrophy of the skin [12, 13]. It characteristically occurs over the knuckles, knees, elbows, anterior chest ("V" sign), back and shoulders ("shawl sign"), malar regions, and bridge of the nose. A pathognomonic heliotrope or purplish discoloration with periorbital edema often involves the upper eyelids. Inspection of the nail beds (aided by magnification) typically discloses dilated capillary loops at the base of the fingernails (periungual abnormalities) with irregular thickened and distorted cuticles. The Gottron sign (also known as Gottron's papules or plaques) refers to symmetric, scaling, erythematous, violaceous raised papules and plaques over bony prominences, especially knuckles, proximal interphalangeal joints, and distal interphalangeal joints but can also be seen on the elbows, knees, and ankles (Fig. 65.1) [12]. "Mechanic's hands" or a rough, cracking appearance of the skin of the fingertips may develop. A less well-recognized eruption seen in DM is an erythematous, scaling, and atrophic rash (known as poikiloderma), particularly over extensor surfaces and upper back [14]. Calcium deposits within the skin, known as calcinosis cutis, may occur in juvenile DM but are uncommon in adult DM.

Fig. 65.1 Gottron sign. There is a scaly raised plaque on the middle finger joint. Over the other joints, there is a violaceous erythema

Other Organ Involvement

In both PM and DM, the lungs [14–17] may be involved (Table 65.3). Respiratory symptoms occurring in PM and DM may have a number of different causes, some pulmonary and others non-pulmonary. For example, in the latter category, there may be frank ventilatory insufficiency due to generalized respiratory striated muscle weakness, or dyspnea may result from the rare development of congestive heart failure in the setting of severe cardiac involvement [13].

Table 65.3 Causes of respiratory symptoms in polymyositis and dermatomyositis

Non-pulmonary	Pulmonary
Respiratory muscle weakness	Chronic aspiration
Congestive heart failure	Pyogenic and atypical infections
	Methotrexate toxicity
	Interstitial lung disease

Pulmonary causes comprise parenchymal pulmonary changes stemming from chronic aspiration, pyogenic and atypical lung infections (related to immunosuppressive therapeutics), medication toxicity (notably methotrexate), and interstitial lung disease (ILD) [13].

The prevalence of ILD depends upon the method used to detect lung pathology, with an overall frequency of 5–10 % by radiographic evidence and as high as 30–40 % when pulmonary function testing is employed [17]. ILD may be associated with rapidly progressive respiratory failure. An important serum marker is the anti-Jo-1 antibody (see below), present in more than 50 % of patients with ILD [17–19].

Although clinically symptomatic cardiac involvement in PM and DM, such as congestive heart failure, pericarditis, pulmonary hypertension, and valvular disease, is uncommon, electrocardiographic abnormalities occur in up to 40 % of patients [13]. They comprise nonspecific ST-T wave changes (most frequently), varying degrees of heart block and bundle branch block, and tachyarrhythmias.

Associated Connective Tissue Disorders

The inflammatory myopathies are associated with connective tissue diseases in about 20 % of patients [2]. This so-called overlap group is rather heterogeneous because of the wide variety of conditions that have been linked to PM and DM. They comprise scleroderma, systemic lupus erythematosus (SLE), rheumatoid arthritis, Sjögren's syndrome, and mixed connective tissue disease [18]. Patients with the overlap syndrome are more likely to present with arthralgia, and arthritis and their muscle disease is often milder than in isolated PM or DM and more responsive to therapy.

Although symptoms of muscle pain and weakness are frequent complaints in patients presenting with one of these connective tissue diseases, active myositis is uncommon in scleroderma (5–17 %), SLE (<10 %) and rheumatoid arthritis (13 %), and rare in Sjögren's syndrome [20].

It has become increasingly clear that IBM is also associated with autoimmune diseases like Sjögren's syndrome [21] and SLE [22]. It is also associated with autoantibodies as well as with monoclonal gammopathies, which often recognize various muscle components, especially myonuclei, suggesting disturbed immunoregulation [23, 24].

Association with Malignancy

Although the validity of a possible cause and effect relationship between cancer and inflammatory myopathy has been questioned [25], there is probably a substantially and statistically significant increased association between cancer and DM compared to the normal population. Devere and Bradley [26] found that 40 % of patients over the age of 39 with DM had cancer, whereas only 3.4 % of older patients with PM were found to have a neoplasm. Callen suspects that "roughly 25 % of patients with DM have had, will have, or will develop an internal malignancy," in contrast to only a small increased risk in PM [27]. IBM has not been associated with an increased risk of malignancy [7].

The diagnosis of malignancy can precede or follow the myopathy by months to several years, but most malignancies are identified within 2 years of the presentation of myositis. It is generally thought that ovarian cancer may be overrepresented in women with DM. Callen's review of the literature, however, indicates that any type or site of malignancy is possible, that the tumor site is determined by the prevalence of the tumor in the population, and that sites involved are age related [27]. Several clinical and laboratory features are negatively associated with malignancy, including an accompanying connective tissue disease, pulmonary fibrosis, and a myositis-specific antibody (see below) [27].

We recommend undertaking a careful screening for malignancy in patients presenting with PM or DM, especially the latter. This should include a thorough general physical examination, including the rectum, pelvis, breast, and testicles. Laboratory testing includes routine hematological and biochemical studies, stool analysis for occult blood, chest roentgenogram, mammography and pelvic ultrasound in women, and prostate-specific antigen. Further radiological procedures such as computerized tomography and magnetic resonance imaging studies of the chest, abdomen, and pelvis may be indicated if the initial screening studies reveal a suspicious structural alteration from normal appearance. Early tumor recognition is obviously crucial, and there are reports of improvement in DM with tumor resection [27].

Association with Autoantibodies

Myositis-specific autoantibodies (MSA) are directed primarily against cytoplasmic ribonucleoproteins involved in the process of protein synthesis and are found almost exclusively in patients with myositis (the PM and DM forms, not IBM) [18, 19]. They are heterogeneous with each one occurring in only a small proportion of patients with PM and DM (Table 65.4). It is rare for a patient to have more than one MSA, and hence each one defines a specific subgroup of patients [28]. Although the absence of an MSA cannot exclude

Table 65.4 Myositis-specific autoantibodies in polymyositis and dermatomyositis

Autoantibody	Clinical features
Anti-synthetase (anti-Jo-1)	20 % of DM and PM patients, acute onset in spring, association with interstitial lung disease and nonerosive arthritis, frequent relapse during prednisone taper
Anti-SRP	5 % of PM, onset in autumn, acute weakness with myalgias, frequent myocarditis, resistance to prednisone, poor prognosis (25 %, 5 year survival)
Anti-Mi-2	5–10 % of DM, acute onset with florid rash, good response to immunosuppressive therapy

DM dermatomyositis, *PM* polymyositis, *SRP* signal recognition particle, *Mi* nuclear helicase

Table 65.5 The laboratory diagnosis of idiopathic inflammatory myopathy

Laboratory feature	Finding(s)
Serum CK	Elevated: 5- to 50-fold in PM and DM, 3- to 5-fold in IBM, rarely normal in early or mild DM
ESR	Usually normal, may be elevated in presence of connective tissue disease or malignancy
Electromyography	Abnormal in the majority showing a combination of increased insertional activity/positive waves/fibrillation potentials and short-duration/low-amplitude/polyphasic MUAPs and early recruitment; sometimes, mixed with large MUAPs when chronic
Muscle biopsy	Abnormal in the vast majority with unique histology for DM and IBM and inflammation with muscle fiber necrosis and degeneration/regeneration common to all forms

the diagnosis of PM or DM, their presence has strong predictive value defining subgroups of patients with similar clinical manifestations, disease severity, and response to therapy.

Clinically, the most important MSAs are the *anti-synthetase antibodies*, found in 25–30 % of patients with PM/DM; the *anti-SRP* (*signal recognition particle*) *autoantibody* detected in 4–5 % of cases of PM; and the *anti-Mi-2* (*nuclear helicase*) *autoantibody* found in 5–10 % of DM patients [19]. A fourth autoantibody, the *anti-PM-Scl autoantibody*, is more appropriately designated myositis associated (rather than specific) because it is most closely associated with connective tissues disease and is found in the overlap syndrome—PM associated with scleroderma. Fifty percent of autoantibody positive patients have this clinical combination, others have an undifferentiated connective tissue disease, and some have scleroderma without myositis [28]. Anti-U1RNP has a strong association with myositis in the context of mixed connective tissue disease (features of scleroderma, SLE, rheumatoid arthritis) but is also not specific [19]. Similarly, anti-Ro/SSA autoantibody is more closely associated with connective tissue disease than myositis per se.

Among the five anti-synthetases that have been defined, *anti-aminoacyl tRNA synthetase* (*anti-Jo-1*) MSA is the most prevalent, occurring in 20 % of patients with PM and DM. The anti-Jo-1 autoantibody is directed at histidyl-tRNA synthetase, the cytoplasmic enzyme responsible for catalyzing the formation of histidyl-tRNA from histidyl and its cognate RNA. Anti-Jo-1 positive patients often have a constellation of clinical features, termed *the anti-synthetase syndrome*, comprising the acute onset of myositis in the spring, associations with a nonerosive symmetrical small joint arthritis, low-grade fevers, Raynaud's syndrome, mechanic's hands, frequent relapse with tapering of corticosteroids (see below), and perhaps, most importantly, interstitial lung disease (found in 50–75 % of patients who are anti-Jo-1 positive) [18, 19, 28]. A small number of patients with anti-Jo-1 autoantibody have no evidence of myositis but have other features of the syndrome.

Patients with the anti-SRP autoantibody, almost exclusively in PM, present with acute onset of severe weakness and myalgias in the autumn [19]. Their disease is characterized by frequent cardiac involvement (myocarditis), resistance to immunotherapy, and poor prognosis. Patients with anti-Mi-2 autoantibody (unique because it is directed at a nuclear antigen, in contrast to the other MSAs) virtually all have DM and present with weakness and a florid rash (50 % have the shawl sign and nearly 100 % the V sign). Response to therapy is good and the prognosis is favorable.

Diagnosis

Laboratory Features

Routine hematological and clinical chemistry laboratory and radiologic studies are generally normal unless there is an underlying neoplasm or overlap syndrome with associated connective tissue disease. In the event of the latter, the ESR may be elevated and testing for antinuclear antibodies may be positive. Creatine kinase (CK) is a very sensitive serum enzyme for the diagnosis of myositis, found to be normal in only 4.6 % of patients with PM and DM described by Bohan and colleagues [29]. Nearly 90 % of patients with myositis have CK elevation [30]. Normal values may be found in those with mild or early disease, particularly in instances of DM or IBM [11]. In most patients with PM and DM, CK levels are elevated 5–50 times above normal [11], while in the majority of those with IBM, the CK elevations are mild, usually three- to fivefold normal, rarely exceeding tenfold increases (Table 65.5) [7]. Although other enzymes including lactate dehydrogenase, the transaminases, and, notably, the highly sensitive aldolase are also elevated in active myositis, the CK is most reliable, correlating best with clinical course and other markers of disease activity [29].

Table 65.6 Electromyography in idiopathic inflammatory myopathy

Stage of the disease	Findings
Acute	Fibrillation potentials and positive waves; complex repetitive discharges
	Short-duration, low-amplitude, polyphasic MUAPs
	Early recruitment of motor unit action potentials
Chronic	As above with addition of a population of high-amplitude, long-duration, polyphasic MUAPs (mixed potentials)
Long standing (end stage)	Features of acute and chronic stages and a reduction of motor unit action potentials with reduced recruitment

Fig. 65.2 Motor unit action potentials (MUAPs) typical of active myositis (**b**). The MUAPs are short in duration, low to moderate in amplitude, "spikey," and polyphasic. Contrast with normal MUAPs (**a**) and large-amplitude, long-duration MUAPs seen in neurogenic disease (**c**) (Reproduced with permission from Bromberg and Albers [37])

Electromyography

Needle electromyographic (EMG) study is of great importance in the evaluation, diagnosis, and management of the inflammatory myopathies (Tables 65.5 and 65.6). The classic needle EMG changes in the acute stages of active myositis comprise three major abnormalities [31–37]:

1. *Increased insertional activity*, *positive sharp waves*, *fibrillation potential activity*, *and complex repetitive discharges*. Although these electrodiagnostic features have long been viewed as the hallmarks of acute neurogenic disease, they may also be produced by segmental necrosis of muscle fibers [38]. In this latter case, the necrotic muscle segment separates a distal, healthy portion of the muscle fiber from the part carrying the end plate. An important observation is that fibrillation potentials in myositis are most frequent in paraspinal muscles, so that the study of these muscles should be part of every work-up for myositis (see below) [34–41].
2. *Short-duration*, *low-amplitude*, *and polyphasic motor unit action potentials* (*MUAPs*)—so-called "myopathic" MUAPs (Fig. 65.2). These changes are thought to result from a decrease in the number of functioning muscle fibers per motor unit and from the loss of synchronous firing of the remaining fibers whose function is impaired [36].
3. *Early or rapid recruitment of MUAPs*, where more MUAPs than expected are discharging for a given level of force (Fig. 65.3). This behavior is a reflection of the decreased number of functioning muscle fibers in each motor unit [36, 37, 42].

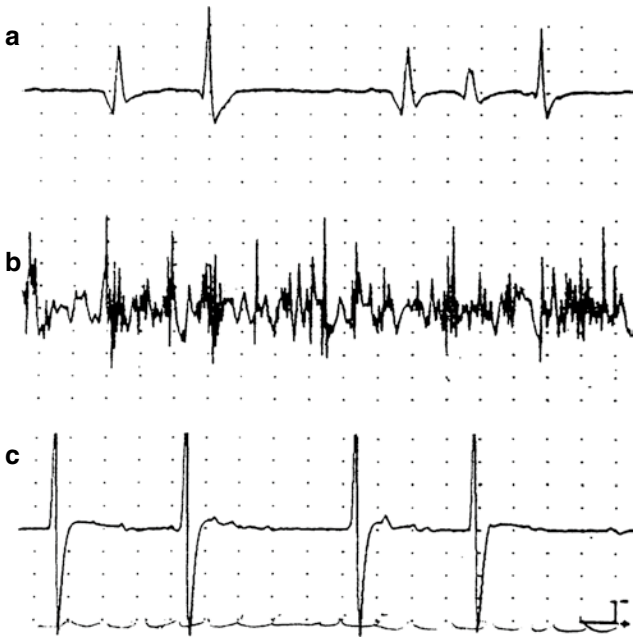

Fig. 65.3 Early or increased recruitment of MUAPs in myositis with many short-duration polyphasic MUAPs despite low level of force (**b**). Contrast with normal recruitment with three MUAPs firing (**a**) and decreased recruitment with one high-amplitude MUAP firing rapidly in neurogenic disease (**c**) (Reproduced with permission from Bromberg and Albers [37])

In the chronic stages of myositis (histologically defined by ongoing muscle fiber necrosis and inflammation), some of the MUAPs are high in amplitude, long in duration, and polyphasic with satellite potentials (Fig. 65.4) [10, 42–44]. These alterations in MUAP appearance probably result from reinnervation by secondary collateral sprouting to the previously denervated muscle fiber segments (see above). Indeed, single-fiber EMG studies in PM [45] and IBM [10, 46] disclose increase in fiber density, increased jitter, and blocking.

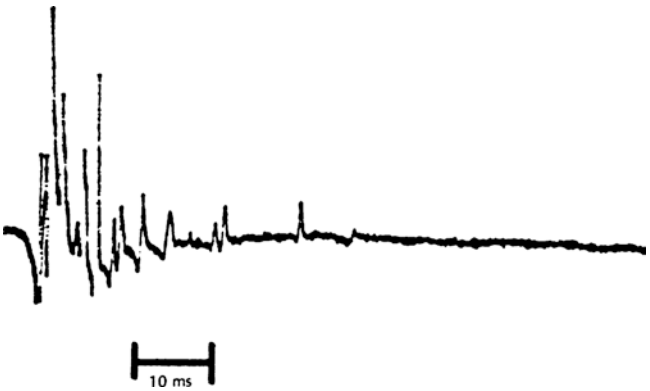

Fig. 65.4 A highly complex MUAP with satellite components gives the total motor unit a long duration (Reproduced with permission from Daube [42])

Table 65.7 Approach to the EMG diagnostic study for inflammatory myopathy

Test	Goal/rationale
Sensory nerve conduction studies	Exclude polyneuropathy (expected to be normal in PM and DM, occasional abnormalities in IBM)
Motor nerve conduction studies	Exclude polyneuropathy and Lambert-Eaton myasthenic syndrome (expect to be normal in PM, DM, IBM except when there is pronounced distal muscle involvement)
Repetitive nerve stimulation	Exclude myasthenia gravis and Lambert-Eaton myasthenic syndrome (expect to be normal in PM, DM, IBM)
Needle EMG	Cast a broad net and always include paraspinal muscles
	Examine most proximal, proximal, mid-limb, and distal in arms and legs
	Examine one side, leaving the other for muscle biopsy

Increased jitter and blocking probably reflects necrotic segments receiving new axonal sprouts, while the increase in fiber density is likely produced by fiber atrophy (as more fibers are close to the recording electrode) and fiber splitting [45, 47]. After two or more years of myositis (PM, DM, and IBM), it is common to encounter in the same muscle the combined presence of long- and short-duration MUAPs, also known as mixed potentials [7]. Finally, in end-stage muscle, loss of all the fibers belonging to some units will lead to a net loss of MUAPs, the EMG signature of which is reduced recruitment.

The electrodiagnostic examination in a patient with, or suspected of, inflammatory myopathy begins with nerve conduction studies (Table 65.7). Sensory amplitudes, distal latencies, and conduction velocities are expected to be normal, unless there is a coexisting poly- or mononeuropathy. In IBM, several studies found an increased incidence of a mild axon-loss peripheral neuropathy [8, 10, 46]. Because conventional motor nerve study parameters are usually measured from distal—small hand and foot—muscles, motor amplitudes are typically normal or only mildly attenuated in myositis. If there is substantial distal muscle involvement, however, motor amplitudes might be reduced. Marked generalized attenuation of motor amplitudes should raise the possibility of Lambert-Eaton myasthenic syndrome and prompt further detailed testing of neuromuscular transmission. Yet, even if distal amplitudes are within the normal range, we generally proceed with repetitive nerve stimulation in the evaluation of the suspected inflammatory myopathy patient because disorders of the neuromuscular junction—both myasthenia gravis and Lambert-Eaton myasthenic syndrome—may present with limb-girdle and proximal muscle weakness.

The needle EMG electrode examination should "cast a broad net." The distribution of EMG findings in PM and DM correlates with the pattern of weakness detected by clinical examination, so that fibrillation potential activity and abnormal MUAPs follow a proximal to distal gradient [37]. In IBM, however, the EMG abnormalities are often strikingly asymmetrical, multifocal, and distally predominant. The needle EMG examination study should always include paraspinal muscles, an approach that derives from the work of several groups [29, 40], notably Streib et al. [41]. These authors performed detailed needle-electrode examinations on 40 patients with inflammatory myopathy. In each patient, eight or more muscles were studied. In 35 % of patients, fibrillation potential activity was found in all examined muscles; in another 35 %, more than ½ of the muscles examined revealed these potentials; in 20 % of patients, <½ of the muscles revealed fibrillation potentials; and in 10 % of patients, fibrillations were found in only one or two muscles. In every patient, fibrillation potentials were found in at least one muscle. The yield of fibrillation potential activity was greatest for paraspinal muscles (93 % of tests performed) and lowest for the first dorsal interosseous (47 %). The yield was greater than 75 % each for each of the spinati, biceps, triceps, and brachioradialis; approximately 75 % for each of the glutei and iliacus; 70 % for the tibialis anterior; 50 % for the gastrocnemius; and 64 % for the vastus lateralis.

The EMG provides an excellent gauge of disease activity [36]. In the phase of active myositis, fibrillation potential activity, positive sharp waves, and increased insertional activity all tend to be widespread and abundant along with "myopathic" MUAPs (Fig. 65.5). With successful treatment (see below), there is a trend toward a decrease in features of "membrane irritability" and a diminution in the proportion of "myopathic" MUAPs. Another indication of treatment response is the presence of only small-amplitude positive waves or fibrillation potentials, in contrast to the 100- to 200-μV size fibrillation potentials seen in the acute phase following partial muscle fiber necrosis [35]. The EMG may also be helpful in determining if the clinical deterioration in a previously stable prednisone treated patient is caused by

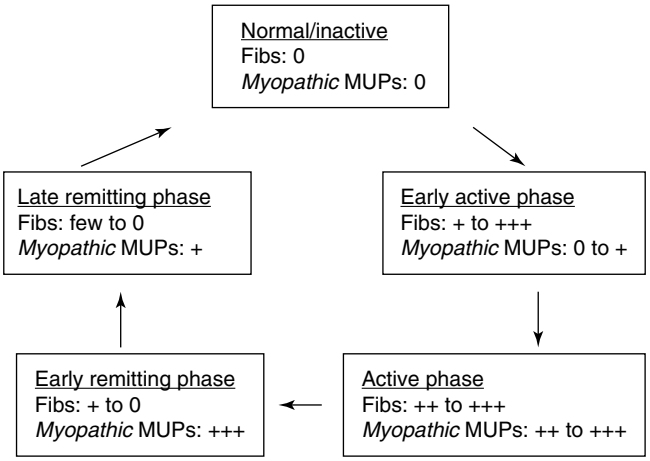

Fig. 65.5 The cycle of EMG changes during stages of polymyositis (Modified with permission from Wilbourn [36]).

Table 65.8 Muscle biopsy findings in the idiopathic inflammatory myopathies

Histopathologic finding	Distinguishing features
Mononuclear cell inflammation	In PM and IBM, inflammation is endomysial; in DM, it is perivascular and interfascicular
Muscle fiber degeneration/regeneration	In PM and IBM, scattered throughout fascicles; in DM, perifascicular; in IBM, there are rimmed vacuoles
Fiber size variation	In IBM, small fibers tend to group or cluster
Oxidative enzyme staining alterations	In DM, occur in perifascicular regions
Capillary damage	Characteristic for DM is capillary endothelial cell damage (with tubuloreticular inclusions by EM) and immune deposits; no alterations in PM and IBM
Muscle nuclei	In IBM, intranuclear (and intracytoplasmic) filamentous inclusions

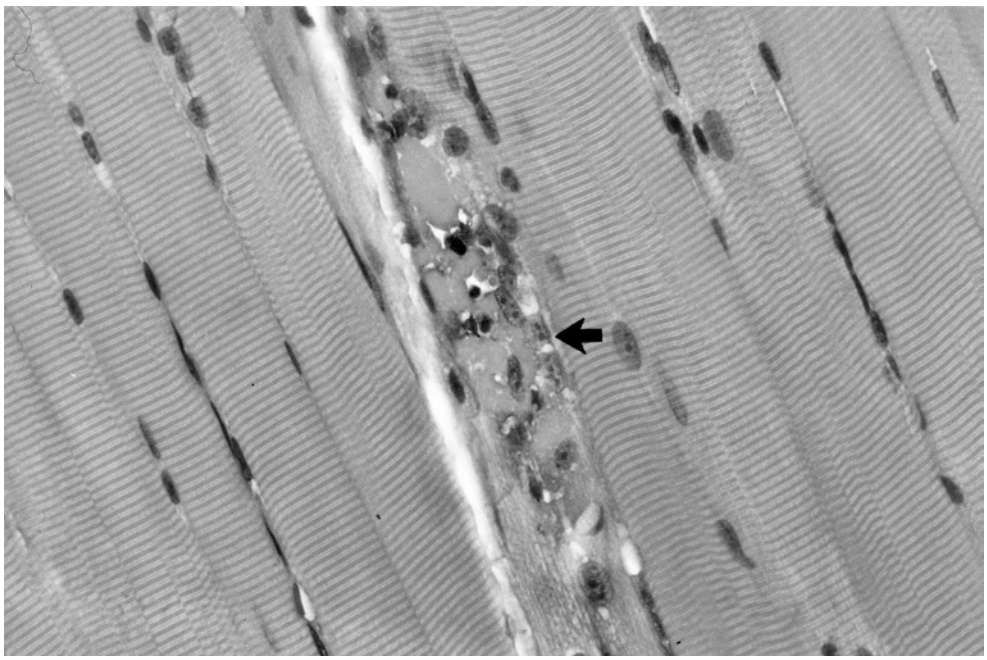

Fig. 65.6 Polymyositis. Segmental necrosis. There is a necrotic muscle fiber (*arrow*) in the center of the photomicrograph surrounded by healthy-appearing muscle fibers. The necrotic fiber has lost normal cross striations. Hematoxylin and eosin × 100 (original magnification)

recrudescence of myositis (disease activity) or instead marks the onset of a superimposed corticosteroid-related myopathy. Steroid myopathy would be favored by finding no evidence of positive waves or fibrillation potentials in the face of the early recruitment of short-duration, low-amplitude MUAPs, while prominent fibrillation potentials with a similar voluntary MUAP pattern would favor recurrent myositis.

Muscle Biopsy

This diagnostic tool is of great importance in the evaluation of a suspected inflammatory myopathy (Table 65.8). Not only does it help exclude other potential causes for the patient's symptoms but also it reveals abnormal histological features unique for DM, IBM, and PM [11]. In general, the inflammatory myopathies are characterized by *segmental muscle fiber necrosis* (Fig. 65.6), *muscle fiber regeneration*, *and mononuclear cell inflammation* (Fig. 65.7). In PM, the inflammatory cells are found among muscle fibers (Fig. 65.8), while in DM, the inflammation is primarily perivascular (Fig. 65.9) and interfascicular [1, 2].

Both DM and IBM have histologically distinctive features of an inflammatory nature so that the diagnosis of these myositides may be suspected in the setting of typical clinical and histopathologic pictures even in the absence of inflammation. Two histologic patterns of muscle fiber injury are characteristic of DM: perifascicular atrophy (Fig. 65.10) and, less

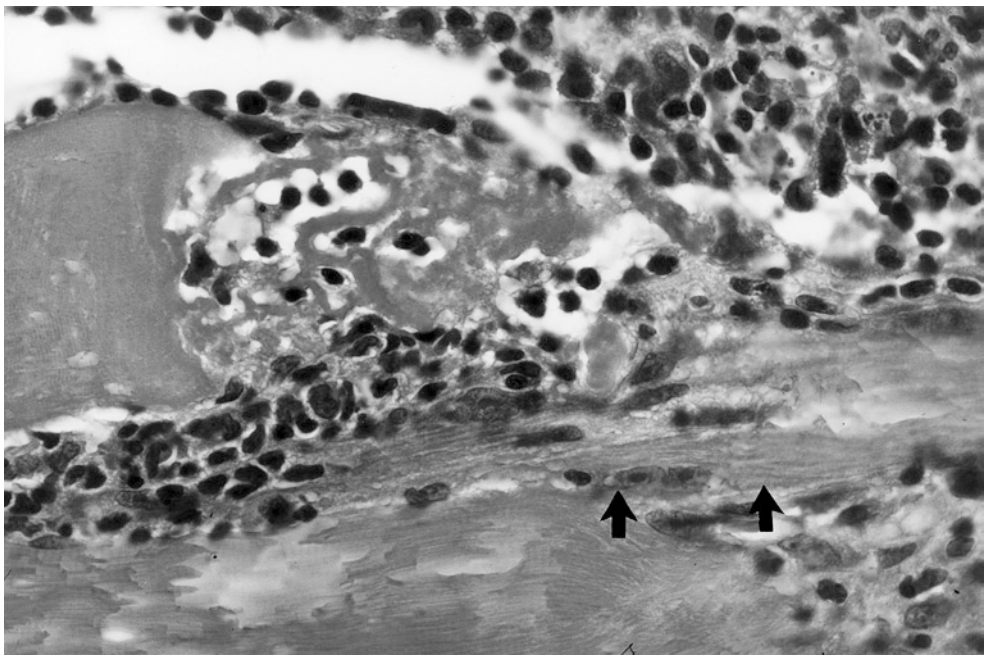

Fig. 65.7 Polymyositis. There is a necrotic muscle fiber surrounded and invaded by mononuclear inflammatory cells. A regenerating fiber is seen adjacent to the necrotic segment (*arrowheads*). Hematoxylin and eosin × 150 (original magnification)

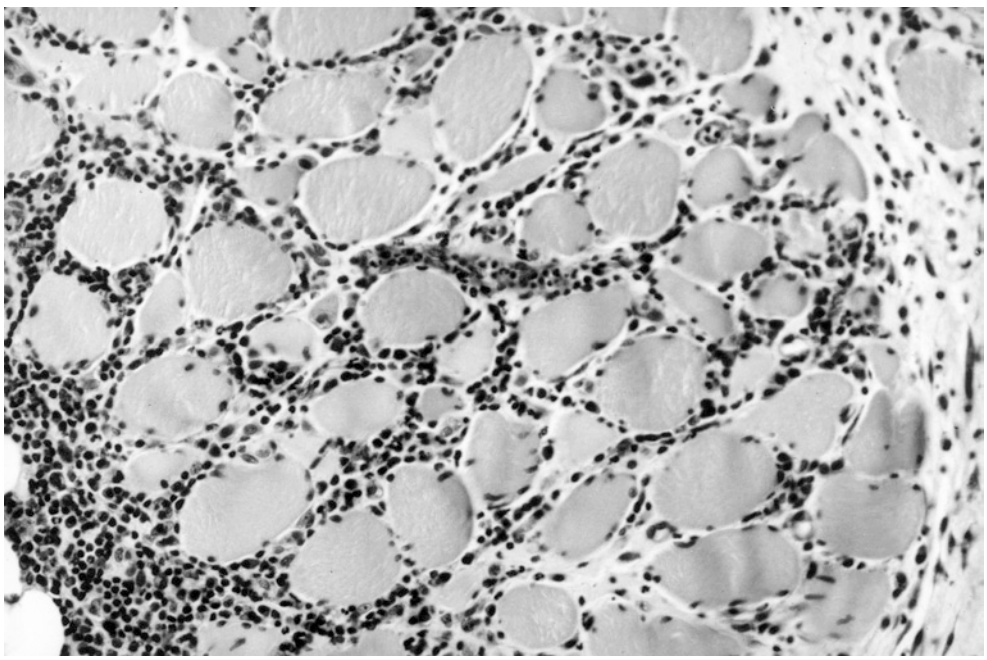

Fig. 65.8 Polymyositis. Inflammatory mononuclear cells surround nonnecrotic muscle fibers. There is pronounced variation in muscle fiber size, and many fibers are atrophic. Hematoxylin and eosin × 50 (original magnification)

commonly, wedge-shaped muscle microinfarcts [11]. Both reflect the presence of a primary abnormality of blood vessels causing ischemic injury to muscle fibers. Perifascicular atrophy is characterized by two to ten layers of atrophic fibers at the periphery of the fascicles [11].

The histologic picture of IBM resembles PM in that in endomysial lymphocytic inflammation, fiber necrosis with phagocytosis and regeneration are present, although these features may be variable and even absent. The characteristic light microscopic features of IBM are *rimmed vacuoles* (Fig. 65.11) within a variable number of muscle fibers [4–7]. Electron microscopy reveals the presence of bundles of 15–18 nm diameter tubular filaments (Fig. 65.12) in the vicinity of the rimmed vacuoles or in the nuclei [4–7].

Intracellular amyloid deposits have been demonstrated in muscle fibers of IBM with Congo red [48]. They were mostly intracytoplasmic, but some were also present in the nucleus. Recent studies have demonstrated that rimmed vacuoles in

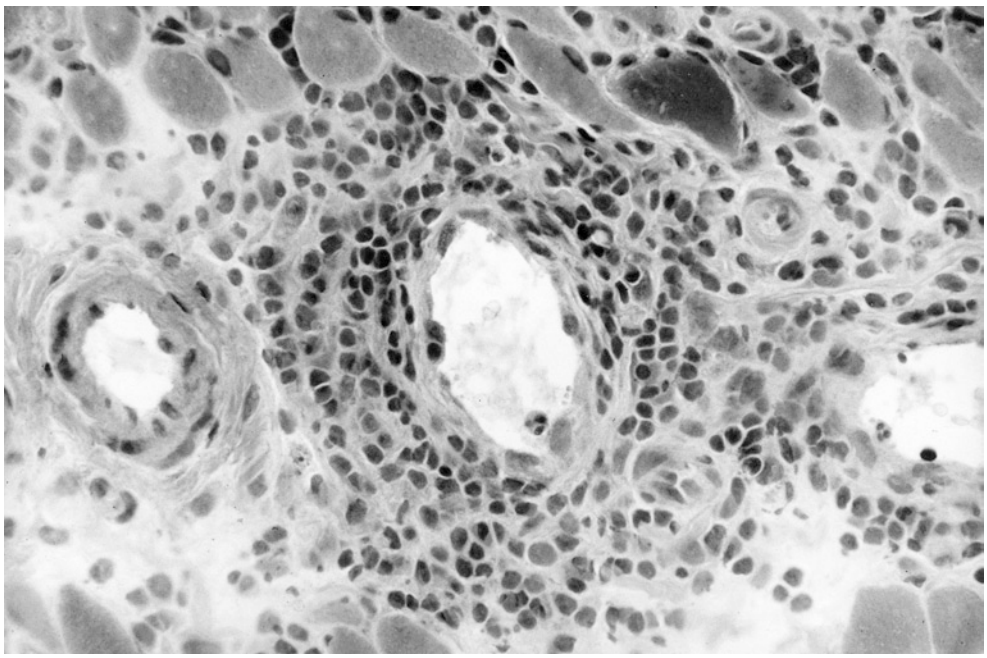

Fig. 65.9 Dermatomyositis. There is pronounced perivascular inflammation in the interfascicular space. Hematoxylin and eosin × 50 (original magnification)

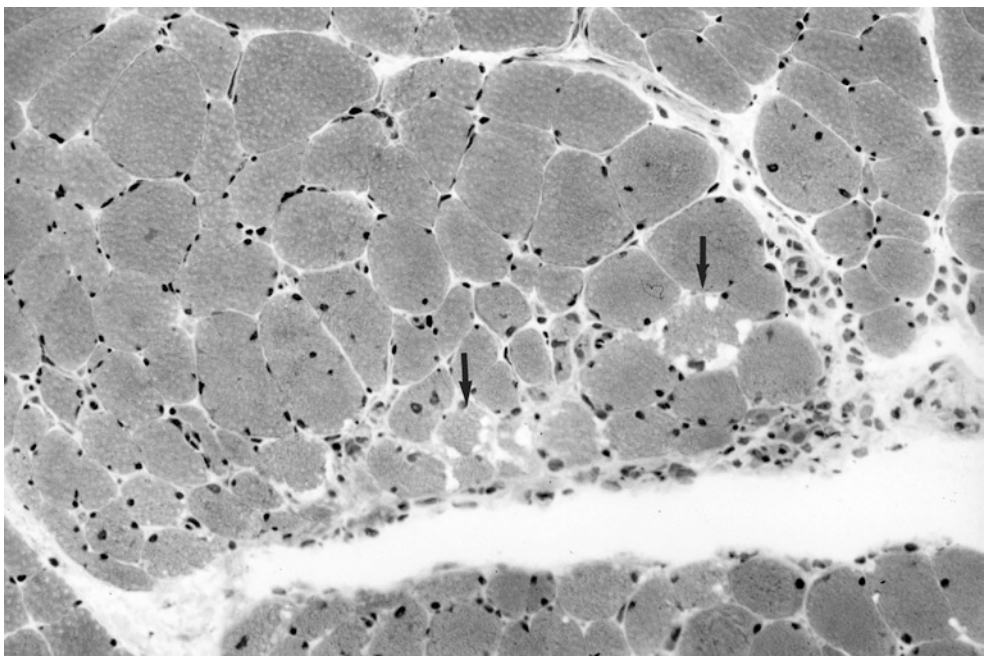

Fig. 65.10 Dermatomyositis. Perifascicular atrophy. Many muscle fibers at the edge of the fascicles are atrophic. Some degenerating fibers are vacuolated (*arrows*). Hematoxylin and eosin × 50 (original magnification)

IBM may show immunoreactivity for "brain-specific" proteins such as β-amyloid, prion protein, phosphorylated tau, ubiquitin, and apolipoprotein E [49]. In some biopsies, there are mitochondrial alterations, manifested by cytochrome oxidase-negative fibers, scattered ragged-red fibers, and an increased number of mitochondria, some containing paracrystalline inclusions noted by electron microscopy [50]. Mitochondrial deletions have also been found in at least half of the patient population with IBM [51].

In PM, the histological findings of fiber necrosis and regeneration lack the requisite specificity for a diagnosis to be established without primary endomysial inflammation being present in at least one muscle biopsy specimen [11]. In some instances (12.5 % in the study of Bohan and colleagues in 1977 [29]) in otherwise typical PM or DM, the muscle biopsy is normal or only mildly and nonspecifically abnormal. Although for some patients the explanation may relate to the mild nature of their disease or to sampling errors, in

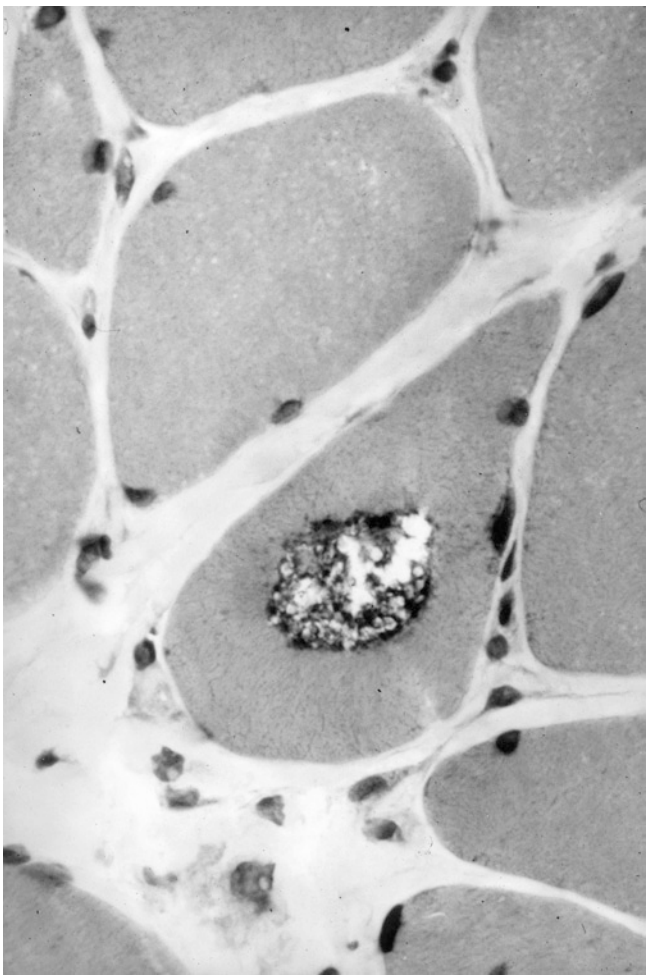

Fig. 65.11 Inclusion body myositis. A vacuole containing basophilic granules ("rimmed vacuole") is seen within a muscle fiber. Hematoxylin and eosin × 1,000 (original magnification)

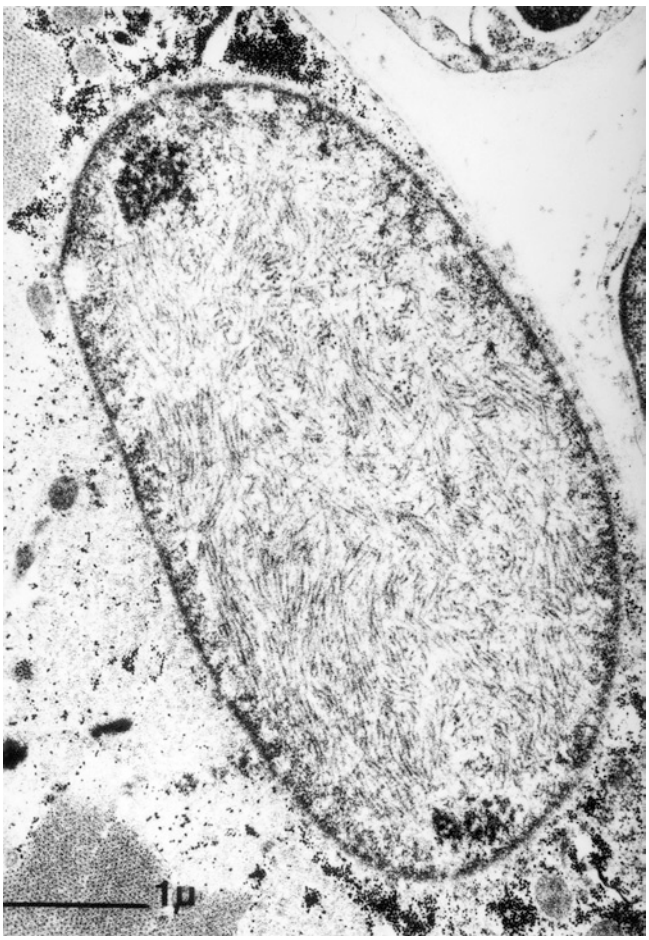

Fig. 65.12 Inclusion body myositis. Intranuclear tubular inclusions, 13–18 nm in diameter × 16,000 (original magnification)

others, a satisfactory reason remains elusive. When reading muscle biopsies, it is important to bear in mind that some of the cardinal features of myositis (necrosis, regeneration, and inflammation) may also be found in the muscular dystrophies and the chronic neurogenic atrophies.

Pathogenesis

Although the exact mechanism of fiber damage is not completely known, there is evidence for an immune pathogenesis in the inflammatory myopathies. In DM, the intramuscular microvasculature is believed to be the early and specific target of a humorally mediated process involving the complement membrane attack complex (MAC) [52–54]. The earliest lesion that precedes inflammation or structural changes in muscle fibers is deposition of the C5b-9 membrane attack complex (MAC) in intramuscular capillaries [55]. Complement deposition leads to necrosis, and thrombosis of capillaries, small arteries, and venules found predominantly in the periphery of the fascicle, resulting in ischemia, myofiber destruction, and perifascicular atrophy. Consistent with the notion that dermatomyositis is mediated largely by humoral immunity is that the inflammatory infiltrate is composed mainly of B cells and helper T cells.

In PM and IBM, histologic findings suggest a cell-mediated immune response directed against muscle fibers [1]. The majority of inflammatory cells are made up of T cells and macrophages. These cytotoxic and suppressor T cells are thought to recognize antigenic targets associated with major histocompatibility complex 1 antigen in muscle fibers, as they surround and destroy healthy, nonnecrotic fibers. In IBM, the filamentous inclusions resemble myxovirus nucleocapsids, and therefore a viral pathogenesis has been suggested but never proven. Immune and degenerative mechanisms appear to be involved in the pathogenesis of IBM, but the relative importance of each is not clear. The observation that quantitative studies of the major histological alterations in IBM reveal a several fold more frequent occurrence of invasion of nonnecrotic fibers by T cells than

Congo-red-positive fibers indicates that immune-mediated mechanisms may be important [56]. On the other hand, the decrease in inflammation during the course of prednisone treatment for IBM while the number of vacuolated and amyloid-positive fibers increases suggests that immune mechanisms are secondary and that the disease is primarily degenerative [57].

Differential Diagnosis

The presence of characteristic weakness and rash, elevation of CK, abnormal EMG, and distinctive histopathology establishes the diagnosis of definite DM. The condition is deemed mild or early DM if there is a characteristic rash and minimal weakness, mild CK elevation, and equivocal abnormalities on EMG, in the setting of a nonspecifically abnormal biopsy that does not show the characteristic pathology of DM (see above) [11]. The diagnosis of IBM is suggested by the clinical characteristics of a long course, distal involvement and asymmetries, the modest CK elevation, myopathic EMG, and the unique histological appearance (see above). Not uncommonly, however, IBM is initially diagnosed as PM, usually because the muscle biopsy specimen fails to disclose the clues of rimmed vacuoles and myopathic grouping and electron microscopy is either not done or does not reveal the characteristic cytoplasmic inclusions. In these cases, lack of response to immunotherapy leads to reconsideration of the diagnosis and a second muscle biopsy, which may establish the diagnosis. The diagnosis of PM is most challenging of all [58]. Without characteristic cutaneous manifestations, a unique distribution of weakness, a defining EMG signature, or a specific pathological appearance, PM may simulate the dystrophies and metabolic myopathies. In addition, infection of muscle, sarcoidosis, endocrinopathies, and the effects of certain drugs and toxins may all produce a similar pattern of muscle weakness. The presence of a myositis-specific autoantibody in patients undergoing an evaluation for suspected inflammatory myopathy has assisted in establishing the diagnosis of PM [19].

Necrotizing myopathy (NM) is a distinct entity in which the dominant histological feature is muscle fiber necrosis; in contrast to DM, IBM, and PM, there is no inflammation and yet NM is thought to be an immunologically mediated condition [59]. It may occur as a manifestation of a paraneoplastic disorder and may be seen in some patients with anti-SRP antibodies and the anti-synthetase syndrome. NM has also been described in a small percentage of patients with a history of statin use. The clinical scenario among this subset of patients taking statins is that following the onset of weakness, the drug is appropriately discontinued and yet weakness persists, and this leads to the decision to undertake a muscle biopsy; the histological picture is one of muscle fiber necrosis without inflammation. When patients are treated with aggressive immunosuppressive therapy, many respond suggesting to investigators that the most appropriate designation for this myopathic disorder is "statin-associated, immune-mediated necrotizing myopathy." Further support for the role of immunity in the pathogenesis of statin-associated NM is its association with autoantibodies directed to a 100-kDa antigen identified as the 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR) protein [60].

Treatment

The natural history of PM and IBM without therapy has not been formally studied. It is possible that in some patients, these diseases may improve or resolve spontaneously. Corticosteroid treatment of PM and DM is started when weakness interferes with activities of daily life. Patients with minimal weakness may be closely followed without specific treatment. We recommend prednisone at 1 mg/kg per day taken as a single morning dose and institute corticosteroid precautions.

Although some patients may improve within days to a couple of weeks, improvement in others may be delayed for 4–6 weeks. It is difficult to know when to start reducing the dose of prednisone, but we generally maintain a high daily dose for 3–4 weeks (unless an unacceptable side effect develops) [1]. Once a clear sustained improvement in muscle strength occurs and the serum CK level falls, one may gradually taper the dose of prednisone over a period of 10 weeks to a dose of 1 mg/kg every other day [1]. If improvement continues during the period of conversion, one can then continue to taper by 5–10 mg every 3–4 weeks until the lowest possible dose which controls the disease is reached. A patient destined to have a good response generally shows substantial return of function in the first 4–6 months of treatment.

In patients on long-term corticosteroid therapy, corticosteroid myopathy is a consideration when an increase in weakness occurs without a major change in serum CK, especially if the urinary creatine is elevated [61]. If a trial of reduced corticosteroid therapy leading to improvement is demonstrated, the diagnosis of corticosteroid myopathy is confirmed. These patients usually also have other steroid side effects. An EMG may also help to distinguish corticosteroid myopathy from more severe inflammatory myopathy. In the latter, abundant fibrillation potentials are expected in weak muscles, whereas in the former, these potentials are usually absent.

Some patients with PM and DM will fail to respond to prednisone even after 12 weeks of high-dose daily treatment [29]. A number of cytotoxic immunosuppressive agents have been used with varying degrees of success in this situation, and these include azathioprine, methotrexate, cyclophosphamide,

chlorambucil, and cyclosporine [1, 11, 62]. Although successful in some, in other patients, improvement may be only partial and slow in coming. In refractory cases of PM, intravenous gamma globulin (IVIG) was demonstrated to have a beneficial effect in uncontrolled studies [63]. For DM, a placebo-controlled study showed dramatic improvement in muscle strength and skin rash [55]. Repeated muscle biopsies showed improvement in the muscle fiber diameters with resolution of the immunopathology [63]. More recently, several small case series or case reports have shown clinical improvement using rituximab in both DM and PM [64–67].

Despite the inflammatory component on muscle biopsy, IBM has been noted to be relatively resistant to traditional immunosuppressive therapy. A number of immunosuppressive agents have been evaluated in therapeutic trials for IBM; however, none have shown significant clinical improvement. A double-blind, placebo-controlled crossover study of IVIG in IBM failed to show a statistically significant improvement in overall muscle strength. There was, however, a trend toward improvement in swallowing and lower limb strength [68] suggesting that a role may yet be found for IVIG in IBM, perhaps as a stabilizing modality [69]. Another double-blind, placebo-controlled study of IVIG and high-dose corticosteroids failed to show changes in muscle strength and concluded that the combination of prednisone and IVIG was ineffective in treating IBM [70].On a positive note, one study showed that the inflammatory myopathy with cytochrome oxidase (COX)-negative muscle fibers, which resembles IBM clinically with slow progression and resistance to corticosteroids, showed improved muscle strength in response to methotrexate therapy [71].In general, empiric treatment with immunotherapy can be attempted in patients with IBM; however, if muscle strength continues to decline, therapy should be discontinued given the risks of long-term steroid and immunosuppressive therapy along with the lack of supportive clinical evidence that immunotherapy is beneficial in IBM.

Prognosis and Outcome

Although features such as the severity of the weakness at onset of the disease, degree of elevation of the CK, and degree of abnormality of the muscle biopsy do not correlate with outcome, a number of unfavorable prognostic factors have been identified [72] (Table 65.9). First, patients with PM and DM associated with malignancy have a significantly higher mortality rate than those without a neoplasm. Second, patients with myositis-specific autoantibodies, specifically anti-synthetase autoantibodies, and anti-SRP autoantibody have a poorer prognosis and are less likely to respond to corticosteroids. Patients with anti-Jo-1 autoantibody are at increased risk for interstitial lung disease, which may be a cause of increased morbidity and mortality. Third, patients with a delay to diagnosis greater than 18 months have a poor chance of complete response to prednisone. Fourth, in the last decade, it has become clear that IBM responds poorly, if at all to treatment with corticosteroids and immunosuppressive agents [4–7, 57]. Because IBM may be diagnosed initially as PM [8], it is possible that patients designated as unresponsive PM in earlier studies actually had IBM.

Table 65.9 Prognostic factors in idiopathic inflammatory myopathies

Unfavorable prognostic factors
Malignancy
Myositis-specific autoantibody (especially anti-SRP)
Interstitial lung disease
Cardiomyopathy
Delay to diagnosis of >18 months
IBM

For patients with PM or DM without unfavorable prognostic factors, however, the outlook for a favorable response to treatment is good, with 70–80 % responding completely or at least partially to corticosteroids [62]. In one of the landmark studies from 1975, two-thirds of corticosteroid treated patients improved to the point of having no functional disability, three or more years after the institution of treatment [26]. For the 20–30 % of patients whose disease remains active despite optimum dose and duration of corticosteroid treatment, one or more of the immunosuppressive agents mentioned above often prove helpful, and in the last few years, IVIG has emerged as an additional effective modality.

Although discontinuation of all medication may ultimately be possible for some patients, most will require a low dose of corticosteroid or immunosuppressive drug or both to remain asymptomatic or at least stable at a partially improved state. Indeed, PM or DM alone or associated with a connective tissue disease (overlap group) may be reactivated (relapse) after a period of stability, leading to deterioration in strength, reappearance of the rash of DM, increase in CK, or some combination of these features [73]. Relapses (2–6 per patient) were noted in 60 % of patients over periods of up to 13 years. Although they could occur at anytime during the course of the illness, they were most frequent during the stable stage of drug maintenance.

Paraspinous Myopathies: The Dropped Head and Bent Spine Syndromes

66

Numthip Chitravas and Bashar Katirji

Introduction

Neck extensor weakness was initially described in late 1980s and early 1990s [1, 2] as "dropped head syndrome" or "floppy head syndrome [3]." This syndrome is characterized by severe weakness of neck extensor muscles resulting in a "chin-on-chest" deformity in the standing or sitting position correctable by passive extension. In contrast to neck extensor weakness, Babinski and Souques coined the term "camptocormia" (derived from the Latin *camptos* meaning bent forward and *cormos* for trunk) [4] in 1916 to describe trunk extensor weakness that resulted in a bent forward posture observed in World War I soldiers attributed to what was believed to be a hysterical conversion reaction [5]. Thereafter, this condition was not well recognized until 1991when Laroche et al. provided evidence of its presence in organic disease and documented abnormal fatty infiltration of the paraspinal muscles [6]. Currently, the terms "bent spine syndrome" and "camptocormia" are used interchangeably to describe pathologically abnormal involuntary forward flexion of the trunk in the upright, but not recumbent, position.

Over the past two decades, both the dropped head and bent spine conditions have received considerable attention. The syndromes have been identified in a broad spectrum of neurological, musculoskeletal, and movement disorders including, in particular, Parkinson's disease, motor neuron disorders (e.g., amyotrophic lateral sclerosis), and primary or secondary congenital or acquired muscle diseases [7–11]. When these conditions are discovered in isolation, the terms isolated neck extensor myopathy (INEM) or isolated trunk extensor myopathy (ITEM) have been utilized [12]. Although it is unclear whether these two conditions share a similar pathogenesis, we find it preferable to use the term "isolated paraspinous myopathy" because it inclusively describes weakness of the cervical, thoracic, and/or lumbar extensor muscles [13, 14].

Clinical Presentation

Isolated Paraspinous Myopathy

Paraspinous myopathy has been reported as a feature in various neuromuscular diseases in both adults and children with variable symptom onset and clinical presentation depending on the underlying cause. Table 66.1 summarizes the neurological conditions that have been reported in association with prominent dropped head or bent spine syndromes. Note that the majority of data are derived from small case series or case reports.

It remains unclear if a gender predilection exists for *isolated cervical paraspinous myopathy*. Patients usually present with the initial symptoms in the sixth decade or later [1, 12, 15, 16]. Patients with congenital myopathies tend to have an earlier age of onset of symptoms. In mild cases, the patient may simply notice difficulty keeping the head erect such as while standing, walking, watching television, driving, or, merely, engaging in conversation (Fig. 66.1). In more extreme cases, the paraspinal musculature completely "gives way," causing the chin to fall forward until it rests firmly against the anterior chest wall. This is at times referred to as the "chin-on-chest" deformity (Fig. 66.2). As a result of the

Polymyositis
Dermatomyositis
Inclusion body myositis
Focal myositis
Isolated paraspinous myopathy
Adult acid maltase deficiency (Pompe's disease)
Carnitine deficiency myopathy
Facioscapulohumeral muscular dystrophy
Myotonic dystrophy
Limb-girdle muscular dystrophy type 2B
Nemaline myopathy
Multicore myopathy
Mitochondrial myopathy
Cushing's disease
Hypothyroid myopathy
Severe hypokalemic myopathy
Movement disorders
Parkinson's disease
Systemic disease
Primary amyloidosis

Fig. 66.1 Patient with moderate isolated neck extensor myopathy. He is able to keep head erect forcefully but when resting the head drops

abnormally declined head position, patients experience considerable difficulty looking directly forward especially while speaking to someone or walking. The neck weakness may develop over a period as short as 1 week up to as long as several months [12]. Dull neck discomfort or burning posterior cervical pain is common. Weakness is essentially restricted to the neck extensor muscles with normal passive head extension, and this differentiates the isolated form from other neurologic or spine conditions. Mild deltoid and sternocleidomastoid muscle weakness have been noted in a few reports [1, 12], but these should not be the prominent symptoms. Dysphagia, another common complaint in isolated cervical paraspinous myopathy, mostly reflects interference of the normal swallowing mechanism by the flexed neck posture rather than actual pharyngeal or esophageal involvement. It usually resolves with passive elevation of the head.

Similar to isolated cervical paraspinous myopathy, *isolated thoracic and/or lumbar paraspinous myopathy* also has a tendency to affect elderly individuals, generally, in the sixth decade or later [4, 10, 17–21] with the youngest reported patient being a 56-year-old woman [22]. The largest case series in the current literature is a retrospective collection of patients over a 10-year period by Laroche and Cintas [23]. Forty patients with delayed-onset, isolated thoracic and/or lumbar paraspinous myopathy were identified with a female dominance (female to male ratio of 3:1). The mean age of patients was 69 years and the mean duration of symptoms was 4.5 ± 4 years. An additional affected family member was identified in up to 40 % of cases. All of the patients in this series presented with weakness in thoracic or lumbar regions or both, resulting in the inability to stand upright (Fig. 66.3). The deformity fully resolves in the recumbent position, and forward flexion of the trunk is often augmented with ambulation. This abnormal posture is exaggerated by activities that require back extension, such as walking up an incline or pulling a shirt over the head (Fig. 66.4). Back pain is also occasionally reported at the onset of weakness. Only a minority of patients have proximal limb muscle weakness, which is more commonly seen in the pelvic rather than scapular distribution. The clinical course is usually benign and patients remain ambulatory with the use of a walking assistance device.

The occurrence of combined dropped head and bent spine syndrome has been reported infrequently [13, 14]. As mentioned earlier, it is unknown whether these two conditions represent disorders within the same clinical spectrum [10, 14, 17].

Fig. 66.2 Patient with severe isolated neck extensor myopathy with "chin-on-chest" deformity. She is not able to raise her head against gravity but the passive range of movement is full

Fig. 66.3 Patient with isolated trunk extensor weakness. Her truncal extensor weakness is worse when she holds her arm foreword, such as while carrying any light object (such as her clinical chart)

Paraspinous Myopathy in Parkinson's Disease

Over the last decade, there has been significant increased awareness of dropped head or bent spine syndromes in patients with Parkinson's disease (PD). The incidence of camptocormia was reported as high as 6–7 % of Parkinson patients [24, 25]. As PD is more prevalent in men, the gender predilection of paraspinous myopathy in PD patients also appears to be male. The latency between onset of PD and the onset of paraspinous myopathy ranges widely from several weeks up to three decades [3, 26, 27]. In one study, the mean duration of paraspinous myopathy in PD was 13.5 years [26].

Fig. 66.4 Patient with isolated trunk extensor weakness leans forward when attempting to remove his shirt. The unusual motion is necessary because lumbar weakness prevents him from extending his back to pull the shirt over his head

The vast majority of the patients develop classic extrapyramidal symptoms of PD, such as resting tremor and bradykinesia, prior to head drop or bent spine. Significant neck or back pain attributed to the abnormal forward flexion of the torso predominates and is often the leading patient complaint. Quite clearly, these symptoms create a significant, additional physical disability with resultant further difficulty in activities of daily living in PD patients. The clinical course is usually slow and progressive. From within the movement disorder community, it has been postulated that the bent forward or "stooped" position manifests due to abdominal muscle rigidity or flexor-dystonia as opposed to weakness of neck or back extensors from a paraspinous myopathy. However, more recent studies claimed that PD patients with paraspinous myopathy did not display any sensory signs (e.g., geste antagoniste) which usually indicate dystonia in PD. Moreover, despite good responses of parkinsonian symptoms from levodopa or with bilateral deep brain stimulation (DBS) in the subthalamic nucleus (STN), the

stooped posture does not usually improve with any of these treatments [26]. A recent review also demonstrated consistent "myopathic" changes in the muscle biopsies of paraspinal muscles in idiopathic PD patients with camptocormia [28]. Whether paraspinous myopathy is a clinical manifestation of PD remains a subject to debate.

Evaluation and Diagnosis

Because neck extensor muscle weakness may be a manifestation of many neurological disorders (see Table 66.1), a careful initial neurological examination is recommended. Occasionally, serial neurological evaluation is helpful. In mild cases, the neck extensor weakness is best demonstrated with the patient attempting to extend the neck while in the prone position with the head hanging off the bed. This maneuver isolates the involved extensor neck muscles. Truncal weakness is also best demonstrated with the patient in the prone position by the inability (or difficulty) to raise the torso off the examination table without the aid of the hands and arms.

Electrodiagnostic study is very helpful for accurate diagnosis and to exclude other neuromuscular disorders. Nerve conduction studies and repetitive nerve stimulation tests are normal in isolated paraspinous myopathy. Interestingly, sensory axonal neuropathy was reported in 70 % of the patients in one study [23]. This has to be cautiously interpreted as there is a higher prevalence of sensory axonopathy from any etiology in the elderly population. A decremental response on repetitive nerve stimulation should warrant a diagnosis of neuromuscular junction disorders (e.g., myasthenia gravis). Often, the needle examination demonstrates the presence of "myopathic" changes in cervical and/or thoracic and/or lumbar paraspinal muscles. The abnormality includes positive sharp waves and fibrillation potentials with low amplitude, short duration motor unit action potentials (MUAPs) (Fig. 66.5) [12]. The limb muscles usually are often normal, but less prominent myopathic changes in deltoid, biceps, or gluteus muscles may be seen [1].

Laboratory studies usually reveal a normal creatinine kinase (CK) level to mild elevation up to 1.5–2 times of upper normal limit [23]. Acetylcholine receptor antibodies, anti-muscle-specific tyrosine kinase (anti-MUSK) antibodies, erythrocyte sedimentation rate (ESR), and C-reactive protein are unremarkable.

Imaging studies include magnetic resonance imaging and computed tomography through affected spinal regions that demonstrate atrophic changes as well as heterogeneous fatty infiltration of the paraspinal muscles extending along the length of the affected spinal segments (Fig. 66.6) [22, 23, 29]. Occasionally, the infiltration extends to the posterior thighs and gluteus muscles [23]. Edematous changes as well as abnormal enhancement after administration of gadolinium contrast on T1-weighted images may be seen. The abnormal enhancement and edematous changes were also reported in the idiopathic PD patients with paraspinous myopathy [12, 26, 30, 31].

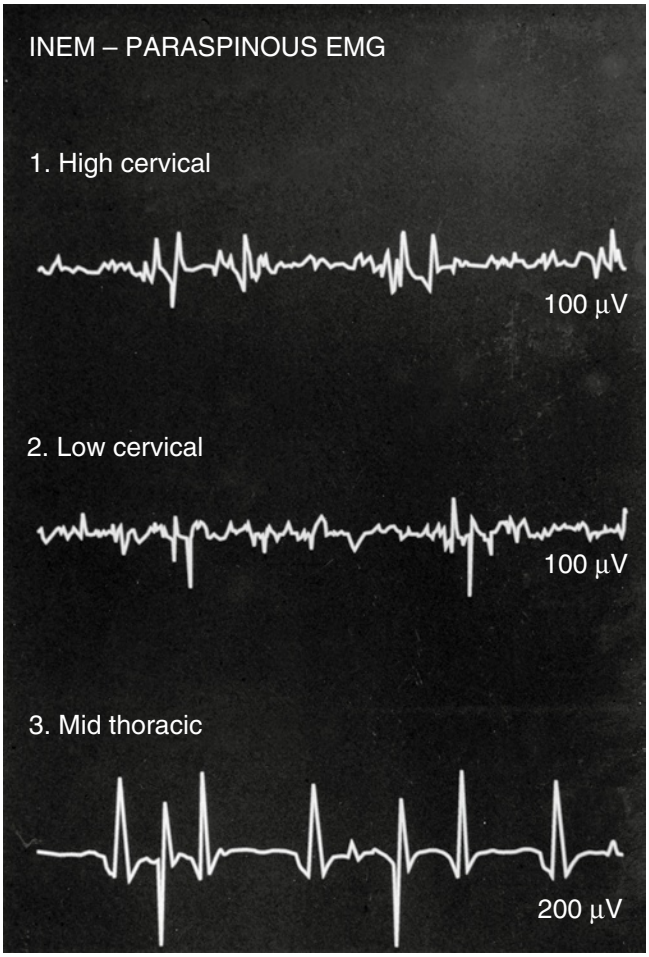

Fig. 66.5 Electromyography of the paraspinal muscles in isolated cervical paraspinous myopathy demonstrates. There are myopathic motor unit action potentials, maximal in the cervical region. The mid-thoracic area is normal

To date, muscle biopsy remains the gold standard for diagnosis for paraspinous myopathy. Due to an easily accessible approach, it is primarily performed in the cervical or thoracic paraspinal muscles. For isolated cervical paraspinous myopathy, as the superior belly of the trapezius muscle normally covers the underlying affected paraspinal muscles, the surgeon may obtain the biopsy specimen from the splenius capitus or the semispinalis in the affected mid-lower cervical region by lifting the lateral edge of the trapezius. Paraspinal muscles in the thoracic and lumbar regions can be approached directly. Deltoid, biceps, gluteus, and quadriceps biopsies may also be obtained to rule out other neuromuscular disorders (e.g., inclusion body myositis). Some authors recommend to perform an MRI of the spine

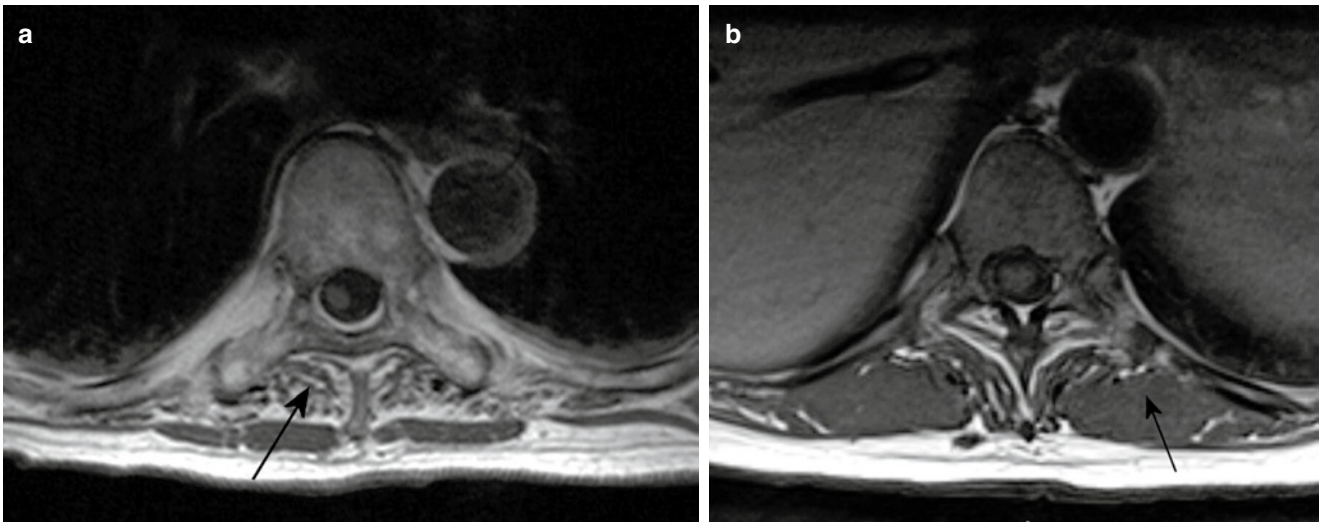

Fig. 66.6 MRI, axial T1-weighted sections of the lower thoracic regions in a patient with isolated trunk extensor paraspinous myopathy (**a**) and an age-matched control (**b**). Note the fatty replacement and atrophied paraspinal muscles in patient comparing to control (*arrows*)

prior to muscle biopsy in order to localize affected tissue and maximize pathological yield (see Fig. 66.6).

Histopathological findings in the majority of patients demonstrate a myopathy marked by variation in fiber size, fiber splitting, increased numbers of internal nuclei, degenerating fibers, proliferation of connective tissue, type 2 fiber atrophy, cyclooxygenase (COX)-deficient fibers, lobular endomysial fibrosis, and fatty replacement [10, 12, 17, 19, 23]. These findings are nonspecific and may sometimes be seen in normal elderly individuals with or without advanced cervical or lumbar spondylosis [32]. When the biopsy reveals angular, esterase-positive fibers with grouped atrophy or fiber-type grouping and targetoid fibers, it is suggestive of a neurogenic process such as amyotrophic lateral sclerosis [22]. Less commonly, nemaline myopathy, inclusion body myositis, or primary amyloidosis is detected on paraspinal muscle biopsy (Fig. 66.7) [29, 31, 33]. Specific analysis with Congo red stain, ubiquitin-binding protein P62 immunohistochemistry, or molecular DNA analysis may be helpful in making these unusual diagnoses.

Muscle inflammation is an uncommon finding. Perivascular and/or endomysial inflammation with or without muscle fiber necrosis has been reported [13, 30, 34, 35]. The inflammation is usually focal and restricted to the paraspinal muscles. It is rarely widespread into the limb muscles. Note that the inflammatory cases often responded favorably to an immunosuppressive treatment, either with steroid or other immunomodulating agents.

In Parkinson's disease with camptocormia, the biopsy revealed uniform muscle pathology. Wrede et al. reported recently that the main histopathological features in PD patients are type 1 fiber hypertrophy, loss of type 2 fiber, loss of oxidative enzyme activity (SDH, NADH, and COX), and increase acid phosphatase reactivity [28]. There was a correlation between the severity of the endomysial fibrosis and the severity of the camptocormia in PD patients. Ultrastructurally, myofibrillar disorganization, Z-band streaming, and electron-dense patches were observed. These findings were consistently found in PD patients who developed paraspinal symptoms, but not in the age and sex-matched, postmortem control paraspinal biopsy. There was also no evidence of inflammation or mitochondrial changes in the affected paraspinal muscles. Interestingly, a higher number of ragged red and COX-deficient fibers were found in the paraspinal muscles of the postmortem control group. This abnormality was also found more in the paraspinal muscles than in deltoid muscles in the same control patients. This raises the possibility that ragged red fibers and COX-deficient muscle fibers may be a normal finding in the paraspinal muscles of the elderly and should not be interpreted as a sign metabolic or mitochondrial myopathy.

Despite an effort to investigate camptocormia in PD, a clear etiology of the paraspinous myopathy has not been elucidated. It is possible that the paraspinous myopathy is a manifestation of Parkinson's disease, but coincidental disorder is also possible [3].

Differential Diagnosis

The differential diagnosis of dropped head or bent spine syndromes includes musculoskeletal and neurological disorders. Osteoporosis, ankylosing spondylosis, and vertebral fracture are the primary differential diagnoses when the observed kyphosis is fixed without resolution while in the supine position. Increased awareness of this condition over the last two decades has led to the current differential diagnoses listed in Table 66.1. An approach algorithm is shown in Table 66.2.

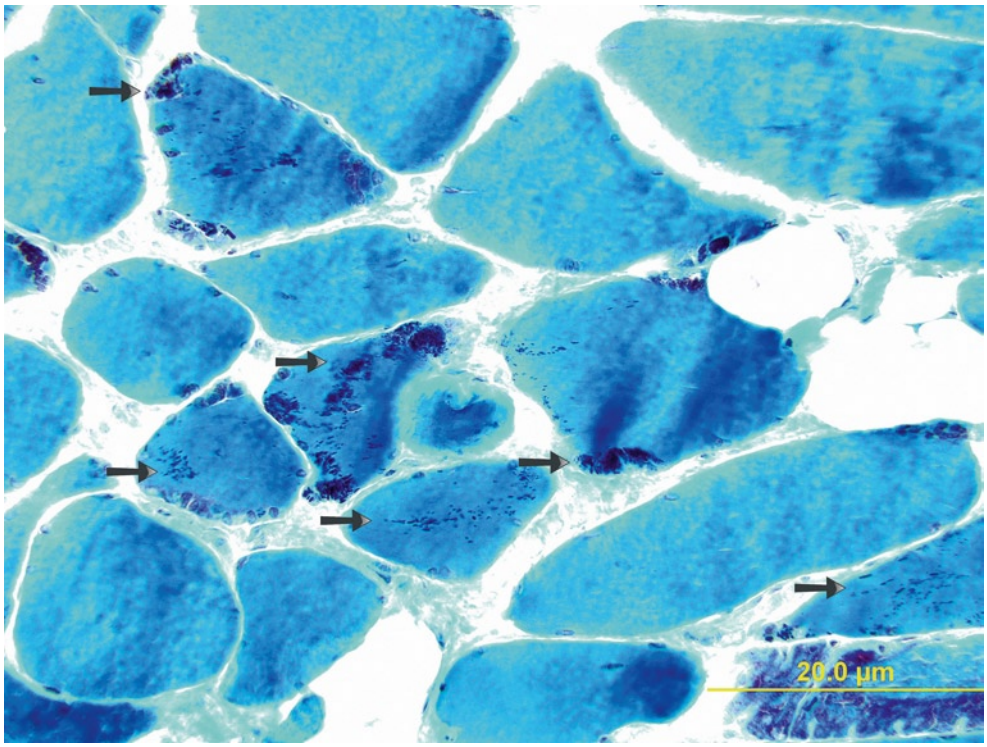

Fig. 66.7 Photomicrograph of the cervical paraspinal muscles from a patient with isolated cervical paraspinous myopathy demonstrating variation in myofiber diameter as well as deposit of nemaline bodies (*arrows*, Trichrome, X 200)

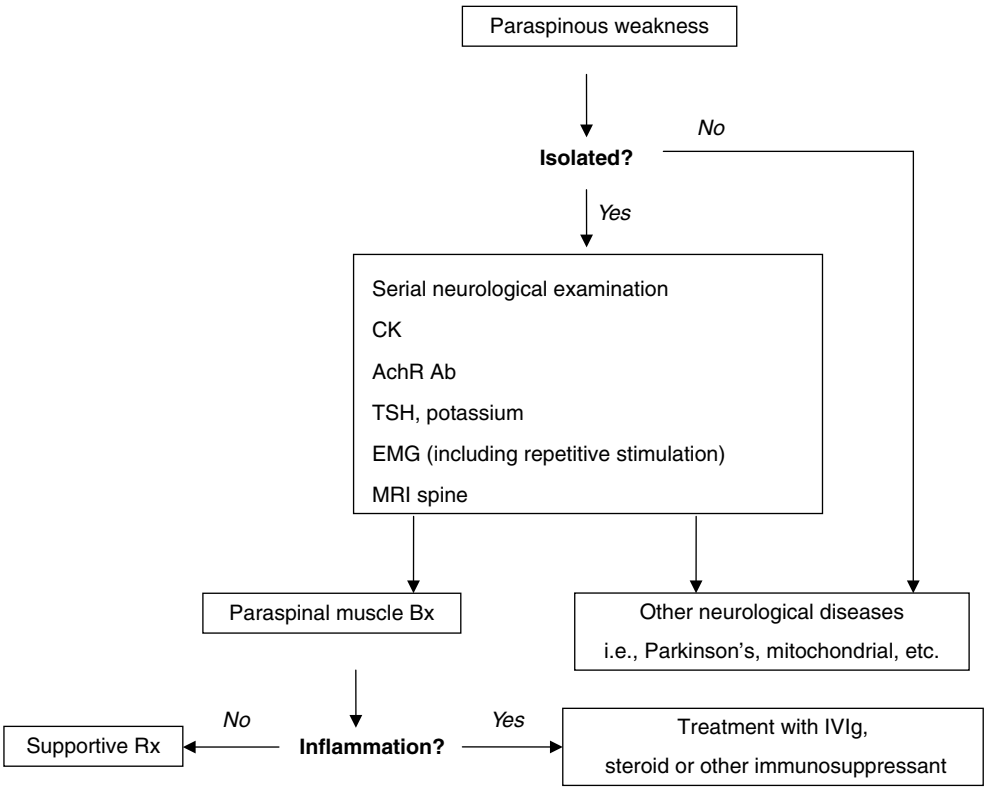
Table 66.2 Approach for paraspinous myopathy



The presence of weakness in regions other than the neck or trunk implicates the diagnosis of a generalized neuromuscular disorder. Myasthenia gravis (MG), amyotrophic lateral sclerosis (ALS), and idiopathic Parkinson's disease are the common neurological disorders associated with paraspinous myopathy. It is estimated that neck weakness is the presenting complaint in 3 % of MG patients [36], 1.3 % of ALS patients [37], and 6 % of idiopathic PD [24, 25]. MG should

be suspected when there is associated ptosis, ophthalmoparesis, generalized weakness, or bulbar dysfunction, while ALS should be considered when there are muscle fasciculations, hyperreflexia, or evidence of a neurogenic process associated with weakness in regions outside of the neck. In PD, patients often have overt extrapyramidal signs prior to the onset of camptocormia and paraspinal muscle weakness [3, 26–28, 38–40].

On the rare occasion, cervical paraspinal weakness can be a primary manifestation of mitochondrial, inflammatory, congenital or metabolic myopathies, chronic inflammatory demyelinating polyneuropathy, or spinal muscular atrophy (see Table 66.1) [33, 41–47].

A significantly elevated CK warrants a diagnosis of polymyositis or other myopathies, while elevated acetylcholine receptor antibodies or voltage-gated calcium channel antibodies are diagnostic of myasthenia gravis or Lambert-Eaton myasthenic syndrome, respectively. Electrodiagnostic (EDX) investigations in patients presenting with isolated neck or trunk weakness may reveal subclinical evidence of diffuse anterior horn cell disease, widespread myopathy, or impaired neuromuscular transmission even before a more extensive clinical findings become evident.

The characteristic anteriorly flexed head posture seen in isolated cervical paraspinous myopathy may also be seen in spasmodic torticollis. However, in torticollis, there is typically a component of rotational or lateral deviation. While torticollis is easily excluded by the presence of extensor weakness, the distinction is important. A local injection of botulinum toxin into the neck flexors in patients with cervical paraspinous myopathy may have devastating effects, as these patients rely on these muscles to support the head from a reclined position.

Etiology

The cause of isolated paraspinous myopathy is still unknown. Familial clustering described in these cases lead to speculation that this may be a distinct paraspinal muscular dystrophy [17, 26]. Ragged red fibers suggesting a mitochondrial myopathy have been described in small numbers of patients [10, 48]; however, the significance of this abnormality in elderly patients remains uncertain. These pathologic findings may very well be coincidental and irrelevant because ragged red and/or COX-negative fibers are commonly seen in the paraspinal more than limb muscles in the normal aging population [17, 32]. Desmin deposits have also been noted in a single biopsy of a patient with dropped head syndrome [49], but it is unclear if this represents an alternative etiology. Others have also postulated that both cervical and thoracolumbar paraspinous myopathies are variant forms of a focal polymyositis [1, 13, 19, 30, 33, 50–52]; however, muscle inflammation is only occasionally seen. Isolated paraspinous muscle weakness may be also the leading or only manifestation of a large number of neuromuscular disorders including congenital myopathies, facioscapulohumeral muscular dystrophy, limb-girdle muscular dystrophy, mitochondrial myopathies, inflammatory myopathies, metabolic myopathies, chronic inflammatory demyelinating polyneuropathy, or spinal muscular atrophy [29, 53].

Katz et al. have postulated that mechanical processes may cause isolated cervical paraspinous myopathy [12]. Once the head begins to fall forward due to aging or because of weakness, the effect of gravity exerts an increasing downward pull. This posture leads to overstretched paraspinal muscles that are no longer able to generate adequate contractile force according to the Starling curve [54, 55]. Prolonged overexertion from the combination of abnormal posture and weakness may also result in myonecrosis. Factors that increase susceptibility to the onset of such a process might include loss of elastic tissue with aging [56], the acquired posture of the head or trunk with aging or disease, or senile degeneration of the spinal column. Similarly, camptocormia in Parkinson's disease may be explained by a poor function of mechanical load receptors or proprioceptive dysregulation of paraspinal muscles. As known, Parkinson patients have an impaired central mechanism that influences the muscle tone via the polysynaptic reflexes. The poor accuracy of movement of a joint may lead to the "overstretch" position causing repetitive and chronic muscle injury which eventually creates myopathic changes and result in loss of muscle strength. Future research is warranted to verify this hypothesis.

Treatment and Management

There is no proven treatment for cervical or thoracolumbar paraspinous myopathy. Corticosteroids and pyridostigmine (Mestinon®) are generally ineffective. Responsiveness to corticosteroids, either with or without additional immunosuppressant therapy, has been previously reported, most notably in a patient whose biopsy showed histological evidence of inflammation suggestive of focal polymyositis [30, 50, 57]. Rarely, intravenous immunoglobulin (IVIg) was used as a treatment modality. It provided great improvement in one patient whose thoracic paraspinal muscle biopsy showed multiple foci of endomysial and perivascular chronic inflammatory cells [13]. Vitamin C, vitamin E, and coenzyme Q supplementation have also been reported to provide benefit in one individual with isolated cervical paraspinous myopathy. In this case, the diagnosis of mitochondrial myopathy was made based on histologic evidence of ragged red fibers.

Invasive mechanical treatment with cervical spine or cervicothoracic fusion and instrumentation is an alternative

treatment [58, 59]; however, the data is very limited and may not be an option if the patient has significant osteopenia or osteoporosis.

Katz et al. have witnessed a clinical improvement in a patient with cervical paraspinous myopathy after a prolonged hospitalization [12]. They attributed the response to "unloading" of the weight of the head during the time he was bedridden. Soft and hard neck collars are uncomfortable for the patient as the chin can fall into the collar and interfere with speech and rotational neck movements. In Fig. 66.8, the patient designed a special brace supporting the head and neck from behind using a rigid backboard attached to a harness worn around the trunk and forehead. In isolated thoracolumbar paraspinous myopathy, patients may benefit from physical therapy to improve range of motion. The use of a cane or wheeled walker is typically necessary for maintaining upright posture, ambulation, and daily activities.

Endocrine Myopathies

67

Michael R. Douglas, Zaki Hassan-Smith,
and Robert L. Ruff

Endocrine disorders are associated with a wide range of clinical presentations, including neuromuscular disorders and particularly myopathies [1, 2]. The wide spectrum of potential endocrinopathies, which includes over- or underproduction of specific hormones, with complex and often overlapping molecular and cellular pathophysiologies, emphasizes the need for a comprehensive assessment of any patient presenting with suggestive symptoms (including fatigue, myalgia, and cramps) and signs (such as wasting or weakness), coupled with a high index of suspicion for an underlying endocrine etiology. In addition to endogenous endocrinopathies, the therapeutic use of glucocorticoids in the treatment of inflammatory conditions frequently results in disabling iatrogenic complications, which can only be minimized through careful patient assessment and management. This chapter highlights the underlying pathophysiology of the most common endocrinopathies, with a particular emphasis on their clinical presentation, relevant investigations, treatment, and prognosis.

Muscle Disorders Associated with Glucocorticoid Abnormalities

Glucocorticoid Excess

The observation that chronic glucocorticoid use directly produces muscle weakness is long established and is commonly noted by clinicians treating patients for a wide range of inflammatory conditions (particularly asthma and rheumatoid arthritis). The causative association is clear, particularly as asthma is not inherently linked with myopathic symptoms, and the iatrogenic myopathy of rheumatoid disease is independent of the degree of debility or duration of this condition. Once flares of disease are successfully treated and high doses of glucocorticoids are reduced to more physiological levels, muscle weakness and wasting reverses [3].

Over the past decade, there have been marked advances in our understanding of the molecular mechanisms of glucocorticoid-induced myopathy, via studies using in vitro cell culture techniques, with results validated using in vivo animal and human models. They have shed light on the important role of glucocorticoids in both normal muscle physiology and in the pathophysiology of muscle wasting in glucocorticoid excess and other disease states including cachexia, sepsis, and disuse atrophy. This research has highlighted potential therapeutic avenues towards the treatment of this common and important phenomenon.

Physiology and Pathology

The principal endogenous glucocorticoid is cortisol, release of which is regulated by the hypothalamic/pituitary/adrenal (HPA) axis. Neurones from the suprachiasmatic nucleus connect with the paraventricular nucleus of the hypothalamus to regulate corticotrophin-releasing hormone (CRH) secretion. CRH stimulates the pituitary to secrete adrenocorticotropic hormone (ACTH) in a pulsatile manner, leading to cortisol secretion from the adrenal cortex. There is a circadian rhythm of secretion, resulting in peak cortisol levels in the early morning with decline through the day until a nadir is reached

DOI 10.1007/978-1-4614-6567-6_67, © Springer Science+Business Media New York 2014

late at night. The HPA axis is under negative feedback control, with cortisol acting on the pituitary and hypothalamus. The axis is further stimulated by mediators of the stress response, particularly proinflammatory cytokines, such as TNF-α, IL-6, IL-1, and LIF.

Glucocorticoid hormones are derived from cholesterol and synthesized in the adrenal cortex, reaching skeletal muscle and other target organs via the blood and because of their lipophilic nature pass the cell membrane by simple diffusion. Further regulation of glucocorticoid actions is provided at the pre-receptor level by the 11beta-hyrdroxysteroid dehydrogenase types 1 and 2 (11beta-HSD) isozymes, which are responsible for the inter-conversion of inactive cortisone and active cortisol at multiple tissue sites, including skeletal muscle [4].

Within the muscle, the hormone binds to steroid hormone receptors, which are the mediators of glucocorticoid action. The hormone receptors form a complex with chaperones (heat shock protein 90), which have well-described functions in protein folding and prevention of aggregation. The hormone receptors are transcription factors that can activate or inhibit expression of target genes via at least three mechanisms: first, the complex of glucocorticoid and steroid receptor binds to chromatin-organized DNA sequences (hormone response elements) within the regulatory region of target genes. This binding initiates chromatin remodeling leading to the activation or inhibition of transcription of the target gene. Second, through protein-protein interactions with other transcription factors, the glucocorticoid-receptor complex can regulate the activity of other genes. During stress or inflammatory conditions, including infection, glucocorticoids may modulate muscle gene transcription. Third, the glucocorticoid with its receptor may influence other signal transduction pathways [5].

Glucocorticoids act to alter the balance of muscle protein turnover by reducing synthesis and increasing breakdown, with muscle atrophy as an active process characterized by the stimulation of specific gene programs. Glucocorticoids stimulate muscle proteolysis largely by activating the ubiquitin-proteasome system (UPS), with contributions from lysosomal and calcium-dependent systems [6].

Activation of components of the UPS by glucocorticoids results both in degradation of myofibrillar proteins and those involved in apoptotic pathways [7]. Further sites of action include key steps in myogenesis by reducing mRNA expression of the myogenic transcription factors (MRF), myogenin and MyoD, with preservation of the negative regulator, the DNA-binding protein Id1 [8, 9].

Glucocorticoids additionally activate forkhead box transcription factors (FOXO) by dephosphorylation [10, 11]. FOXO cause upregulation of a variety of genes involved in muscle atrophy known as “atrogenes” including the muscle-specific E3 ubiquitin ligases, muscle RING finger-1 (MuRF-1), and muscle atrophy F-box (MAFbx/Atrogin-1) through specific promoter-binding events [11, 12]. MuRF-1 and MAFbx/Atrogin-1 associate with components of myosin chain proteins, leading to protein degradation [13]. There is evidence that MuRF-1 is critical for the development of glucocorticoid-induced muscle atrophy, as mice with targeted deletion of this gene are protected from loss of muscle mass when compared to those of a wild-type background [14].

Dexamethasone additionally upregulates the expression of regulated in development and DNA damage responses (REDD1), which subsequently inhibits mammalian target of rapamycin (mTOR), resulting in reduced phosphorylation of its downstream targets ribosomal protein S6 kinase 1 (S6K1) and eIF4E-binding protein-1 (4E-BP1) [15]. Binding of 4E-BP1 to the eukaryotic initiation factor eIF4E inhibits the rate-limiting stage of protein synthesis [16].

As mentioned previously, pre-receptor glucocorticoid regulation via 11beta-HSD1 is involved in the regulation of proteolysis and atrogene expression in both primary human and murine myotubes. Treatment with cortisone increases proteolysis and MuRF-1 and MAFbx/Atrogin-1 expression while pretreatment with the 11beta-HSD1 inhibitor, carbenoxolone, attenuates these effects [17]. Other potential regulators of these pathways include glycogen synthase kinase 3 beta (GSK3beta) and the transcription factor C/EBPbeta. GSK3beta appears to be required for the induction of skeletal muscle atrophy by glucocorticoids, as evidenced by a series of experiments using pharmacological inhibitors and gene knock down approaches in a murine skeletal muscle cell line [18]. GSK3beta is a target for phosphorylation by Akt, leading to inhibition of activity. C/EBPbeta expression is increased in various states characterized by muscle wasting. Silencing its expression in rat skeletal myotubes inhibits dexamethasone-induced proteolysis and MuRF-1 and MAFbx/Atrogin-1 expression [19].

Glucocorticoid actions are likely to be partially mediated via indirect pathways, including via the actions of insulin growth factor 1 (IGF-1), in which production in muscle is suppressed in states of glucocorticoid excess [20]. IGF-1 increases protein synthesis via PI3k/Akt/mTOR and GSK-3beta signaling and satellite cell proliferation [21, 22]. It also increases phosphorylation of Akt, leading to inhibition of FOXO and subsequent effects on downstream signaling which result in reduced proteolysis [23, 24]. Similarly, recent data suggests that impaired insulin signaling via IRS-1/PI3K plays an important role in muscle atrophy induced by glucocorticoids [25]. Interventions that act to increase IGF-1 signaling attenuate glucocorticoid-induced muscle atrophy in animal models. Rats treated simultaneously with recombinant human growth hormone and glucocorticoids and those induced to have local overexpression of IGF-1 in skeletal muscle have preservation of muscle mass [20]. Although there are hints of efficacy in small-scale trials [26], growth hormone treatment in humans with glucocorticoid-induced myopathy has not been assessed in large-scale randomized trials.

Myostatin, a secreted growth factor known to negatively regulate muscle mass, has also been shown to be an important modulator of glucocorticoid-induced muscle atrophy. The effects on muscle were identified via several routes, including the observation that inactivating mutations of the gene in "Belgian Blue" cattle are associated with a "double-muscling phenotype" [27]. Transgenic mice with an absent myostatin gene have muscle fiber hypertrophy or hyperplasia, and targeted overexpression of myostatin in skeletal muscle leads to tissue atrophy [28]. Rats with dexamethasone-induced muscle atrophy have dose-dependent increases in mRNA and protein expression of myostatin. Furthermore, myostatin gene deletion prevented glucocorticoid-induced muscle atrophy in transgenic mice [29]. In vitro data demonstrate that myostatin antagonizes IGF-1 and results in activation of genes involved in proteolysis. Myostatin has been implicated in the pathogenesis of preferential muscle-fiber-type atrophy, with evidence of its close association with the myosin heavy chain isoform IIb in normal muscle [30] and of increased expression in type II fibers in disease [31]. Inhibition of myostatin has therefore emerged as a potential therapeutic strategy in type II diabetes mellitus, obesity, and also muscle atrophy [32].

Fasting and inactivity worsen the course of clinical and experimental steroid-induced myopathy, which is observed to decrease the synthesis and increase the breakdown of both myofibrillar and soluble muscle protein in rats. Recovery of muscle from starvation requires a reduction in glucocorticoid levels for muscle to convert from a catabolic to an anabolic state [33]. However, starvation or severe dietary protein and energy restriction do not alter the muscle catabolism seen with high-dose steroid treatment [34], suggesting that the effects of starvation and glucocorticoid treatment are additive but not synergistic. The clinical implications are that dietary supplementation of a patient with an otherwise adequate protein intake will not reverse steroid-induced myopathy, but starvation or protein deprivation will accelerate steroid myopathy, and steroid treatment will slow or prevent the recovery of muscle mass in a previously malnourished person who is being refed.

Although it is well known that glucocorticoids preferentially induce type 2 fiber atrophy, the reasons for this are not clear. Skeletal muscle contains a high concentration of glucocorticoid receptors [35], but differential receptor numbers do not explain this effect. Soleus muscle is predominantly composed of type 1 fibers yet has a higher density of glucocorticoid receptors than does extensor digitorum longus, which expresses a large percentage of type 2 fibers. Effects may in part be mediated through physical activity, as it is well established that inactivity worsens clinical and experimental steroid myopathy [36]. Type 2B fibers are active less frequently than type 2A or type 1 fibers [37], and the differences in normal activity patterns may contribute to the greater steroid-induced atrophy seen with type 2B fibers [38]. A possible explanation for the increased sensitivity of inactive muscles to glucocorticoids is that inactivity leads to an increase in the concentration of glucocorticoid receptors [37]. The additive effects of inactivity and glucocorticoid treatment on muscle function may also partially explain why patients who receive neuromuscular blocking agents tend to develop steroid myopathy particularly quickly.

Conversely, increased muscle activity may partially prevent glucocorticoid-induced atrophy [39]. Therefore, physical therapy may be useful in preventing and treating muscle weakness and wasting in patients receiving glucocorticoids. Studies have demonstrated that resistance exercise training 6 months after heart transplantation restored fat-free mass to a level greater than before transplantation and dramatically increases skeletal muscle strength [40]. Endurance and resistance training attenuate steroid-induced muscle atrophy [41].

ACTH excess may have directly myopathic effects, distinct from its induction of glucocorticoid synthesis [42, 43]. This is evidenced by patients treated for Cushing disease with adrenalectomy, who subsequently developed clinical, electrodiagnostic, or histological evidence of myopathy. These patients had proximal weakness and wasting, but other aspects of their clinical presentation were different from steroid myopathy as some patients had sharp waves or fibrillation potentials on EMG and biopsy of three patients revealed prominent subsarcolemmal lipid deposits. Furthermore, ACTH administration to rabbits results in focal necrosis of muscle fibers with extensive deposition of fat, which is not a characteristic of steroid myopathy [44]. In rat phrenic nerve-diaphragm preparations, excessive amounts of ACTH impair neuromuscular transmission by decreasing the quantal content [45]. The underlying pathogenic mechanisms of ACTH on muscle are not known.

Androgens may partially antagonize the catabolic actions of glucocorticoids. These anabolic steroids may act by displacing glucocorticoids from their cytosolic receptors or directly via androgen receptors in muscle. In some animal studies, androgens partially prevented glucocorticoid-induced muscle atrophy, impaired ribosomal function, and increased 3-MeHis production in rats [46]. In other studies, androgens did not prevent glucocorticoid-induced muscle atrophy [47]. Overall, however, anabolic steroids have not been very successful in treating iatrogenic steroid myopathy [48]. A possible explanation for the unsuccessful results is that androgens will correct the ribosomal defect but not the mitochondrial dysfunction produced by glucocorticoids. One study found that a combination of anabolic steroid and vitamin B complex was more effective than an anabolic steroid alone in preventing steroid myopathy in rats [49].

Clinical Presentations

Glucocorticoid excess most commonly results from exogenous administration during treatment for a wide range of conditions [50]. Other cases result from adrenal overproduction

of cortisol, either secondary to adrenal nodular tumors, hyperplasia or neoplasia, or adrenocorticotropic hormone (ACTH) overproduction by pituitary or other neuroendocrine tumors. Glucocorticoid excess leads to a wide range of tissue effects, including osteoporosis, central obesity, skin manifestations, and the induction of the metabolic syndrome. Cushing first noted that patients with endogenous glucocorticoid excess developed proximal muscle wasting and weakness [51], with patients experiencing difficulty with climbing stairs or combing their hair, and subsequent reports described a similar syndrome in patients with ectopic production of ACTH.

The onset of weakness is usually insidious. The weakness is primarily proximal, with the legs more severely involved than the arms; cranial-nerve-innervated muscles and sphincters are spared. Myalgias frequently accompany the weakness. Serum levels of muscle-associated enzymes (lactate dehydrogenase (LDH), creatine kinase (CK) and aldolase) are usually normal but may be reduced as outlined below [52]. The same patterns of muscle involvement and enzyme activity are found in patients with iatrogenic steroid myopathy and endogenous glucocorticoid excess [3].

Steroid myopathy has been reported in patients ranging from 2 to 84 years of age and has occurred in patients suffering from a variety of diseases treated with glucocorticoids [53]. Between 50 and 80 % of patients with Cushing disease develop appreciable muscle weakness [3]. The incidence of muscle weakness associated with chronic steroid treatment among studies varies from 2.4 to 21 %. These figures indicate only those patients who developed severe weakness and, therefore, are likely to underestimate the actual incidence of steroid-induced weakness. Isolated respiratory muscle weakness may occur with inhaled corticosteroids [54]. When patients treated with glucocorticoids are monitored with quantitative strength testing, a majority of patients show a significant decline in strength after a few weeks of treatment [55]. Women are more likely to develop steroid myopathy with the same glucocorticoid dose [56].

Acute myopathy, developing within a few days of administration of glucocorticoid treatment, has been described in patients treated with large doses of steroids for asthma [57]. Many of these patients received mechanical ventilation and neuromuscular blockade with curare-like agents in this context. Several factors appear to contribute to the rapid onset of weakness and wasting, including prolonged immobility, the use of curare-like agents which may potentiate the action of glucocorticoids, and concurrent sepsis, which may accelerate muscle proteolysis.

Differential Diagnosis

In many clinical situations, the diagnosis is usually straightforward. However, it is often difficult to decide whether deterioration in strength of a patient with inflammatory myopathy treated with steroids is the result of steroid myopathy or a flare in the inflammatory myopathy. As steroid myopathy takes time to develop, weakness that occurs at the onset of steroid treatment is probably caused by an exacerbation of the inflammatory disease and is best treated by continuing or increasing the dose of steroid. Similarly, if the weakness occurs without any other stigmata of steroid usage, it is probably not steroid induced. Elevation in the serum levels of muscle-associated enzymes suggests that the weakness is at least partially due to the inflammatory myopathy.

Recent studies have demonstrated statistically significant reductions in serum CK and plasma myoglobulin in patients with Cushing's disease and also in healthy volunteers who were treated with short-term dexamethasone, as compared to healthy controls. Despite these variations, the majority of the patients had muscle enzyme levels that remained within the laboratory normal reference range [58, 59]. Furthermore, normal enzyme levels do not rule out a flare in the inflammatory myopathy. Muscle biopsy is helpful in distinguishing inflammatory myopathy from steroid myopathy but only if there is an active inflammation, which may be difficult to find in the context of steroid treatment. EMG may be useful in distinguishing steroid myopathy from inflammatory myopathy, as fibrillation potentials are not a feature of steroid myopathy but are often present in inflammatory myopathies.

Creatine excretion is elevated in both steroid and inflammatory myopathy, but the creatine excretion may be useful in differentiating the two myopathies. A change in the creatine excretion value can precede a change in strength by weeks. If the weakness is steroid induced, decreasing the steroid dosage will lower the creatine excretion, which will be followed by clinical improvement. Lowering the steroid dosage in a patient with flare of inflammatory myopathy should produce increased creatine excretion followed by further weakness.

Evaluation and Diagnosis

For endogenous disease, the diagnostic approach requires both the definite recognition of Cushing's syndrome and the subsequent identification of the underlying etiology. Accepted screening tests include 24-h collection for urinary-free cortisol (minimum duplicate testing), late-night salivary cortisol (again, minimum duplicate testing), and the 1 mg dexamethasone suppression test (DST) [60]. The next step is to distinguish between ACTH-dependent and ACTH-independent etiologies. Suppressed serum ACTH levels are suggestive of ACTH-independent disease and should be followed by computerized tomography (CT) of the adrenals. Detectable ACTH levels are suggestive of ACTH-dependent disease and can be followed by a corticotrophin-releasing hormone (CRH) test in combination with a 48-h DST and magnetic resonance imaging (MRI) of the pituitary. Bilateral inferior petrosal sinus sampling is the gold standard for distinguishing between ACTH secretion from pituitary and

ectopic sources, but cannot reliably lateralize secretion within the pituitary and is an invasive procdure [60, 61].

Among patients with steroid myopathy, there is a wide variation in the dose and duration of steroid treatment associated with the onset of weakness. However, patients who have received steroids for less than 4 weeks rarely develop severe steroid myopathy [57]. Lowering the steroid dose or reducing endogenous glucocorticoid production usually corrects the weakness.

EMG findings are variable, typically finding normal insertional activity and motor unit potentials, with the latter occasionally of low amplitude and short duration. Despite reports of fibrillation potentials accompanying the brief duration motor unit potentials, spontaneous electrical activity is typically absent [50]. Noninvasive electrophysiological tests have been used to assess changes in glucocorticoid-induced myopathy, including a recent study estimating muscle fiber conduction velocities (MFCV) from surface EMG measurements, which were significantly reduced in patients with Cushing's disease in comparison to healthy controls (mean relative differences 26 % in vastus lateralis and 11.6 % in tibialis anterior) [58]. These differences contrasted with the lack of changes observed on needle electromyography in these patients, with the authors attributing this to the relative lack of sensitivity of this technique to type II fiber pathology.

Histological studies in either iatrogenic steroid myopathy or in Cushing's disease find selective atrophy of type 2 fast twitch glycolytic muscle fibers. Lipid droplets are infrequently seen in type 1 fibers. Increased muscle glycogen is noted in type 2 fibers. Electron microscopic studies find mitochondrial aggregation, swelling and vacuolization, and myofibrillar degeneration [62]. The motor nerve axons and terminals appear normal even when there was severe muscle atrophy and muscle spindle atrophy is only found in type 2 fibers.

Treatment and Prognosis

Glucocorticoid excess is associated with significant morbidity, with 5-year survival rates as low as 50 % in early series. Modern management and treatment of Cushing's disease has led to a significant improvement in these figures, with a near normalization in mortality [63]. The management of steroid-induced myopathy is primarily treated by decreasing steroid dosage to the lowest possible level, which can be challenging depending on the underlying inflammatory condition. During the phased reduction, the possibility of adrenal suppression should also be considered and excluded where possible. Although any commonly used glucocorticoid can cause steroid myopathy, the fluorinated steroids, triamcinolone, betamethasone, and dexamethasone appear more likely to produce weakness [57]. Patients develop weakness when switched from other steroids to equivalent doses of triamcinolone or dexamethasone and recover from dexamethasone or triamcinolone-induced weakness when converted to an equivalent anti-inflammatory dose of another steroid [64]. Therefore, switching to a nonfluorinated agent is prudent, and where possible, an alternate-day treatment regimen should be instituted.

Often this is not an option, and patients are often dependent on glucocorticoid therapy for the treatment of their underlying condition. Recent years have seen a great focus on the development of novel therapeutic strategies for the prevention and treatment of glucocorticoid-induced muscle atrophy. Much of the present data is at a preclinical stage of use, with robust clinical trial data awaited. Research includes the development of dissociated glucocorticoids, in which the trans-repression function of the glucocorticoid receptor on gene transcription of proinflammatory transcription factors (believed to be responsible for beneficial effects) is segregated from the trans-activation function (believed to be responsible for the adverse side effects). Many compounds which have shown initial promise in vitro have not translated into in vivo benefits [65]. It has since been recognized that trans-activation also appears to play a role in the anti-inflammatory effects of glucocorticoids [66].

Other potential pharmacological approaches attempt to target pathways involved in glucocorticoid-induced myopathy. These include hormonal therapies such as GH and androgen therapy, myostatin inhibitors [67], selective 11beta-HSD1 inhibitors [68], growth hormone peptide-2 (GHRP-2), clenbuterol, branched chain amino acids (BCAAs), and creatine. Testosterone has anabolic actions in a range of disease states characterized by cachexia and muscle wasting. Administration blocks glucocorticoid-induced protein degradation in cell lines and muscle atrophy in animal models, potentially by blocking changes in expression of the translational repressor protein REDD1, by reducing mTOR inhibition, and by increasing muscle IGF-1 [69–71]. Administration of the adrenal androgen, dehydroepiandrosterone (DHEA), to those taking chronic glucocorticoid therapy has been proposed for over a decade, but robust clinical trials are still awaited [48]. Selective 11beta-HSD1 inhibitors have been developed as potential therapies for type II diabetes mellitus, obesity, and the metabolic syndrome, and their assessment in muscle atrophy would be of interest [68], but no large-scale randomized trials have been published to date.

GHRP-2, a GH secretagogue inhibitor receptor (GHS-R) agonist, attenuates dexamethasone-induced MuRF-1 mRNA in rat soleus muscle and MAFbx/Atrogin-1 and MuRF-1 expression a murine muscle cell line [72]. The use of this agent is currently at the preclinical stage. The well-established actions of catecholamines in inhibiting skeletal muscle protein breakdown have been investigated in studies using the selective beta-2 adrenoceptor agonist clenbuterol, finding opposing effects to glucocorticoids on muscle mass and fiber-type switching in mice [73], effects potentially mediated

via increases in muscle cAMP levels and reductions of the ubiquitin-proteasome system (UPS) activity [74]. These promising observations are tempered by questions surrounding the cardiovascular effects of such treatment in humans [75]. BCAAs were found to protect against dexamethasone-induced soleus muscle atrophy in rats, with attenuation of atrogin-1 expression [76]. Creatine supplementation was shown to attenuate dexamethasone-induced gastrocnemius and diaphragm muscle weight losses and the loss of type IIb fibers in rats [77].

Resistance exercise therapy prevents corticosteroid-induced myopathy in some patients and should be encouraged in patients receiving glucocorticoids. Patients with myopathy should therefore still receive physical therapy [40], although recovery may take many weeks to months. In one study, exercise training attenuated dexamethasone-induced muscle extensor digitorum longus atrophy, markers of insulin resistance, and muscular glycogen loss in rats [78]. In a separate study, exercise prior to steroid treatment attenuated effects on body and muscle weight, type II muscle cross-sectional area in plantaris, and myofibrillar protein content. The adaptations of muscle to exercise are partly attributed to stimulation of some of the pathways outlined earlier including by modifying local growth factors such as IGF-1 and modifying PI3K/Akt/mTOR signaling [79].

Adrenal Insufficiency

Pathology

In primary adrenal insufficiency (Addison's disease), the defect is adrenal in origin, whereas in secondary insufficiency, the defect is at the level of the hypothalamus or pituitary. The causes for primary insufficiency are wide ranging, with the most common etiology autoimmune (65 %, including polyendocrine deficiency syndromes types I and II), followed by tuberculosis (20 %), and the remainder of causes relating to infiltrative processes (such as malignancy, sarcoidosis, amyloidosis, fungal infection), or genetic/congenital disorders (particularly congenital adrenal hypo- and hyperplasia, ACTH resistance, adrenoleukodystrophy) [80].

The commonest cause of secondary adrenal insufficiency relates to hypothalamic-pituitary-adrenal suppression following exogenous steroid use, usually in the context of oral steroid use; however, it has also rarely been described in association with inhaled or intranasal steroid use [81, 82]. Other causes include lesions in the region of the hypothalamus and pituitary, trauma, and isolated ACTH deficiency.

Muscle weakness and fatigue caused by loss of adrenal hormones are related to impaired muscle carbohydrate metabolism, water and electrolyte balance, and muscle blood flow [50]. Anorexia and fasting hypoglycemia occur because of adrenal insufficiency [83]. In the absence of glucocorticoids during fasting, amino acids are not metabolized from muscle for hepatic gluconeogenesis resulting in hypoglycemia. Additionally, subjects with Addison's disease appear to have an enhanced sensitivity to insulin partly as a result of increased affinity of the sarcolemmal insulin receptor further exacerbating hypoglycemia.

Acute withdrawal of hydrocortisone replacement therapy in patients with established Addison's disease results in decreased energy expenditure and urea production, increased glucose oxidation, and insulin sensitivity, suggesting that muscle and body weight loss is due to an alternative mechanism such as reduced appetite [84]. Muscle glycogen stores are depleted, and epinephrine activation of glycogen phosphorylase in both skeletal muscle and liver is suppressed [85]. Further effects are likely to result from the adrenergic insensitivity which occurs during adrenal insufficiency, with hypotension a frequent consequence of hypovolemia and reduced adrenergic vasoconstriction [86]. The vasculature is sensitive to locally released vasodilators, so that blood pressure may decline with exercise, partially accounting for the diminished work capacity associated with adrenal insufficiency.

Patients with adrenal insufficiency disease are prone to hyponatremia, hypovolemia, and hyperkalemia, which have potentially important effects on muscle function. The hyponatremia state is multifactorial, resulting from both the inability to deal with water loads stemming from the loss of glucocorticoid antagonism of antidiuretic hormone and a reduction in the glomerular filtration rate [87] and excessive renal excretion of sodium as a consequence of reduced mineralocorticoid activity, further exacerbating hypovolemia [86]. Hyperkalemia has two principal causes, including the inability to increase physiological mineralocorticoid output to compensate for higher potassium loads and a reduced capacity for muscle to take up potassium as a consequence of glucocorticoid deficiency-induced effects on membrane Na^+, K^+ pump content and activity [88], leading to potassium depletion of muscle tissues. The resultant weakness may be exacerbated by prolonged sarcolemmal depolarization secondary to the hyperkalemic state, leading to sodium channel inactivation and loss of membrane excitability [89, 90].

Clinical Presentations

Thomas Addison included descriptions of muscle weakness in his seminal description of patients diagnosed with adrenal insufficiency [91], and subsequent reports have highlighted the spectrum of neuromuscular and musculoskeletal symptoms and signs associated with the syndrome, including muscle contractures, muscle pains, and arthralgias [92–94]. Reports of the incidence of muscle dysfunction in adrenal insufficiency vary, with some reports stating that weakness and fatigue are nearly universally found [95] and with other reports suggesting a range between 25 and 50 % experiencing generalized weakness, muscle cramping, and fatigue [83].

Although adrenal insufficiency frequently occurs in association with other endocrine disorders, which can complicate the clinical assessment of a weak patient, the finding of muscle weakness and fatigability in patients with isolated ACTH deficiency indicates that hypoadrenalism in isolation can lead to significant weakness [83]. Adrenal insufficiency may produce isolated respiratory muscle weakness [96] or may precipitate underlying myasthenia gravis, as described in several challenging clinical cases [97–99]. Further complications can result from electrolyte disturbances, including the well-recognized association of hyponatremia, when severe, with rhabdomyolysis [100]. The co-occurrence of these features appears to be rare in clinical practice, with only three published case reports of this triad occurring together [101–103]. The etiology of adrenal insufficiency-associated rhabdomyolysis has been attributed primarily to cellular edema secondary to the hypo-osmolar extracellular fluid. The cause remains speculative, particularly as cases of adrenal insufficiency coexisting with rhabdomyolysis in the absence of significant hyponatremia have been published, suggesting alternative independent mechanisms [104].

Joint flexion contractures are commonly observed and have even been reported as the initial manifestation of adrenal insufficiency [105–109], including unusual cases of abdominal-crural contractures [110, 111]. These commonly reported features may well be a consequence of a connective tissue disorder rather than a primary muscle phenomenon. Adrenal insufficiency has also presented alongside Guillain-Barre syndrome [112], and other modes of presentation include migratory myalgia, sciatica-like pain, and low back pain [83]. Cardiomyopathy has be observed in the context of adrenal insufficiency, with both pediatric and adult cases reported [113–115].

Further clinical phenotypes include presentations of adrenal insufficiency in conjunction with defects of the mitochondrial and somatic genome, including X-linked congenital adrenal hypoplasia (CAH). This rare developmental disorder of the human adrenal cortex is caused by deletion or mutation of the DAX-1 gene, which encodes a nuclear hormone receptor. CAH occurs as part of a contiguous gene syndrome together with glycerol kinase deficiency and Duchenne muscular dystrophy. Most boys present with salt wasting and hyperpigmentation during the neonatal period, with aldosterone deficiency usually preceding cortisol deficiency. The ACTH test may be necessary to detect cortisol deficiency in infants [116]. Other mitochondrial disorders include Kearns Sayre syndrome, which presents with ophthalmoplegia, pigmentary retinopathy, heart block, and ataxia, with associated adrenal insufficiency (and other endocrinopathies such as growth hormone deficiency, hypogonadism, diabetes mellitus, and hypoparathyroidism) described [117, 118].

Differential Diagnosis

The spectrum of clinical presentations is very wide, as highlighted above, and the differential diagnosis is correspondingly broad. This requires a high index of suspicion and highlights the importance of "thinking endocrine" when considering patients presenting with apparent neuromuscular weakness [2].

An important condition to consider – particularly in the acute setting – is hyperkalemic periodic paralysis, which may occur in association with adrenal insufficiency. A flaccid quadriparesis associated with hyperkalemia is described in patients with primary adrenal insufficiency [119], which resembles familial hyperkalemic periodic paralysis, with triggers including potassium intake or exercise. In contrast, however, these patients do not have a family history of periodic paralysis, and the condition resolves with glucocorticoid replacement. Lowering the serum potassium by glucose administration or other means usually reverses the paralysis. Between attacks of weakness, membrane hyperexcitability is seen in both familial and Addisonian hyperkalemic periodic paralysis. Paramyotonia congenita also present with hyperkalemic paralysis, clinical episodes of flaccid weakness, paradoxical myotonia, and cold-induced weakness and EMG may show myotonic discharges. Paramyotonia and hyperkalemic periodic paralysis are caused by mutations of the skeletal muscle sodium channel [120].

Evaluation and Diagnosis

The diagnosis of adrenal insufficiency requires plasma cortisol, renin, ACTH assays, and ACTH stimulation test. Myopathy secondary to adrenal insufficiency is diagnosed clinically since serum muscle enzymes are usually normal, as are electrodiagnostic studies.

One published study of muscle function in patients with adrenal insufficiency found that patients had preserved maximum voluntary quadriceps forces but altered contractile properties and decreased endurance [121]. In a more recent review of 16 cases, a wide range of neurophysiological abnormalities were identified, although EMG studies were normal in a large proportion of patients (8 out of 14 cases examined). Other findings included myogenic features, continuous firing, or denervation. Nerve conduction studies were normal in 6 out of 10 cases, with a wide range of motor and/or sensory conduction abnormalities in the remaining 4 cases. Muscle biopsies were normal in 3 cases, with variably reduced numbers and/or atrophy of either type I or type II fibers in the remaining 4 cases [122].

Treatment and Prognosis

Management of patients with adrenal insufficiency in association with weakness should be directed at treating the underlying cause of adrenal dysfunction, which should improve weakness. Patients with primary insufficiency

require both glucocorticoid and mineralocorticoid replacement, while glucocorticoid replacement is nearly always sufficient for secondary adrenocortical insufficiency. In the acute clinical scenario, treatment of the paralytic condition may necessitate intensive care management for cardiac and respiratory complications and should focus on the correction of electrolyte abnormalities first followed by hormonal replacement. Dramatic improvements in muscle function are seen with replacement of hydrocortisone; however, treatment may be chronic and lifelong depending on etiology. Long-term muscle stiffness has been reported in some cases [122].

Muscle Disorders Associated with Thyroid Disease

Physiology and Pathology

The thyroid gland releases thyroid hormones, primarily thyroxine (T4), into the circulation. In the periphery, T4 is converted to the more bioactive triiodothyronine (T3). T4 and T3 enter the skeletal muscle by active transport [123], to act at several potential cellular sites, including the plasma membrane, cytoplasm, mitochondrion, and cell nucleus. These sites of action are generally categorized as genomic if they involve binding to intranuclear thyroid hormone receptors and nongenomic at other sites. A full description of the underlying molecular mechanisms of action is outside of the scope of this review, but is comprehensively described in Cheng et al. [124] and Davis et al. [125]. The genomic actions are mediated via thyroid hormone nuclear receptors (TRs), which are found as four T3-binding isoforms (α1, β1, β2, and β3) (alpha1, beta1, beta2, and beta3). Receptor transcriptional activity is regulated at multiple levels, via T3 itself, thyroid hormone response elements, tissue-dependent expression of TR isoforms, and co-regulatory proteins (both corepressors and co-activators). Nongenomic actions are similarly complex, including functions at the plasma membrane which involve the integrin αvβ3 and ERK-dependent pathways, resulting in ion channel modulation (particularly the activity of the Na^+/H^+ exchanger) [126] or linking into downstream nuclear events, including cellular division.

Thyroid hormones have long been known to increase the basal metabolic rate, skeletal muscle heat production, and mitochondrial oxygen, pyruvate, and malate consumption, and these properties are reflected in actions of T3 at the mitochondria. Recent studies suggest that these effects may be mediated by mitochondrial T3 receptors, linking into the glucose transporter 2 (GLUT2) and components of ATP-sensitive potassium channels [127]. Overall effects on skeletal muscle properties include increased glucose uptake and glycolytic activity, with stimulation of glycogenolysis.

The full complexity of the effects of thyroid hormones on skeletal muscle has been revealed in recent microarray studies using both animal models and human patients.

A transcriptional survey of ten patients who underwent thyroidectomy with subsequent thyroxine supplementation to physiological levels found that 607 genes were differentially expressed following thyroxine replacement. Sixty percent of genes were positively regulated, with 40 % negatively regulated, with a significant proportion of genes having roles in energy and fuel metabolism [128].

Hyperthyroidism

Hyperthyroidism is a common disorder, affecting approximately 2 % of women and 0.2 % of men. The most common cause is Grave's disease – autoimmune thyroid disease – in which the action of thyrotropin (TSH) stimulating autoantibodies results in the overproduction of thyroxine (T4) and (T3). Less commonly, toxic nodular goiters lead to hyperthyroidism through localized autonomous overproduction of thyroid hormone. A female predominance of 3:1–4:1 with a mean age of onset near the end of the fifth decade has been noted in numerous epidemiological studies. Thyrotoxicosis accelerates muscle protein degradation. Increased degradation of skeletal muscle protein is also seen in patients without myopathy and therefore is not a consequence of muscle weakness. Fat oxidation and lipoprotein lipase activity are increased in thyrotoxic patients [129].

Clinical Presentations

Acute Thyrotoxic Myopathy

Muscle weakness and atrophy are commonly found in hyperthyroidism, with several large patient surveys describing neuromuscular complaints in up to 80 % of patients, with marked muscle weakness in over half [130, 131]. The incidence of weakness and wasting increases with the duration of illness and is more commonly observed in older patients. The actual degree of weakness does not generally correlate with the biochemical severity of the thyrotoxicosis.

The weakness is primarily proximal and is often out of proportion to the amount of muscle wasting, although severe wasting may occur in some cases. Distal weakness may occur but usually develops in the latter stages and is less prominent than associated proximal weakness. Myalgia, fatigue, and exercise intolerance are common complaints. Breathlessness is a common symptom of patients with hyperthyroidism, with up to 90 % of patients complaining of dyspnea at the time of diagnosis, although overt respiratory insufficiency requiring ventilatory support due to respiratory muscle weakness and fatigue is rare [132]. Bulbar muscle involvement has been reported in thyrotoxicosis, although investigating alternative causes (including myasthenia gravis)

is important in patients with dysarthria, dysphagia, or dysphonia. Sphincter function is not involved. Severe acute hyperthyroidism – sometimes termed a "thyroid storm" – can be associated with rhabdomyolysis with myoglobinuric renal failure [133]. Rarely, an inflammatory myopathy occurs with thyrotoxicosis, which may necessitate corticosteroid therapy [134]. This presentation can occasionally lead to a coincident diagnosis of polymyositis and thyroid disease (both cases of hyper- and hypothyroidism have been reported in these cases) [135].

Association of Thyroid Disorders with Myasthenia Gravis

There is a significantly greater incidence of thyroid disorders in patients with myasthenia gravis than expected by chance, with 5.7 % of myasthenic patients hyperthyroid, 5.3 % hypothyroid, and 2.1 % having a nontoxic goiter [136]. There have been several reports of sudden onset of generalized weakness with bulbar palsy in thyrotoxic patients, and it is likely that some of these are acute presentations of myasthenia gravis, coincident with thyrotoxicosis. These patients had dramatic responses to neostigmine, and thymic hyperplasia was found in one of the two anticholinesterase-sensitive patients who were studied postmortem [50].

Thyroid Eye Disease

Thyroid eye disease (TED), also known as thyroid-associated ophthalmopathy and Graves' ophthalmopathy/orbitopathy, is a chronic inflammatory condition of orbital tissue and is nearly always associated with immune thyroid disease, although patients may be hyperthyroid (80 %), hypothyroid (10 %), or euthyroid (10 %) [137, 138]. The condition is restricted to the orbit, with no involvement of skeletal muscles beyond the extraocular muscles. Clinically evident ophthalmopathy occurs in approximately 50 % of patients with Graves disease, although subclinical disease is detectable using imaging modalities such as orbital infrared imaging, MRI, ultrasound, or radioisotope imaging in up to 90 % of patients [139–141].

The clinical features are wide ranging, in both their presentation and severity. Proptosis is most classically seen, with a degree of restrictive ophthalmoplegia. Severe exophthalmos is associated with prominent chemosis and eyelid edema, which can produce corneal ulceration. If swelling of orbital contents becomes severe, optic nerve compression may occur.

The causes of TED remain unclear, with a range of environmental (including smoking) and genetic risk factors identified [139]. The cellular pathophysiology has been defined, to some extent, with lymphocytes and macrophages identified within the retro-orbital connective tissue, secreting cytokines. Orbital fibroblasts appear integral to the pathological process, with proliferation leading to enlargement of extraocular muscles. The secretion of glycosaminoglycans into the extracellular space is associated with tissue edema and an increase in perimysial connective tissue. Extraocular muscle fibers are not directly damaged. Several potential antigenic targets expressed in extraocular muscle and orbital fibroblasts are found, but their precise role in disease development is unknown. Recent studies suggest that autoantibodies directed against the insulin-like growth factor 1 receptor (IGF-1R), which is overexpressed on fibroblasts derived from patients with TED, may be important mediators of the condition, although this is controversial [142].

The treatment of TED is tailored to the severity and rate of progression of symptoms. Mild manifestations usually respond to topical adrenergic blocking agents, with or without dark glasses and prisms. Systemic glucocorticoids reduce orbital swelling if adrenergic blockers fail and are particularly indicated in patients at high risk of visual deterioration [143]. Small trials of second-line agents, including anti-cytokine therapies, suggest that Rituximab may be an effective therapy [141, 144]. Indications for orbital decompression surgery potentially include compressive optic neuropathies not responsive to glucocorticoids, exposure keratopathies, and cosmesis [145].

Thyrotoxic Periodic Paralysis

Thyrotoxic periodic paralysis (TPP) is a relatively rare but important form of thyroid-associated weakness. Patients with TPP – who are typically male, South East Asian Ethnic origin, and aged 20–40 years – experience recurrent attacks of proximal weakness of variable duration (minutes to days). The actual incidence or prevalence of the condition is unclear, although a large case series reported that nearly 10 % of 432 Oriental patients with thyrotoxicosis manifest episodes of periodic paralysis [146]. Despite the emphasis of the disorder being more common in Oriental patients, a case series from Argentina suggests that TTP may be underappreciated in Caucasian populations [147].

Attacks may be precipitated by heavy carbohydrate intake, muscle cooling, or rest after exercise, although mild exercise may actually prevent an impending attack. The weakness is typically generalized but can also be relatively focal and limited to groups of muscles that were exercised. Bulbar, respiratory, and sphincter function are rarely compromised [148]. Hypokalemia is almost uniformly present, and hypophosphatemia and mild hypomagnesemia are also common features of TPP [149]. Thyroid function tests are often only mildly deranged.

Recent studies suggest that TPP results from a complex interaction of genetic susceptibility, thyrotoxicosis, and environmental factors (diet or exercise). The condition is linked to mutations in the inwardly rectifying potassium channel Kir2.6 (encoded by the KCNJ18 gene). This protein is transcriptionally regulated by T3, leading to increased protein expression in the thyrotoxic state [150]. The dynamic nature

of the muscle tissue changes was demonstrated in a recent study showing that in TPP several neurophysiological (voltage-gated currents and conductance) and muscle biopsy (histochemical fiber type) parameters were similar to those found in patients with hypokalemic periodic paralysis, which normalized once a euthyroid state was achieved [151]. These studies therefore strongly suggest that mutations in the expressed gene result in functional changes in channel current densities and/or alterations in downstream intracellular signaling properties, leading to the clinical manifestations of TPP [152].

Treatment for TTP involves supportive therapy for the acute event, with cautious correction of potassium and magnesium levels (to avoid rebound hyperkalemia), followed by treatment directed at the hyperthyroid state [149]. Nonselective beta-adrenergic blockers such as propranolol are a useful adjuvant until full control of thyroid function – which should cure TPP – is established using standard therapies.

Differential Diagnosis

The potential clinical features of thyrotoxicosis are wide ranging [153], requiring a high index of suspicion in milder cases, and the myopathy associated with hyperthyroidism should be distinguished from other myopathies, myasthenia gravis, polymyositis, myopathy of adrenal insufficiency, and steroid-induced myopathy. The pattern of weakness, progression of symptoms, disproportion between muscle weakness and atrophy, fold of skin above the weak muscle, and deep tendon reflex examination are useful in differentiation. Hyperthyroid myopathy can be confirmed with thyroid hormone assay and resolution of symptoms with return to the euthyroid state.

Evaluation and Diagnosis

In a typical clinical practice, thyrotoxicosis is usually straightforward to establish, using a high-sensitivity TSH assay as a screening test, finding low levels in significant thyrotoxicosis. Serum levels of CK, SGOT, LDH, and myoglobin are usually normal or low – unless the patient presents with rhabdomyolysis and acute renal failure. Assays for autoantibody titers typically find that 95 % of patients with Grave's disease have positive TPO-microsomal antigen antibodies and 50 % have positive antithyroglobulin antibodies.

The literature on neurophysiological features of thyrotoxic myopathy was shaped by the 1979 study of Puvanendram and colleagues, in which 48 thyrotoxic patients were evaluated clinically and neurophysiologically [154]. The majority of patients had abnormal proximal muscle EMG measurements, with short duration motor unit potentials and increased polyphasic potentials; in contrast only about 20 % of patients have abnormal distal muscle needle EMG patterns. The abnormalities were particularly marked in patients with significant clinical weakness, and other EMG features, such as spontaneous electrical activity (including fibrillations or fasciculations), were rare. Following treatment of the hyperthyroid state, EMG patterns normalized. Although well established in the literature, these relatively clear-cut views have been challenged by a more recent study, which found that 24 % of patients had neuropathic changes by needle EMG, further complicated by 19 % of patients manifesting a sensorimotor axonal neuropathy [131].

Histological appearances are variable, with both light and electron microscopic studies of muscle finding normal appearances or occasionally showing varying degrees of fatty infiltration, fiber atrophy, and nerve terminal damage [155]. These nerve terminal changes had previously been hypothesized to potentially account for the observed worsening of myasthenia gravis by thyrotoxicosis [156].

Treatment and Prognosis

Following diagnosis, three forms of therapy are commonly used, including destruction of the thyroid using radioiodine, blockade of hormone synthesis using antithyroid drugs, and surgical resection or removal of the thyroid gland. Adrenergic blocking agents may improve muscle strength acutely, especially of respiratory muscles, and glucocorticoids – which block the peripheral conversion of T4 to T3 – may be useful in the acute treatment of thyrotoxicosis [157, 158]. However, the specific treatment for thyrotoxic myopathy is returning patients to the euthyroid state. Within 4 months of treatment, all symptoms of weakness resolve and persistent weakness is rarely reported [131].

Hypothyroidism

Hypothyroidism is a common endocrine condition, second only to diabetes mellitus, with a prevalence approaching 18 per 1,000 in the general population [159]. As with hyperthyroidism, hypothyroidism has a female predilection, with a female/male incidence ratio of approximately 10:1. The prevalence increases with age, with 2–3 % of older women diagnosed with hypothyroidism [160]. The condition is most commonly primary, usually related to Hashimoto's thyroiditis, although it may result from several iatrogenic causes (both medical and surgical).

Pathology

Metabolic changes of hypothyroidism affect muscle function in multiple ways, reducing oxygen consumption and basal metabolic rate through actions on mitochondrial oxidation capacity, muscle oxidative enzyme activity, and glucose uptake [161]. Muscle glycogenolysis is impaired, resulting in fasting hypoglycemia and possible accumulation of glycogen. In addition, hypothyroidism produces an insulin-resistant state, with likely effects detailed previously. Hypothyroidism reduces the

number of adrenergic receptors on muscle cells, resulting in diminished glycogenolysis [162] which may contribute to development of muscle cramps and fatigability. Both protein synthesis and degradation are reduced with net protein catabolism. Hypothyroidism reduces Na^+-K^+ pump activity and renal sodium resorption in the distal tubule, leading to relative hypovolemia, decrease in the cardiac output, and myokymia [50].

It is well known that hypothyroidism markedly prolongs the tendon reflex relaxation time [163]. This occurs in non-myxedematous patients and likely reflects the slowing of calcium sequestration by sarcoplasmic reticulum and prolongation of the twitch rather than mechanical damping by excess connective tissue.

Clinical Presentations

Muscle stiffness, aching, and slight weakness are present in the majority of hypothyroid patients and occasionally are the only indication of thyroid disease. The primary manifestations of myopathy in hypothyroidism are proximal weakness, stiffness, myalgia, myoedema (local contracture produced by tapping or fatigue, slowed pinching the muscle), and, less commonly, cramps and muscle enlargement [50, 131, 164]. Reflex changes are common, and severe weakness with muscle enlargement occurs in few cases. Hypothyroidism may present with rhabdomyolysis or respiratory muscle weakness [165, 166]. Long-standing hypothyroidism may produce a slowly progressive proximal myopathy, and muscle disease can occur without features of myxedema.

Reported EMG findings in hypothyroid myopathy are highly variable, ranging from normal through to low amplitude polyphasic motor unit potentials and sporadically increased insertional activity and positive waves. Fibrillations or fasciculations may occur but probably suggest a coexistent neuropathy. These are commonly found in hypothyroidism (and are typically sensorimotor axonal in character); furthermore, about a quarter of patients have neurophysiological evidence of carpal tunnel syndrome [131]. The incidence of neurophysiological myopathic changes is controversial. One report of 16 untreated hypothyroid patients found myopathic changes in 46.6 % [167]. In a further prospective study of 23 neurologically asymptomatic patients with hypothyroidism, myopathic changes were found (without spontaneous activity) in 74 % of patients, with abnormalities most commonly found in the deltoid muscles and less commonly identified in the vastus lateralis (39 %) and tibialis anterior (26 %) muscles. Neuropathies were identified in 52 %, principally of a motor demyelinating pattern, with 30 % of patients having a carpal tunnel syndrome [168].

In contrast, in a more recent study of 40 patients with untreated primary hypothyroidism, 30 % of patients had clinical muscle weakness, 45 % with diminished (or absent) deep tendon reflexes, 15 % had a neuropathy, and only 7.5 % had a myopathy. Carpal tunnel syndrome was again commonly found in 32.5 % [169]. It was speculated that the low incidence of myopathy in this cohort may have related to early diagnosis of the condition, prior to the development of complications.

The neurophysiological features of myoedema – defined as stationary muscle mounding after muscle percussion without electrical muscle activity – are unremarkable, even by single fiber EMG. These findings are common – they were observed in 88 % of surveyed patients with a range of neurological diseases. Myoedema is therefore not specific to hypothyroidism, although is more clinically prominent in this condition [170, 171].

Light microscopy of involved muscles demonstrates a variety of changes: atrophy, necrosis or hypertrophy of fibers, increased number of nuclei, ring fibers, glycogen accumulation, and increased interstitial connective tissue [172]. Basophilic inclusions without limiting membranes are sometimes seen in type 1 fibers. The neuromuscular junction generally appears normal in hypothyroidism. Ultrastructural studies have frequently demonstrated multiple abnormalities, including mitochondrial swelling and inclusions, myofibrillar disorganization and fragmentation, glycogen accumulation, lipoid granules, dilation of the sarcoplasmic reticulum, autophagic vacuoles, central core changes, and T-tubule proliferation [173]. Some of these changes have been observed to resolve with thyroid replacement therapy.

Differential Diagnosis

Other endocrine, toxic, inflammatory, and limb-girdle myopathies are within the differential diagnosis of hypothyroid myopathy. Myoedema (see above) occurs in about one-third of hypothyroid patients but is also seen in a variety of disorders associated with malnutrition and wasting. Hypothyroidism should be considered in patients with rhabdomyolysis, but other etiologies – as detailed in previous sections – should always be considered.

Evaluation and Diagnosis

Hashimoto's thyroiditis is usually investigated via standard thyroid function tests (TSH and T4 levels) in combination with antithyroid peroxidase (TPOAb) and antithyroglobulin (TgAb) antibody testing [174]. Primary hypothyroidism is characterized by high TSH and low free and total T4, whereas but in secondary hypothyroidism, TSH and total T4 are both in the low range indicating hypothalamic or pituitary dysfunction. Antithyroglobin antibodies are useful pointers to autoimmune thyroiditis. Serum CK activity is elevated in many hypothyroid patients, with levels up to tenfold higher than normal, even in the absence of overt muscle disease [163, 175]. This may become a less frequent finding than previously reported, as the increased use of screening tests is likely to lead to patients with milder disease at the point of diagnosis [131]. Serum myoglobin has been found to be elevated in some patients with severe hypothyroidism, although creatine excretion is usually not elevated [176].

Treatment and Prognosis

The only effective treatment is to restore the patient to a euthyroid state, with a reasonable prognosis for recovery, with CK levels correcting rapidly with thyroid replacement. A prospective study found that, after a mean of 6 months of treatment, the majority of patients had made a good recovery, although a quarter of patients still experienced neuromuscular symptoms at 1 year, with more than 10 % having weakness on formal examination [131].

Muscle Disorders Associated with Pituitary Dysfunction

Growth Hormone Excess

Physiology and Pathology

Human growth hormone (GH) is a single-chain 191 amino acid polypeptide secreted from eosinophilic (somatotroph) cells in the anterior lobe of the pituitary. GH acts primarily by stimulating the formation of locally synthesized somatomedins, also known as insulin-like growth factors (IGF), of which IGF-1 is the most important. Blood levels of IGF-1 therefore correlate with circulating levels of GH. IGF-1 binds to the cell surface tyrosine kinase IGF-1 receptor [177], resulting in auto-phosphorylation and recruitment of insulin receptor substrate (IRS) proteins. Downstream targets include Ras/Raf/MEK and ERK, which are involved in proliferation; PI3K/AkT, which have effects on protein synthesis; NFkB, which inhibits apoptosis; and MyoD/P21, which has effects on differentiation [178].

GH is an important regulator of protein metabolism and is the primary anabolic hormone during stress and fasting [179], potentially via effects on fatty acid oxidation and oxidative and glycolytic carbohydrate metabolism, thus reducing glucose utilization, with associated insulin resistance. Excessive amounts of GH increase protein synthesis and possibly retard protein breakdown in muscle [180].

The most striking finding of GH excess is the resultant decreased force-generating ability, despite increased fiber diameters [181]. Impaired carbohydrate metabolism and possibly restricted muscle blood flow may partially explain this deficit. In rats with excess GH, for example, proximal and trunk muscle hypertrophy develop, yet muscles have reduced twitch and tetanic tensions [181–183]. Thus, increased protein content does not improve contractile ability, which may result from several factors. In rat muscle, chronic GH administration may decrease myofibrillar ATPase activity, despite the increased concentrations of actin and myosin [184]. Studies in humans are more limited, although a case report from a single acromegalic patient found that intercostal muscle fibers were slightly depolarized, with an elevated action potential threshold [185]. Thus, excessive amounts of GH may both decrease surface membrane excitability and impair myofibrillar contractile ability.

Experimental and clinical studies support growth hormone as a regulator of cardiac muscle function. Transgenic mice, which overexpress growth hormone, demonstrate systolic contractile dysfunction, and ultrastructural studies of the heart show mitochondrial abnormalities. Acromegalic cardiomyopathy is characterized by myocardial hypertrophy with interstitial fibrosis, lympho-mononuclear infiltration, and areas of monocyte necrosis which often result in biventricular concentric hypertrophy [186].

Clinical Presentations

Pierre Marie first described the presentation of acromegaly in 1886, which included two personal cases and five from prior literature [187]. The clinical features included preserved muscle bulk, hypotonia, and increasing proximal weakness as the disease progressed. These early clinical observations of acromegalic patients have been replicated in numerous studies, with more recent reports using MRI and dual-energy x-ray absorptiometry (DXA) finding increased total lean mass but normal total muscle mass compared to normal controls [188].

Proximal weakness and decreased exercise tolerance occurs in approximately 50 % of patients, without apparent racial predilection, and is typically insidious in onset and gradually progressive. Respiratory muscles are also affected, with reduced inspiratory and expiratory muscle function in the presence of an increased total lung capacity [189]. Extraocular myopathy is a rare presenting feature of acromegaly, with case reports finding symmetrical involvement [190, 191]. Assessment is complicated by the frequent incidence of rheumatological signs and symptoms, including musculoskeletal pain (90 %), neck pain (50 %), and osteoarthritis of the hip (84 %) and knee (34 %) [192]. The classic coarsening of facial features and costochondral enlargement are common signs of GH excess [193–195].

Cardiovascular disease, characterized by cardiomyopathy, concentric left ventricular hypertrophy (LVH), and diastolic dysfunction, is commonly associated with acromegaly and account in part for the reduced exercise performance seen in such patients [196].

Evaluation and Diagnosis

For screening and follow-up of acromegaly, basal GH and age-matched IGF-1 levels are the most convenient tools. The most accurate test for diagnosis and prediction of outcome after therapy is the lack of GH suppression during oral glucose tolerance test [197, 198]. Serum levels of CK or aldolase may be slightly elevated [194, 199, 200]. Creatine excretion is normal or only slightly increased.

Approximately 50 % of acromegalic patients have myopathic changes on needle EMG; in other cases, findings are

either nonspecific or normal [194, 200, 201]. Short duration motor unit potentials and an increased frequency of polyphasic potentials are occasionally found in clinically unaffected patients [202]. Diffuse hypertrophic neuropathy or nerve entrapment, usually of the median nerve, occurs in about half of patients. The neuropathy and myopathy usually develop independently and follow separate courses.

Muscle histology may show atrophy of both type I and II fibers [202], mixed fiber-type hypertrophy and atrophy [201], or preferential type II fiber loss [194]. Light microscopic evaluation of muscle reveals isolated fiber necrosis, vascular degeneration, nuclear enlargement with prominent nucleoli proliferation and hypertrophy of satellite cells, increased muscle glycogen, lipofuscin accumulation, and, rarely, round cell infiltrates. Ultrastructural studies show excessive amounts of lipofuscin and glycogen, loss of myofibrils, thickening of capillary basement membranes, increase in satellite cells, altered mitochondria (pleomorphism, elongation, metrical pallor and cristae abnormalities), inclusion bodies, and vesicular dilatations. With effective biochemical control of GH secretion post-surgery, resolution of ultrastructural features has been described [203].

Treatment and Prognosis

According to Endocrine Society guidelines, treatment of acromegaly should be individualized and provided by an experienced multidisciplinary team [204]. Modalities include Transsphenoidal surgery (TSS), medical therapy, and radiotherapy, with TSS as the initial treatment of choice in most cases. Medical therapy includes somatostatin analogues (octreotide and lanreotide), dopamine agonists (cabergoline), and a GH receptor antagonist (pegvisomant), with radiotherapy generally used as a third-line treatment option. Current consensus advocates long-term monitoring of biochemical parameters of GH secretion (OGTT, Serum IGF-I), tumor growth (MRI), along with screening for complications such as hypopituitarism, cardiomyopathy, obstructive sleep apnea, and colonic polyps [204].

Acromegaly is associated with an overall increase in mortality and morbidity resulting from effects on cardiovascular, musculoskeletal, neurological, and endocrine systems. The overall mean standardized mortality ratio (SMR) in a recent meta-analysis was 1.72 (95 % CI 1.62–1.83) [205], with correlations between GH levels and mortality risk. Growth hormone has critical affects on cardiac muscle, and cardiovascular abnormalities represent the major cause of death in patients with acromegaly [205, 206].In a study of 205 patients with acromegaly, patients had reduced left ventricular ejection fractions and just under a 12-fold increased prevalence of LVH compared with normal controls. Increased disease duration was most closely associated with cardiomyopathy [207]. A separate study showed that higher serum IGF-1 levels were associated with higher rates of cardiomyopathy, suggesting that the association is dose dependent [208]. Effective biochemical control of excess GH secretion by TSS and medical therapies, including somatostatin analogues and pegvisomant, has been shown to reduce LVH and improve cardiac function [209].

In treated patients, marked changes in body composition are seen by 1 year, with significant reductions in skin, muscle, and visceral organ mass and a corresponding increase in adipose tissue mass [210]. The myopathy usually resolves when GH levels return to normal; however, deficits may still be detectable years after effective remission of biochemical disease [199, 202].

Hypopituitarism

Pathology

The causes of adult hypopituitarism include thrombosis of the pituitary circulation, pituitary region tumors, head injury, granulomatous destruction, surgery, radiotherapy, iron overload, congenital abnormalities, encephalitis, and meningitis. Pituitary failure in adults causes severe weakness and fatigability with disproportionate preservation of muscle mass. The muscle manifestations of hypopituitarism are primarily attributable to loss of thyroid and adrenal hormones, which are outlined elsewhere in this chapter, with resultant deficits potentially reversed by hormonal replacement.

Clinical Presentations, Evaluations, and Diagnosis

In recent years, however, the particular importance of adult growth hormone (GH) deficiency in causing muscle weakness has been increasingly recognized. GH-deficient patients are weaker, have reduced muscle mass, have increased fat mass, and have impaired exercise capacity and endurance compared to normal individuals [211–214]. Muscle weakness is thought to be secondary to reduced muscle mass, as intrinsic fiber strength is not reduced [211].

Hypokalemic periodic paralysis has been described as an atypical presentation of muscle involvement in GH deficiency [215]. Activation of the Na^+/K^+ ATPase by insulin/IGF-I signaling, resulting in increased transport of K^+ into cells, was proposed as a potential mechanism and symptoms reversed with GH replacement and optimization of glycemic control.

Screening for GH deficiency in patients with fibromyalgia has been advocated following studies suggesting an increased prevalence in this population. In one large study, 34 % of patients ($n=493$) were found to have subnormal IGF-I levels, while 22/127 (17 %) had evidence of GH hyposecretion on insulin tolerance testing, eight of which had severe deficiency [216]. A small-scale study of GH replacement in fibromyalgic patients found significant effects on a range of

disease-related symptoms, but results from larger scale studies are awaited [217].

Several studies have examined the neurophysiological features of GH deficiency. In one study, EMG findings at baseline in GH-deficient patients showed reduced mean frequencies compared to normal controls, with proposed mechanisms including reduced cross-sectional fiber area, reduced type 2 fibers, and increased intramuscular fat deposition [214]. No significant changes in EMG results were seen after 6 months GH treatment. In a separate study, 14 out of 20 patients with GH deficiency had abnormal EMG and/or interference pattern analysis (IPA) studies. Seven of these patients had repeat IPA studies after 12 months of GH treatment, of which six had normal results, with the remaining patient showing improvement [218].

Treatment and Prognosis

Current evidence suggests that short-term treatment with recombinant GH leads to improvements in muscle strength, improved exercise capacity – as measured by maximal power output and oxygen uptake – and increases in lean mass [212, 213]. These results should be interpreted cautiously, as the data on long-term follow-up of GH replacement originates from open-label studies, with controlled studies limited to short-term follow-up periods [213]. It is likely that long-term treatment (beyond 5 years) is required to normalize strength to age-predicted levels [219, 220].

There is a complex interplay between anterior pituitary hormones and their effects on muscle mass and strength. GH is known to reduce total body 11beta-HSD1 activity, resulting in a reduction in local active glucocorticoids and possible pro-anabolic effects [221]. GH deficiency is therefore characterized by activation of glucocorticoids, which may partly explain the observed increased central adiposity and muscle wasting. Testosterone therapy for hypogonadism results in increased lean mass and reduced fat mass and has also been shown to improve grip strength compared to placebo [222]. Effects of androgen therapy on muscle may result from potentiation of GH/IGF-I signaling pathways.

Previously studies have raised interest in the role of GH replacement to prevent age-related sarcopenia, in light of the physiological reduction in GH secretion with age – the so-called somatopause. This treatment is not currently recommended, however, in view of lack of functional improvements and long-term safety concerns [223].

Prepubertal panhypopituitarism is usually idiopathic or associated with a suprasellar tumor and is characterized by dwarfism, with lack of muscular and sexual development. Panhypopituitarism in children produces muscle wasting, with a reduction in cell number and size. In contrast to the disease in adults, GH replacement is essential to correct the muscle disorder because of the critical role of GH (and/or IGF) in muscle development [177, 211, 224–226].

Muscle Disorders of Calcium and Vitamin D Metabolism

Physiology

Parathyroid hormone (PTH), along with vitamin D and calcitonin, collectively controls calcium homeostasis, with important roles in bone metabolism and structure, resulting in a tightly maintained serum calcium level. Vitamin D is found in two forms which are important in humans – vitamin D_2 (ergocalciferol) and D_3 (cholecalciferol) which have actions on the intestine, kidneys, parathyroid glands, and bone, with more recently described effects on skeletal muscle. The two forms have similar biological properties, but are not bioequivalent (reviewed in Houghton et al.) [227], and the related literature, particularly related to therapeutic supplementation, therefore, needs to be interpreted with great caution. Vitamin D_3-related metabolic pathways involve the production of 7-dehydrocholesterol, which isomerizes under the action of UV radiation exposure in the skin to produce cholecalciferol (the inactive, unhydroxylated form of vitamin D_3). Alternatively, cholecalciferol can be obtained from a range of dietary sources. Cholecalciferol binds to the vitamin D-binding protein and is transported to the liver where it is hydroxylated by cholecalciferol 25-hydroxylase to calcifediol (also known as calcidiol, 25-hydroxyvitamin D_3), followed by further hydroxylation in the kidney by 25-hydroxyvitamin D-1α-hydroxylase to calcitriol (1,25-hydroxyvitamin D_3). Calcitriol is the most active form of vitamin D_3 and exerts its principal actions by binding to the vitamin D receptor (VDR), a member of the steroid hormone receptor of ligand-activated transcription factors to modulate the activity of numerous genes and gene products, increasing calcium absorption in the gut, bone resorption, and renal reabsorption of phosphate [228–230]. The VDR can be found in both the cytoplasm and nucleus of many cells, and as with many other hormone receptors, sites of action are typically classified as genomic or nongenomic. Binding of calcitriol to the VDR promotes the association of VDR with the retinoid X receptor (RXR), resulting in binding of the complex to vitamin D response elements present in DNA. Co-regulatory proteins (both co-activators and repressors) associate with the complex to modulate gene transcription (reviewed in Pike et al.) [231].

PTH is an 84 amino acid peptide secreted by the chief cells of the parathyroid glands and functions to increase extracellular calcium concentrations. The hormone binds to the parathyroid hormone receptors – two PTH receptor genes PTH1R and PTH2R are found in mammals – to activate adenyl cyclase and phospholipase C [229] and direct mineral and ion transport of the bone and kidney as well as through indirect pathways on the small intestine through actions on vitamin D synthesis. The full range of actions of PTH on

in vivo gene transcription are extremely wide, with microarray studies finding that approximately 1,000 gene sets are modulated, leading to differential cell signaling, gene transcription, and cytokine production [232].

In contrast to the physiological actions of PTH, calcitonin, a 32 amino acid peptide secreted by the parafollicular cells of the thyroid, reduces blood calcium levels, largely through antagonistic pathways, activated through binding to high-affinity calcitonin receptors (reviewed in Naot et al.) [233]. Although clearly bioactive, the absolute physiological relevance of calcitonin in mammals is the subject of debate (reviewed in Hirsch et al.) [234].

Effects of Vitamin D on Muscle

The unequivocal demonstration of the direct effects of vitamin D on muscle followed the identification and cloning of the VDR from skeletal muscle cell lines [235–237]. The genomic effects include influences on muscle calcium uptake, phosphate transport across the cell membrane, and muscle cell proliferation and/or differentiation [238]. Calcium uptake is mediated through altered activity of calcium pumps, both within the sarcoplasmic reticulum and sarcolemma, changing the contractile properties of muscle [239]. Activation of the nuclear VDR results in the increased production of certain proteins, including calcium-binding proteins, which include calbindin and calmodulin [240, 241].

Further actions of vitamin D on muscle occur rapidly – within minutes – and are not antagonized by RNA/protein synthesis inhibitors, suggesting nongenomic effects. The underlying molecular pathways are not clear, but may involve the modulation of calcium entry into the cell at the membrane, G protein-mediated activation of phospholipase C, and/or the activation of mitogen-activated protein kinase (MAPK) signaling pathways [242, 243].

PTH stimulates protein degradation in skeletal muscle [244]. The PTH effect is partially mediated by elevated intracellular calcium which may result from activation of calcium channels by cAMP and a PTH-induced increase in mitochondrial calcium permeability [245]. The increased intracellular calcium may in turn activate intracellular proteases, and cAMP-dependent phosphorylation of the inhibitory subunit of troponin modulates the calcium sensitivity of the calcium-binding subunit of the protein [50].

Primary and Secondary Hyperparathyroidism and Metabolic Bone Disease

The muscle disorders associated with primary and secondary hyperparathyroidism and metabolic bone disease are grouped together because of their clinical similarities, although the clinical and pathological characteristics of these disorders are described separately to emphasize variations in their presentation, with the overall etiology and pathogenesis considered together [50].

Pathology

This category of muscle disorders results from elevations in parathyroid hormone (PTH) (primary and secondary hyperparathyroidism) and impairment of vitamin D activity (secondary hyperparathyroidism and osteomalacia). As would be expected, the similarity of the muscle disorders associated with primary hyperparathyroidism, uremia, and osteomalacia is likely to reflect the parallel and overlapping effects of PTH excess and vitamin D deficiency on muscle metabolism. Animal models have confirmed that isolated Vitamin D deficiency leads to muscle wasting, with impaired muscle force generation, and delayed relaxation. The extent of weakness does not correlate with electrolyte (calcium or phosphate) levels, and dietary replacement of these agents does not correct the disorder [246]. Excitation-contraction coupling is deranged, with calcium uptake ability and storage capacity of mitochondria impaired [247], along with depressed myofibrillar ATPase activity [248]. Muscle wasting may be a consequence of overall reduced protein synthesis. The close similarity of clinical presentations is mirrored in animal models of both uremia and vitamin D deficiency [247].

Studies in human subjects are generally more complex to perform, and results occasionally contradictory. Many have been performed in patients with renal failure, who are unable to convert 25-hydroxyvitamin D_3 to the bioactive 1,25-hydroxyvitamin D_3 [229]. Muscular weakness and other less specific musculoskeletal symptoms including aches and cramps are well-recognized features of patients with chronic renal failure [249], but the underlying pathogenesis is likely to be multifactorial. Muscle biopsies of patients with renal failure demonstrate abnormalities of muscle energy metabolism which are partially due to alterations in the function of key enzymes of oxidative and glycolytic metabolism [250].

Early small-scale studies suggested that vitamin D supplementation of patients with renal failure led to an improvement in muscle strength, including an improvement of EMG parameters, without causing significant changes in calcium or phosphate levels [251].

Primary Hyperparathyroidism

Primary hyperparathyroidism is a common endocrine disorder, typically resulting from a benign parathyroid adenoma (in 80 % of cases) or more rarely from multiglandular involvement or parathyroid carcinoma. Women are more

commonly affected than men (with a ratio of 3:1), with a peak incidence of diagnosis between the ages of 50 and 60 years. When severe, the resultant hypercalcemic state leads to a wide range of systemic symptoms classically associated with the condition, including polyuria, constipation, nausea, and kidney stones. Hypercalcemia is frequently associated with depressed serum phosphate levels, elevated serum alkaline phosphatase levels, and hypercalciuria. Urinary creatine excretion is elevated, but serum levels of CK and aldolase are usually normal [252]. Osteopenia may be manifest on bone radiographs and may even suggest the diagnosis.

In modern clinical practice, patients are frequently asymptomatic at diagnosis, with the diagnosis made following a screening serum calcium level for an unrelated problem [253]. Relatively mild and/or nonspecific neuromuscular symptoms, particularly muscle cramps, weakness, and fatigability, are commonly reported by patients with mild primary hyperparathyroidism, but overt signs of muscle disease are far less common [252]. When evident, examination may reveal symmetric proximal muscle weakness and atrophy, and severely affected patients may develop a waddling gait or be unable to walk. Of note, the severity of the clinical weakness does not usually correlate with the magnitude of the electrolyte disturbance. Bulbar and sphincter function are usually spared.

EMG studies in patients with primary hyperparathyroidism frequently show decreased motor unit potential size and increased frequency of polyphasic potentials without spontaneous activity [254]. A further report found that three patients with severe proximal weakness and bulbar involvement had fasciculations and a reduction in the number of recruitable motor unit potentials with normal nerve conduction velocities, suggesting an etiological link to amyotrophic lateral sclerosis (ALS) [255]. However, a subsequent study did not support a relationship, as parathyroidectomy did not alter the clinical course of the underlying ALS [256]. Histological analysis of muscle from patients with hyperparathyroidism generally found no abnormalities, but type 2 fiber grouping with internal nuclei and small group atrophy may be observed [257]. Others report type 2 fiber atrophy, focal areas of atrophy with polymorphonuclear cell infiltrates, vacuolar degeneration, and thickening of arteriolar and endomysial basement membranes with accumulation of glycoproteins [258].

Treatment for primary hyperparathyroidism via parathyroidectomy alleviates symptoms and improves strength [259, 260].

Secondary Hyperparathyroidism: Renal Failure

Patients with chronic renal failure frequently develop secondary hyperparathyroidism with a myopathy that resembles that seen in primary hyperparathyroidism [261]. Initially, lower extremity weakness predominates, but with time all four limbs are affected. Parathyroid hormone excess, uremic toxins, vitamin D deficiency, aluminum toxicity, and carnitine deficiency have all been implicated in the underlying pathogenesis of the myopathy.

Diagnostic tests find electrolyte abnormalities consistent with the degree of underlying renal failure. Hypocalcemia is found, resulting from poor vitamin D production and subsequent phosphate retention by the failed kidneys. Serum levels of CK and aldolase are usually normal [262].

Typically, electrodiagnostic studies show myopathic changes, but patients also frequently have diminished motor nerve conduction velocities and signs of distal sensory neuropathy [261, 263]. The usual form of uremic myopathy is associated with type 2 fiber atrophy. Ultrastructural studies show nonspecific changes of Z-line degeneration and vacuolization [261]. Electron microscopy reveals increased lipofuscin located mostly beneath the cell membrane [262]. The myopathy is characterized by calcium deposits in necrotic muscle, suggesting ischemia and arteriolar and capillary stenosis caused by medial calcification and fibrous intimal proliferation. The vessel changes may represent an extreme, as capillary and arteriolar basement membrane thickening and calcium deposition occur in patients without myoglobinuria or elevated serum CK levels [261].

Treatment of the underlying deficit with vitamin D replacement generally reduces the incidence of myopathy, and renal transplantation may lead to complete resolution of myopathic symptoms.

Osteomalacia

Myopathy may occur in osteomalacia caused by dietary deficiency, malabsorption of vitamin D, or abnormal vitamin D metabolism-associated renal tubular acidosis or anticonvulsant use. Myopathic findings may be present prior to the characteristic bony changes of osteomalacia, which can confuse the diagnosis. Boys with X-linked type 1 hypophosphatemic rickets do not develop weakness, as vitamin D metabolism is normal in this condition, but the kidney does not respond adequately, leading to renal phosphate wasting [50].

Clinical Presentations, Evaluation, Diagnosis, and Prognosis

A significant proportion of patients with osteomalacia complain of weakness or myalgia, with the majority experiencing a gradual onset of proximal weakness [247, 264]. The frequently nonspecific presentation, with generalized malaise, fatigue, myalgia, and general weakness, can overlap with a wide range of other conditions, including fibromyalgia, polymyalgia rheumatica, and psychiatric disorders. Patients with osteomalacia have elevated serum calcium and phosphate levels, with increased or normal PTH levels [247].

Serum alkaline phosphatase is often increased, but not invariably, and serum levels of vitamin D are required to confirm the diagnosis [264].

Needle EMG shows short duration, low amplitude, and polyphasic motor unit potentials [265]. In contrast, the light and electron microscopic findings are usually minimal, but may show type 2 fiber atrophy, with fatty infiltration, interstitial fibrosis, variation in fiber size, proliferation of fiber nuclei, loss of myofibrils, and Z-line thickening [266]. The myopathy of osteomalacia improves with vitamin D replacement but may take more than 6 months [264].

Hypoparathyroidism

Hypoparathyroidism is most commonly iatrogenic, resulting from surgical excision of the parathyroid glands or occasionally from vascular injury. Idiopathic hypoparathyroidism also exists as an isolated entity, in association with thymic agenesis and wide range of other systemic abnormalities, such as DiGeorge syndrome, or as part of familial condition associated with deficiency of adrenal, thyroid, and gonadal function [267, 268]. Pseudohypoparathyroidism is characterized by signs of hypoparathyroidism in association with distinctive skeletal anomalies and, frequently, intellectual impairment. PTH levels are normal or elevated in pseudohypoparathyroidism as the disorder results from a defective cellular response to PTH. A mutation of a guanyl nucleotide-binding protein gene is a cause of some forms of pseudohypoparathyroidism [269]. In both pseudo- and true hypoparathyroidism, patients are hypomagnesemic, with associated muscle tetany [270] and occasional signs of chronic myopathy.

The nerve axon hyperexcitability is caused by electrolyte disturbance, with decreased serum free calcium and magnesium concentrations. The voltage-sensitive channels in nerve are controlled by the transmembrane electric field. Depolarization of the cell decreases the electric field, which triggers the opening of voltage-sensitive sodium channels. Decreased free serum calcium will reduce normal amount of surface charge screening, which will reduce transmembrane electric field just as depolarization does. Therefore, hypocalcemia or hypomagnesemia reduces the action potential threshold without changing transmembrane potential.

Tetany

Hypocalcemia and hypomagnesemia produce hyperexcitability of nerve fibers with spontaneous and repetitive discharges, which results in perioral and distal sensory disturbance, carpopedal spasm (extension and adduction of the fingers with associated flexion of metacarpophalangeal joints), and diffuse muscle cramping [270]. Latent tetany can be provoked through hyperventilation, by tapping the facial muscles (Chvostek sign) or by occluding venous return from an arm resulting in carpopedal spasm (Trousseau sign). Ischemia lowers the threshold of nerve fibers and combined with hypocalcemia could account for Trousseau signs [50]. Normocalcemic tetany may occur as a familial disorder [271]. Alkalosis in dialysis patients and postoperative hypocalcemia after thyroidectomy are common causes and may be prevented with vitamin D and calcium supplementation [272].

The treatment of choice is a slow intravenous infusion of calcium, which can be administered as a slow intravenous push with cardiac and blood pressure monitoring for severely deficient cases. Hypomagnesemia should also be treated, with dose reductions in the presence of renal impairment. Chronic treatment of hypocalcemia requires dietary supplement of calcium and vitamin D. After several weeks, treatment doses are adjusted to achieve a physiological blood calcium level. If the patient does not initially respond to vitamin D_2 supplementation, then 1- or 1,25-hydroxyvitamin D_3 may be tried to circumvent impaired vitamin D activation.

Chronic Myopathy in Hypoparathyroidism

The diagnosis of hypoparathyroidism is usually straightforward, manifest with reduced serum calcium, phosphate, and barely detectable serum parathyroid levels. Myopathy rarely complicates hypoparathyroidism. Weakness and CK elevation may be relatively mild, and muscle biopsy may be normal or show atrophic fibers [273]. The condition partially resolves with calcium and vitamin D treatment, which correct underlying electrolyte abnormalities [274]. A similar syndrome is described in patients with pseudohypoparathyroidism who have elevated serum CK and LDH activity without weakness.

Muscle biopsies have demonstrated diminished glycogen phosphorylase activation [275]. Serum levels of muscle-associated enzymes normalized with calcium and vitamin D_2 treatment. The relation between these syndromes and hypoparathyroidism or pseudohypoparathyroidism is unclear. Some patients with mitochondrial myopathy have associated hypoparathyroidism [276].

Toxic Myopathies

68

Ralph W. Kuncl and Gary J. Romano

Introduction

Toxic myopathies continue to be underrecognized clinically even while the number of substances identified as myotoxic increases. One reason is that the literature continues to be crowded with uncritical case reports of toxic "myopathy" that are often nondescript syndromes of a sense of asthenia, fatigue, and/or myalgia in which myopathy is inadequately documented [1]. Toxic myopathies are defined as toxic disorders where the primary clinical feature is weakness and there is compelling morphological, electrophysiological, serum enzymological, or metabolic evidence of muscle disease [2].

Drugs and toxins may cause muscle damage in a variety of ways. They may *directly* injure muscle fibers, as in toxic necrotizing myopathies (Table 68.1 and Fig. 68.1). Alternatively, myotoxic effects may occur *indirectly* through electrolyte derangements (e.g., ethanol), muscle ischemia, excessive muscle activity (e.g., neuroleptics), lysosomal or mitochondrial damage, or immune mechanisms. The effects of muscle toxins may be generalized affecting multiple muscle groups or focal involving only those muscles which were injected with an offending agent. Lastly, the toxic effects on muscle may occur acutely after ingestion or may require chronic exposure.

Table 68.1 Drugs, neutriceuticals, and foods causing necrotizing myopathies

Statins (HMG-CoA reductase inhibitors)[a]
Red yeast rice; Zhibitai; monacolin K
Fibric acid derivatives
Zidovudine
Clevudine
Ethanol
Emetine
Organophosphates
Epsilon-aminocaproic acid
Etretinate
Procainamide
Bupivacaine
Edible mushrooms

[a]Including atorvastatin (Lipitor®), cerivastatin (Baycol®), fluvastatin (Lescol®), lovastatin (Mevacor®), pitavastatin (Livalo®), pravastatin (Pravachol®), rosuvastatin (Crestor®), and simvastatin (Zocor®)

General Principles

Diagnostic Principles

The diagnosis of toxic myopathy is based on key principles:

1. Drug challenge or de-challenge alone does not make a drug-induced myopathy "probable." The symptoms or signs must follow the administration of drug, usually by weeks to months; they must decline or resolve within weeks when the drug is removed or when the dose is decreased; they should recur when/if the drug is rechallenged and monitored. When weakness is the outcome measure, symptoms and signs in necrotizing and vacuolar myopathies resolve within 5–7 weeks of drug discontinuation, following the time course of muscle fiber regeneration.
2. Temporal association or correlation with drug usage, no matter how tempting, does not imply causation. The connection between the drug and the symptom must make pathophysiological sense.

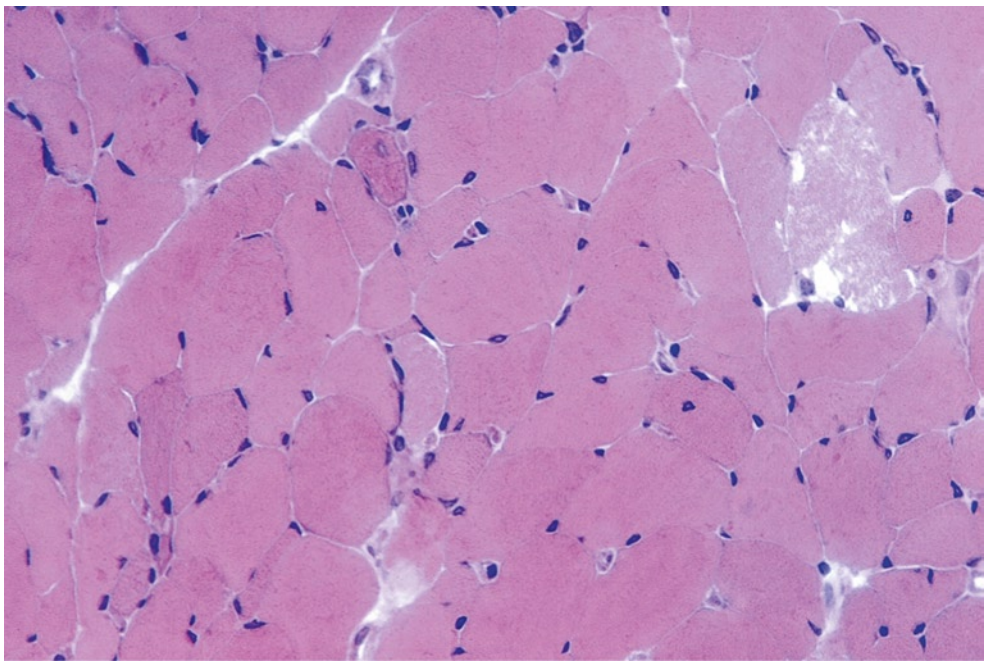

Fig. 68.1 Necrotizing myopathy. Scattered necrotic and regenerating fibers, as seen in HMG-CoA reductase myopathy and other necrotizing myopathies (see text)

3. The determination of creatine kinase (CK) alone, without muscle biopsy, is often insufficient for diagnosis.
4. Toxic myopathy is often a diagnosis of exclusion. For that reason, biopsy is often useful and necessarily so if the differential diagnoses are structurally characteristic or unique (e.g., colchicine, chloroquine, zidovudine).

Differential Diagnosis

In most case series, the most common cause of elevated CK when drug effects are excluded is hypothyroidism. The most common causes of pain in presumed toxic myopathies turn out to be osteoarthritis and cervical or lumbar spondylotic radiculopathy. Cramps and muscle pain are far more common in denervating disorders than in primary myopathies (excluding metabolic disorders of glycogen and lipid metabolism). The differential diagnosis of any suspected toxic myopathy should include consideration of hypothyroidism, hyperthyroidism, hyperparathyroidism, limb girdle muscle dystrophy, the manifesting carrier state of Becker or Duchenne muscular dystrophy, polymyositis, dermatomyositis, inclusion body myositis, and steroid-induced muscle atrophy, all of which have obviously different therapeutic implications.

Creatine Kinase Basics

Vigorous exercise, bruises, needle electromyography (EMG), and intramuscular injections increase serum CK activity in the first 12–48 h. Inactivity decreases the CK level, no matter what the cause of CK elevation is or in fact whether the baseline CK is normal, by one-third to one-half within 3 days. After an insult is removed that caused the CK to rise – even in widespread rhabdomyolysis – the CK declines with a half-life of about 24 h. Therefore, if the CK level is the outcome measure, it nearly always declines by >95 % or normalizes within 5–7 days (i.e., approximately 5 half-lives of CK clearance) (Fig. 68.2). For example, in a reported series of 13 severe statin-induced necrotizing toxic myopathies (7 with acute rhabdomyolysis and 5 of those with myoglobinuria), 1 met the 95 % CK reduction criterion by 3 days, 11 by 5–7 days, and 1 by 8 days [2]. Therefore, a conservative criterion for resolution of a typical necrotizing toxic myopathy is that a 95 % reduction of the CK level occurs 95 % of the time within 1 week of discontinuation of drug.

Terminology Confusion

Myositis and *myopathy* are not synonymous. Muscle *necrosis* is the death of many cells and always secondarily involves inflammatory cells, primarily macrophages, engulfing the already dead myocytes. The process is segmental in the mature myofiber. By contrast, the term myositis denotes an inflammatory myopathy characterized by *non-necrotic* muscle cells that are surrounded and invaded by autoaggressive T lymphocytes and macrophages. This so-called primary inflammation must be observed to make the diagnosis with certainty, although it is usually accompanied by active necrosis as well. This would be a particular distinction to make, with therapeutic importance, in the differentiation of HIV-associated inflammatory myopathy from zidovudine toxic myopathy. Toxic myopathies are most often purely

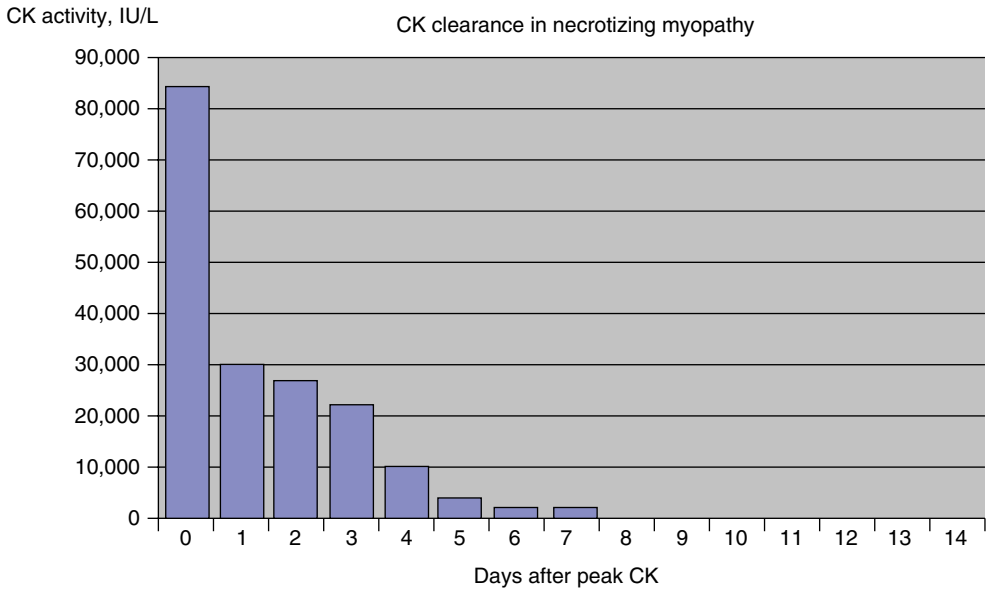

Fig. 68.2 Creatine kinase clearance in necrotizing myopathy. A 68-year-old woman with hypercholesterolemia, hypertension, and obesity was hospitalized with statin-induced acute rhabdomyolysis without myoglobinuria. The peak CK of 84,500 IU/L occurred on the day of admission, at which time the drug was immediately discontinued. By day 5 after discontinuation, the CK had decreased to 3,746 (a 96 % reduction), and it was in the normal range when next tested on day 14. At presentation, she had difficulty even rising from a chair or bed and required assistance to walk. She recovered uneventfully. Within only 3–4 days, she had noticeable improvement in muscle strength and gait. Within 6 days, she was making transfers from chair to bed or standing with minimal assistance. Within 2 weeks, muscle strength testing was markedly improved and she had only mild residual hip flexor weakness but full recovery of the extensors, adductors, abductors, and external rotators of the hips and of all distal leg muscles. At that time, she could walk 250 ft unassisted, could climb 18 stairs, and was fully independent in activities of daily living. She was not further examined until week 11, when her muscle exam was completely normal (Reprinted from Kuncl [2], with permission from Lippincott Williams & Wilkins)

necrotizing or vacuolar. Vacuolar myopathies are so named because the *earliest* pathological change is vacuolation in the absence of necrosis (examples are the small lysosomal accumulations in chloroquine myopathy and the large autophagic vacuole accumulation in colchicine myopathy).

The term *rhabdomyolysis* describes a necrotizing myopathy that is both widespread and fulminantly *acute*, important descriptors that many trialists have ignored. It is often painful, perhaps because of interstitial edema stretching the fascial planes. When it is severe enough to cause the CK to rise to the range of ~50,000 IU/L (or more than about 100 times the upper limit of normal), it is associated with myoglobinuria and pigmenturia, which can cause acute renal failure and death. Myoglobin can be measured in the urine by sensitive immunoassays (as opposed to the orthotolidine dipstick test) whenever the CK is elevated into the thousands; therefore, it is no more significant than the CK level itself and does not in and of itself signal dangerous myoglobinuric renal failure. Rhabdomyolysis is not therefore synonymous with myoglobinuria or necrotizing myopathy. A specific level of CK cannot define the pathology. For example, some clinical trials of statins, for the mere convenience of not mistaking trivial CK elevations on infrequent venipunctures, have operationally defined CK elevations greater than tenfold as myopathy or even as rhabdomyolysis. This is absurd, because the CK may be elevated manyfold by exercise or hypothyroidism or sarcolemmal leakage in muscular dystrophies without the process of necrosis. A host of meta-analyses continue the fiction, combining misleading reports of placebo-level myalgia with rhabdomyolysis, confusing the real picture [3]. Not making these several distinctions can lead to diagnostic confusion and mismanagement.

Lipid-Lowering Agent-Related Myopathies

Necrotizing myopathy can occur in patients treated with a variety of lipid-lowering agents, including 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) and fibric acid derivatives.

Necrotizing Myopathies Induced by Statins

HMG-CoA reductase inhibitors, or "statins," are the mainstay of lipid-lowering therapeutics and are one of the safest and most frequently prescribed classes of drugs in the world. The microsomal enzyme 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG-CoA reductase) catalyzes the conversion of HMG-CoA to mevalonic acid, an important step in

cholesterol biosynthesis. A number of fungus-derived inhibitors of this enzyme have been developed for the treatment of hypercholesterolemia, including lovastatin (Mevacor®), pravastatin (Pravachol®), simvastatin (Zocor®), fluvastatin (Lescol®), atorvastatin (Lipitor®), cerivastatin (Baycol®), and more recently rosuvastatin (Crestor®) and pitavastatin (Livalo®). These inhibitors decrease the synthesis of mevalonic acid which is a precursor to cholesterol, ubiquinone, and dolichol.

Clinical Presentation

HMG-CoA reductase inhibitors may cause a mildly elevated CK shortly after treatment is first begun, but this rarely progresses to a necrotizing myopathy in patients who are not taking other predisposing medications. When necrotizing myopathy does occur, patients typically present with the subacute or chronic onset of proximal muscle weakness, with or without myalgia or muscle tenderness. But it is important to note that musculoskeletal aches and pains are common adverse events with *many* drugs, are seen frequently in most placebo groups, and are therefore not likely to be causally relevant. Serum CK is virtually always elevated, but the degree of CK elevation does not define the pathology. Far rarer, fulminant widespread necrosis – that is, rhabdomyolysis – may be diagnosed when CK is greatly elevated in the range of >50,000, a range at which myoglobinuria (pigmenturia and an orthotolidine-positive dipstick test in urine that is not explained by hematuria) may occur and elevated serum creatinine may indicate acute renal failure. EMG of involved muscles may reveal abnormal spontaneous activity (positive sharp waves and fibrillation potentials) and occasionally myotonic discharges. When myopathy occurs acutely, motor unit morphology is normal, but reductions in motor unit action potential (MUAP) duration and amplitude occur in weaker patients with a more insidious course. In that case, the EMG is indistinguishable from that of polymyositis. Muscle biopsies show myofiber necrosis and regeneration.

Myopathy is clearly dose related and usually takes months to develop [4, 5]. Recovery, even from rhabdomyolysis, is complete and rapid, within days or weeks [6]. Frequent talk of prolonged statin myotoxicity comes from noncritical case reports of mainly pain rather than actual myopathy. Statins are not stored and do not have prolonged effects (see below). Two small series have recently been reported in which necrotizing myopathy occurring during statin therapy did not respond to drug discontinuation, but did improve after treatment with immunosuppressive agents [7, 8]. While these cases of "immune-mediated necrotizing myopathy" cannot be definitively attributed to statins because of ubiquitous use of those drugs, analysis of a parallel cohort found that statin use appeared significantly more common in patients with immune-mediated necrotizing myopathy than it was in patients with pathologically confirmed polymyositis, dermatomyositis, or inclusion body myositis [7].

Statin myopathies are greatly overdiagnosed; common mistakes are improper interpretation of the referred musculoskeletal pain of arthritis, radiculopathy- and denervation-induced cramps, or, less commonly, the symptoms of pain in other inflammatory or hypothyroid myopathies. The diagnosis of toxic myopathy is by exclusion of its other mimics, not merely by the association with statins. This can be illustrated by the consecutive series of the last 36 referred cases one of us (RK) has reviewed of *presumed* statin-induced myopathy (based on a combination of statin use with either or both of CK elevation or muscle pain), in which the ultimate diagnoses were based on neuromuscular examinations, on electromyography and muscle biopsy when done, and on whether the CK curve obeyed the principles outlined above (Table 68.2).

It is interesting that only a third of these cases suspected to be statin myopathy actually turned out to be so. Other authors have estimated from large controlled cohort studies that two-thirds (frequency 327 of 480) of all suspected statin myopathies are not attributable to statins but are non-myopathic, mistaken pain diagnoses [9, 10]. In clinical trials, the minor muscle pains reported, often on the order of 5 % of subjects, are equally present in statin and placebo groups [9]. Given all the facts above, we strongly recommend baseline measurement of CK levels (excluding exercise), because a knowledge of asymptomatic baseline elevations helps determine whether the statin is responsible for any later symptom or CK elevation. This is supported by at least one clinical advisory group [11].

Epidemiology

The precise frequency of human statin myotoxicity is unknown, as the literature is fraught with errors of attribution of myalgia as toxicity (see above), biased case ascertainment [12], missing the significance of CK elevations that are less than tenfold elevated (which contains most of the cases of statin myopathy), and operational definitions of myotoxicity that are useful for clinical trials but useless in clinical practice or pathology. It is safe to say that myopathy is rare, on the order of 1 in 10,000–20,000 person-years, and that rhabdomyolysis is far rarer, on the order of 1 in 100,000 person-years, according to meta-analytical data summarizing those clinical trials that use the fraught operational definitions [9]. A much more informative epidemiologic approach was a 6-year cohort study that concluded the risk of myopathy was greatest for the fibrates (relative risk ratio 42) than for statins (relative risk ratio 7.6), for which the risk is 2.3 per 100,000 [10]. The use of the FDA MedWatch Adverse Event Reporting System may underestimate the incidence of hospitalized rhabdomyolysis by some 70–95 % [13] and is fraught with the reporting biases of secular trend,

Table 68.2 Final diagnosis in patients referred for presumed statin myopathy

Final neuromuscular or musculoskeletal diagnosis	*N*		
Statin-induced myopathy	13		
Statin-induced acute rhabdomyolysis		7[a]	
With myoglobinuria			5
Without myoglobinuria			2
Statin-induced chronic necrotizing myopathy		6[b]	
Osteoarthritis with radiculopathy from degenerative cervical or lumbar spine disease	11		
Chronic elevated CK of unknown cause[c]	5		
Polymyositis (1) or dermatomyositis (1)	2		
Rheumatoid arthritis (without inflammatory myopathy)	1		
Hypothyroidism	1		
Exercise-induced CK elevation	1		
Total body pain syndrome	1		
Chronic depression alone	1		
Total	36		

In a consecutive series of 36 patients referred with the presumptive diagnosis of statin-induced myotoxicity, the ultimate diagnosis was based on neuromuscular examinations, EMG and muscle biopsy when done, and whether the CK curve obeyed the principles outlined in the text above

[a]Due to drug interaction with gemfibrozil in 4 of the 7

[b]Due to drug interaction with gemfibrozil in 2 of the 6

[c]Hypothyroidism and other known causes of elevated CK excluded

the newest drug reporting effect, product withdrawals effects, and publicity [13, 14]. A better approach was a side-by-side comparison of 26,562 statin-only subjects against 35,046 placebo subjects comprising 301,372 person-years of follow-up in a meta-analysis of prospective randomized, placebo-controlled trials of statins [15]. The adverse myotoxic effects turn out to be even rarer than previously thought [15], usually minor, but easily recognizable and reversible even when serious. It is therefore safe to say that these drugs have very high safety windows [16], which make them far safer than aspirin by at least an order of magnitude but nevertheless capable of causing severe and even fatal acute necrotizing myopathy.

Mechanistic Hypotheses

The exact biochemical pathophysiological mechanisms of statin myopathy are not fully known, but progress has been made. The most prominent hypotheses being tested relate to the degree of lipophilicity, effects on ion channels in sarcolemma, intracellular calcium homeostasis, potential deficiency of ubiquinone, primary mitochondrial membrane pathology, organic anion transporters, and the catchall category of energy depletion [3, 17]. Statins vary in their potential myotoxicity, but correlational studies among them have not been revealing of the precise incriminating mechanisms. A side-by-side meta-analysis concluded that risk of myotoxicity varied in prospective randomized, placebo-controlled trials of various statins in this order, from most to least: atorvastatin > [pravastatin = simvastatin = lovastatin] > fluvastatin [15]. This did not correlate well with lipophilicity/hydrophilicity partition coefficients or with cytochrome P450 isoform metabolism. Of all the reported pharmacokinetic and pharmacodynamic characteristics of the statins [18], the rank order above is most in line with the fact that atorvastatin has the longest elimination half-life (15–30 h) and can accumulate slightly with daily dosing, whereas fluvastatin has the shortest (0.5–2.3 h). The presumed lipophilicity risk that was once hypothesized based on in vitro data [19] is probably an artifact of in vitro studies of L6 myoblasts, satellite cells, and fibroblasts, which cannot reliably transport hydrophilic statins like pravastatin [20]. Mechanisms of statin absorption, distribution, protein binding, and excretion with short elimination half-lives all predict non-accumulating steady-state concentrations with once daily dosing; therefore, the pharmacokinetic and pharmacodynamic data are incompatible with theories of long-lasting myotoxicity (see above) [18].

It is clear that the myotoxicity is *not* secondary merely to lowering of plasma cholesterol levels or inhibition of cholesterol synthesis by other means, such as inhibition of squalene synthesis [21]. Rather, myotoxicity occurs within the muscle fiber itself and is a more distal effect of HMG-CoA reductase inhibition and the subsequent reduction of the downstream cascades that lower mevalonate, ubiquinone (coenzyme Q10), the isoprenoids farnesol and geranylgeraniol, and squalene [16–18, 22].

Statins have been hypothesized to impair muscle mitochondrial functions secondarily as the result of impaired isoprenylation of ubiquinone. Depletion of isoprenoids has also been invoked to contribute to statin myopathy through suppression of small GTPases such as Rab, which are responsible for trafficking of proteins from the endoplasmic reticulum to Golgi [23]. In in vitro studies supplementation of downstream products like mevalonate, farnesol, and geranylgeraniol mitigated myotoxicity [24], offering rather strong support for the idea that statin myotoxicity, at least for lovastatin and pravastatin, reduced the posttranslational modification by geranylgeraniol of low-molecular-weight proteins that might have regulatory consequences [24]. However, it is a giant step to the in vivo situation in humans. At present the isoprenylation theory remains unproven, and the ubiquinone hypothesis is unsupported, because decreased serum concentrations of ubiquinone did not cause corresponding decreases in muscle tissue ubiquinone during short-term treatment with simvastatin in humans [25, 26]. Coenzyme Q10 supplementation trials have most often been poorly designed, underpowered, or uncontrolled and have not shown any convincing effect [27].

Animal Models

In the rat, the most heavily glycolytic, fast-twitch myofibers (type IIb) are preferentially affected early by necrosis in lovastatin, cerivastatin, and simvastatin [17, 28], whereas the mitochondrial-rich oxidative, slow-twitch myofibers (type I) are relatively spared. Although these differences have been attributed solely to fiber-type metabolic differences, they could also relate to larger fiber diameter as a risk factor, because in the rodent, unlike the human, type II fibers are significantly larger in diameter than type I. The rodent model is well worked out and is not only dose dependent but time dependent [17]. Of course, necrosis always affects mitochondria predominantly and early because of sarcoplasmic edema, disturbance of sarcolemmal ion channels, and their function in accumulating calcium. But a primary and exclusive mitochondrial pathology for statin myopathies is not proven. The earliest ultrastructural change seen in *non-necrotic* myofibers in experimental statin myopathies has been the accumulation of intracellular membranous whirls, myeloid figures, and heterogeneous membranous vacuoles resembling subsarcolemmal autophagy [17, 28]. All such vacuoles contain both mitochondrial remnants and other membranous organelles and hence can be considered secondary effects of disturbed membrane recycling [29]. The absence of mitochondrial respiratory dysfunction after statins in rabbit muscle also suggests mitochondrial mechanisms are not primary [30]. Statin myopathy does not at all resemble the primarily mitochondrial pathology of zidovudine (see below); a single report suggesting a mitochondrial pathology in human biopsies from patients with muscle pain was a misinterpretation of normal lipid and of age-related rare ragged red fibers or COX-negative fibers at frequencies seen in control biopsies [31].

In a robust rat model of statin pathophysiology, chronic treatment in vivo with fluvastatin or atorvastatin decreased rat forearm strength and increased the resting cytosolic calcium concentrations up to 60 % in intact extensor digitorum longus muscle fibers (which are mostly glycolytic and fast-twitch) [32]. As further demonstrated in tendon-to-tendon whole myofibers, this occurred not by affecting sarcolemmal permeability but by increasing caffeine-stimulated Ca^{2+} release from SR and Ca^{2+} permeability from mitochondria via the permeability transition pore. Increased free sarcoplasmic intracellular calcium levels of this magnitude are known to disrupt excitation-contraction coupling and stimulate a host of enzymes, including phospholipase A_2, protein kinase C, and calpains, as further elaborated in an extended review and hypothesis [33].

Genetic Susceptibility

The most definitive pharmacogenetic study used a genome-wide association examination of 300,000 markers in 85 patients who had statin myopathy (defined conservatively as sustained high CK levels above three times the upper limit of normal but five times the baseline level irrespective of muscle symptoms or CK above ten times the upper limit of normal with muscle weakness) from a single clinical trial of high-dose simvastatin [4]. It showed a strong association between instances of simvastatin myopathy and common variants in a single gene, *SLCO1B1*, which encodes the organic anion-transporting polypeptide OATP1B1 that regulates the hepatic uptake of statins [4]. More than 60 % of patients with statin myopathy in this series had the variant single nucleotide polymorphism in the C allele. This worldwide collaborative effort is a signal advance in pharmacogenetics, following upon a series of provocative earlier reports of polymorphisms in solute transporter genes affecting hepatic uptake of statins and other outcomes, but the large collaborative study was well powered and took advantage of a unique clinical trial database to find an unequivocal association [34]. More recently the STRENGTH trial [35] found an association between the SLCO1B1 risk allele and statin "adverse events." Although the primary composite endpoint was quite nonspecific (including discontinuation for *any* adverse event at all, or myalgia or muscle cramps irrespective of CK, or CK elevated greater than three times the upper limit of normal), it is notable that a secondary endpoint specifying musculoskeletal side effects or muscle symptoms alone also showed a statistically significant association.

The SEARCH trial found that severe acute myopathy (narrowly defined as CK greater than 10 times upper limit of normal) occurred 52 times more frequently with high-dose (80 mg) simvastatin than low-dose (20 mg), and such severe myopathy was most likely to occur in the first year of use, presumably because myopathy tends to occur early in patients at risk because they carry the SLCO1B1 variants [4, 5].

Other studies that have hypothesized [36] or purported to find occasional single nucleotide polymorphisms in candidate genes for cytochrome P450 isoforms were unconvincing and confounded by different statin regimens, other concomitant drugs, and the lack of statistical correction for multiple comparisons in the large numbers of candidate genes and single nucleotide polymorphisms that were examined [reviewed in 4, 37, 38]; they were not confirmed by the above genome-wide study [4]. Other disease-causing mutations or carrier states for McArdle disease, carnitine palmitoyltransferase II deficiency, coenzyme Q metabolism, and others [37] seem likely merely to have been discovered as a bystander effect of increased vigilance in statin trials and in selected series in which diagnosis of statin myopathy was less rigorous.

Given that statins differ with regard to their dependence on ion transporters and other metabolic enzymes, it stands to reason that genetic variations predictive of myopathy will likely differ across the statins. Until our understanding of the biology and these genetic risk factors is more complete, it

will not be warranted or cost effective to perform genetic screens on all patients before starting statin therapy. However, with future advances in our understanding of statin biology and the declining costs of genotyping, it will someday be feasible to use genetic markers to guide the personalized use of statins for each patient in order to both optimize lipid-lowering effects and minimize the risk of myopathy.

Drug Interactions

Drug interactions are key concerns for physicians prescribing statins. Statins are capable of causing necrotizing myopathy by themselves, but the vast majority of cases of rhabdomyolysis are caused by drug interactions with fibrates, macrolide antibiotics, azole antifungals, and cyclosporine [39] (Table 68.3). In a comprehensive review of statin rhabdomyolysis, 59 of 74 cases were caused by drug interactions, and 23 of those were attributable to fibrates, most commonly gemfibrozil [39]. The interaction with fibrates may be merely additive with statins, because although theoretically fibrates can impair liver function and decrease hepatic extraction of statins, thus raising plasma drug levels, actual trials of lovastatin with gemfibrozil in combination did not find elevated statin levels, indicating that a pharmacokinetic interaction is unlikely but additivity occurs [18].

The drug interactions with statins are manifold, and the pharmacokinetics and pharmacodynamics that determine them are complex [40]. An important category of drug interaction with statins comprises the long list of other drugs that share a cytochrome P450 metabolism. Lovastatin, simvastatin, and atorvastatin depend on the CYP3A4 isoform of cytochrome P450, and therefore, other drugs that compete with or inhibit that isoform will increase plasma levels of the statin and its toxicity [41]; such drugs include agents from every class, but the more common culprits are cyclosporine, erythromycin, ketoconazole, diazepam, cimetidine, diltiazem, warfarin, amiodarone, verapamil, and compounds in grapefruit juice [42]. Older-generation pravastatin and fluvastatin, or second-generation rosuvastatin and pitavastatin, which do not use the CYP3A4 isoform, represent alternatives. Given the high frequency of hyperlipidemia in transplant patients, cyclosporine represents a special case. It not only inhibits CYP3A4 but inhibits the hepatic transporter for statins, and that double whammy means all statins can interact pharmacokinetically with cyclosporine. The FDA has issued guidance and safety label changes on dose limitations for simvastatin specifying interacting drugs that are contraindicated with high-dose simvastatin based on the SEARCH trial [5].

Table 68.3 Drugs reported to increase the risk of HMG-CoA reductase inhibitor-related myopathy

Category	Drug (common name)
Most common:	
Immunomodulatory	Cyclosporine
Lipid-lowering fibrate	Gemfibrozil
Macrolide antibiotic	Erythromycin
	Azithromycin
	Clarithromycin
Azole antifungal	Itraconazole
	Ketoconazole
Less common:	
Calcium channel blocker	Mibefradil
	Diltiazem
	Verapamil
Antidepressant	Nefazodone
Anxiolytic	Diazepam
Antacid	Cimetidine
Anticoagulant	Warfarin
Antiarrhythmic	Amiodarone
Other	Grapefruit juice

Biomarkers

As outlined above, statin-induced necrotizing myopathy is often confused with nonspecific musculoskeletal symptoms, transient and self-limited myalgias occurring after initiation of statin therapy, and pain due to non-myopathic causes. This diagnostic uncertainty, coupled with the concern about rare, but potentially fatal rhabdomyolysis, often leads to an overly conservative approach to the patient who develops muscle or musculoskeletal symptoms while taking a statin. Unfortunately, the only biomarker in common use is serum creatinine kinase, which has high sensitivity but low specificity except in serious cases of rhabdomyolysis. A predictive biomarker that would allow for diagnosis of patients with the earliest stages of statin-induced necrotizing myopathy would greatly improve diagnosis and management. Such a biomarker would allow identification of patients at risk before rhabdomyolysis occurs and also obviate the need for statin discontinuation in patients whose symptoms are not due to myonecrosis. Several candidate biomarkers of skeletal muscle toxicity are under study, including troponin 1 [43], fatty acid-binding protein 3 [44], and 1- and 3-methyl histidine [45], but all of these are still in early preclinical testing and none has as yet advanced to rigorous clinical validation for statin-induced myonecrosis. An imaging biomarker that may have utility as a research tool is measurement of phosphocreatine exercise recovery kinetics using ^{31}P-magnetic resonance spectroscopy, which has been used to demonstrate prolonged metabolic recovery in patients after statin administration, indicating (secondary) impairment of mitochondrial oxidative function. However, in a very small pilot study ($N = 10$), a significant correlation with muscle symptoms was not apparent [46].

Patient Management

Management of the patient with potential statin-induced myopathy should be guided by a few basic principles: (1)

Other causes of CK elevation or muscle pain should be excluded, including especially hypothyroidism, strenuous physical activity, other necrotizing drug agents (see below), and alcohol abuse; (2) CK levels should be checked at baseline and in all patients with muscle weakness or pain; (3) in patients who are asymptomatic or have tolerable muscle symptoms and CK < 2–3-fold elevated, statin therapy may be continued or the dose reduced, and symptoms and CK levels may be used as a guide to stop or continue therapy. In patients who develop necrotizing myopathy with CK > 3–5-fold elevated, the statin should be stopped and CK monitored for the expected rapid decline of 95 % over 5–7 days. Weakness will recover within weeks. In those patients who present with acute widespread necrotizing myopathy (rhabdomyolysis) (with CK > 10 times the upper limit of normal, or >10,000 IU/L, or with elevated serum creatinine), statin therapy should always be stopped; (4) eliminating any likely interacting drug may be sufficient. (5) A decision whether and how to restart statin therapy should be guided by the severity of the injury – in those with rhabdomyolysis, the decision should be based on the risk vs. benefit for the individual patient; for less severe cases, therapy should be restarted either at a lower dose of the same statin or at an equivalent dose of a statin with lower theoretical risk of toxicity. The National Lipid Association and others have published management algorithms reflecting some of these therapeutic principles [47, 48].

A Note on *Monascus purpureus* ("Red Yeast Rice" Myopathy)

There is now growing evidence that the fungus *Monascus purpureus* is myotoxic. It grows on rice or corn silage and has been cultivated as a fermented food product in China for more than a millennium. The purplish red color of the mold gives it the common name "red yeast rice." It is commonly present in many Asian foods as a colorant or ingredient, such as in pickled tofu, red rice vinegar, Peking duck, and Chinese barbecued pork. The discovery that it contains a family of several monacolin compounds, one of which, monacolin K (the same as the active ingredient in lovastatin), inhibits HMG-CoA, and that it can lower cholesterol levels [49] has led to its use as a so-called "natural" self-administered neutriceutical in the USA. Typical of neutriceuticals, there is controversy whether it is a dietary supplement or ought to be regulated as a drug; other ingredients in red yeast rice may include several sterols, isoflavones, and monounsaturated fatty acids [50]. Currently, commercial preparations are not quality controlled or standardized as to content, dosage of active ingredients, or contaminants. The monacolin K content may be as low as 0.2 % of total product, yielding doses on the order of 10 mg in dietary sized portions. Therefore, red yeast rice should be considered like all impure plant alkaloids and derived foods and herbs – a complex mixture of unknowns. Lovastatin (monacolin K) was isolated from *Aspergillus* when originally produced as Mevacor® but is also found naturally in certain fungi like the edible, nontoxic "oyster" mushroom, *Pleurotus ostreatus*. The FDA does not actively regulate red yeast rice, but it has taken legal action, as has Merck, the original maker of lovastatin, to suppress health claims about cholesterol lowering in commercial preparations that contain significant amounts of monacolin K. The lack of FDA oversight is a barrier to the prevention of the toxicity of red yeast rice.

The traditional Chinese medicine Zhibitai contains red yeast rice equivalent to 10 mg of lovastatin plus Chinese hawthorn, oriental water plantain rhizome, and large-head atractylodes rhizome, and the mixture is claimed to have been equivalent in efficacy and safety to 10 mg of atorvastatin in an 8-week, double-blind, randomized trial, with no myopathy reported in either treatment group [51]. The question arises why one would not take lovastatin alone in pure form rather than an irrational mixture of variable purity and composition.

Organized surveillance, now sometimes coined "pharmacovigilance," revealed four cases of red yeast rice-associated myotoxicity in Italy in a 5-year period [52]. The amount of red yeast rice ingested ranged from 5 to 1,200 mg/day for 2–6 months and was ingested in the form of either *Monascus purpureus* alone or *Monascus purpureus* in a complex mixed supplement (Colestat®, Statinat Crinos®, Armolipid Plus®). The only significant manifestation was modestly elevated CK in the range of 288–401 IU/L. However, the fact that the CK resolved on de-challenge and there were no concomitant medications in these patients raises strong suspicion of myotoxicity. This likely confirms previous single reports of necrotizing myopathy or modest CK increases in more complicated but less well-founded cases [49, 53, 54]. It is tempting to conceive of this myotoxicity as merely statin myopathy, but the complexity of the mold-as-food product means any one of the ingredients of red yeast rice could be the culprit.

Fibric Acid Derivatives

Etiology and Pathogenesis

Clofibrate, bezafibrate, and fenofibrate are branched-chain fatty acid esters that are thought to act by inhibiting hepatic release of lipoproteins, particularly VLDL. The mechanism by which they cause myopathy is unknown, but the finding that these agents induce myotonic discharges in experimental animals suggests that they cause alterations in the sarcolemma [55, 56]. Gemfibrozil is another fibric acid derivative that appears to cause myopathy mainly in patients who are also taking a statin. Since these compounds are associated with disproportionate elevations of serum aminotransferases and even cytolytic hepatitis, myopathy may be

caused by fibrate-associated alteration of hepatic function leading to impaired elimination of HMG-CoA reductase inhibitor metabolites. Alternatively, the two myopathies may be merely additive.

Clinical Presentation

The necrotizing myopathy caused by fibric acid derivatives often presents as painful weakness within 2–3 months of starting the drug (or, in the case of gemfibrozil, when commencing dual therapy with a statin) and is usually associated with an elevated CK and occasionally with myoglobinuria. Needle EMG findings are similar to those associated with statins. In animal models, clofibrate causes myotonic discharges [55, 56].

Predisposing Factors

These compounds are renally excreted, and most patients who develop myopathy while taking clofibrate, bezafibrate, or fenofibrate have some degree of renal failure (the half-life of these compounds increases as much as sevenfold in uremia [57]). In addition, these drugs are bound to albumin, which explains the increased incidence of myopathy in patients with nephrotic syndrome [58]. Gemfibrozil probably does not cause myopathy when taken alone. The myotoxic interaction with statins is well established (above), but large prospective studies of patients taking gemfibrozil in combination with statins demonstrated that the risk of myopathy is relatively low (≤0.4 %) [59, 60].

Treatment/Prognosis

In all reported cases, withdrawal of fibric acid derivatives leads to a fairly rapid clinical improvement and decline in serum CK levels.

Corticosteroid-Induced Muscle Atrophy

Cushing was the first to describe proximal muscle weakness in patients with elevated endogenous glucocorticoid levels. Eventually, the syndrome of muscle weakness and wasting was recognized as a common complication of corticosteroid treatment. The term "steroid myopathy" is a misnomer, as corticosteroids cause damage by atrophy, not cell death or architectural damage.

Etiology and Pathogenesis

Glucocorticoids are lipid-soluble steroid hormones that pass freely through the cell membrane into the cytoplasm where they bind to specific receptors. Glucocorticoid receptors are members of a superfamily of hormone receptors that exert their effects by influencing nuclear gene expression. The hormone-receptor complex binds to specific DNA sequences called "glucocorticoid-response elements" to regulate transcription of steroid-responsive genes.

The mechanisms by which glucocorticoids cause muscle weakness and wasting are related to the important role these hormones play during the fasting state to mobilize amino acids from skeletal muscle protein for direct oxidation and gluconeogenesis. In conjunction with insulin, glucocorticoids mediate these changes in protein turnover through a decrease in protein synthesis and an increase in the rate of proteolysis. Lower rates of protein synthesis are due primarily to decreased rates of peptide chain initiation and primarily affect type 2 muscle fibers [61]. Starvation also leads to increased protein breakdown in muscle, and glucocorticoids are essential for this large activation of proteolysis. Of the three major proteolytic systems active in muscle (lysosomal, calcium-dependent, and the ATP-dependent protease systems), it is the ATP-dependent, ubiquitin-proteasomal pathway that is responsible for the bulk of protein breakdown during fasting. Goldberg and others [62–65] demonstrated that glucocorticoids activate this pathway in fasting and other catabolic states (cachexia, sepsis, disuse, and denervation) by enhancing the expression of components of the proteasomal pathway such as ubiquitin. Corticosteroids affect a host of other growth factors and transcription factors, including downregulation of expression of IGF-1 in muscle (thus decreasing muscle protein synthesis), downregulation of the transcription factor myogenin that plays a role in differentiation of satellite cells, and upregulation of the transforming growth factor-β superfamily member myostatin (thus negatively regulating muscle growth) (for a review of molecular pathways in steroid atrophy, see [66]).

In neural tissues, steroid hormones also have more rapid effects that are mediated through direct effects on the neuronal membrane, rather than through receptor mechanisms. However, to date, such rapid effects have not been described in muscle. Glucocorticoids also cause weakness by affecting membrane excitability and excitation-contraction coupling mechanisms. Although these mechanisms may play a role in the development of acute quadriplegic myopathy [67] (see Chap. 76), the preponderance of evidence suggests that they are not important in chronic steroid atrophy [68, 69].

Clinical Presentation

Corticosteroid atrophy may result from prolonged exposure to endogenous or exogenous elevation of corticosteroid levels. All synthetic glucocorticoids can cause it, but the incidence is higher in patients treated with the 9-alpha fluorinated corticosteroids [70]. Doses equivalent to 30 mg/day of prednisone or higher increase vulnerability, whereas significant

atrophy rarely occurs with doses of 10 mg/day or less and is less frequent with alternate-day regimen [71].

Muscle weakness and atrophy usually occur insidiously and predominantly affect proximal muscles. The legs are usually more severely affected than the arms, and bulbar muscles are usually spared. Reflexes are normal except with severe muscle weakness. Myalgia is uncommon. This pattern of weakness is indistinguishable from that of polymyositis. Patients with corticosteroid atrophy may display other clinical stigmata typical of adrenocorticoid excess including obesity, facial plethora, or easy bruisability, for example.

Differential Diagnosis

Glucocorticoids are frequently employed in the treatment of patients with inflammatory neuromuscular disorders, including the inflammatory myopathies, polymyositis, and dermatomyositis. A common diagnostic dilemma occurs when such patients experience a worsening of weakness following an initial positive response to corticosteroids. In this scenario, the physician must distinguish between steroid toxicity and refractory disease (in which case an increase in dosing may be warranted).

As in other endocrine myopathies (except hypothyroidism), the serum CK level is normal. An elevation in serum levels of muscle enzymes suggests that the inflammatory myopathy remains active, in part. The needle EMG may also be valuable. In patients with inflammatory myopathies, the presence of abnormal spontaneous activity (fibrillation potentials) suggests that muscle fiber necrosis is ongoing and that the myopathy is not responding to the current steroid dose. Finally, muscle biopsy can distinguish inflammatory myopathy from steroid atrophy if the muscle sample contains active inflammation. Nevertheless, both conditions may coexist, so that a clinical trial of corticosteroid dose reduction or switching to another immunotherapy may be required.

Evaluation

Needle EMG examination is normal except in severe cases in which type I fibers are affected. In such cases, small amplitude, short duration polyphasic MUAPs and early recruitment patterns may be seen. Insertional activity is, however, normal and fibrillation potentials are absent, owing to the lack of muscle fiber necrosis.

The primary histological finding in corticosteroid atrophy is type 2 fiber atrophy [70] (Fig. 68.3). Electron microscopy reveals loss of myofibrils, folding of basal lamina secondary to the atrophy, an increase in lipid droplets and subsarcolemmal glycogen, and enlarged mitochondria [72, 73]. In acute quadriplegic myopathy, there is a selective loss of myosin thick filaments (see Chap. 76).

Treatment/Prognosis

The most effective treatment of corticosteroid myopathy is to reduce the dose to the lowest level possible, switching to a non-fluorinated corticosteroid or to alternate-day dosing. Full recovery usually takes at least several weeks, but a dose reduction by half should noticeably affect strength within 2 weeks.

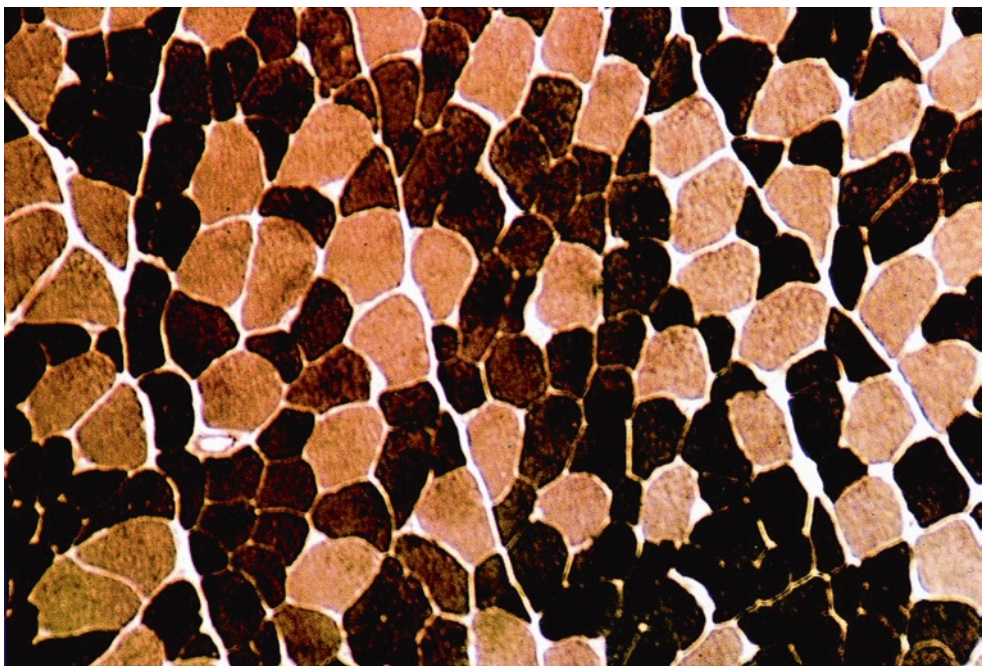

Fig. 68.3 Type II atrophy. ATPase stain at pH 9.4 showing small dark-staining type II fibers, as may be seen in corticosteroid-induced muscle atrophy

Inactivity may worsen corticosteroid myopathy [74], and exercise may be useful in lessening and treating the effects of glucocorticoids on muscle [75].

Amphiphilic Drug Myopathy

Etiology and Pathogenesis

Chloroquine, the antimalarial and antirheumatic drug, was first reported to cause a toxic myopathy in 1948. Since then it became clear that a number of drugs that share structural features with chloroquine cause similar changes in muscle and other tissues (Table 68.4). These compounds are large cationic amphiphiles. They contain both a hydrophobic region and a primary or substituted amine group which can bear a net positive charge. These properties determine how the drugs interact with cell membranes and organelles to cause disease [76].

Effects on Membranes Causing Myofiber Necrosis

The hydrophobic region allows amphiphilic drugs to partition into membranes, where they interact with anionic groups of acidic phospholipids. This may result in conformational changes and a reduction of the surface charge of the plasma membrane. Such changes may then interfere with plasmalemmal function, causing changes in the movement, fusion, permeability, transport, and receptor functions of membranes [76–78].

In skeletal muscle, these effects on surface and internal membranes are recognized as a necrotizing myopathy. In severe and acute cases, such a myopathy may be clinically indistinguishable from other necrotizing myopathies. However, more frequently these drugs cause repeated cycles of segmental necrosis that are not severe enough to present acutely. This manifests as a chronic myopathy, characterized histologically by "myopathic" grouping of longitudinally branched "subfibers" that result from cycles of segmental necrosis, followed by myoblast regeneration and incomplete myotube fusion. Drugs typical of this necrotizing/regenerating response are chlorphentermine, chlorcyclizine, triparanol, and iprindole. Interestingly, these particular amphiphilic compounds have a higher lipid solubility, lower water solubility, and higher pH in solution than are other drugs in this class. All drugs in this class are probably potential causes of necrotizing myopathy, but the clinical significance is uncertain in some instances, because the effects occur at nonpharmacological doses [76–78].

Table 68.4 Drugs causing amphiphilic drug myopathy

Effects on Lysosomes Producing Vacuolization

Non-protonized forms of these compounds are able to enter the lysosomal compartment, where they become protonized in the acidic milieu, accumulate, and form complexes with polar lipids of lysosomal contents. By disturbing lysosomal membrane stability, they can cause alkalinization of the lysosomal compartment, inhibiting lysosomal enzymes that require a low pH. These effects are manifest pathologically by the accumulation of vacuoles containing lipid and membranous material, that is, the "lipidosis" which is the hallmark of amphiphilic drugs in other tissues [76–78].

In skeletal muscle, such changes are recognized on histochemical stains as vacuolization of non-necrotic myofibers (Fig. 68.4) and at the electron microscopic level as accumulation of autophagic vacuoles containing a variety of lamellar, reticular, or myeloid lipid-containing inclusions. Interestingly, the drugs that are prone to cause abnormal autophagy have higher water solubility, lower lipid solubility, and lower pH in solution than are the other drugs in the amphiphilic class. Drugs typical of this response include chloroquine, hydroxychloroquine, and doxorubicin, and the myopathies they produce are clinically important.

Similarities to Other "Rimmed Vacuole" Myopathies

Whereas each of the above-described morphological features is not specific by itself and may be seen in many different myopathies, the combined presence of vacuoles, myeloid bodies, and necrosis is characteristic of amphiphilic drug myopathy in both humans and animals. Experimental animal models were produced using several of these compounds [77, 79, 80], the best studied of which is chloroquine myopathy. Experimental chloroquine myopathy received increased attention because of its pathological and biochemical similarities to the so-called "rimmed vacuole" myopathies, such as inclusion body myopathy and the distal myopathies. In addition to their similar morphological features, protein and mRNA levels of certain specific gene products, including tau, beta-amyloid precursor protein, and ubiquitin, are increased in vacuolated fibers in chloroquine myopathy as well as the other "rimmed vacuole" myopathies [81–87]. Yet the two are not pathologically identical, since none of the tubulofilamentous inclusions seen in most rimmed vacuole myopathies are present in chloroquine myopathy. Nevertheless, chloroquine myopathy may prove to be a useful experimental model for the study of the pathogenesis of inclusion body myopathy

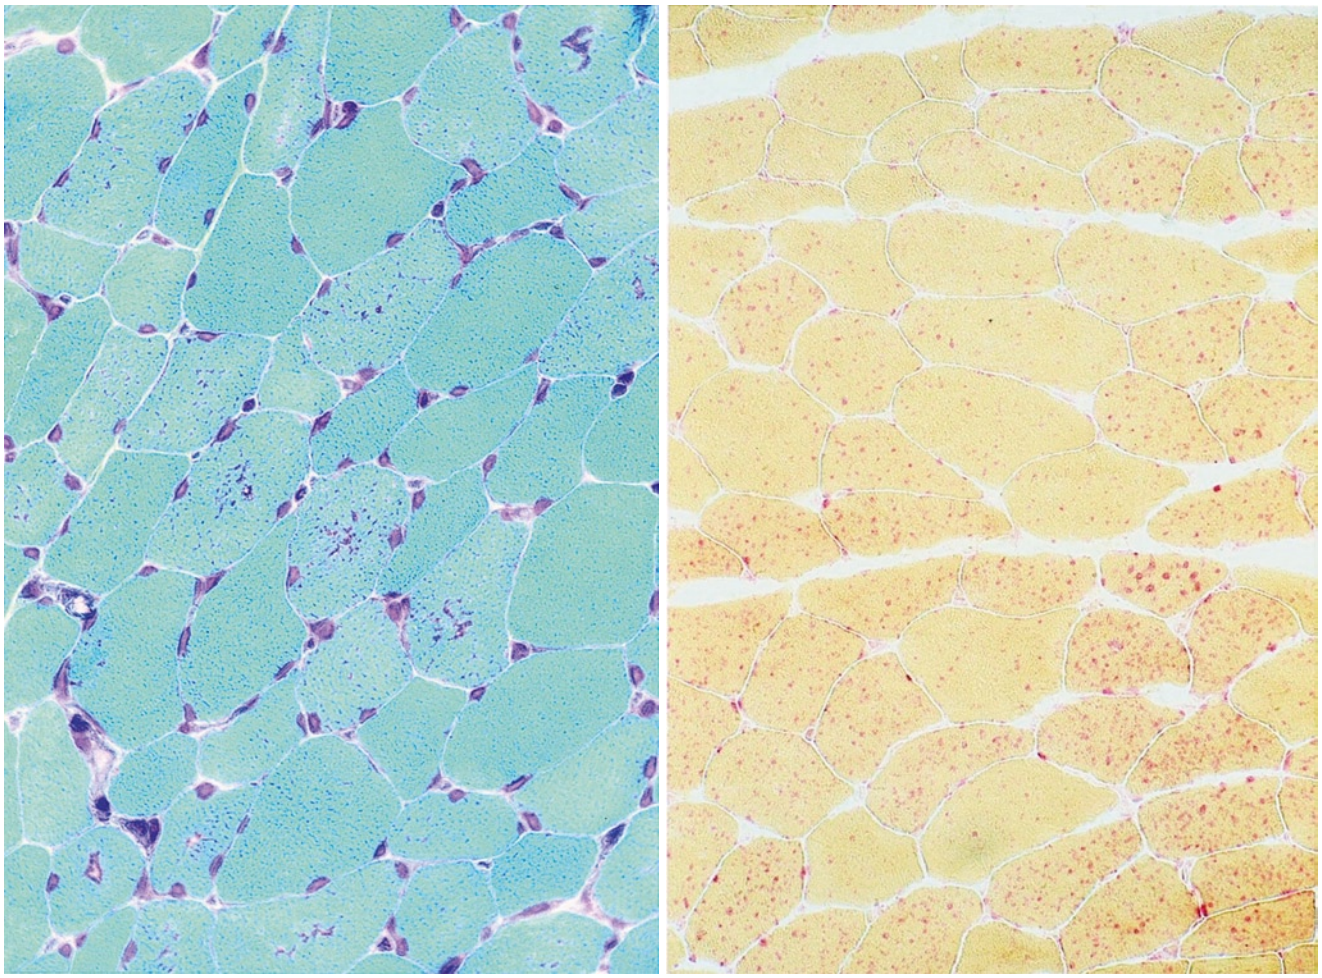

Fig. 68.4 Chloroquine myopathy. Excessive numbers of scattered lysosomes as the primary pathological change (*left panel* modified Gömöri trichrome stain, *right panel* acid phosphatase stain)

and the inherited "rimmed vacuole" myopathies, for which other animal models are unavailable [88].

Clinical Presentation

Chloroquine, Hydroxychloroquine

The frequency of this toxic myopathy has increased in recent years as the utility of these drugs has been rediscovered. It typically presents with slowly progressive proximal weakness after months or years of use at doses as low as the equivalent of 200 mg of chloroquine per day. Serum CK levels are modestly elevated. Needle EMG shows a proximal myopathy with increased insertional activity and fibrillation potentials. It is sometimes associated with an axonal neuropathy, retinopathy, or cardiomyopathy [76, 89].

Amiodarone

The toxicity associated with this antiarrhythmic drug is characterized by phospholipid-containing myeloid inclusions in cells of multiple organ systems, including peripheral nerve, muscle, cardiac muscle, and other tissues. Although the peripheral neuropathy caused by this agent has more functional impact on patients and is more common, amiodarone can also cause an acute, often mild, necrotizing vacuolar myopathy [90–92]. Interestingly, the membrane and lipid inclusions may persist in muscle and nerve as long as 2 years after drug discontinuation, probably due to the long half-life of the drug (40–50 days). Myopathy with amiodarone use may also be secondary to hypothyroidism caused by the drug.

Differential Diagnosis

Since chloroquine is often used in the treatment of rheumatological disorders, this toxic myopathy is most often mistaken for an inflammatory myopathy related to the primary autoimmune disease. A muscle biopsy is necessary for a definitive diagnosis and to determine whether to add further immunosuppressive agents or withdraw chloroquine.

Prognosis

Symptoms slowly resolve many months after chloroquine, hydroxychloroquine, or amiodarone therapy is stopped.

Anti-microtubular Myopathy

Nearly a half century ago, the anti-microtubular agent vincristine was shown to cause a vacuolar myopathy with membranous inclusions [93–97]. However, despite the use of colchicine for treatment of gout since 1763 and knowledge of its anti-arthritic properties by the ancient Greeks, its neuromuscular toxicity in humans has only recently been recognized [98, 99].

Etiology and Pathogenesis

Muscle biopsy shows a distinctive vacuolar myopathy [99, 100]. Unlike the vacuoles seen in other muscle disorders, the vacuoles in colchicine myopathy are very large and spindle shaped. They are typically oriented longitudinally and are highly localized either right below the sarcolemma or in the center of myofibers. These vacuoles stain positively for acid phosphatase and for lipid, indicating that their contents are lysosomal in origin (Fig. 68.5). The changes are not well appreciated in standard paraffin sections but require frozen sections. Necrotic fibers are rare. Electron microscopy reveals remnants of primary lysosomes and spheromembranous bodies in the vacuoles, as well as perinuclear aggregates of densely packed filamentous material. Cytoplasmic deposits of finely granular material immunoreactive for alpha- and beta-tubulin are described [101].

Colchicine is weakly amphiphilic, and there are pathological similarities between colchicine myopathy and that of other amphiphilic drugs. However, a number of observations suggest that colchicine causes myopathy through disruption of muscle microtubular systems rather than through amphiphilic chemical effects. These are (1) its similarity to vincristine myopathy, (2) the well-known interactions of lysosomes with microtubules in most eukaryotic cells and the demonstration of a relevant microtubule network in skeletal muscle [102], (3) colchicine blockade of exocytosis of acetylcholine receptors in lysosomes of cultured rat skeletal muscle at concentrations near the K_d for colchicine binding to tubulin [102], and (4) the cytoplasmic accumulation of tubulin-immunoreactive granular material in colchicine myopathy. The mechanism is now clear. Disruption of a microtubule cytoskeletal network, upon which depends the recycling of membranous material that myofibers abundantly turn over and exocytose, leads to defective movement or localization of lysosomes, resulting in accumulation of autophagic vacuoles [2, 76, 102].

Clinical Presentation

The syndrome of chronic colchicine myopathy was defined in a large series of patients treated for gout [99, 103] and is stereotypic enough to allow easy recognition. Patients are most often men, over age 50, with secondary gout, receiving standard oral doses of colchicine, 0.5–0.6 mg twice a day. They present with the subacute onset of proximal muscle weakness of 1–6 months' duration. The serum CK is always elevated (up to 50-fold in the most symptomatic and one- to threefold in subclinical cases). Needle

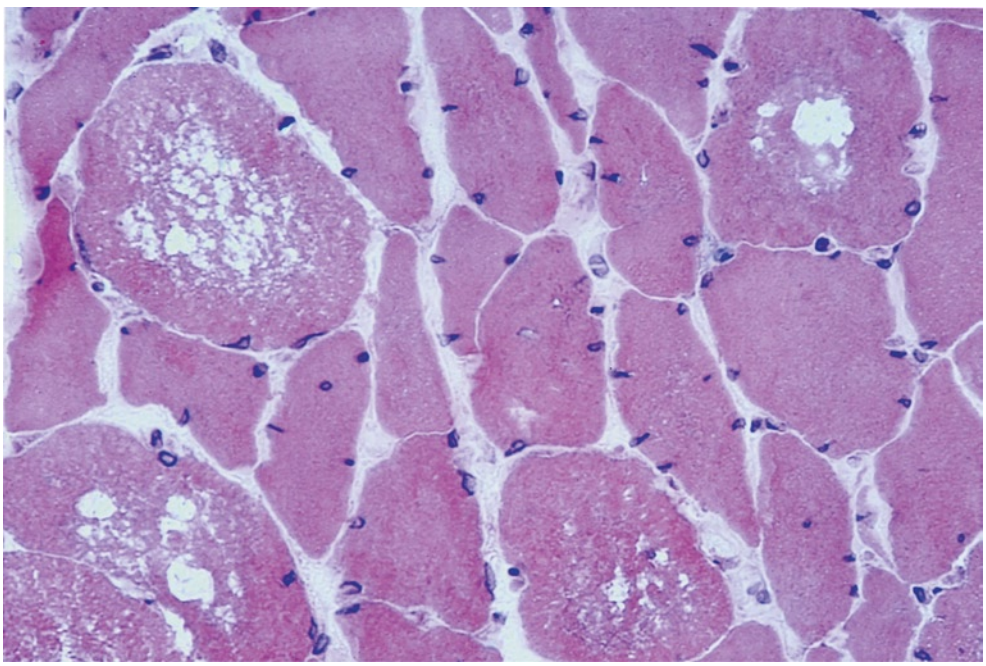

Fig. 68.5 Colchicine myopathy. Large coalescing vacuoles with heterogeneous contents as the primary pathological feature (H and E stain). These can be proven to be lysosomes by acid phosphatase histochemistry (not shown)

EMG shows a myopathy with abnormal spontaneous activity in 60 % of proximal muscles examined [103], simulating polymyositis for which it is commonly mistaken [99]. Both clinical and electrical myotonia may also be present. Most patients have a sensorimotor axonopathy that is functionally less disabling, hence the term *myoneuropathy*.

Although a mild axonal neuropathy is common in patients taking vincristine, myopathy from that drug is relatively rare because it is typically used only intermittently as part of a chemotherapeutic protocol [76].

Predisposing Factors for Colchicine Myopathy

Chronic renal insufficiency, which is commonly associated with gout, is the most identified risk factor [99, 104]. This is probably because colchicine is partially excreted renally and the clearance of the drug from plasma is reduced in renal failure. Occasional cases may be due to *excessive self-dosing* [98]. Because the major route of excretion is hepatic, *liver disease* may eventually become recognized as an important risk factor as more cases of myopathy are seen in patients treated with colchicine for familial Mediterranean fever [101], amyloidosis [105], primary biliary cirrhosis [106], and proliferative vitreoretinopathy [107].

Drug Interactions

Because colchicine is such a commonly used drug, toxicity may be expected to occur frequently in combination with other commonly used drugs. Thus, many cases of toxic myopathy that can be fully explained by colchicine alone but have occurred in the context of other drugs (usually in the clinical context of either renal insufficiency or organ transplantation, as colchicine uses both renal and hepatobiliary excretion) have been attributed without evidence to the concomitant drug itself or to the drug combination. Cyclosporine is such an example, and although a direct myotoxicity of cyclosporine has been hypothesized, it is unsubstantiated. Colchicine myopathy occurs in organ transplant recipients who develop cyclosporine-induced gout [108–110]. All of these patients had some degree of renal insufficiency and all improved following reduction or withdrawal of colchicine.

It should be no surprise that myopathies occur when statins and colchicine are used together, given the ubiquity of use of both drugs. An illustrative case report of myopathy [111] from the combination of simvastatin and colchicine in the context of renal insufficiency postulated the likely cause for interaction. In that case, neither drug alone could be implicated, because both drugs were stopped simultaneously and the patient recovered within 2 short weeks. The fact that the statin had been taken without toxicity for 2 years and the myopathy followed abruptly (within 2 weeks) after the institution of colchicine (it usually takes months for colchicine exposure to cause myopathy) implicated a drug interaction. Both simvastatin and colchicine are dependent on demethylation by the CYP3A4 isoenzyme of the cytochrome P450 system and would therefore compete for this pathway [112]. The same system is used by certain other statins (lovastatin and atorvastatin) [42, 113] as well as many other drugs (see above). By contrast, other statins that do not use the CYP3A4 system, such as fluvastatin and pravastatin, would be predicted not to interact with colchicine and would be better choices in patients with chronic renal insufficiency and gout.

Differential Diagnosis

Colchicine myopathy is frequently misdiagnosed as polymyositis [99]. The original large case series found that the most symptomatic patients with colchicine myopathy were all misdiagnosed as polymyositis and several were inappropriately treated with prednisone. The diagnostic criteria of polymyositis, namely proximal weakness, CK elevation, and myopathic EMG with evidence of membrane instability, are common to both colchicine myopathy and polymyositis. Mistakes in interpretation of these diagnostic criteria for polymyositis arise because they are not equally sensitive or additive in estimating the probability of the diagnosis. In evaluating probable polymyositis, the electromyographer will differentiate colchicine myoneuropathy by searching for evidence of myotonic discharges, mild chronic distal denervation, and abnormal sensory potentials. Finally, a muscle biopsy in polymyositis, if typical – that is, showing primary inflammation and necrosis – should take diagnostic precedence. Other causes of subacute myopathy with axonal neuropathy include chronic uremic myopathy (which rarely causes CK elevation) and toxic myopathies caused by chloroquine, alcohol, amiodarone, and vincristine [99].

Treatment/Prognosis

Both muscle strength and serum CK levels normalize within 4 weeks of a reduction in dose or discontinuation of colchicine in most patients.

Mitochondrial Myopathies

Etiology and Pathogenesis

Zidovudine

The nucleoside analog zidovudine, initially known as AZT (3′-azido-2′,3′-dideoxythymidine), is a reverse transcriptase inhibitor that is a potent suppressor of human immunodeficiency virus (HIV) replication. Early on, it was a

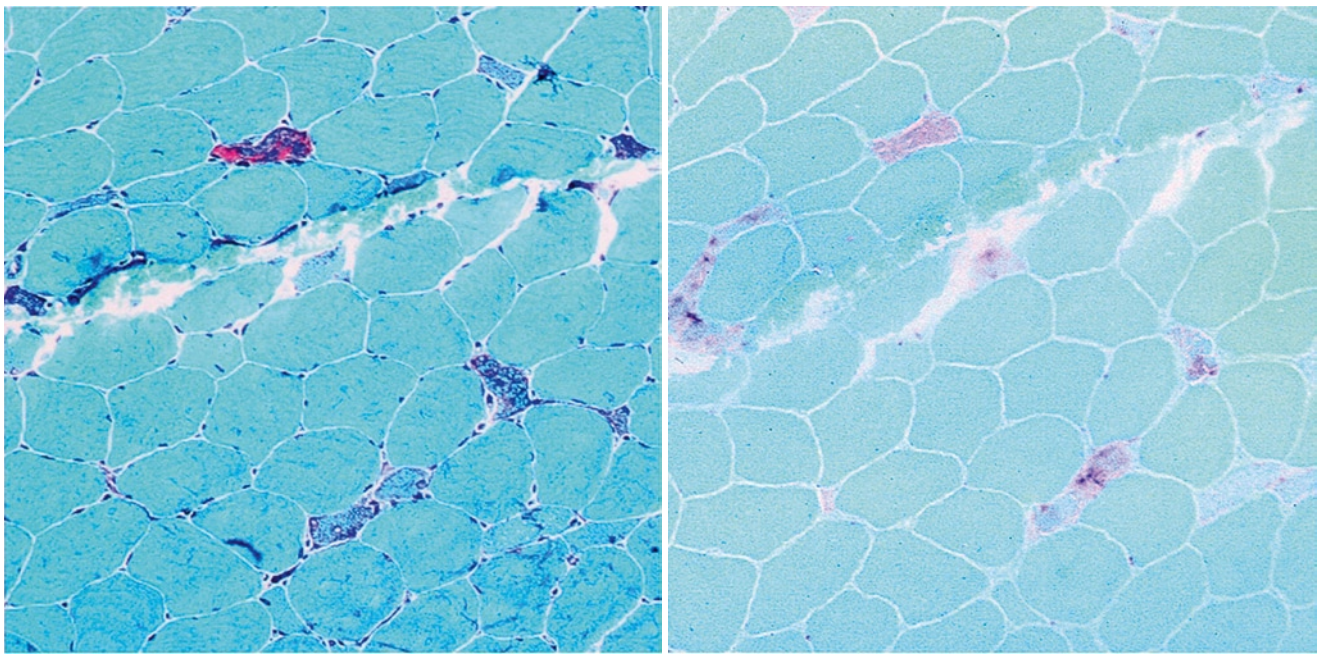

Fig. 68.6 Pseudo-ragged red fibers in zidovudine myopathy. Atrophic degenerating fibers staining red on Gömöri trichrome (*left panel*) and containing abundant lysosomes as shown by serial section stained with acid phosphatase (*right panel*)

principal drug used in the treatment of patients with HIV infection but now is used primarily in developing countries, primarily because of low cost. However, one of the major limitations in the use of zidovudine is a number of potentially severe side effects, including toxic myopathy. Another drug in the class (clevudine, see below) causes similar effects by the same mechanisms.

Because myopathy may occur as a complication of HIV infection in the absence of treatment with zidovudine or other drugs, there was initially some uncertainty as to whether zidovudine caused a distinct myopathy [114–116]. It is now clear that zidovudine causes dose-dependent changes in skeletal muscle consisting of (1) atrophic degenerating fibers filled with lysosomes and degenerating mitochondria, staining red on Gömöri trichrome (pseudo-ragged red fibers, which are smaller and have less "ragged" outpouchings from mitochondrial proliferation than the true ragged red fibers in mitochondrial myopathies) (Fig. 68.6); (2) necrotic fibers; (3) profuse numbers of cytochrome oxidase-negative fibers (Fig. 68.7); and (4) reactive mitochondrial proliferation in a few succinate dehydrogenase-blue or true ragged red fibers. Scattered interstitial lymphocytes typical of HIV-infected tissue, nascent rods caused by denervation, and cytoplasmic bodies typical of cyclic degeneration/regeneration may confuse the picture but are not specific to zidovudine. Zidovudine myopathy is considered a "mitochondrial myopathy" because of evidence of depletion of mitochondrial DNA (mtDNA) [117], a decline in mitochondrial respiratory chain capacity in affected muscle fibers [118], and accumulation of intermyofibrillar lipid droplets consistent with a defect in fatty acid utilization [119]. The depletion of mtDNA is attributed to zidovudine's effects on DNA polymerase gamma, an enzyme found only in the mitochondrial matrix [117]. An independent toxic effect on mitochondria is not ruled out [120].

Dalakas and coworkers suggested that the accumulation of lipid droplets in zidovudine-affected muscle fibers is due to decreased utilization of fatty acids. They showed that degenerating muscle fibers have increased numbers of lipid droplets and decreased total muscle carnitine levels [119]. Furthermore, they showed that L-carnitine protects against the effects of zidovudine on cultured human myotubes and also enhances recovery of zidovudine-associated destruction of myotubes following zidovudine withdrawal [121, 122]. Reductions in both muscle and plasma carnitine levels are described in other mitochondrial myopathies [123, 124], and plasma carnitine levels are reportedly reduced in zidovudine-treated patients [125]. Some suggested that muscle mitochondrial dysfunction leads sequentially to accumulation of coenzyme A esters, formation of acylcarnitine, and finally depletion of muscle carnitine pools [123].

These human pathological features [117, 126] have now been reproduced in an animal model by short-term exposure of rat skeletal muscle cell cultures to zidovudine for only 48 h at concentrations of 10–100 μg/ml [127]. As the authors suggest, this in vitro assay may be an efficient model in which to test potential mitochondrial toxicity of other similarly structured drugs during their development.

Clevudine

Clevudine (Revovir®; Levovir®; 1-[2-deoxy-2-fluoro-b-L-arabinofuranosyl]thymine; 1-[(2*S*,3*R*,4*S*,5*S*)-3-fluoro-4-hydroxy-5-(hydroxymethyl)oxolan-2-yl]-5-methylpyrimidine-2,4-dione),

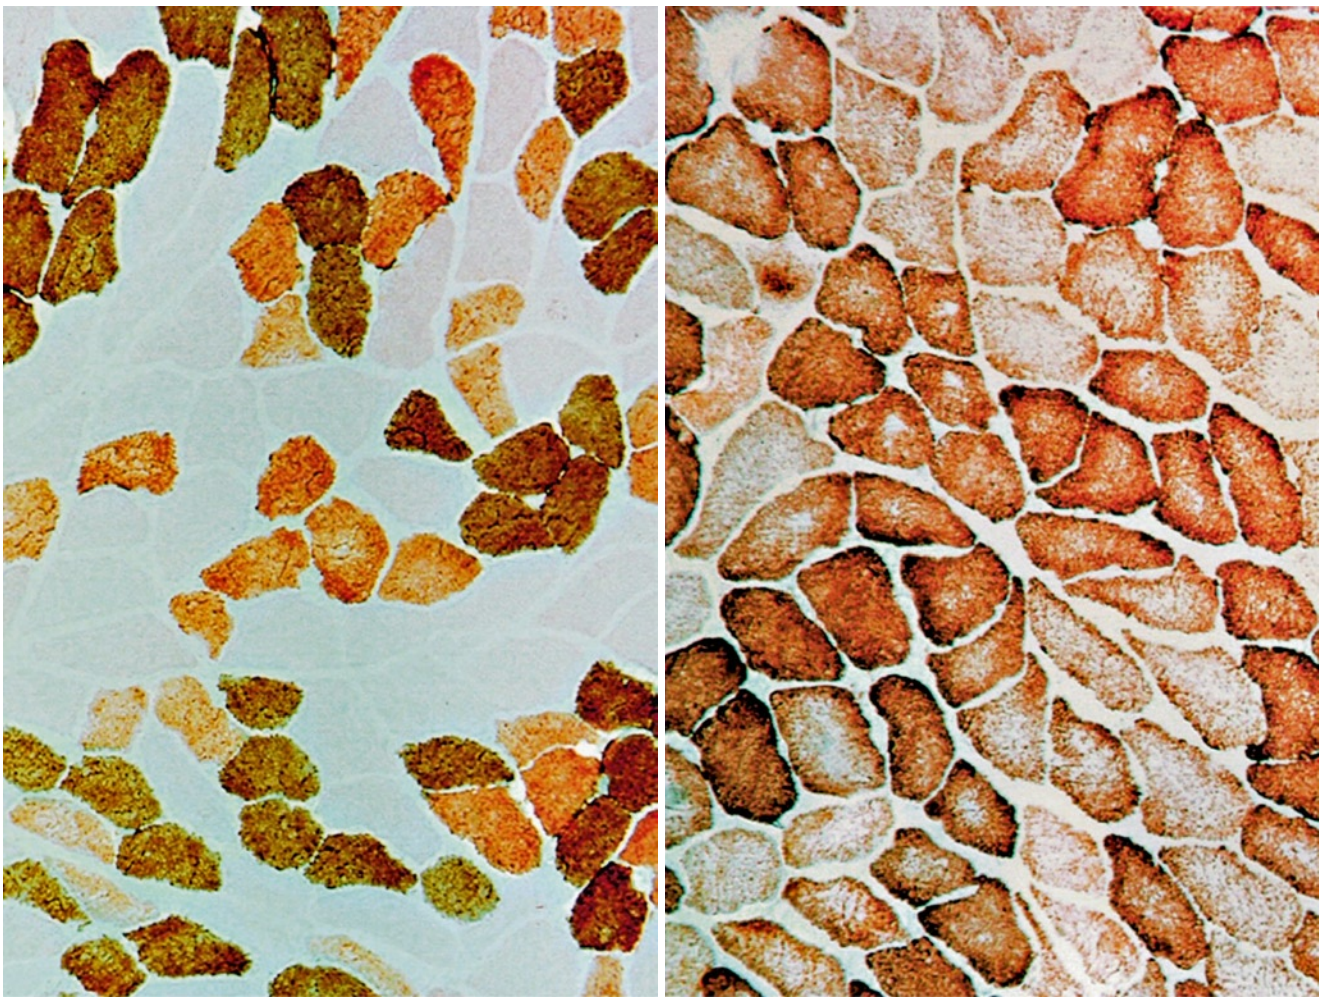

Fig. 68.7 Cytochrome C oxidase-negative fibers in zidovudine myopathy. Innumerable fibers contain no histochemical cytochrome oxidase activity in zidovudine myopathy (*left panel*), as compared to normal cytochrome oxidase activity in HIV-inflammatory myopathy (*right panel*)

a new pyrimidine nucleoside analog drug for hepatitis B, also causes characteristic mtDNA depletion, profuse COX-negative fibers [128, 129], and myonecrosis [130, 131]. The mechanism of myotoxicity is therefore likely to be identical to that of zidovudine.

Clinical Presentation

The spectrum of muscle disease in HIV-infected individuals treated with zidovudine ranges from patients with mild myalgia and CK elevation without muscle weakness to those with frank myopathy [132, 133]. Whether this broad clinical spectrum represents different degrees of zidovudine myopathy or whether it includes patients with overlaps among HIV-associated inflammatory myopathy, zidovudine myopathy, and HIV-related muscle wasting has not always been clear in published reports and cannot be ascertained without muscle biopsy.

Patients who have received a total dose of more than 250 g of zidovudine or a course of treatment ≥9 months are at risk of developing frank zidovudine myopathy [118, 134]. In this unambiguous form, it is characterized by the insidious onset of muscle pain and proximal weakness. Wasting of pelvic and shoulder girdle muscles is usually modest unless HIV wasting syndrome is superimposed. Serum CK levels are near the upper limit of normal to moderately increased, perhaps somewhat suppressed because of superimposed reduction of muscle mass. Needle EMG reveals findings of a myopathy (early recruitment of short duration, small amplitude polyphasic MUAPs) with abundant fibrillation potentials. The needle EMG is therefore indistinguishable from HIV-associated inflammatory myopathy. Nerve conduction studies are normal unless there is an associated HIV distal sensorimotor polyneuropathy [118, 134].

Differential Diagnosis

The differential diagnosis of proximal weakness in an HIV-infected patient includes zidovudine myopathy, the HIV-related inflammatory myopathy identical to polymyositis, HIV-related muscle wasting syndrome, or some combination of these [135]. Occasionally, however, neuropathic processes in HIV patients, such as an acute or chronic demyelinating

inflammatory polyneuropathy, may also present with a pattern of proximal weakness resembling a myopathy.

Myalgia and an elevated CK are insufficient to distinguish between zidovudine myopathy and other myopathic disorders in the HIV-infected patient. Diagnostic criteria for zidovudine myopathy should include the presence of objective muscle weakness, myopathic needle EMG, muscle biopsy documenting a degenerative myopathy *without* primary inflammation surrounding and invading non-necrotic myofibers, and abundant COX-negative myofibers (scores to hundreds per thousand myofibers).

Treatment/Management

The decision whether to discontinue zidovudine in patients with toxic myopathy is not always a straightforward one. An accurate diagnosis, often resting on muscle biopsy, is essential. Although withdrawal of zidovudine does reverse the histological and molecular features of the toxic myopathy [117, 136], and nearly all patients demonstrate substantial improvement in strength, not all achieve complete reversal of clinical manifestations [135]. These presumably include patients with overlapping HIV-related wasting syndrome or HIV-associated inflammatory myopathy. Also, discontinuation of zidovudine may have deleterious effects on the HIV-infected patient not otherwise treated with modern, highly active antiretroviral multidrug regimens. The toxic myopathy is dose/time related and in our experience it nearly always responds to a 50 % dose reduction while the patient's strength is monitored quantitatively for 4–6 weeks. Alternatively, zidovudine can be completely withdrawn. CK should be monitored weekly. If the patient's strength measurably improves and CK normalizes (recognizing that CK may decline from inactivity without clinical improvement), zidovudine can be either retried at a reduced dose or replaced with other multidrug antiretroviral agents. If the patient's strength does not improve, the diagnosis of HIV-associated inflammatory myopathy should be considered.

Alcohol-Related Myopathy

The myotoxic effects of alcoholism are diverse and include the syndromes of acute necrotizing myopathy, myoglobinuria, hypokalemic myopathy, chronic atrophic myopathy, and cardiomyopathy.

Acute Necrotizing Alcoholic Myopathy

Etiology and Pathogenesis

The pathogenetic mechanism of acute alcoholic necrotizing myopathy is unknown. Segmental necrosis of individual muscle fibers is the predominant finding on light microscopic examination – indistinguishable from other necrotizing myopathies. Electron microscopy does not reveal any pathogenetic clues, only the nonspecific separation of myofibrils and other cellular elements by fluid-filled spaces and aggregates of degenerating mitochondria typical of any necrotizing process [137].

Clinical Presentation

Acute alcoholic myopathy is characterized by the sudden onset of focal or diffuse muscle cramps, tenderness, swelling, and weakness. The CK is usually quite high, and when necrosis is severe, transient myoglobinuria occurs.

Predisposing Factors

The incidence of acute alcoholic necrotizing myopathy is probably quite low and almost always occurs in chronic alcoholics *during or immediately after a binge of heavy drinking*. In an experimental rodent model, it occurs only in protein-caloric malnutrition, not in the fed state [137].

Treatment/Prognosis

Following the withdrawal of alcohol, cramps subside within 1–2 days, and the pain and swelling within 1–2 weeks. Muscle power returns in 10–14 days.

Acute Hypokalemic Alcoholic Myopathy

Etiology and Pathogenesis

Hypokalemia is common among patients with alcohol withdrawal symptoms. Muscle biopsy during the acute phase of hypokalemic alcoholic myopathy shows marked vacuolization but only scant necrosis and myophagocytosis (Fig. 68.8).

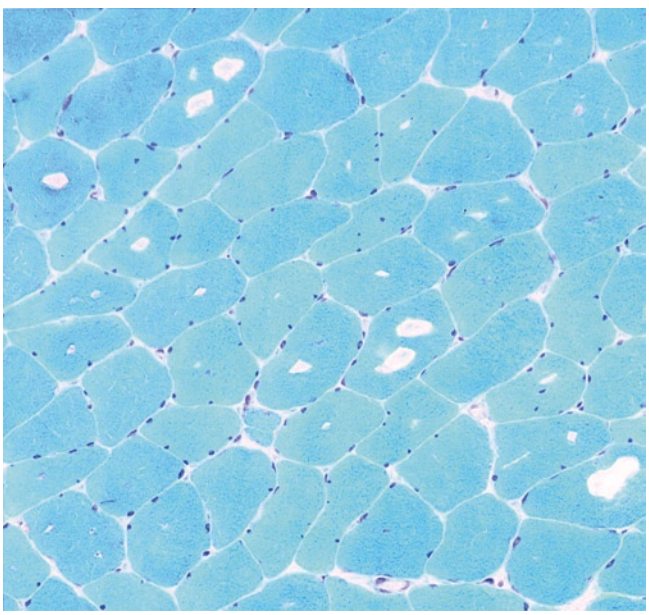

Fig. 68.8 Vacuolar myopathy. Numerous large empty vacuoles are dilated sarcoplasmic reticulum and T-tubules, as seen in hypokalemic myopathy due to alcohol or other agents (Modified Gömöri trichrome stain)

This vacuolar myopathy is due to dilatation of sarcoplasmic reticulum and T-tubules. Other drugs that place patients at risk for severe hypokalemia include laxatives, thiazide diuretics, glycyrrhizate (licorice), amphotericin, and lithium.

Clinical Presentation

In this syndrome, acute muscle weakness occurs *without* cramps, pain, tenderness, or swelling. Serum potassium is typically below 2.5 meq/L. Serum CK and aldolase are markedly elevated.

Treatment/Prognosis

Repletion of serum potassium improves muscle strength within 4–7 days, and complete recovery is achieved within 2 weeks.

Chronic Alcoholic Myopathy

Whether a chronic primary myopathy due to ethanol toxicity exists is debated. The controversy centers around whether the typical histological findings observed in weak muscles of chronic alcoholics – type II atrophy, increased numbers of subsarcolemmal nuclei, variation of fiber size, and occasional necrosis and regeneration of individual fibers – can all be attributed to chronic denervation alone [138]. In favor of a distinct myopathic component are the absence of fiber-type grouping and the lack of a correlation between these histological findings and the presence of clinical neuropathic symptoms or nutritional state [139, 140]. Also, the toxic myopathy in chronic alcoholism is usually dose dependent [141]. In our experience, the chronic myopathies in alcohol users combine the features of the remodeling that occurs after cycles of necrosis and regeneration (fiber size variability and myopathic grouping) with mild vacuolar changes, both characteristics of the acute types of alcoholic myopathy.

Alcoholic Cardiomyopathy

The syndrome of alcohol cardiomyopathy has been attributed to the direct effects of ethanol with chronic use [141], to cobalt poisoning in beer drinkers, or to vitamin B deficiency (beriberi).

Other Less Common Myotoxic Syndromes

Differential Diagnosis

By definition, a toxic necrotizing myopathy results when a substance *directly* causes muscle fiber necrosis (see Figs. 68.1 and 68.2). Syndromes in which muscle fiber necrosis occurs secondarily to other intervening mechanisms, such as the coma-crush syndrome with narcotic drug overdose, should not be included in this category. Common necrotizing toxins like statins, fibric acid derivatives, and ethanol were described above. Most others, like epsilon-aminocaproic acid, procainamide, or etretinate, are far less common now, but a number of these other less common toxic muscle disorders have been well documented (Table 68.5).

Table 68.5 Less common myotoxic syndromes

Epsilon-aminocaproic acid
Etretinate
Emetine (Ipecac®)
Organophosphates
Snake venoms
Bupivacaine
Edible mushrooms
Toxin-associated inflammatory myopathies:
D-penicillamine
Procainamide
Toxic oil syndrome
Eosinophilic myalgia syndrome (contaminated L-tryptophan)
Focal myopathy due to IM injection:
Pentazocine (Talwin®)

Necrotizing Agents

Many substances may cause myonecrosis if the dose is sufficient, as illustrated by the bizarre cases of acute necrotizing myopathy from lindane powder accidentally sprinkled on broccoli (mistaken for monosodium glutamate) [142] and from paraphenylenediamine (used in hair coloring) mistakenly ingested as "coffee" [143]. What are of more importance to the clinician are those substances that, with chronic use, may cause a necrotizing myopathy that may be misdiagnosed. Although necrotizing myopathies probably comprise the most common myotoxic syndromes, the molecular mechanism of myotoxicity in most cases remains unknown.

Emetine

Emetine (*Ipecac*®) causes (usually) painless proximal weakness that is reversible. This is often accompanied by elevated CK and electrocardiographic abnormalities, related to its cardiotoxicity. This myopathy is recognized by morphologically distinct floccular or geographic inclusions [144, 145].

Organophosphates

Poisoning by *organophosphate anticholinesterase compounds*, usually the result of insecticide exposure, causes a necrotizing myopathy [146, 147].

Epsilon-Aminocaproic Acid

Epsilon-aminocaproic acid is a potent antifibrinolytic agent also causes a necrotizing myopathy, sometimes severe enough to cause myoglobinuric renal failure and severe weakness [148, 149]. Myopathy occurs at doses as low as 10 g/day and with usage as little as 14 days, but most cases occurred with more than 24 g/day for more than 4 weeks.

Edible Mushrooms

The first reports from France of the association between ingestion of the edible mushroom *Tricholoma equestre* and subsequent true rhabdomyolysis and cardiac myotoxicity (CK levels in the 50,000–600,000 IU/L range) in 12 patients [150] triggered other confirmative case reports from Poland, Finland, Taiwan, and Alaska. The French syndromes, which occurred over a decade of reporting, were fulminant intoxications presenting about a week after three consecutive meals containing the mushrooms. Myotoxicity was confirmed in mice administered with an aqueous extract from the same mushroom species, which reproduced dose-dependent, mild, but significant 2.5-fold increase in CK in animals that were gavage fed very large amounts of *T. equestre* powder (2–6 g/kg doses) for three consecutive days; lipid-soluble extracts of the mushroom powder produced even more substantial sixfold elevations of CK [150]. More extensive mouse modeling has proven that the causal relationship is more widespread in the mushroom order, showing that the myotoxicity is not species specific but seen in a wide variety of gourmet, edible mushrooms that have been eaten by humans no doubt for centuries and sold commercially, including but probably not limited to the following species: chanterelle (*Cantharellus cibarius*), several *Russula* species, orange birch boletus (*Leccinum versipelle*), and the sheep polypore (*Albatrellus ovinus*) [151]. These many phylogenetically distinct genera of wild, edible mushrooms caused dose-dependent CK elevation at moderately high intake in the mouse diet for substantial 5-day exposures, compared to controls. Variance in the responses suggests individual susceptibility. In these experiments, there was no morphological abnormality by routine paraffin histology, but that is an insensitive technique. In humans, the correlative estimated dosage necessary would be a moderately high dietary consumption over several days, and that is realistically possible. On the positive side of the nutritional ledger, a variety of wild mushroom species have been shown to lower LDL cholesterol levels in rodents. The advocacy for mushrooms as part of a healthy diet, and the value of mushrooms to both gourmands and hobbyists mean vigilance of this new myopathy is warranted.

Toxin-Associated Inflammatory Myopathies

Toxin-associated inflammatory myopathies may occur in patients receiving d-*penicillamine* [152, 153] and *procainamide* [154]. The myopathic manifestations of the epidemic toxic oil syndrome [155] and *tryptophan*-associated eosinophilia-myalgia syndrome [156] were also inflammatory in nature (see Chap. 79).

Focal Myonecrosis

In the wild and in snake handlers, focal myonecrosis is caused by the *snake venom* components single-chain peptides and A_2 phospholipases [157]. The high specificity of venom phospholipases suggests a specific binding to membrane receptors, leading to vacuolization, lysis, and necrosis of skeletal muscle cells. As an iatrogenic occurrence, intramuscular bupivacaine injection in high dose also causes focal myonecrosis and is probably a daily but unrecognized event.

Repeated intramuscular injection of the narcotic *pentazocine* has been reported to cause focal myonecrosis, which in severe cases of self-injection can lead to fibrotic contractures [158].

Newer Agents

Sonedegib® (LDE225, Novartis) is a member of a relatively new class of drugs that are selective antagonists of the smoothened receptor, which is a G-protein-coupled receptor that positively regulates hedgehog signal transduction and is linked to the pathogenesis of several human cancers [159]. Currently in phase I and II trials demonstrating high efficacy against advanced solid-tumor malignancies, Sonedegib has been surprisingly associated with high elevations of serum CK, surprising because preclinical studies did not evidence any myopathy [160]. The mechanism of myotoxicity is as yet unknown. Although substantial CK elevation most often indicates myonecrosis, current evidence completely contradicts a mechanism of acute rhabdomyolysis or any chronic necrosis for that matter with this drug.

Unproven Toxic Myopathic Syndromes

The literature is replete with reports of toxic "myopathy" in which there is no consistent morphological, electrophysiological, serum enzymological, or metabolic evidence of muscle disease. These are typically no more than syndromes in which one or more of the symptoms of fatigue, muscle pain or cramps, and even proximal weakness are present [76].

Fatigue is not a cardinal myopathic symptom, perhaps occurring more commonly from depression, central nervous system disorders, or peripheral and neuromuscular junction disorders. Nevertheless, *solvent-induced myopathies* were

reported solely on the basis of fatigue. A number of solvents including acetone, benzine, naptha, and xylene were implicated as myopathic agents despite normal strength, needle EMG, and muscle histology. CK was minimally elevated in these patients, and 24 % of unexposed controls had CKs above the upper limit of normal [161].

Similarly, pain, myalgia, and cramps are not signs that localize disease to muscle. Yet, "painful myopathies" were attributed to *labetalol* [162], *mercaptopropionyl glycine* [163], and *polyvinyl chloride* [164] without convincing laboratory evidence of muscle injury. In clinical drug trials, aches, pains, or cramps are frequent in placebo groups.

Even the cardinal symptom of proximal weakness is not, by itself, an indication of myopathy, as it can be seen in other neuromuscular disorders and even central nervous system disease. Severe, rapidly reversible weakness attributed to *rifampicin* has been called myopathy without significant electrophysiological, histological, or serum enzymological abnormality [165]. Probable *tetracycline*-induced myasthenia has been mistakenly called myopathy [166]. "*Iron-overload* myopathy" was diagnosed when motor nerve conduction velocities were slowed, muscle fibers were denervated and contained stainable iron, and yet no definitive myopathic features were present [167].

A recurring example of the unproven myopathic syndrome is that associated with *cyclosporine* treatment. A review cites dozens of case reports in which patients treated with cyclosporine reported "muscle symptoms including myalgia, cramps, and muscle weakness, sometimes associated with CK elevation" [168]. In total, these included 34 patients, of whom, only 2 had supposedly taken cyclosporine alone [169, 170]. One of those had only pain, which resolved when the drug was stopped and recurred when it was reintroduced. In the other 32 patients, cyclosporine was administered with other drugs thought to be myotoxic, including colchicine, steroids, and statins. Those few reports purporting to show that removal of cyclosporine improved symptoms (usually muscle pain or other subjective complaints) also involved changes in other drugs which were more likely to be myotoxic. Muscle pathology, which was examined in fewer than half of the cases, was never convincing. Findings included type II atrophy (5/15 patients), rare necrotic fibers (4/15 patients), and excessive numbers of central nuclei (1/15 patients). Finally, needle EMG findings were also rarely convincing. Thus, the existence of a "cyclosporine myopathy" has not been proven.

The widely cited Naranjo scale [171], which is used to estimate the probability of adverse drug reactions, is probably at fault. A case in point is the mistaken attribution of "severe myopathy" to low-dose, short-term use of gabapentin for neuropathic pain [172], when in actuality the more probable cause of a severalfold elevation of CK (no biopsy was performed) was the elderly patient's haloperidol-treated psychomotor agitation and delirium, which are well known, but trivial, causes of motor activity-related CK elevation. Similar errors confusing temporal association with causation have led to reports of "Naranjo-probable" myopathies from many commonly used drugs, including rifampicin, tetracycline, labetalol, proton pump inhibitors (omeprazole, lansoprazole), cyclosporine, solvents, polyvinylchloride, mercaptopropionyl glycine, and even epidural (hence intramuscular) triamcinolone [172]. Generally, such misattributions, based solely on correlation with drug de-challenge, are in case reports that are confused by multiple concomitant drugs (including statins) and complicated medical problems, that lack consideration or control of physical activity or other causes of CK elevation, and that are unfounded by muscle biopsy. Alternatively, if a myopathy did occur, it may be that a drug interaction is to blame, as, for example, via effects on the cytochrome P450 system.

These examples illustrate how toxic myopathies can be *over*diagnosed on precious little evidence. The presence of such unproved syndromes in the clinical literature means that reports of "toxic myopathy" must be critically evaluated.

Viral Myositis

Myalgia is extremely a common symptom in viral infection while pathologically proven myositis is rare. Coxsackievirus in the enterovirus group was the first virus reported to cause muscle inflammation in human. Myalgia was reported in patients with epidemic pleurodynia in the 1940s, but inflammatory change in muscle biopsy was discovered few years later. Myositis associated with influenza virus infection was reported afterwards in the 1950s.

Etiology and Pathogenesis

Several features of the pathogenesis of myositis related to viral infection are still unclear. Details of the penetration of viral particles and the molecular basis of susceptibility or resistance to viral infection remain to be determined. The mechanisms underlying the destruction of the cytoarchitecture are still unresolved. In the case of Coxsackievirus, damage to the contractile proteins and condensation of nuclear chromatin are the initial changes [1, 2], whereas in echovirus infection dilatation of the sarcoplasmic reticulum precedes other changes [3].

Immunopathological mechanisms of acute viral-induced skeletal muscle injury have not been evaluated in detail. The immune response does not appear to play a significant role in the acute phase of viral-induced injury for the following reasons: (1) The early cellular changes in muscle precede any inflammatory response. (2) Younger animals whose immunologic responses are probably less well developed are more susceptible to muscle infection. (3) Immunosuppression does not prevent viral-associated muscle injury and increases the mortality associated with viral infection [4, 5]. However, an initial viral infection may trigger an immune-mediated polymyositis.

The possible causal relation between viral infection and inflammatory myositis comes from early isolation of Coxsackievirus B from the muscle of a child with dermatomyositis [6]. Subsequently, Adams et al. in 1965 and Chou in 1967 discovered eosinophilic intranuclear and intracytoplasmic inclusion in the muscle from the patients with chronic myositis [7, 8]. The inclusions contained aggregates of microtubular filaments with a diameter of 115–118 nm, which resembled paramyxovirus nucleocapsids. However, subsequent attempts to identify viral antigen by immunocytochemical methods were unsuccessful [9].

More recent literatures still focused on relating evidence between viral infection and inflammatory myositis. One recent case control study had demonstrated higher frequencies of detection of EBV genome and anti-Epstein-Barr nuclear antigen in patients with dermatomyositis and polymyositis compared to the matched control group [10]. Viruses in retrovirus group such as human immunodeficiency virus (HIV) and human T lymphocytic virus 1 (HTLV-1) have also been reported related to the development of idiopathic inflammatory myopathy in many case reports [11–15]. Adenovirus type 2 was isolated from muscle biopsy of two patients with inclusion body myositis [16]. Mumps viral antigen also was demonstrated in the sarcoplasm of the muscle with this disorder by immunocytochemical method [17]. However, these findings cannot be reproduced in subsequent studies and so far there is very little evidence to support true relation between viral infection and chronic inflammatory myositis. Nevertheless, it remains possible that a viral infection may trigger an immune-mediated myositis.

Clinical Syndromes Related to Viral Myositis

Epidemic Pleurodynia

Epidemic pleurodynia first described in the 1940s [18, 19] is also referred to as epidemic myalgia, Bornholm disease, or Devil's grip. The disorder is usually caused by group B Coxsackievirus [20]; however, it may also be caused by some group A Coxsackievirus and echovirus. This syndrome typically occurs in children in the summer or fall. The onset is abrupt in 75 % of the patients, while some patients have prodromal symptoms of headache, anorexia, and mild myalgia for 1–10 days. The major symptom is severe chest wall pain. Deep breathing or coughing accentuates the pain and accounts for the misleading name "pleurodynia," since the pleura itself is not actually involved. Other associated symptoms include fever, headache, cough, anorexia, nausea, vomiting, and diarrhea. Symptoms often last few days up to 2 weeks and then resolve spontaneously. Pleurodynia may also be associated with other sequelae from picornavirus infection such as aseptic meningitis, orchitis, or pericarditis.

Coxsackievirus and echovirus may also cause rhabdomyolysis, which can occur in a wide range of age group [21, 22]. The pathogenesis of myositis caused by Coxsackievirus is still unclear. The evidence of viral infection can be obtained by detection of virus in the stool sample or fourfold rise in the titer from serologic testing.

Routine laboratory tests are usually normal. Muscle pathology is often normal [23] although in some reports, the muscle biopsies revealed inflammatory changes in the muscle [24, 25]. There is no specific treatment for the condition and treatment is mainly supportive and symptomatic.

Benign Acute Childhood Myositis

This clinical syndrome was first reported in the 1950s under the name of "myalgia cruris epidemica" and was later on confirmed to be related to influenza virus infection [26]. Influenza B virus was identified in more than half of the patients, influenza A virus in 10 %, and parainfluenza and adenovirus in the minority of the cases. The disorder usually occurs in children during the epidemic of influenza, and myositis develops in only a small fraction of the children with influenza. Adults are usually not affected, although there were case reports that described this condition in adults [27]. Boys are more affected than girls with a male to female ratio of 2:1. The mean age of onset is 8 years old [28]. The disease is characterized by transient severe pain and tenderness affecting the calves that typically occurs 3–5 days (range 0–18 days) after the onset of an upper respiratory tract infection [28]. The children often refuse to walk. Alternatively, they may toe-walk or ambulate with stiff legs and hold their feet in plantar flex posture. The calves are very tender and may be mildly swollen. Pain lasts for 4–10 days and spontaneously resolves. Approximately one-third of cases, the muscle pain can occur in multiple muscle groups in addition to calves. Recurrent myositis is rare and usually occurs from a different strain of virus that causes the first episode.

Most laboratory tests are normal in benign childhood myositis, including erythrocyte sedimentation rate (ESR). Moderately elevated serum creatine kinase (CK) is frequently found. The serum CK level can be very high in children who develop myoglobinuria. CK level is usually normalized over few weeks. Some children also have elevation of the serum glutamic oxaloacetic transaminase (SGOT) and lactate dehydrogenase (LDH) activity. Needle EMG in severe cases shows low amplitude, brief duration motor unit action potentials (MUAPs), most prominent in calf muscles but are also found in clinically uninvolved muscles in upper and lower extremities [29, 30]. Muscle biopsy is not routinely performed and often reveals nonspecific findings. However, a single report demonstrated that influenza virus could be isolated from muscle tissue in a patient with myoglobinuria [31].

Treatment is symptomatic and consists mainly of bed rest, hydration, and antipyretic agents.

Acute Viral Myositis

Myalgia is common during viral infection. Certain strain of influenza virus type A [32] or type B [31] can produce a severe diffuse myopathy with rhabdomyolysis and myoglobinuria. In a 1918 outbreak of influenza in the United States and Great Britain, myositis was noted in 10–20 % of patients. Acute viral myositis in adults tends to be more severe than in children. The onset of symptoms is usually abrupt. Myoglobinuria, fever, myalgia, and swelling of muscles are common. Severe myalgia and myoglobinuria may develop during the acute phase of the illness [33, 34] or as the respiratory and gastrointestinal phases of the illness are resolving. Respiratory complications, acute renal failure, and myocarditis can occur in severe cases. Recovery from weakness usually occurs within 2–3 weeks.

Laboratory tests reveal elevated serum CK level, which is highest in the patient with myoglobinuria. Elevated ESR occurs in approximately half of cases. Elevated blood urea nitrogen and creatinine are also seen in association with myoglobinuria. Muscle biopsy reveals either diffuse or patchy area of myositis characterized by muscle cell necrosis and a perivascular and interstitial inflammatory infiltrate [31, 35]. Pathologic changes in acute viral myositis are focal and pathologic changes may be missed by muscle biopsy sample. Orthomyxovirus-like particles were found in the muscle from patients with influenza A-associated myositis [35]. Influenza B virus was isolated from the muscle of a patient with acute myositis with myoglobinuria about 2 weeks after the onset of symptoms. The viral particles were found within the membrane-bound vacuoles near the sarcolemma. Viral particles occasionally could be seen budding

from the limiting membrane of subsarcolemmal vacuole to the lumen of the vacuoles [31].

Treatment consists of supportive treatment with bed rest and adequate hydration to prevent renal complications. Antiviral agents such as amantadine have not been specifically evaluated for the treatment of acute myositis.

Other viruses may also produce acute diffuse myopathy. These include parainfluenza virus [36, 37] and respiratory syncytial virus [38], which causes myalgia and muscle weakness associated with respiratory tract infection as in influenza. Coxsackievirus also causes myoglobinuric polymyositis in newborn infants [39, 40] and adults [41]. Diffuse myalgia, muscle weakness, and myoglobinuria may occur with acute infection of adenovirus [42, 43], Epstein-Barr virus [44–47], respiratory syncytial virus [38], cytomegalovirus [48], herpes simplex [44], and herpes zoster [49, 50] . Echovirus infection can lead to acute myositis with rhabdomyolysis [51, 52]. Dengue virus has been reported to be associated with myositis and rhabdomyolysis in severe cases [53].

Epidemic Benign Myalgia of the Neck

Epidemic benign myalgia of the neck is characterized by severe occipital and neck pain, fever, headache, and occasionally nausea and vomiting, lasting approximately 4–5 days [54–56]. The syndrome most frequently affects young adults and is usually associated with epidemic influenza [26].

Although the clinical presentation may resemble aseptic meningitis, the cerebrospinal fluid (CSF) is normal and photophobia is absent. Positive serology for influenza virus type A and B may be detected in patients with epidemic benign myalgia of the neck. There are no reports of electrodiagnostic (EDX) studies or muscle pathology in this syndrome. Treatment consists mainly of supportive measures. Myalgia of the neck usually spontaneously resolves in 4–5 days.

Retrovirus-Associated Myositis

Myopathy Associated with Human Immunodeficiency Virus (HIV)

HIV-related muscular complications were first recognized and were more prevalent during the early phase after the initial description of acquired immunodeficiency syndrome (AIDS) between the late 1970s and 1980s. After the development of newer antiretroviral agents, the prevalence of HIV-associated myopathies has decreased but may be still seen in developing countries or in patients with inadequate treatment. The myopathies related to HIV infection need to be differentiated from the other muscular conditions found in HIV-infected patients, which mainly include muscular complication of antiretroviral therapy and myopathies related to opportunistic infections.

Subacute progressive inflammatory myopathy is probably the most common type of muscle manifestation related to human immunodeficiency virus (HIV) infection. This type of myopathy may occur early in the course of the infection but is more common with advanced disease.

Etiology and Pathogenesis

The pathogenesis of HIV-associated myopathy is unclear. The primary pathogenic mechanism responsible for muscle fiber injury appears to be similar in HIV-associated polymyositis and idiopathic polymyositis, which is through antigen-directed cytotoxicity mediated by CD8+ cytotoxic T cells [57, 58]. Although HIV can be detected by polymerase chain reaction (PCR) from muscle biopsy specimens in some patients, an electron microscopic study found viral particles only occasionally in the endomysial lymphoid cells [59]. From current evidences, it is more likely that the myopathy is caused by a cell-mediated autoimmune response triggered by HIV rather than by the direct HIV infection of the muscle.

Clinical Manifestations

HIV infection may cause several types of muscle pathology ranging from myopathy and polymyositis to rhabdomyolysis. Patients with HIV infection may develop subacute or slowly progressive inflammatory myopathy during the course of the disease. Myopathy usually occurs in patients with advanced HIV infection but sometimes occurs in early stages of HIV infection [60]. Also, myopathy may present together with other neurologic manifestation of HIV including peripheral neuropathy and dementia syndrome.

Patients present in similar fashion as adult onset acquired polymyositis, with subacute or slowly progressive muscle weakness and myalgia involving proximal muscles symmetrically [60–64]. Acute onset of severe weakness with myocardial involvement or dysphagia may also occur [65]. The myopathy associated with HIV infection needs to be differentiated from other causes of myopathy that can also occur in HIV patients including drug-induced myopathy (zidovudine and didanosine), HIV wasting syndrome, and opportunistic infections [66–68].

Diagnosis and Evaluation

Laboratory findings reveal elevated serum CK, which is often up to 10–15 times of normal ranges. Myoglobinuria is uncommon. Needle EMG findings show increased spontaneous activity with fibrillation potentials and low amplitude, brief duration MUAPs [61]. Muscle biopsy shows inflammatory cell infiltrates, which are mostly CD8+ cytotoxic lymphocytes and macrophages, in perivascular, perimysial, or endomysial locations, with invasion of necrotic and nonnecrotic muscle fibers [59]. Frank necrotizing vasculitis is not seen, but perivascular inflammatory cells are common.

Necrotizing myopathies without inflammatory cells infiltration have been described [69]. There were also rare case reports of granulomatous myositis with multinucleated giant cells in HIV-infected patients [57, 70]. In some cases, nemaline rods, which originate from contractile proteins in the Z disc, may be found in muscle fibers [71], although they are more commonly described in association with AZT-associated myopathy. This evidence suggests that HIV or reaction from inflammatory cells may be damaging to structural or contractile element in the muscle.

Treatment

Treatment of HIV myopathy depends on the severity of muscle weakness and stage of HIV infection. There are no controlled studies assessing the efficacy of medication treatments for HIV myositis. Generally, if the patient is not already on antiretroviral medications, they should be instituted. Oral corticosteroid shows clear benefit and is often used as first-line treatment, but there is always the risk of further immunosuppression and opportunistic infections. Treatment with other immunosuppressive agents that include azathioprine, methotrexate, and cyclosporine was reported [72]. Intravenous immunoglobulin (IVIG) may be useful. In mild cases, who presented with myalgia without clear proximal muscle weakness, nonsteroidal anti-inflammatory drugs can be used [73].

Other HIV-Related Muscle Conditions

Other Types of HIV-Associated Myopathies

Nemaline myopathy has been described in patients with HIV infection. The patients present during the early stage of HIV infection with painless, progressive muscle wasting, weakness, and elevated muscle enzymes. Muscle biopsy showed the presence of nemaline rods from the electron microscope findings. Although usually there were no inflammatory cells or necrotic fibers in muscle biopsy of these cases, some patients in the reports have shown response to steroid treatment [71, 74, 75].

Similar to patients with HTLV-1 infection (see below), cases with inclusion body myositis also were reported in HIV-infected individuals with clinical manifestation, and muscle pathology resembles the sporadic inclusion body myositis [57, 76]. The role of virus in the pathogenesis of HIV-associated inclusion body myositis appears to only be the trigger for autoimmune response more than to directly infect the muscles [57, 64, 76].

Opportunistic Infections Involving Muscle in HIV Patients

HIV infection is associated with progressive immunosuppression and development of multiple systemic opportunistic infections. Musculoskeletal infections from various opportunistic infections were reported in the patients with HIV infection which include pyomyositis from bacteria, cytomegalovirus, *Toxoplasma gondii, Mycobacterium tuberculosis, Mycobacterium avium intracellulare*, and rarely *Cryptococcus*. Pyomyositis had been a disease that occurred primarily in tropical countries but has been increasingly encountered in western countries because of the HIV pandemic [77–83]. *Staphylococcus aureus* is the most common organism that causes pyomyositis in HIV patients. Salmonella and Streptococcus are responsible for approximately10 and 4 % of the cases, respectively [84, 85]. *Mycobacterium tuberculosis* and atypical mycobacteria are rare causes of pyomyositis.

Pyomyositis affects mostly patients with advanced HIV infections (median CD4 count of 24). Risk factors for pyomyositis include underlying muscle abnormalities, exercise-induced trauma, and hematogenous spreading of the infection. Patients usually present with localized pain and swelling in large muscle groups, with or without elevation of serum CK. Fever and leukocytosis may not be prominent [80, 86]. Multiple abscesses also occur [63]. Imaging studies of muscles with ultrasound, magnetic resonance imaging, or computed tomography with contrast reveal enhancing lesions in the affected muscles [83]. Treatment with systemic antibiotics and aspiration or drainage of the abscess results in resolution of the infection in the majority of patients [63, 84].

Human T Cell Leukemia Virus Type 1 (HTLV-1)-Associated Myositis

Human T cell leukemia virus type 1 (HTLV-1) is a cause of T cell leukemia in adults and HTLV-1-associated myelopathy (HAM) or tropical spastic paraparesis. HTLV-1 virus is found worldwide, but is endemic in southwest Japan, Caribbean Islands, Central Africa, and South America. The majority of the patients infected with HTLV-1 will remain asymptomatic chronic carrier and only 1–5 % will develop T cell leukemia or HAM in their lifetime [87–89]. The virus is transmitted through blood products, breast feeding, and sexual contact. Evidence of myopathy and inflammatory myopathy has been demonstrated in several case reports of HAM patients. However, there are no distinguishing clinical manifestation and pathologic features that can differentiate myopathies in HTLV-1 patients from myopathies seen in noninfected patients. These findings suggest that the presence of virus may trigger the pathogenesis of myopathy in HTLV-1 patients but is not the direct cause of muscle pathology [90]. HTLV-1-related polymyositis may occur in isolation or in association with HAM. HTLV-1-related myositis is reported in Jamaicans, in Haitians, and rarely in native Americans [91, 92]. Although tropical spastic paraparesis

from HTLV-1 is quite common in Japan, polymyositis is less prevalent there which suggests that other factors may play roles in the development of myositis.

Etiology and Pathogenesis

Similar to HIV-associated myositis, the true pathogenesis of HTLV-1-associated myositis is unclear. In vitro experiments demonstrate that HTLV-1 virus can infect CD8 and T4 cells but does not directly infect the human myotubule cells in tissue culture. In vivo, antibody to HTLV-1 virus can be demonstrated in inflammatory cells from muscle biopsies but is not found in the muscle fiber itself [93, 94]. T cell-mediated inflammatory reaction and major histocompatibility complex (MHC) type 1-restricted cytotoxic process are likely responsible for creating inflammatory reaction in the patient with HTLV-1-associated myositis [90, 93].

Clinical Manifestations

The clinical presentation of HTLV-1-associated myositis includes progressive muscle weakness and elevated serum CK indistinguishable from HIV-related myositis or idiopathic polymyositis. HTLV-1-related polymyositis may occur in isolation or in association with HAM or T cell leukemia [95, 96]. HTLV-1-associated myositis should be suspected in patients with HAM, who develop proximal muscle weakness or neck weakness. Patients with idiopathic inflammatory myositis who live in the endemic area should be screened for HTLV-1 infection, although the result may not really change the plan of management [62, 92, 97].

Other type of muscle pathology was also described in patients with HTLV-1 infection, although the evidence that supports correlation with the virus is less strong compared to patients with myositis. These include reports of inclusion body myositis in HTLV-1-infected individuals [98–100].

Diagnosis and Evaluation

Serum CK level and HTLV-1 antibody titer are elevated. Needle EMG findings show myopathic MUAPs with presence of fibrillation consistent with inflammatory myopathy. Muscle biopsy reveals similar findings as in idiopathic inflammatory myositis and HIV-associated myositis [91, 92, 101]. HTLV-1 is found in the inflammatory cells but not in muscle fibers. There are reports describing inclusion bodies in the muscle of patients with HIV and HTLV-1-associated myositis [99].

Treatment and Prognosis

A few reports indicated that oral prednisone improved HTLV-1-associated myositis and reduces serum CK levels, although the clinical response was not consistent as most of the idiopathic polymyositis cases [97, 102, 103].

Bacterial Pyomyositis

Pyomyositis is a bacterial infection of skeletal muscle often with abscess formation. This disorder is also referred to as "tropical pyomyositis" due to its common geographic distribution [104, 105]. Cases of pyomyositis in the United States and Europe were considered rare in the 1970s [106]. However, after the 1980s, the incidence of pyomyositis in the western countries has then increased, which was likely related to the discovery of the HIV in late the 1970s [79, 80, 86]. Pyomyositis in western countries is currently seen in HIV-infected patients, oncology patients receiving chemotherapy, patients with autoimmune diseases on immunosuppressive therapy, and patients with diabetes [107–109].

Etiology and Pathogenesis

Pyomyositis occurs by extension of infection from adjacent tissues or by hematologic spread. Hematogenous infection usually develops when there is a primary source of infection elsewhere, which causes transient bacteremia in a setting of minor muscle injury at the site of pyomyositis. The most common organism that causes pyomyositis is *Staphylococcus aureus*, accounting for over 90 % of the cases in tropical countries [110] and approximately 70 % in the United States [79, 107]. Other organisms responsible for pyomyositis include group A and B hemolytic streptococci, *Escherichia coli, Streptococcus pneumoniae*, and *Yersinia* and *Legionella* species [111, 112]. Group B streptococci (*Streptococcus agalactiae*) are one of the new emerging organisms that cause soft tissue infection, pyomyositis, necrotizing fasciitis, and sepsis in patients with diabetes and multiple medical conditions [109, 113, 114]. There are also a few reports of pyomyositis caused by *Neisseria gonorrhoeae*, *Staphylococcus epidermidis, Proteus mirabilis*, *Aeromonas* species, *Salmonella* species, and anaerobic bacteria such as *Bacteroides* species [115–123]. Microscopically, intramuscular abscesses consist of a central area of necrotic tissue containing inflammatory cells, which are predominantly neutrophils. Macrophages, lymphocytes, and occasionally eosinophils and variable degrees of granulation tissue can be seen surrounding the area of necrotic tissue.

Clinical Manifestations

Staphylococcal pyomyositis commonly presents with fever and local swelling and tenderness in the affected muscles [124–127]. The evolution of pyomyositis may take 10–20 days to progress from the stage of local swelling of the muscle to the suppurative stage with prominent fever, tenderness, and purulent collection within the muscle [126]. Muscle

abscesses are usually small and do not result in acute swelling. History of local muscle trauma may precede the development of abscess in some cases [117, 128, 129]. Risk factors for the development of pyomyositis include HIV infection, intravenous drug use, diabetes, and steroid use [130–133]. The most common sites of involvement are the quadriceps, glutei, and deltoid muscles [126]. Pyomyositis of the paraspinal muscles may present with severe back pain [134].

Spontaneous streptococcal pyomyositis is less common than Staphylococcal pyomyositis. Pyomyositis due to group A beta-hemolytic streptococci may be virulent and associated with severe septicemia and a rapidly fatal outcome [110, 135–137]. Streptococcal pyomyositis also can occur in a more protracted clinical course or causes localized abscess in the muscle as in Staphylococcal infection [130, 138, 139].

Clostridial myositis (gas gangrene) is the most lethal type of infectious myositis. The infection is caused by large gram-positive spore-forming anaerobic rod organisms with *Clostridium perfringens* being the most common species isolated from wounds. Prior trauma, ischemia, pyogenic infection, and the presence of foreign body are risk factors that cause conversion of the clostridial spores into vegetative forms that can produce toxins. The clostridial toxins are responsible for producing multiple systemic manifestations such as septic shock and disseminated intravascular coagulation. The incubation period before the development of clostridial myonecrosis is often 2–4 days. The onset is acute and tense edema and local tenderness may be the only prominent findings very early in the course. Later on, the serosanguinous discharge with unpleasant foul odor together with the development of dark hemorrhagic blebs and areas of green black cutaneous necrosis appears and crepitus is detectable. High fever, hypotension, and disseminated intravascular coagulation then rapidly occur [110, 140–142].

Diagnosis and Evaluation

Diagnosis of pyomyositis is based on clinical manifestation of fever and local tenderness in specific muscles. Differential diagnosis of pyomyositis includes other soft tissue infection or conditions that can cause local swelling, pain, and tenderness such as intramuscular hematoma, deep soft tissue infection, septic arthritis, and venous thrombosis. Laboratory investigations reveal neutrophilic pleocytosis and elevated ESR. In patients with HIV infection, the absence of elevation of white blood cell count can be seen [107]. Serum CK is normal or elevated. Blood culture may be negative in up to 60 % of cases, since the bacteremia is often transient except in the cases that patients become septic [107]. Establishing the diagnosis of pyomyositis can be difficult in the patients with subtle local swelling and muscle tenderness. Ultrasound, CT scan, and MRI of muscles are useful in localizing the pyogenic abscess for diagnosis and needle aspiration [143–147]. Soft tissue X-ray is helpful in demonstrating interfascial gas in the case of clostridial myonecrosis.

Establishing the causal organism is important for the selection of the effective antimicrobrial agents. Gram stain and culture of the purulent discharge from surgical drainage or radiologically guided aspiration should be performed. Special stains and culture for other organisms such as Mycobacterium and fungus should also be performed when there is clinical suspicion of infection by other organisms, especially in immunocompromised patients.

Treatment and Prognosis

Before the abscess formation occurs, the infection may respond to antibiotics without surgical drainage. Well-formed abscesses require prompt incision and drainage together with intravenous antibiotics. The initial choice of antibiotics should provide good coverage for gram-positive organism especially for *S. aureus*. In immunocompromised patients, the choice of antibiotics should be broad spectrum before the identification of the causative organisms in gram stain or culture. Total duration of antibiotics usually needs to be at least 3–6 weeks [129]. In the cases of clostridial gas gangrene, excision of all involved muscles and adjacent tissue, as well as fasciotomy to decompress and drain the swollen fascial compartments, is required together with antibiotic treatment. Mortality rate of pyomyositis ranges from 1 to 4 %, despite treatment [107].

Fungal Myositis

Fungal infection of muscle is uncommon and usually occurs in immunosuppressed patients. Candida species is the most common fungus to cause myositis. Other fungi that produce myositis are *Cryptococcus neoformans* [148], *Aspergillus* spp. [149], *Pneumocystis jiroveci, Coccidioides* spp., *Sporothrix schenckii* [150], *Actinomyces* spp., and *Histoplasma capsulatum* [151, 152]. These organisms cause myositis in the setting of disseminated infection.

Candida myositis usually occurs in the setting of disseminated candida infection in an immunocompromised host or with a prolonged use of broad-spectrum antibiotics [153]. The patients present with high fever, diffuse erythematous skin rash, progressive myalgia, and muscle tenderness [154, 155]. Muscle tenderness is often severe and affects lower extremities predominantly [155].

Muscle biopsy shows areas of multiple microabscesses, hemorrhagic necrosis, and infiltration of the muscle by budding yeast, pseudohyphae, and inflammatory cells [153, 156]. Hemoculture may be positive in the setting of disseminated

candidiasis. The most common candida species causing muscle infection is *Candida tropicalis* but other candida species have also been reported [153, 155, 156].

Despite the treatment with intravenous amphotericin B for disseminated candida infection, the prognosis in general for the patient with systemic candida infection is poor and mortality rate is high [154].

Tuberculous Myositis

Granulomatous myositis caused by *Mycobacterium tuberculosis* and atypical mycobacterium species is uncommon. Other organisms in the mycobacterium species that cause soft tissue and muscle infections, in addition to Mycobacterium tuberculosis, are *M. ulcerans, M. marinum, M. fortuitum, M. chelonae, M. haemophilum, and M. xenopi* [157, 158].

Clinical Manifestations

Tuberculous myositis is seen in both normal and immunocompromised hosts [159, 160]. The infection often extends from adjacent primary foci of infection such as lung, pleura, joints, abdominal abscesses, or cutaneous lesions [161, 162]. This causes single or multiple muscle abscesses. Hematogenous spreading of infection also occurs [163]. One of the most common sites for tuberculous myositis occurs from direct extension of infection from vertebral osteomyelitis causing tuberculous psoas abscess. The clinical presentation is usually more indolent compared to cases of bacterial pyomyositis [159, 164–166]. Single or multiple masses of different sizes can be found on palpation of the involved muscles. Enlarged regional lymph nodes may occur [163]. Local trauma at the time of disseminated infection may contribute to the abscess formation [164].

Diagnosis and Evaluation

Diagnosis is based on clinical history of tuberculous infection, history of contacting tuberculosis, and indolent presentation of the intramuscular abscesses. CT scan and MRI of the affected muscles are helpful in identifying the site of intramuscular abscesses [167, 168]. Needle aspiration or surgical drainage of the mass is often required, and the final diagnosis is made based on the pathologic findings and acid-fast stain or culture for *Mycobacterium tuberculosis* [159, 164].

Histopathological study of infected muscle reveals granulomatous inflammation, consisting of histiocytes and macrophages surrounding the area of necrosis and caseation. The acid-fast bacilli are found in the inflammatory cells and in the necrotic tissue within the lesion [165]. Culture for mycobacteria may take weeks but is important for the identification of the organism and its sensitivity to antituberculosis agents.

Treatment and Prognosis

Treatment for tuberculous myositis consists of surgical drainage and administration of antituberculous drugs [159, 164, 165].

Sarcoid Myopathy

Sarcoidosis is a systemic granulomatous inflammatory disease of unknown etiology that involves multiple organs, primarily the pulmonary and lymphatic systems. The initial manifestation involves bilateral hilar adenopathy, pulmonary infiltrates, skin lesions (such as erythema nodosum), uveitis, and arthritis. Sarcoidosis is more prevalent in the African-American population and in women compared to men. The disorder is uncommon in childhood [169]. Incidence of myopathy ranges from 1 to 60 % of patients with sarcoidosis based on different series in literature. The majority of patients with myopathy are asymptomatic [169, 170].

Clinical Manifestations

Muscle weakness in sarcoidosis may present as acute myositis, chronic myositis, or neurogenic atrophy due to peripheral neuropathy or muscle involvement may be asymptomatic [171–177]. Acute or chronic myositis is the most common clinical presentation causing weakness, pain, and tenderness affecting proximal more than distal muscles [170, 178–181]. Muscle cramps and contracture also are described [182]. Dysphagia presumably from esophageal dysfunction and respiratory and extraocular muscle involvement is reported [183–186]. On examination, the nodular lesions in the muscle can be palpated in some patients [187]. Rarely, sarcoidosis can present with a tumorlike lesion in the muscle [187–189]. The myopathy may occur accompanied with peripheral neuropathy. Chronic sarcoid myopathy may cause significant muscle atrophy and wasting.

Diagnosis and Evaluation

The diagnosis of sarcoid myopathy is usually based on history of progressive proximal muscle weakness in a patient with clinical suspicion of systemic sarcoidosis. Systemic sarcoidosis has varied clinical presentations. Acute sarcoidosis usually develops over few weeks and presents with mild

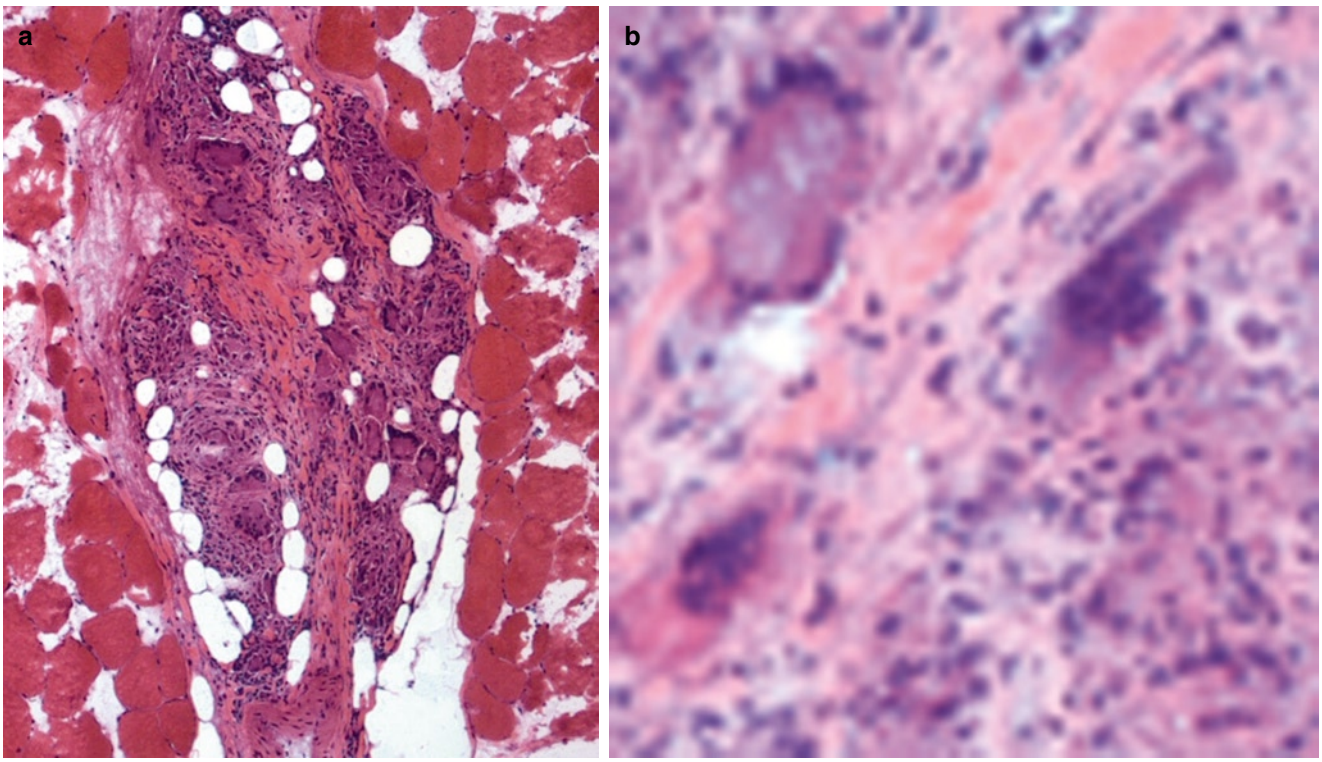

Fig. 69.1 Muscle biopsy from patient with sarcoid myopathy showing a large granuloma with clusters of epithelioid cells, lymphocytes, and giant cells (**a**: lower magnification; **b**: higher magnification) (H and E stain)

constitutional symptoms such as fever, fatigue, malaise, anorexia, or weight loss together with respiratory symptoms. The insidious form of the disease develops over several months with respiratory symptoms without constitutional symptoms [190]. The asymptomatic form, which represents approximately 10–20 % of cases, is detected mostly by routine chest X-ray. Skin lesions and eye involvement are also seen in 25 % of the cases. When neurosarcoidosis is the only manifestation of the disease, the diagnosis is difficult and often requires histopathological confirmation [181, 191].

About 90 % of patients with sarcoidosis have abnormalities on chest X-ray at some time during the course of the disease. Chest X-ray in systemic sarcoidosis often reveals hilar lymphadenopathy and interstitial infiltration of the lungs. Serum angiotensin-converting enzyme (ACE) is usually elevated in sarcoidosis. Although not always specific for the disease, serum ACE can be helpful in differentiating sarcoidosis from other granulomatous inflammatory diseases. Gallium scan is used in locating the specific sites of inflammation in the patient with clinical manifestations suggestive of systemic sarcoidosis [192–194]. Whole body fluorodeoxyglucose proton emission tomography (FDG-PET) has also been reported useful in some cases for locating the specific sites of inflammatory tissues for biopsy [195, 196]. MRI of the muscle in nodular type of muscular sarcoidosis sometimes shows distinctive star-shaped central structure of decreased signal intensity in the axial MRI images with peripheral enhancement with gadolinium [194, 197]. However, the MRI often reveals normal or nonspecific findings in the myopathic type of muscular sarcoidosis without intramuscular nodules [194]. EDX studies in sarcoid myopathy reveal findings consistent with myopathic or myopathic and neuropathic features in patients with concomitant peripheral nerve involvement. Muscle biopsy shows granulomatous inflammation in the connective tissue surrounding the muscle fascicles. The pathologic changes are focal and serial sections of muscles may be required to establish the diagnosis. The granuloma consists of clusters of epithelioid cells, lymphocytes, and giant cells (Fig. 69.1a, b) [198–200]. Large granulomas tend to compress and destroy the adjacent muscle fibers but muscle fiber necrosis is not common. There are no specific criteria to definitely distinguish pathologic changes in sarcoidosis from other granulomatous inflammatory disorders [201–203].

Treatment and Prognosis

Sarcoid myopathy and systemic sarcoidosis usually respond well to treatment with corticosteroids with significant improvement of muscle strength and systemic symptoms.

However, patients with very chronic myopathic manifestation may not response well to corticosteroid and may remain disabled [204, 205]. In some patients, treatment with nonsteroidal anti-inflammatory medications results in improvement of systemic symptoms [170, 171, 178, 179, 181, 206]. Treatment with other immunosuppressive agents, such as methotrexate or azathioprine, may be used in cases unresponsive to steroid treatment [188, 207]. Spontaneous remission may occur in a small portion of patients.

Lyme Myositis

Lyme disease is a systemic infection caused by the spirochete *Borrelia burgdorferi*, which is transmitted by tick bite [208].

Clinical Manifestations

The initial presentation includes characteristic rash (erythema migran), accompanied by flu-like symptoms, followed several weeks or months later by migratory arthritis, musculoskeletal pain, and neurologic and cardiac abnormalities [208–210]. Muscle weakness and myalgia is one of the presenting clinical manifestations of the disease, and chronic musculoskeletal pain usually occurs in the chronic phase of the disease [211–215]. Myocardial involvement may also occur [215, 216]. Orbital myositis associated with Lyme disease is reported [217, 218].

Diagnosis and Evaluation

Diagnosis of myopathy in Lyme disease is based on the presence of muscle weakness and myalgia in the setting of Lyme infection. Serology is often useful in making the diagnosis of Lyme disease after the first 3–6 weeks of infection. However, the serologic results need to be interpreted with caution since the presence of infection by other spirochete may create false-positive results [208, 210, 211]. Muscle biopsy in patients with musculoskeletal involvement often reveals infiltration of the muscle by lymphocytes and other mononuclear inflammatory cells [215, 219]. Using special stains for spirochetes, the organism can be identified in the muscle fibers [220].

Treatment and Prognosis

Treatment of myopathy related to Lyme disease is similar to the treatment of systemic disease with appropriate antibiotics such as tetracycline, penicillin, and cephalosporin. A prolonged course of treatment may be required in the patient with a long clinical course [208, 210, 211].

Myositis Secondary to Parasites

Trichinosis

Trichinosis occurs secondary to infection by the nematode *Trichinella spiralis*. The other parasites in the Trichinella species can also cause muscle infection but are uncommon. The infection involves multiple organs with predilection to the muscles. The transmission often occurs through ingestion of undercooked pork, bear, or walrus meat containing Trichinella pseudocysts (Fig. 69.2) [221, 222]. Trichinosis is found in nearly every region of the world, except Australia.

Etiology and Pathogenesis

Following ingestion of the meat containing pseudocysts, the gastric enzyme digests the cystic enclosure leaving the larvae to inhabit in the gastrointestinal system. After fertilization in the intestine, the male parasite dies while the female parasite penetrates the deep layer of the intestine. The young larvae pass through the intestinal mucosa into the bloodstream and to the muscles, where they then enter the muscle fibers and transform to the encysted form. The pseudocyst wall consists of connective tissue and cellular components from reaction of the host [223, 224]. Inflammatory cells in the early stage of inflammation are mainly polymorphonuclear leukocytes and eosinophils. In the chronic stages, calcification of the pseudocyst occurs, and mononuclear inflammatory cells replace the polymorphonuclear leukocytes [225].

During the period that the larvae encyst in the muscles, there is evidence of muscle degeneration and regeneration. Elevation of muscle's alkaline phosphatase is detected in the muscle fiber invaded with Trichinella in the acute stage of infection [226]. Between 2 and 4 weeks after the infection, the capsule surrounding the parasite gradually thickens, and in the chronic infection, the capsule will start to become calcified with no further destruction of muscle fibers [227].

Clinical Manifestations

The usual incubation period after ingesting meat with pseudocysts is between 2 and 12 days. The prodromal manifestations consist of abdominal pain and diarrhea. This is followed in the second week by fever, subconjunctival hemorrhage, periorbital edema, and myalgia, which predominately affects proximal muscles [228–232]. Trichinosis presenting as an acute severe myositis mimicking polymyositis can occur [233, 234]. The severity of clinical symptoms appears to be related to the number of Trichinella larva per gram of muscle [235]. Clinical examination reveals weakness and tenderness of the muscles, which may also involve the extraocular, intercostal, and diaphragmatic muscles [228]. Skin manifestations mimicking dermatomyositis rash, periorbital edema, and subconjunctival hemorrhage may occur [236]. Myocarditis may be seen although rare resulting

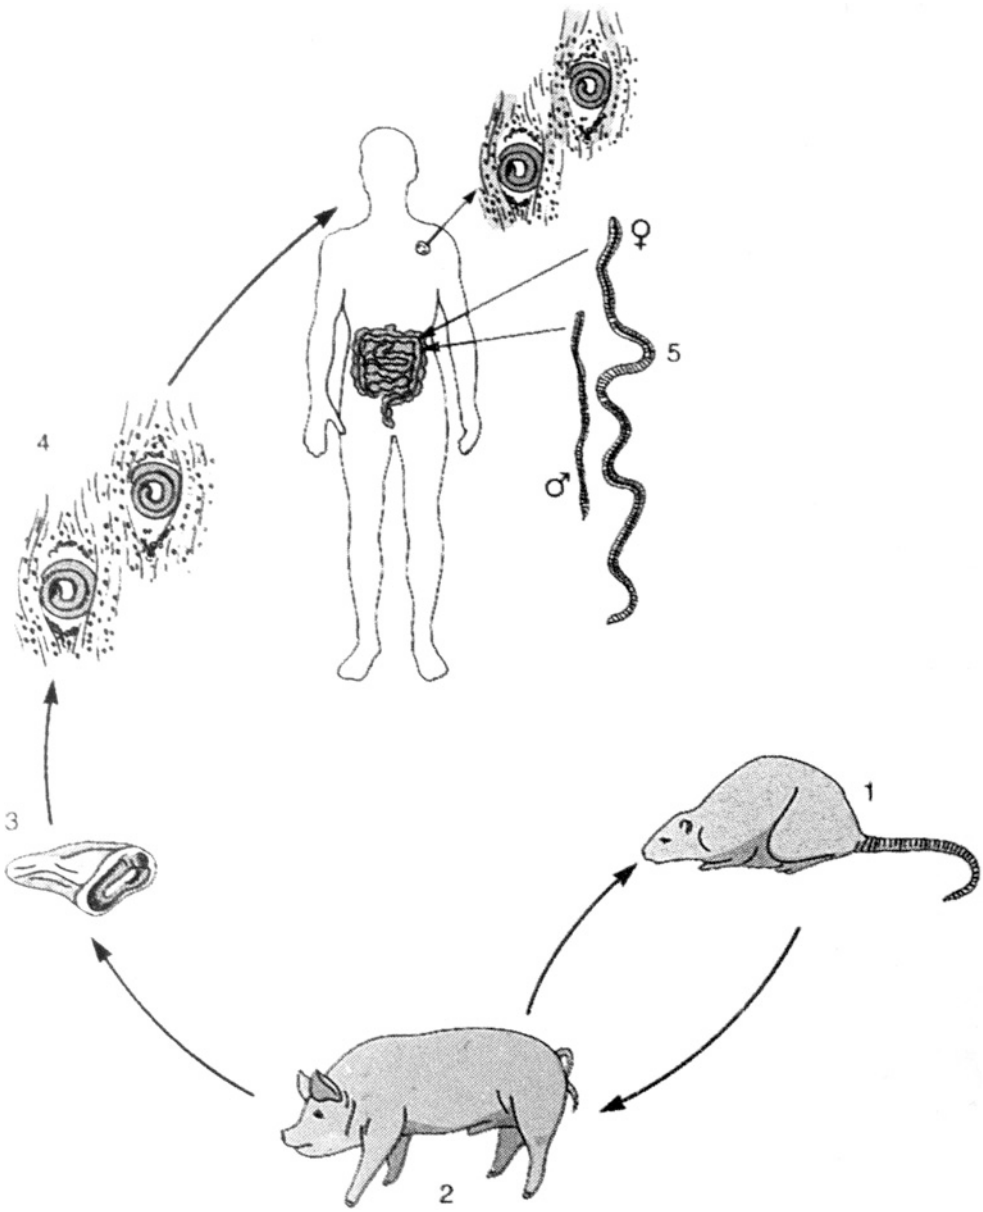

Fig. 69.2 Life cycle of Trichinella spiralis. This nematode causes a zoonotic infection that circulates between rats (*1*) and various carnivores. Trichinosis in human commonly results from eating raw or inadequately cooked pork or pork products such as sausages. Domestic pigs (*2*) and wild boar usually acquire the infection by eating infected rats (1). Infection is acquired by eating muscle (*3*) containing the encysted larvae (*4*). These excyst in the small intestine and develop into minute adults (*5*) in the mucosa. About 5 days after infection, the females, now mature, deposit larvae that migrate through the tissues to reach skeletal muscles in which they again encyst. Larvae deposition into muscle may continue for a week or more. Finally, the larvae become calcified. (Reproduced with permission from W Peter, HM Gilles. Color Atlas of Tropical Medicine and Parasitology, [4th ed]. St. Louis: Mosby-Year Book, 1995)

in tachycardia and may lead to cardiac failure. Headache, altered mental status, and nuchal rigidity occur in severe cases associated with central nervous system involvement [237, 238]. Myalgia from trichinosis may last for several months without treatment. Symptoms from myositis often start to improve when the parasitic larvae are encapsulated and calcified.

Diagnosis and Evaluation

Diagnosis of trichinosis is based on clinical presentation of acute weakness and myalgia in the patient with prior history of ingesting undercooked meat. Laboratory investigation shows increased eosinophil in the blood. Serum CK is elevated acutely. Needle EMG reveals fibrillation potentials and myopathic MUAPs [229]. Serology test for Trichinella antibodies becomes positive in 3–4 weeks after acute infection [229, 239, 240]. The definite diagnosis is obtained by muscle biopsy, which shows pseudocyst containing Trichinella larvae [241].

Treatment and Prognosis

Treatment with antiparasitic agents such as thiabendazole, mebendazole, and albendazole is effective against the larvae in gastrointestinal tract and may be effective against encysted larvae [230, 232, 242, 243]. A Herxheimer-like reaction can occur from simultaneous destruction of larvae from different sites and additional treatment with corticosteroids may be required [232]. Myalgia secondary to Trichinosis may persist for several months but serious complication or death rarely occurs [242].

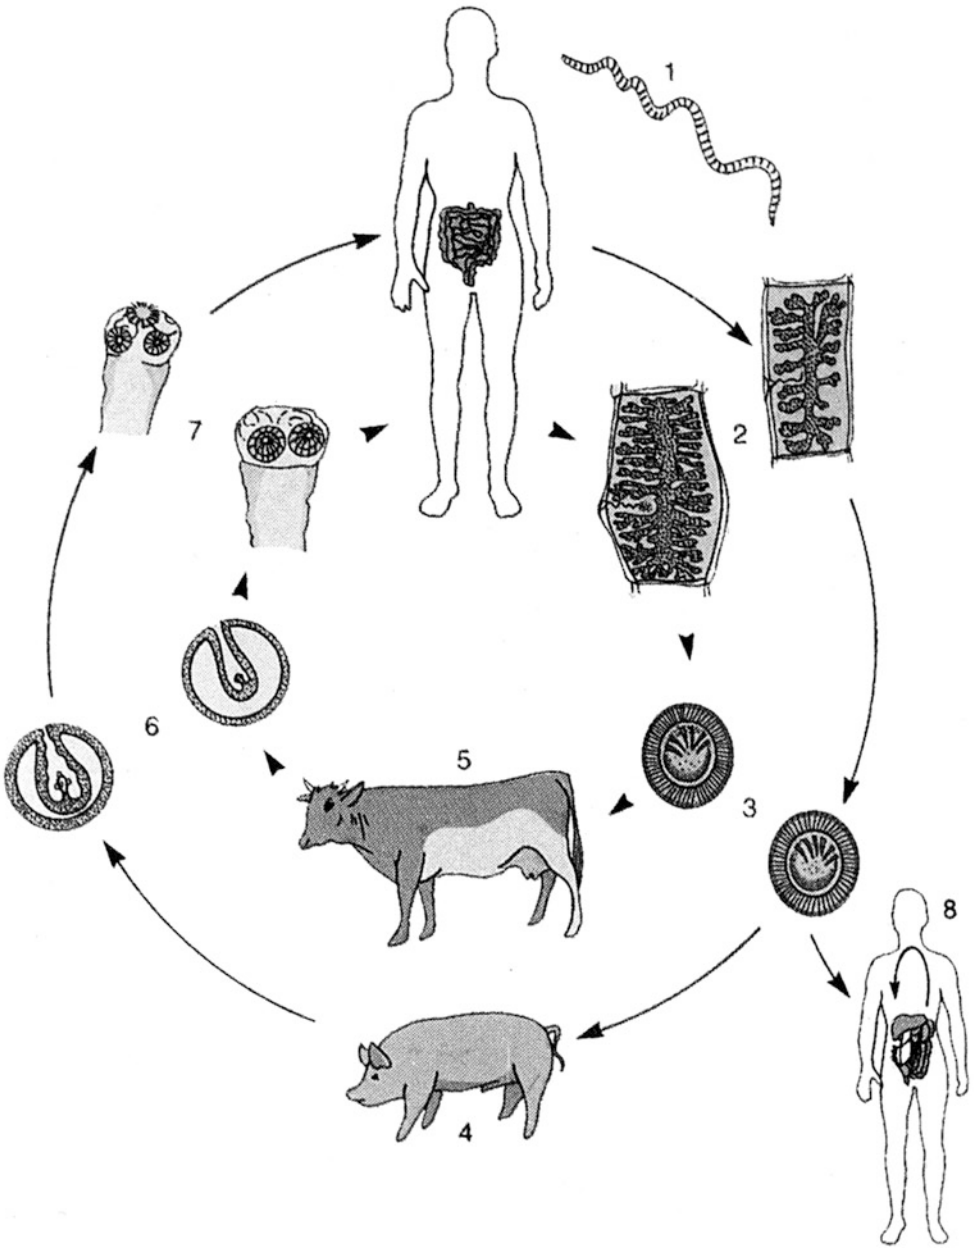

Fig. 69.3 Life cycle of Taenia solium and *Taenia saginata*. The adults (*1*) of both species live in the small intestine of human, the definitive host. The gravid segments (*2*) are very active and escape through the anus, releasing large numbers of eggs (*3*) in the perianal region or on the ground, where they can survive for long periods. When ingested by pigs (*4*) (Taenia solium) or cattle (*5*) (Taenia saginata), the eggs hatch, each releasing an oncosphere which migrates through the intestinal wall and blood vessels to reach striated muscle within which it encysts, forming cysticerci (*6*). When an inadequately cooked meat containing the cysts is eaten by man, the oncosphere excysts (*7*), settles in the small intestine, and develops into adult cestodes (1) over the next 3 months or so. If the eggs in the Taenia solium segments are released in the upper intestine (by contaminated food or water), they can invade the host (autoinfection) (*8*), setting potentially dangerous larval infection, known as cysticercosis, in muscle, brain, or any other tissues. (Reproduced with permission from W Peter, HM Gilles. Color Atlas of Tropical Medicine and Parasitology, [4th ed]. St. Louis: Mosby-Year Book, 1995)

Cysticercosis

Cysticercosis results from infection by *Taenia solium*, which occurs after ingesting undercooked meat especially pork. Ingesting fecal-contaminated food and water is another route of infection. Cysticercosis occurs in all parts of the world especially in Central and South America, Asia, Africa, Eastern Europe, and Spain, where there is poor sanitation of the water supply and sewage.

Etiology and Pathogenesis

Cysticercosis occurs from infection by a tapeworm, *Taenia solium*. The most frequent mode of transmission to humans is through fecal-oral contamination by ingestion of *T. solium* eggs excreted in the feces of intermediate hosts such as pigs or human. Ingesting the cysticercus in the undercooked pork meat does not directly lead to encysted larvae within the host, unless the host then again ingests the ova-contaminated food or water later.

When human ingested the undercooked pork meat with *T. solium* cysticerci, which contains mature larvae, the mature larvae hatch from the cysticercus and attach to the intestinal mucosa, which they inhabit for several years and where fertilization occurs. The ova are excreted in the feces and are ingested by the intermediate host such as pigs or are ingested by humans through fecal-contaminated food or water (Fig. 69.3). The embryo is released from the ova in the stomach by gastric enzymes and then

penetrates the intestinal mucosa into the lymphatic and bloodstreams to various organs. The larvae, then, grow rapidly in the tissue and develop scolex with hooks and suckers. The larvae often reach, in 2–3 months, its mature stage (cysticercus), which measure 5–6 mm in length and 8–10 mm in width. When humans ingest the undercooked pork, the mature larvae hatch from the cysticercus, attach itself to the intestinal mucosa, and begin another cycle [242, 244, 245].

Clinical Manifestation

Cysticercosis mainly affects the central nervous system and muscle. The involvement of the central nervous system is secondary to cysticercus cyst in the brain parenchyma resulting in an inflammatory reaction in the surrounding tissue leading to focal neurologic deficits. Seizures, obstruction of CSF pathways, and meningoencephalitis may occur in the central nervous system cysticercosis.

Muscle involvement in cysticercosis is not uncommon and is well described. Muscle involvement by cysticercosis is often asymptomatic. Calcified cysts in muscles sometimes are incidentally noted on the X-rays of the extremities. Weakness, muscle enlargement, and muscle tenderness are the main clinical manifestations that are described in symptomatic cases [246–249]. Muscle pseudohypertrophy has been reported, which often is symmetrical and occurs in limb girdle muscles [246, 250–252]. Nodular changes in the muscle may be found on deep palpation of the involved muscles. Involvement of extraocular muscles causing proptosis and ophthalmoparesis occurs [253–255]. Skin manifestations, such as subcutaneous nodules, sometimes accompany the skeletal muscle involvement.

Diagnosis and Evaluation

The diagnosis of cysticercosis is often based on clinical history and the presence of focal neurologic deficits, muscle weakness, and muscle pain in the patients from areas with poor sanitation. The presence of *T. solium* ova, which cannot be differentiated from *T. saginata* ova, in the feces alone is not sufficient for diagnosis of cysticercosis. Serologic testing of blood or CSF by enzyme-linked immunosorbent assays can be used to confirm the evidence of infection by *T. solium* [256]. Radiologic imaging such as CT or MRI or even plain X-ray revealing calcified cysts in the brain or muscles is helpful in judging for the extent of the disease [257–259]. Muscle biopsy may be required for definite diagnosis of skeletal muscle involvement. The cysticerci can be seen by gross examination of the muscle biopsy specimen as oval-shaped, milky white cysts of approximately 1 cm in size, containing fluid and a single scolex. Microscopically, the different components of the larvae are seen [242, 246, 247, 252].

Treatment and Prognosis

The antiparasitic agent, praziquantel and niclosamide, is the drug of choice for treating the adult form of *T. solium* in the intestine. Albendazole and steroid are used to treat central nervous system cysticercosis, and treatment results in a reduction of the number and size of the cysts [260]. The effectiveness of the antiparasite in the treatment of cysticercosis in muscles is established [244, 245, 261, 262]. The intramuscular viable cysts usually were treated with albendazole or praziquantel. Surgical removal of large intramuscular cysts may be required in some cases [263].

Myositis Secondary to Other Cestodes or Nematodes

Cestodes that can cause infection in muscles include the tapeworm in the *Spirometra* species and tapeworms in the genus *Echinococcus*. *Spirometra mansonoides* infects dogs and cats and, sometimes, causes infection in humans as accidental intermediate hosts. The infective stage of the parasite, which is the second-stage larva called sparganum, enters the human host through the oral route or open wounds and then encysts mainly in the subcutaneous tissue and muscles, but can also involve the eyes, brain, spinal cord, or viscera [264–267]. Most patients in the United States acquire infection through drinking water that is contaminated with first-stage larvae from a shallow pool or well [268]. In Asia, the parasites are usually acquired by eating undercooked snake or frog meat [269]. The patients present with slow-growing subcutaneous nodules or nodules in the muscles, which increase in size over several months and occasionally migrate distally. Excisional biopsy of the nodule is required for diagnosis. Pathology reveals presence of the sparganum in the nodule [270–272]. Surgical removal of the nodule is the treatment of choice.

Tapeworms in the genus Echinococcus include *Echinococcus granulosus* and *Echinococcus multilocularis*, which cause infections in dogs and wolves, as the definitive host, and human as an intermediate host. Cases of Echinococcus infections are found in the Middle East, parts of Europe, and Central and South America. The infection in humans (hydatidosis) is acquired through ingestion of food that has been contaminated by feces of the definitive hosts. The patients present with lobular cyst (hydatid cyst) in the muscle [273, 274] and in other visceral organs [275, 276], which slowly grows over several years and often calcifies. Thigh muscles are the most common location for muscle involvement. The nodule is usually not painful but the cyst may become infected by bacteria and result in abscess formation. Diagnosis requires surgical removal of the cyst. X-ray, ultrasound, or CT scan of the muscle may be helpful in identifying the cyst location [277]. Serology testing for serum

antibody to Echinococcus is also helpful for diagnosis. Definite treatment is surgical removal of the hydatid cysts [242]. Medical treatment with albendazole or praziquantel may be needed before surgery in cases that leakage of the cyst content may occur [278].

Other nematodes that cause muscle infection include *Toxocara canis* and *Toxocara cati*, *Ancylostoma caninum*, and dracunculiasis. *Toxocara* species usually cause visceral larva migrans in children, who acquire the infection by ingesting the soil contaminated with ova from infected dogs and cats. Clinical manifestations vary from asymptomatic with persistent eosinophilia to severe systemic infection with fever, hepatosplenomegaly, pneumonitis, and myalgia [279, 280]. Ocular and central nervous system involvement also occurs [279, 281, 282]. The invasion of muscle by *Toxocara* species usually causes granulomatous changes in the muscle. Pathologic finding reveals necrotic zone of the muscle centrally surrounded by granulomatous inflammatory reaction. Treatment with antiparasitic agents, such as albendazole, may be beneficial in cases of visceral larva migran [242].

Ancylostoma caninum normally causes cutaneous larva migrans and enters the host by directly penetrating the skin. Muscle infection from Ancylostoma is rare. The patient reported with muscle infection had severe cutaneous and visceral larva migran and developed tenderness and enlargement of the thigh muscle several months after the onset of the systemic infection [283]. The muscle biopsy revealed a nonencapsulated hookworm larva within the muscle fiber with inflammation surrounding the degenerative muscle fibers [242, 283].

Dracunculiasis, a common disease in Africa, India, and the Middle East, results from the nematode *Dracunculus medinensis*. The infection occurs after ingestion of the infected intermediate host, which is a crustacean called cyclops. The parasite then slowly migrates to the skin within a duration of 1 year causing focal induration in the subcutaneous tissue, fever, erythema, or periorbital edema. The mature parasites also create tracks in the connective tissue between the muscle and cause inflammatory reaction along the wall of the tracks and sometimes pyomyositis [284]. Some parasites usually die along the tracks and cause chronic calcifications. Treatment is by surgical removal of those parasites that come to the subcutaneous tissue or penetrate the skin. Treatment with antiparasitic agents helps to suppress the symptoms but usually cannot successfully eradicate the parasites [242, 285].

Myositis Secondary to Infection with Protozoa

Myositis secondary to infection from protozoa is relatively rare. The infection in human is usually acquired by ingesting the infected or contaminated meat or by living in close association with the definitive host. The protozoa reported to cause myositis are *Toxoplasma* species, Sarcocystis, *Trypanosoma* species [286, 287], and Microsporidium [288]. Malaria is reported to be associated with necrosis of the skeletal muscle and rhabdomyolysis [289, 290].

Toxoplasmosis

Toxoplasmosis is a systemic infection that occurs from coccidia, *Toxoplasma gondii*. Infection is more common in the immunocompromised hosts. A congenital form of toxoplasmosis also occurs. The patient presents with fever lymphadenopathy, hepatosplenomegaly, pericarditis, myocarditis, pneumonia, or meningoencephalitis. Myositis usually occurs with the systemic infection but may also occur in isolation [291, 292].

Etiology and Pathogenesis

Toxoplasmosis is found worldwide. Goats, cats, hogs, dogs, sheep, and cattle are affected by the protozoan *Toxoplasma gondii.* The most common mode of transmission to human is contact with cat feces or ingesting infected undercooked pork or lamb meat. Reactivation of the infection may occur in the chronic asymptomatic host, who becomes immunocompromised. Toxoplasmosis can also be transmitted through the placenta and blood products [242].

The most common mode of transmission is ingestion of infected meat, which contains Toxoplasma cysts. Ingesting oocyst-contaminated food may also transmit the disease. The oocyst, which contains the sporozoite form of toxoplasmosis, is excreted only in cats. Bradyzoites are then released from the cysts in the gastrointestinal tract and multiply. The tachyzoites then penetrate the nearby cells and leukocytes, which leads to disseminated infection through the bloodstream. The proliferation of the tachyzoites within the cells leads to necrosis of the cells. Tachyzoites eventually are destroyed by the host immune system, but the cysts containing bradyzoites persist for a long time in their host [242].

Clinical Manifestation

Polymyositis from toxoplasma infection often has a subacute presentation [291, 292]. Patients present with subacute progressive fever, myalgia, and muscle weakness similar to idiopathic polymyositis [293–299]. Lymphadenopathy and other signs of systemic toxoplasma infection are helpful in distinguishing toxoplasma-associated polymyositis from idiopathic polymyositis. Immunocompromised patients may also have clinical manifestations of infection involving other systems such as the central nervous system [300].

Diagnosis and Evaluation

Myositis secondary from toxoplasma infection should be considered in the immunocompromised patient with or without systemic manifestation of toxoplasmosis. Muscle

enzymes are usually elevated when muscle involvement occurs. Needle EMG examination reveals findings consistent with subacute polymyositis. Serology testing for toxoplasmosis may be helpful. A high titer of IgM antibody or a rise in IgG antibody titer testing over 3–4 weeks suggests the diagnosis [301, 302]. However, a single positive serology testing for toxoplasmosis can be a result from a remote chronic infection [242]. Demonstration of cysts or toxoplasma trophozoites from histopathological sections or isolation of toxoplasma from body fluid provides definitive diagnosis of toxoplasmosis. Muscle biopsy in toxoplasma-associated myositis reveals inflammatory cells, which are composed of histiocytes and lymphocytes in the perimysium and endomysium. Giant cells are sometimes present in inflammatory aggregates [293, 303, 304]. Toxoplasma tachyzoites are seen in the intracellular vacuoles as a crescentric or oval-shaped organism, stained with Wright and Giemsa stain. Toxoplasma cyst, which contains Toxoplasma bradyzoites, is easier to identify around or within the inflammatory cells and within the muscle fibers and usually stained well with the periodic acid Schiff (PAS) stain [305].

Treatment and Prognosis

The treatment of choice is with a combination of pyrimethamine and sulfadiazine, which eliminates the trophozoites in the acute stage of infection but is not as effective against the cyst form [242, 306].

Part IX

Neuromuscular Disorders: Miscellaneous Neuromuscular Disorders and Syndromes

Myokymia and Neuromyotonia

70

Anne F. Josiah and Laurie Gutmann

Introduction

Myokymia and neuromyotonia are terms used to refer to specific clinical presentations and electrophysiologic findings associated with hyperexcitability of the peripheral axon [1, 2]. Myokymia is recognized as a spontaneous, continuous, undulating, vermicular movement of muscle. Focal clinical myokymia was first described in the legs in 1894 by Schultze and in the face in 1902 by Bernhart. The first description of generalized myokymia was by Denny-Brown and Foley in 1948 [3]. Neuromyotonia is also a continuous movement of muscle but is more generalized and results in muscular contractions and stiffness. The term, neuromyotonia, was first used by Mertens and Zschocke in 1965 [4]. Many terms have been used to describe this clinical phenomenon, including neuromyotonia [4], continuous muscle fiber activity [5], Isaacs' syndrome [5], neurotonia [6], Morvan's fibrillary chorea [7], and Morvan's syndrome [8]. In the literature, the clinical disorders of neuromyotonia and myokymia are sometimes difficult to distinguish, as the terms are not used in a consistent fashion. Both are associated with the same electrophysiologic accompaniments of myokymic discharges and, occasionally, neuromyotonic discharges. Some authors consider these two types of discharges to be a continuum [9]. In this chapter, the similar etiologies, clinical picture, and electrophysiologic studies will be reviewed. The more recent association with channel disorders will be highlighted.

Etiology and Pathogenesis

Myokymia and neuromyotonia may be focal as well as generalized. The etiology of both types of myokymia and neuromyotonia is generally felt to be from a channel abnormality. A hereditary form of myokymia has been described as well as an autoimmune form of neuromyotonia [10–12]. Chromosome 12p13 has been identified as the gene for episodic ataxia and myokymia [10, 11, 13]. Potassium channel genes and a calcium channel gene map close to this locus. Antibodies to potassium channels have been identified in patients with Isaacs' and Morvan's syndrome [12]. Up to 50 % of patients with acquired neuromyotonia have antibodies to voltage-gated potassium channels [4, 7, 8]. Association with myasthenia gravis, thymoma, malignancy, amyloidosis, paraproteinemia, inflammatory demyelinating polyneuropathies, chronic graft-versus-host disease, penicillamine use, and lymphoma, along with response to plasma exchange and immunosuppression, has also been noted [11, 14–21]. Transient neuromyotonia has been recorded following oxaliplatin infusions, accompanied by paresthesias and dysesthesias with jaw and neck tightness, worsened with cold [22, 23]. The transient nature of symptoms implies a channelopathy, and a recent study implies a calcium-dependent potassium channel [24].

Myokymia and neuromyotonia may occur in mass lesions such as brainstem tumors and cysticercosis [25, 26], multiple sclerosis, timber rattlesnake bites, and a delayed effect after radiation therapy [21, 26–29]. The authors have also observed myokymia and neuromyotonia as a transient finding after severe anoxic injury. The clinical presentation is identical to the presentation in those with immunologic associations.

Myokymic discharges refer to the underlying electrophysiological abnormality in both clinical myokymia and neuromyotonia. The discharges are single motor unit action potentials which fire at rates of 5–150 Hz in bursts (Fig. 70.1). They may be doublets, triplets, or multiplets, firing at regular or slightly irregular intervals. The generator for these discharges is felt to be at some point along the motor axon. Ephaptic transmission from axon to axon may cause the multiple

B. Katirji et al. (eds.), *Neuromuscular Disorders in Clinical Practice*,

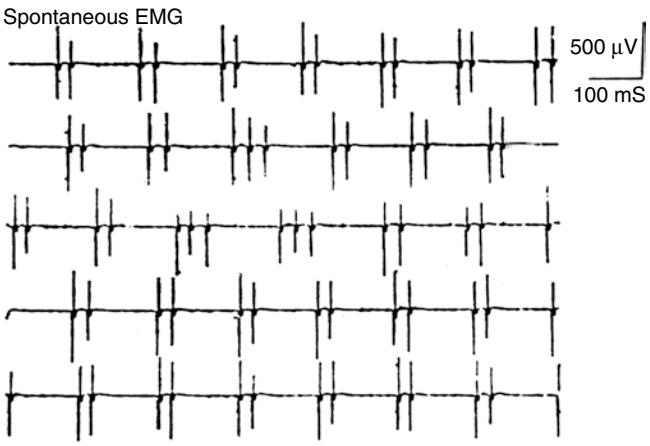

Fig. 70.1 Myokymic discharges firing at a rate of 7 Hz. Note the regular firing of bursts. Doublets predominate with occasional triplets

discharges linked together, but its exact role is not clear. These may be seen in a variety of disorders, including all those listed above. In addition, rare bursts of myokymic discharges may be seen in some focal neuropathies such as carpal tunnel syndrome or radiculopathies [27]. These latter are, however, not associated with clinically evident myokymia.

Neuromyotonic discharges fire at high frequencies (i.e., 150–300 Hz), last a few seconds, and may begin and end abruptly. They are not necessarily recurring and may have some slight waning of amplitude and frequency. The discharges may occur spontaneously or be initiated by needle movement, voluntary effort, or nerve percussion. They often occur intermixed with myokymic discharges.

With the discovery of the genetic abnormality of a potassium channel in episodic ataxia/myokymia and antibodies to voltage-gated potassium channels in acquired neuromyotonia, the pathogenesis of myokymia and neuromyotonia is felt to be an axonal channelopathy [9, 11, 12, 30]. This presumably results in abnormal firing of axons with the resulting clinical and electrophysiological picture. Development of abnormal transmission from the application of plasma from patients with neuromyotonia and potassium channel antibodies to in vitro mouse nerves implicates this further [18, 31].

The most common finding in muscle biopsies is mild denervation with some fiber-type grouping [18, 32, 33]. One report of predominance of type 1 myofibers proposed the possible conversion of fiber types through continuous stimulation by the neuromyotonic discharges [15]. In nerve biopsy specimens, loss of myelinated fibers has been described as well as marked decreased numbers of unmyelinated fibers [34].

Clinical Presentation

Clinical neuromyotonia is best described in patients with continuous muscle fiber activity or Isaacs' syndrome. It has been described in infants [35], but more commonly in adults. There is usually an insidious onset of persistent muscle contractions involving the distal extremities most severely, but also involving proximal extremities, trunk, and facial muscles. There may be hyperhidrosis and reddening of the skin. Persistent contraction often occurs following exercise. Often, a rippling of the continuously contracting muscles can be seen. Electrophysiologic recordings in the contracted muscles reveal myokymic discharges intermixed with occasional neuromyotonic discharges.

Morvan's syndrome is a form of neuromyotonia in which the above symptoms and findings are accompanied by encephalopathy with insomnia, hallucinations, and confusion [8]. The syndrome was first described by Morvan in 1890 and was referred to as Morvan's fibrillary chorea.

Neuromyotonia may be intensified after voluntary muscle contraction and persists for several seconds after attempted relaxation similar to myotonia of muscle origin. Unlike myotonia, however, neuromyotonia does not occur following muscle percussion. When it occurs only after voluntary contraction, it has been termed neurotonia [6]. A brief persistent muscle contraction is seen and is associated with bursts of motor unit potentials. There are no spontaneous discharges at rest. It is not clear whether neurotonia is a distinct clinical entity or a variation of neuromyotonia.

Clinical myokymia may occur focally, most commonly in the face or limbs. Patients with multiple sclerosis, pontine gliomas, or status-post irradiation have described persistent contraction of facial muscles. Focal myokymia of the face, when seen in patients with multiple sclerosis, is transient and usually indicates a new lesion. Facial myokymia has also been described in vestibular schwannomas and pontine neurocysticercosis and associated with an inherited disorder, familial dyskinesia with facial myokymia [21, 34, 36, 37]. Clinically, it may be seen as vermicular movements under the skin or a persistent contraction/distortion of the facial muscles, which has been referred to as clinical myokymia or focal neuromyotonia. Due to the persistent contraction, it is probably more appropriately called focal neuromyotonia. Electrophysiologic discharges in affected muscles are myokymic with occasional neuromyotonic discharges [25, 27, 28, 38]. Ocular neuromyotonia may cause episodic diplopia. The majority of patients with this disorder have received radiation therapy to the sellar and parasellar regions [39]. Isolated laryngeal myokymia, a rare entity described in relation to an ectatic vessel displacing the medulla, may cause a hoarseness or quivering quality of the voice [40].

Focal myokymia can also affect an extremity, as may occur following radiation. Patients may present with complaints of focal movement or an uncomfortable sensation in the extremity. The spontaneous wavelike movements under the skin occur while awake or asleep, the same as clinical neuromyotonia [27].

Generalized myokymia may occur in the setting of an immune-mediated disorder, either isolated or as part of an

autoimmune disease, or more rarely can be a part of a genetic disorder. Generalized myokymia has been described with toxins (rattlesnake venom) which may be related to their effect on the potassium channel [29, 41, 42]. The authors have also observed and recorded generalized myokymia as a transient phenomenon among patients with severe anoxic injury, usually within the first 48 h.

The most common inherited cause is episodic ataxia with myokymia [11, 27]. The myokymia in these disorders may well be just a less severe form of neuromyotonia without persistent muscle contraction. Episodic ataxia with myokymia is a rare familial disorder that presents with brief episodes of ataxia and dysarthria, lasting seconds to minutes with associated clinical myokymia in distal muscles during attacks. Some patients develop contractures in their Achilles tendons due to persistent myokymia/neuromyotonia. This genetic disorder has been mapped to chromosome 12p13, with a missense point mutation of the potassium channel gene, KCNA1 [11]. A highly varied phenotype has been observed in patients with gene mutations involving KCNA1, as severe neuromyotonia without prominent episodic ataxia has been described [43]. Inherited neuromyotonia has been linked to other mutations of the potassium channel. Dedek et al. described a syndrome of benign familial neonatal seizures and myokymia linked to KCNQ2, which encodes a voltage-gated potassium M subunit [44]. Rare generalized myokymia has been described in the setting of spinocerebellar ataxia and paramyotonia congenital [13, 45].

Differential Diagnosis

The presenting complaints in a patient with Isaacs' and Morvan's syndromes are usually muscle discomfort and persistent contraction, delay in muscle relaxation, and, in some cases, hyperhidrosis. The differential diagnosis includes drug intoxication, snake envenomation, hypocalcemic state with tetany, chronic inflammatory demyelinating polyneuropathy, myotonic disorders, and stiff-man's syndrome (see Chapter 71). For focal clinical myokymia/neuromyotonia, the differential is all of the disorders noted above, in addition to multiple sclerosis, pontine tumor, ectatic vessel or other mass lesion, amyloidosis, and postirradiation effects. Clinical myokymia may also occur following denervation with profuse fasciculation potentials. Differentiation is made on needle electromyography demonstrating fasciculation potentials instead of myokymic discharges.

Evaluation and Diagnosis

Electrophysiologic studies, including standard nerve conduction studies as well as needle electromyography, must be done to determine if the patient has myokymic and/or neuromyotonic discharges. The presence of these spontaneous electrical discharges in a patient clinically suspected to have neuromyotonia is confirmatory, in the absence of significant nerve conduction study abnormalities. Repetitive discharges after voluntary action or after single shock have also been described [6, 28]. Laboratory studies, such as serum protein electrophoresis and voltage-gated potassium channels, which are now available commercially, may help in planning treatment. Genetic testing may be considered in patients with generalized neuromyotonia when clinically appropriate.

The presence of slowed conduction with or without conduction block in the presence of myokymic discharges should lead one to pursue the diagnosis of acute or chronic inflammatory demyelinating polyneuropathy.

Patients with focal neuromyotonia/myokymia of the face warrant an imaging study of the brain, preferably an MRI scan, looking for a pontine lesion from either tumor or multiple sclerosis. At times, a muscle biopsy may be helpful, such as in a patient who may have a chronic denervation syndrome or a systemic disorder as seen in amyloidosis manifesting with focal muscular symptoms [15].

Treatment and Management

The treatment of Isaacs' and Morvan's syndromes is predominantly symptomatic. Isaac initially used phenytoin with success, which continues to be a useful treatment (Fig. 70.2). Carbamazepine has also been used [5, 17, 34]. Effective drugs most likely work by altering channel properties in nerves and reducing spontaneous discharges.

In acquired neuromyotonia, presumably of autoimmune origin, plasmapheresis and IV immunoglobulin treatment have been successful in relieving symptoms in patients with severe symptoms who have failed symptomatic medicines [17, 31, 46]. Whether or not recurrent treatments with plasmapheresis or IV immunoglobulin are necessary is not evident from the literature. The role of prednisone and other immunosuppressive agents has not been fully evaluated [47].

Prognosis

In Isaacs' original patients as well as other patients, response to medication and reduction in symptoms were noted [5, 33]. Resolution or reduction of electrophysiologic abnormalities has also been documented. A 14 year follow-up of Isaacs' original patients showed continued response to phenytoin with eventual remission [32]. When medications needed to be reduced or changed, due to side effects, the patients' symptoms returned. However, studies with follow-up periods longer than of Isaacs' patients do not exist.

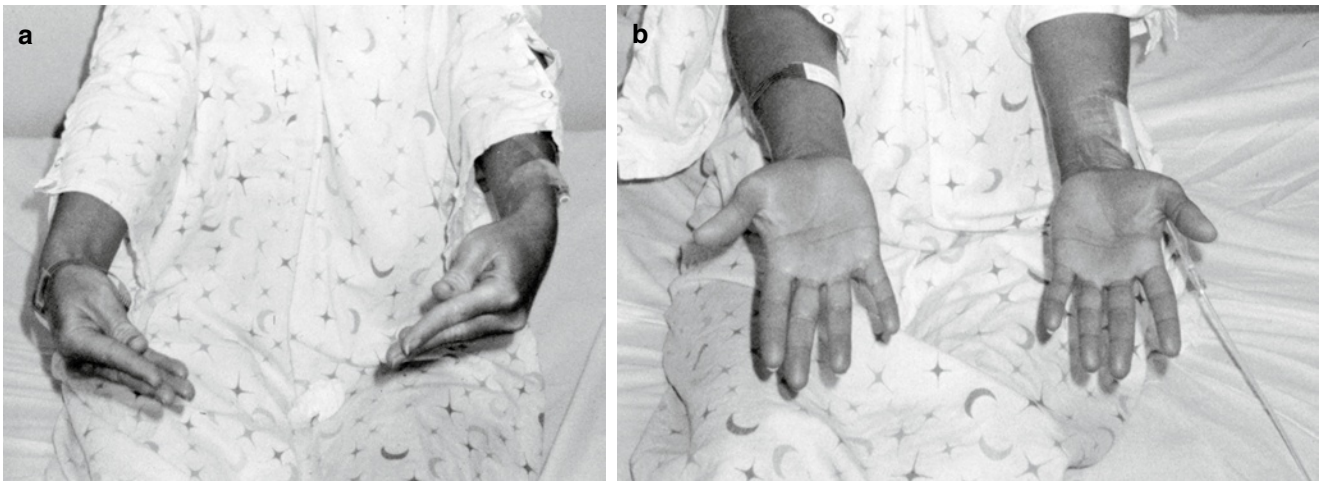

Fig. 70.2 (**a**) Patient with Isaacs' syndrome before treatment. Note the contractions in the hands. (**b**) Same patient after treatment with intravenous fosphenytoin and resolution of contractions

Overall, the prognosis for patients with generalized neuromyotonia (Isaacs' or Morvan's syndrome) is fair to good for resolution of symptoms. In other patients with myokymia/neuromyotonia, the underlying disease process will determine the prognosis.

Muscle Cramps and Fasciculations

71

James B. Caress and Bandhu Paudyal

Introduction

Muscle cramps and fasciculations commonly affect healthy individuals, particularly in the setting of exercise, but also frequently occur in diseases of the peripheral nerves. Disturbances of metabolism including renal and liver failure also predispose to cramps and fasciculations. The physiology of the lower motor neuron accounts for most of the observed behavior of cramps and fasciculations, and there is emerging evidence that these neuromuscular phenomena are manifestations of peripheral nerve hyperexcitability. There are many proposed treatments for muscle cramps but most have not been evaluated rigorously.

Muscle Cramps

Muscle cramps are a nearly universal phenomenon [1], with a prevalence of around 50 % in people over 65 years old [2]. Cramps are a common complaint in general medical practice but are an unusual chief complaint in a neurologist's office. There are several common neurological conditions associated with frequent cramps, but the primary complaint is usually weakness or paresthesias. More rarely, muscle cramps occurring in apparent isolation present to the neurologist for consideration of the common benign etiologies as well as more serious conditions where cramps are a primary feature. Muscle cramps most frequently occur during exercise or during sleep and usually in the intrinsic foot or leg muscles. The exact pathophysiology of cramps is debated but most experimental and empiric evidence demonstrates that pathology of the lower motor neuron is of critical importance. A key point in the clinical assessment is to clarify that the patient's complaint of "cramps" meets that clinical definition and does not signify claudication, myalgia, dystonia, or spasticity. Treatments may be effective but there is little in the way of evidence-based medicine to guide clinicians in their therapy decisions.

Definition

A muscle cramp is defined as a sudden onset, painful, palpable, involuntary muscle contraction that can be terminated by passive stretching of muscle (Table 71.1) [3]. True muscle cramps, sometimes called "ordinary" cramps, need to be distinguished from other painful muscle conditions that do not follow the electromyographic (EMG) or clinical description of cramps (Table 71.2). These include electrical contractures, myotonic and neuromyotonic conditions, focal dystonias (e.g., writer's cramp), and vascular claudication. Patients with metabolic myopathy may experience painful involuntary muscular contractions following exercise that satisfy most of the clinical criteria for muscle cramps but do not respond to stretching and may resolve over longer periods of time. These painful contractions are termed "electrically silent contractures" because they are associated with electrical silence on needle EMG rather than the profuse motor unit activity recorded during a true cramp. Silent contractures may coexist with true cramps in some patients. Muscle tightness and pain related to exercise can occur in myotonic and neuromyotonic disorders, but these conditions have strikingly different EMG signatures that cannot be confused easily with true cramps. Claudication, due to vascular insufficiency, is often mistaken for cramps because it is similarly painful and occurs in calf muscles. However, a palpable "knot" of contraction is not present and

the pain is ameliorated by rest rather than stretching. Writer's cramp and other focal dystonias are task specific rather than exercise induced and have slower onset and resolution than muscle cramps. Pain associated with dystonia is gradual in onset, unlike the explosive and severe pain that occurs with a cramp.

Spasms associated with upper motor neuron lesions

Etiology of Cramps

While the clinical description of cramps is clear, the pathophysiology of cramps is more controversial. The EMG appearance of a cramp is either single or multiple motor unit action potentials firing at high frequencies (>10–30 Hz) [1] (Fig. 71.1). By EMG alone, it can be difficult to distinguish a cramp from a forceful voluntary contraction, although in some instances the firing frequency of individual motor units during a cramp is faster (>50 Hz) than can be achieved even with maximal voluntary effort. These direct observations indicate that cramps are initiated and sustained by repetitive firing of lower motor neurons and not generated at the muscle fiber membrane or the upper motor neurons. This corresponds with the clinical experience that cramps occur frequently in motor neuron disease and other neuropathic disorders. While the localization to the lower motor neuron seems clear, the exact mechanism of how cramps are generated and sustained is still debated. Proposed theories implicate either a "central" source, denoting events at the level of anterior horn cell, or a "peripheral" cause whereby the cramp is generated in the terminal axons of motor neurons. It is possible that both central and peripheral conditions are necessary to explain the complex neurophysiology of cramps in healthy and diseased states.

Denny-Brown's description of the EMG of spontaneous cramps concluded that cramps originate in the distal motor neuron [4]. The crucial observation was that cramps were associated with frequent fasciculation potentials that changed in morphology. The varying shape suggested that each fasciculation originated in a different branch of the terminal arborization of the motor neuron. Norris et al. [1] confirmed that motor units rather than muscle fiber discharges caused the observed EMG activity during a cramp; however, other

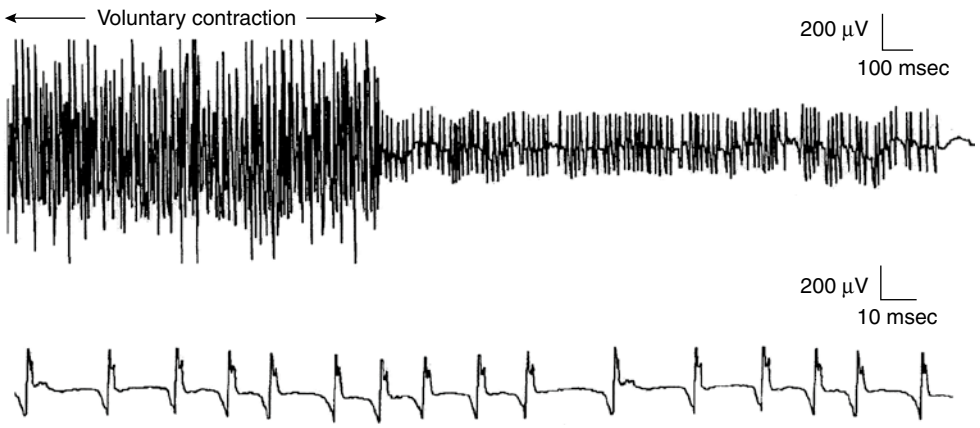

Fig. 71.1 Cramp discharge. In this example, the patient is first forcibly contracting his gastrocnemius muscle with an EMG needle electrode placed in the muscle. Following relaxation, a cramp discharge is seen (latter part of top waveform, expanded view – bottom waveform). In a cramp discharge, EMG shows either a full interference pattern of motor unit action potentials or one or several motor units firing repetitively and sometimes irregularly at high frequencies (usually 40–60 Hz), as in this example (Reproduced from Preston and Shapiro [110], with permission from Butterworth Heinemann)

observations led him to conclude that cramps have a central origin. Norris cited synchronous motor unit activation during a cramp and a reduction in cramp intensity following contraction of the appropriate antagonist muscle as evidence that cramps originate at the level of anterior horn cells. There is additional evidence for a central origin of cramps including studies that describe cramp cessation following sensory nerve stimulation [5, 6]. Further support of the "central" theory comes from the proposal that the membrane of the motor neuron soma has two equilibrium states, one at a resting potential and the second at a higher suprathreshold potential. This "bistability" allows for self-sustained high-frequency semi-rhythmic firing. Under the right conditions, in various animal preparations, a brief depolarization will switch the membrane from the resting value to the suprathreshold value [7–9]. The similarities between these experiments in animals and the features of muscle cramps in humans led Baldissera and coworkers to induce cramps by repetitive stimulation in three patients with frequent spasms of varying etiologies. By selectively stimulating the IA afferents at the popliteal fossa at intensities below the motor threshold, they were able to generate spontaneous sustained contractions in the soleus, suggestive of a cramp. The investigators theorized that hyperpolarizing the motor neuron soma would terminate the cramp and demonstrated this by supramaximally stimulating the tibial nerve and noting attenuation of the ongoing EMG activity. Stimulating the skin overlying the intrinsic foot muscles terminated cramps perhaps due to inhibition of spinal motor neurons. This study provides some evidence that experimental cramps may be produced from a central generator in individuals who suffer from unusual cramp syndromes.

Bertolasi et al. [10] expanded upon experiments first performed by Lambert [11] to provide support for a "peripheral" cause of muscle cramps. In a healthy subjects, repetitive supramaximal electrical stimulation of the tibial nerve at the ankle reliably produced cramps in intrinsic foot muscles. This stimulation could generate a cramp distal to a complete nerve block and resolved with stretching despite the nerve block prohibiting any afferent information from reaching the spinal cord. Cramps could not be induced when the muscle was passively stretched during the same stimulation. These experiments demonstrate that muscle cramps can be produced, maintained, and manually terminated in the absence of afferent input to the central nervous system or anterior horn cell. In fact, the study indicates that the physiology of the distal motor neuron is sufficient to account for the key clinical observations of cramps.

Ross and Thomas performed a variety of experiments that offer some evidence for a combined central and peripheral mechanism of cramps [12]. They induced cramps in the gastrocnemius and soleus muscles of seven subjects by forceful plantar flexion and observed the pattern of motor unit firing with a unique array of surface and intramuscular electrodes. At the onset of cramp in the medial gastrocnemius, motor unit activity ceased in the other muscles of the posterior calf. This selective activation of the medial gastrocnemius was not possible voluntarily, suggesting the involuntary nature of the observed contraction. This observation quantitatively confirmed earlier observations that cramps are localized to a specific muscle and, often, a discrete part of that muscle [1, 13].

The individual motor unit firing rate was significantly faster during a cramp (up to 89 Hz) than during maximal voluntary activation. Firing rates of individual motor units slowed gradually rather than by a quantal jump to a slower frequency as might be expected if "bistability" (see above) of motor neuron discharge rates were the operative factor in sustaining the cramp. These points favor a peripheral etiology of cramps, but further observations from this experiment suggest a possible central influence. The decay in motor unit firing rates during these provoked cramps is similar to that observed in sustained voluntary maximal contractions [14], and terminating the cramp by passive, forceful dorsiflexion of the foot typically generated a surge of motor unit activity in all of the calf muscles. The authors suggest that the stretch provokes a surge of Ia afferent activity generating the burst of motor units that is followed by Golgi tendon organ generated Ib activity, inhibiting the anterior horn cells and terminating the cramp. Reduction of the tonic vibration reflex and enhancement of the H-reflex following a cramp but not after voluntary contraction indicates that motor neuron excitability is increased after a cramp but does not prove that central excitation is present at the moment of cramp initiation. The investigators concluded that changes in synaptic input to motor neurons play a role in the generation of exertional cramps and speculated that a positive feedback loop exists following strong contraction that leads to a self-sustained involuntary contraction or cramp [12].

Layzer has theorized that unmyelinated branches of the terminal arborization are susceptible to the excitatory influences of extracellular ions, muscle metabolites, and neurotransmitters such as acetylcholine [15]. In neuropathic situations, immature collateral nerve sprouts might have reduced membrane stability and fire spontaneously during mechanical deformation. He speculated that muscle in the shortened position was "crumpled" and might generate spontaneous electrical activity in the terminal branches in response to the mechanical deformation. Once a local discharge developed, the contraction might then deform adjacent areas of muscle, allowing the cramp to shift and spread as is observed clinically [12, 13]. Fluid loss and ion imbalance from dehydration would promote this chain reaction through a mechanical effect of a contracted extracellular space in the vicinity of nerve terminals.

In summary, the pathophysiology of cramps is still controversial. The finding that the chief clinical phenomena of muscle cramps including improvement with stretching can be reproduced distal to a nerve block and so without apparent participation of the anterior horn cell bodies or synaptic input strongly suggests of a peripheral mechanism [16]. Yet, the development of a muscle cramp may be influenced by events in the spinal cord under physiologic conditions.

Clinical Evaluation of Muscle Cramps

When cramps become frequent, they may interfere with working and sleeping and can rarely become disabling [17]. Healthy individuals commonly suffer cramps during exercise or sleep, but cramps may also signify a variety of neuromuscular and metabolic conditions (Table 71.3). When evaluating the patient with problematic muscle "cramps," the initial task is to differentiate muscle cramps from other common disorders such as vascular claudication, muscle strain, and neuropathic pain, and usually, the history and neurological exam are sufficient to distinguish between these conditions. Attention should be paid to events surrounding the onset of the cramp, including provoking factors such as exercise, cold temperature, and sensory or emotional stimuli. Special note should be made if cramps are reported in muscles outside of the legs as this is unusual and may suggest an alternative condition such as myalgia or a serious neuropathic process like motor neuron disease. If the "cramp" involves multiple muscles in a limb, especially an agonist/antagonist pair, or more than one limb simultaneously, the movement is more likely to be an upper motor neuron-generated spasm (e.g., flexor spasms) or dystonia rather than a true cramp which is generally limited to one muscle. This distinction can also be useful when malingering or conversion disorder is suspected. As with most neuropsychiatric disease, these patients will gladly provoke their tremendous "cramps" which typically involve simultaneous contraction of agonist/antagonist pairs and involve the entire limb. In contrast, motor neuron disease patients plagued with frequent cramps may refrain from manual exercise testing for fear of provoking a painful cramp. Patients with frequent exercise-induced cramps, benign nocturnal cramps, benign fasciculation syndrome (BFS), and cramp-fasciculation syndrome have normal neurological exams.

Blood tests in the evaluation of muscle cramps include serum electrolytes test (including calcium and magnesium), thyroid studies, and creatine kinase and liver function tests (Table 71.4). Antibodies directed against voltage-gated potassium channels can be measured in those with disabling cramps or whenever an immune-mediated or paraneoplastic syndrome is suspected [18]. Standard EMG will identify patients with motor neuron disease and radiculopathy and may be helpful in identifying benign fasciculation syndrome patients and those with muscle contractures due to metabolic myopathy. Ischemic exercise testing should also be considered to identify metabolic myopathies if electrical contractures are suspected. Repetitive electrical stimulation may identify persons with an abnormally high propensity to suffer cramps [17, 19]. Cramps resulting from supramaximal repetitive electrical stimulation of the distal peroneal and tibial nerves at frequencies at or below 10 Hz indicate peripheral nerve hyperexcitability with an increased tendency toward cramping [20].

Table 71.3 True cramp types and their proposed therapies

True cramp type	Proposed therapy
Exercise/heat	Intravenous saline, salt tablets, oral rehydration
Nocturnal	Stretching, quinine, verapamil, phenytoin, carbamazepine
Dialysis	Salt tablets, sodium-enriched dialysate, quinine, L-carnitine, nifedipine, vitamin E
Pregnancy	Magnesium, B complex vitamins
Cirrhosis	IV albumin, taurine, branched chain amino acids, vitamin E
Neuropathic conditions	Phenytoin, carbamazepine, levetiracetam, gabapentin, quinine

Clinical Syndromes and Treatment

Heat and Exercise Cramps

These occur in healthy individuals participating in extreme physical exercise with variable degrees of muscle fatigue, dehydration, and electrolyte depletion. While heat and exercise cramps are sometimes referred to as separate entities, it may be that they have the same physiological basis with heat merely increasing the risk of hypovolemia. Profuse sweating followed by rehydration with pure water leads to hyponatremia and subsequent severe cramps in the muscles most heavily stressed. In the 1935, Talbott chronicled the experiences of miners and factory workers performing heavy labor under conditions of extreme heat [21]. He described extremely painful and widespread cramp "attacks" that would start in the distal arm muscles followed by leg and abdominal cramps. He reported that "feeble twitchings," perhaps fasciculations, of a muscle would herald a cramp

and that the attack could last for hours without treatment. Hyponatremia occurred in these workers, and the cramps would resolve as normal levels of serum sodium were established via intravenous saline infusions presumably by correcting hyponatremia and hypovolemia. Salt tablets were effective in preventing heat cramps [21]. Dextrose solutions did not relieve heat cramps, suggesting that hyponatremia is critical for the initiation of heat cramps. Heat cramps did not occur unless hyponatremia was accompanied by a loss of total body sodium or hypovolemia. This finding is supported by the clinical observation that cramps do not occur in the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) or with water intoxication where total body sodium is normal [22].

Exercise cramps are common in athletes undergoing extreme physical exercise with variable degrees of muscle fatigue, dehydration, and perhaps electrolyte depletion. They can occur during exercise or for some hours following exercise [23]. Several small studies have evaluated athletes following intense exercise and found a relative hyponatremia in the cramp group [24–26], but other studies have not found a difference [27]. Of course, the metabolic state of the intercellular milieu surrounding the muscle and innervating fibers during cramping is unknown and may not reflect conditions as measured in the serum. Another potential explanation for exercise cramps is that with muscle fatigue, there is an alteration of neuromuscular control resulting in peripheral nerve hyperexcitability and cramps, but there is no direct evidence at this time [27].

Cramps Associated with Other Medical Conditions

Cramps commonly complicate hemodialysis and usually occur toward the end of the session when fluid loss is maximal [28]. Both intravenous hypertonic dextrose [29] and saline may promptly alleviate these cramps [30]. Performing dialysis with a sodium-enriched dialysate reduces the incidence of muscle cramps [31], and salt tablets are efficacious in prevention [32]. Other proposed therapies for dialysis patients with cramps include quinine sulfate [33], L-carnitine [34], nifedipine [35], and 400 IU per day of vitamin E [36].

About half of cirrhotic patients experience painful cramp episodes several times per month and nearly one-third suffer cramps three or more times per week [37]. The incidence of cramps appears to be independent of the mechanism of liver failure but correlates with worsening liver function [38]. Ascites, lower mean arterial blood pressure, and higher plasma renin activity predict the development of cramps [37], suggesting that reduced effective circulatory volume is the underlying risk factor for cramps in cirrhotics. However, in a study of 100 nonalcoholic cirrhotic patients, there was no correlation of the presence of cramps with serum electrolytes, creatinine, glucose, bilirubin, or albumin levels. Muscle biopsies from cirrhotic patients show depletion of ATP which may prevent muscle relaxation, predisposing to cramps [39]. There are clinical trials demonstrating a reduction in cramps following weekly infusions of intravenous albumin [37] and 3–6 g/day of taurine, an amino acid that reduces myotonic discharges [40] with no major side effects [41, 42]. Similarly, an open-label study of branched chain amino acid supplements in the late evening dramatically decreased nocturnal cramp in a small group of advanced cirrhosis patients [43]. Vitamin E levels in cirrhotics with cramps are reduced compared to those without cramps perhaps due to a higher degree of fat malabsorption, and oral replacement of vitamin E decreased cramps in this group in a small, uncontrolled trial [44].

Severe hypothyroidism [45, 46] and hyperthyroidism [47] may cause painful muscle contractions which may be electrically silent contractures rather than true cramps.

Nifedipine [48, 49], clofibrate [50, 51], cyclosporine [52], and beta-agonists [53, 54] are associated with cramps. Although diuretics have been implicated in muscle cramps, a study performed in general medical patients did not reveal an association between cramps and diuretic use [2]. Excessive alcohol consumption may cause muscle spasms due to persistent motor unit discharges [55] or exacerbate an underlying metabolic myopathy, resulting in either cramps or electrical contractures [56]. There is no evidence that moderate alcohol intake predisposes to nocturnal cramps or exercise-induced cramps.

Leg cramps of pregnancy typically occur at night beginning in the second trimester. They occur in up to 30 % of pregnant women and are a daily event in 28 % of pregnant women who report cramps. A randomized, double-blind, placebo-controlled trial demonstrated that oral magnesium supplementation diminished cramp frequency and severity without changing serum magnesium levels [57]. The supplemental magnesium may have boosted intracellular magnesium levels. Hypomagnesemia may cause motor neuron irritability similar to tetany from hypocalcemia. B vitamins may also be effective in the treatment of cramps during pregnancy [58].

Lower motor neuron disorders including polyneuropathy, radiculopathy, and, especially, amyotrophic lateral sclerosis (ALS) are frequently punctuated with cramps [22]. Muscle cramps afflict 62 % of ALS patients [59] and are the most frequent cause of discomfort in ALS patients occurring in 55 % of those reporting pain [60]. Many drug therapies including quinine sulfate, clonazepam, magnesium, gabapentin, lioresal, dantrolene, and diphenylhydantoin have been suggested for the treatment of cramps in ALS, but few have been rigorously examined. A randomized and blinded trial of tetrahydrocannabinol failed to show any benefit [61]. An open-label study of levetiracetam showed reduced cramp frequency and severity [62]. In a study examining the efficacy of vitamin E to slow the progression of ALS, vitamin E did not affect cramps over the course of a year [63].

There may be inherited conditions where muscle cramps are the chief complaint. The reported cases show dominant inheritance and the conditions appear to be neuropathic, but no gene has been identified [64, 65]. Other neurologic disorders which are particularly characterized by cramps include Machado-Joseph disease [66], hereditary angiopathy, nephropathy, aneurysms, and muscle cramps due to COL4A1 gene mutations [67] and Satoyoshi syndrome, a rare condition characterized by a constellation of findings including painful muscle spasms, alopecia, amenorrhea, skeletal deformities, and diarrhea [68]. The onset is usually in childhood, although adult cases sharing many of the features are described. There is emerging evidence for an autoimmune etiology in these cases, but other reports suggest a recessive inheritance [69, 70]. The scarcity of the disorder and lack of consistent clinical findings or biomarkers hinder efforts to clearly define Satoyoshi syndrome.

A study of 50 cancer patients complaining of new muscle cramps revealed associations with a variety of neurogenic conditions, most commonly peripheral neuropathy from chemotherapy. Cramps also indicated direct cancerous invasion or radiation injury of peripheral nerves and were frequently an early sign of unrecognized neurologic dysfunction [71].

Benign Nocturnal Cramps

These sudden onset and extremely painful cramps usually occur in calf muscles and awaken patients from sleep. They are common in the healthy, elderly population yet are also observed with neuropathy and with peripheral vascular disease [72]. These cramps occur typically within the first few hours of sleep and may be extremely disruptive if they become recurrent during the night [73]. Familial cases of nocturnal cramps have also been reported [74].

Muscle stretching three times daily has been advised to prevent nocturnal cramps [75], but a randomized study comparing calf stretching versus a sham non-stretching exercise failed to show benefit [76]. Other investigators proposed that sleeping with the feet in a passively plantar-flexed position predispose persons toward calf cramps [77], consistent with the well-established relationship between muscle shortening and cramps [10]. Theoretically, cramps would be reduced if the patient wore an ankle-foot orthotic to bed.

Until the 1990s, the mainstay of nocturnal cramp treatment was quinine sulfate. Quinine is purported to prevent muscle cramps by reducing motor end-plate excitability or by increasing the muscle membrane refractory period [78]. Over the ensuing years, several small, controlled clinical trials showed mixed results for the efficacy of quinine [79–84]. A meta-analysis of six randomized, double-blind, placebo-controlled trials of quinine sulfate utilizing crossover designs with 107 non-dialysis patients revealed a 27 % decrease in nocturnal cramps during a 4-week period [85]. Severity and duration of the cramps were not altered. While this meta-analysis may confirm the efficacy of quinine, the weak clinical effect may not offset the small but definite risk of serious adverse reactions. While tolerated by most people, quinine can cause nausea, vomiting, blurred vision, tinnitus, vertigo, and hearing loss. Severe visual side effects include night blindness, scotomata, loss of color vision, and permanent blindness [86]. Life-threatening thrombocytopenia occurs in one in 1,000 to 3,500 patients [87]. Patients with renal failure or hepatic cirrhosis are at greater risk of developing serious toxicity.

Due to the lack of clear efficacy and quinine's dangerous potential toxicities, the US Food and Drug Administration (FDA) banned over-the-counter quinine for cramps in 1995. In 2006, the FDA cautioned consumers about their off-label use and ordered unapproved quinine drugs to be removed from the market stating 665 reports of serious adverse events and 93 deaths due to quinine since 1969 [87–89]. Quinine-containing preparations should be avoided in all patients except those with truly disabling cramps who have provided clear understanding of the marginal benefits and significant risks with informed consent and careful monitoring when no other agents relieve symptoms [89].

Other drugs that could be considered for the treatment of nocturnal leg cramps include vitamin E, verapamil, phenytoin, carbamazepine, gabapentin, magnesium, baclofen, vitamin B complex, tonic water containing quinine, nifedipine, botulinum toxin injections, and levetiracetam [16, 35, 90–93]. However, the purported efficacy of these drugs frequently rests on small, uncontrolled studies or anecdotal reports.

Fasciculations

Fasciculations are easily recognized in the clinic as the spontaneous, involuntary, irregular, and painless twitching of part of one muscle. On needle EMG, fasciculations are defined as a discharge of a single motor unit and typically fire in an irregular and relatively slow (0.1–10 Hz) pattern [94]. Fasciculations generate concern in the clinic because of their ominous association with motor neuron disease. "Benign" fasciculations tend to fire faster than "malignant" fasciculations [95] but are not distinguishable on the basis of EMG waveform as highly complex fasciculation potentials can be seen in both conditions [96]. The presence of atrophy, weakness, other EMG abnormalities, or tendon reflex abnormalities in association with fasciculations is the most reliable way to make the distinction. Caffeine, beta-agonists, D-penicillamine, overcorrection with synthetic thyroid preparations, and stress [97–99] have been associated with frequent fasciculations.

The pathogenesis of fasciculations is less controversial than that of muscle cramps. Early studies demonstrated the

neural origin of fasciculations [100] with impulses generated in the peripheral nerve rather than the spinal cord or motor cortex [101, 102]. Collision experiments have demonstrated that most fasciculations are generated in the terminal portion of the axon [101, 103]. Roth [104] studied the F-wave responses from spontaneous fasciculations. The morphology of the fasciculations changed, but the shape of F-wave responses was identical, suggesting that fasciculations are generated in the terminal arborization of the motor neuron. The situation may be more complex in some ALS patients where analysis of the firing pattern of fasciculations suggested both peripheral and spinal sources could generate fasciculations in the same muscle [105]. Stretching of the affected muscle reduced fasciculation frequency in ALS [106], suggesting that mechanical changes in the distal arborization of the motor neuron play an important role in the generation of fasciculations as well as cramps.

Benign Fasciculation Syndrome

While an occasional fasciculation is reported by 70 % of healthy people, only 2 % report daily fasciculations [107], and those with frequent fasciculations are often diagnosed with benign fasciculation syndrome (BFS). Blexrud and colleagues reported that patients diagnosed with BFS have frequent fasciculations beyond what is normally experienced by most people [99]. In a retrospective study, 121 persons were interviewed an average of 7 years after receiving the diagnosis of BFS. Almost all patients had complaints of muscle twitching, and many others had additional complaints such as fatigue, muscle cramps, transient migratory paresthesias, and generalized myalgias. One-third of the group worked in the medical profession and 14 % listed concern about ALS as a chief complaint. Several BFS patients had family members with ALS or multiple sclerosis. In the study, all had normal neurological exams and standard nerve conduction and EMG studies with the exception of fasciculations. Although the examining neurologist noted only sparse fasciculations on neurologic exam, excessive fasciculations were noted by EMG in at least one muscle in 68 % of the group. The investigators concluded that BFS is not simply an increased awareness of occasional fasciculations experienced by most people, although a heightened awareness of the potential ominous significance of fasciculations may spur presentation to a neurologist. During a follow-up period of 2–32 years, none of these patients developed ALS or any other significant neurological disorder. Half of the group reported spontaneous improvement in their condition, and less than 5 % worsened. A minority of patients reported a viral upper respiratory or gastrointestinal infection within the month prior to the development of fasciculations. This observation combined with the frequent occurrence of transient paresthesias in the BFS group led the investigators to speculate that some patients develop BFS following a mild, acute generalized polyradiculopathy [99]. There are very infrequent case reports of patients with evident fasciculations but normal neurologic and EMG exams who go on to develop motor neuron disease within several years so it may not be accurate to label fasciculations "benign" until 4–5 years have passed [108].

BFS may be diagnosed in patients with the chief complaint of painless muscle twitching and minor symptoms of cramping, paresthesias, myalgia, or fatigue who have normal neurological and electrophysiological examinations, with the exception of excessive fasciculations. These patients may be reassured that it is highly unlikely that they will develop motor neuron disease.

Cramp-Fasciculation Syndrome

The diagnosis of cramp-fasciculation syndrome (CFS) should be considered in patients with disabling cramps not provoked by exercise or heat, and normal neurologic and EDX examinations. CFS may overlap with BFS where non-disabling cramps are frequently noted, and some authors have included this group within a wider category of peripheral nerve hyperexcitability that includes patient with non-disabling symptoms [20]. Tahmoush et al. described CFS patients as plagued by frequent, disabling muscle cramps but normal neurological exams except for visible fasciculations or clinical myokymia. CBC, electrolytes, thyroid studies, serum protein electrophoresis, and ischemic exercise tests were normal, but creatine kinase levels were sometimes mildly elevated. EMG examination revealed fasciculations without other abnormal spontaneous activity or motor unit abnormalities. Repetitive nerve stimulation (up to 5 Hz) of distal motor nerves provoked afterdischarges of involuntary motor units in all patients. These afterdischarges, which may have been cramp potentials, were greatest in the intrinsic foot muscles and were not attenuated by ischemia or by proximal nerve block. Regional curarization abolished the abnormal discharges. Carbamazepine was often dramatically effective in relieving the cramps, and efficacy persisted after the medicine had been discontinued [17]. In a larger sample of patients with symptoms of peripheral nerve hyperexcitability, repetitive stimulation was helpful in identifying those with CFS and other conditions along the spectrum of hyperexcitable nerve disorders [109].

BFS and CFS appear to have some clinical overlap and might be the most benign of hyperexcitable nerve disorders. The syndrome of acquired neuromyotonia may represent the other end of the spectrum where there is an immune-mediated attack on potassium channels [18]. The effectiveness of a sodium channel blocker, carbamazepine, in CFS suggests that CFS and BFS may be milder versions of a peripheral nerve ion channel disorder.

Stiff-Man Syndrome

72

Franco Folli, Annamaria Prioletta†,
Angelo Quattrini, and Giuseppe Galardi

Introduction

Stiff-man syndrome (SMS) is a rare disorder of the central nervous system, characterized by progressive and fluctuating muscle rigidity with superimposed painful spasms; at rest the latter may occur spontaneously or be precipitated by sensory stimuli. The disease involves the muscles of the limbs, trunk, and neck, sometimes asymmetrically [1, 2]. The diagnosis is established by the finding of a characteristic electromyographic pattern indicating continuous normal motor-unit activity at rest. Such activity is abolished by sleep, general or spinal anesthesia, peripheral nerve blockade, curare, and intravenous diazepam [2].

Ornsteen described a patient with clinical features suggestive of SMS in 1935, calling it "chronic generalized fibromyositis" [3]. Moersch and Woltman described the syndrome in 1956 and coined the term "stiff-man syndrome," which they found to be more frequent in males [1]. However, current evidence shows the disease to be slightly more common in women [1, 3–9]. Additional reports of SMS soon appeared [10–19], and an association with diabetes mellitus, hyper- and hypothyroidism, and epilepsy was diagnosed in 10 % of patients [3, 4, 8, 13, 18, 20–26].

Etiology and Pathogenesis

Stiff-man syndrome associated with type 1 diabetes mellitus and organ-specific autoimmune diseases.

The pathogenesis of SMS is a matter of active investigation with a variety of clinical, pharmacological, and laboratory evidence pointing to a functional impairment of the γ-aminobutyric acid (GABA) inhibitory system. Moersch and Woltman found no significant pathological changes at autopsy [1]. This finding has since been confirmed with few exceptions, which suggest loss of GABA-ergic cells in the cerebellar cortex or anterior motor horns [12, 26–30]. In addition to causing muscular rigidity, disruption of the GABA systems could explain the frequent association of epilepsy, autonomic instability, and psychiatric manifestations among SMS patients [2, 20, 27–41].

A report in 1986 of a 48-year-old woman with SMS and epilepsy and the abrupt onset of diabetic ketoacidotic coma lead to the search for a possible pathogenic link between SMS and type 1 diabetes mellitus [42]. The patient had complement-fixing islet cell (ICA), gastric parietal cell, and thyroid autoantibodies. The patient had a human leukocyte antigen (HLA) phenotype A 1/28, B 8/44, Cw5/x, and DR3/4. These data suggested an autoimmune pathogenesis of diabetes in the patient. The onset of signs of autoimmunity in a patient affected by a rare and elusive disorder of the central nervous system prompted the search for signs of autoimmunity against the central nervous system [25]. The serum and the cerebrospinal fluid (CSF) of the patient were used for immunohistochemical analysis of rat brain and produced specific immunostaining in all brain regions in a distribution corresponding to the known distribution of GABA-ergic nerve terminals (Fig. 72.1) [25, 43–45]. A less intense immunoreactivity

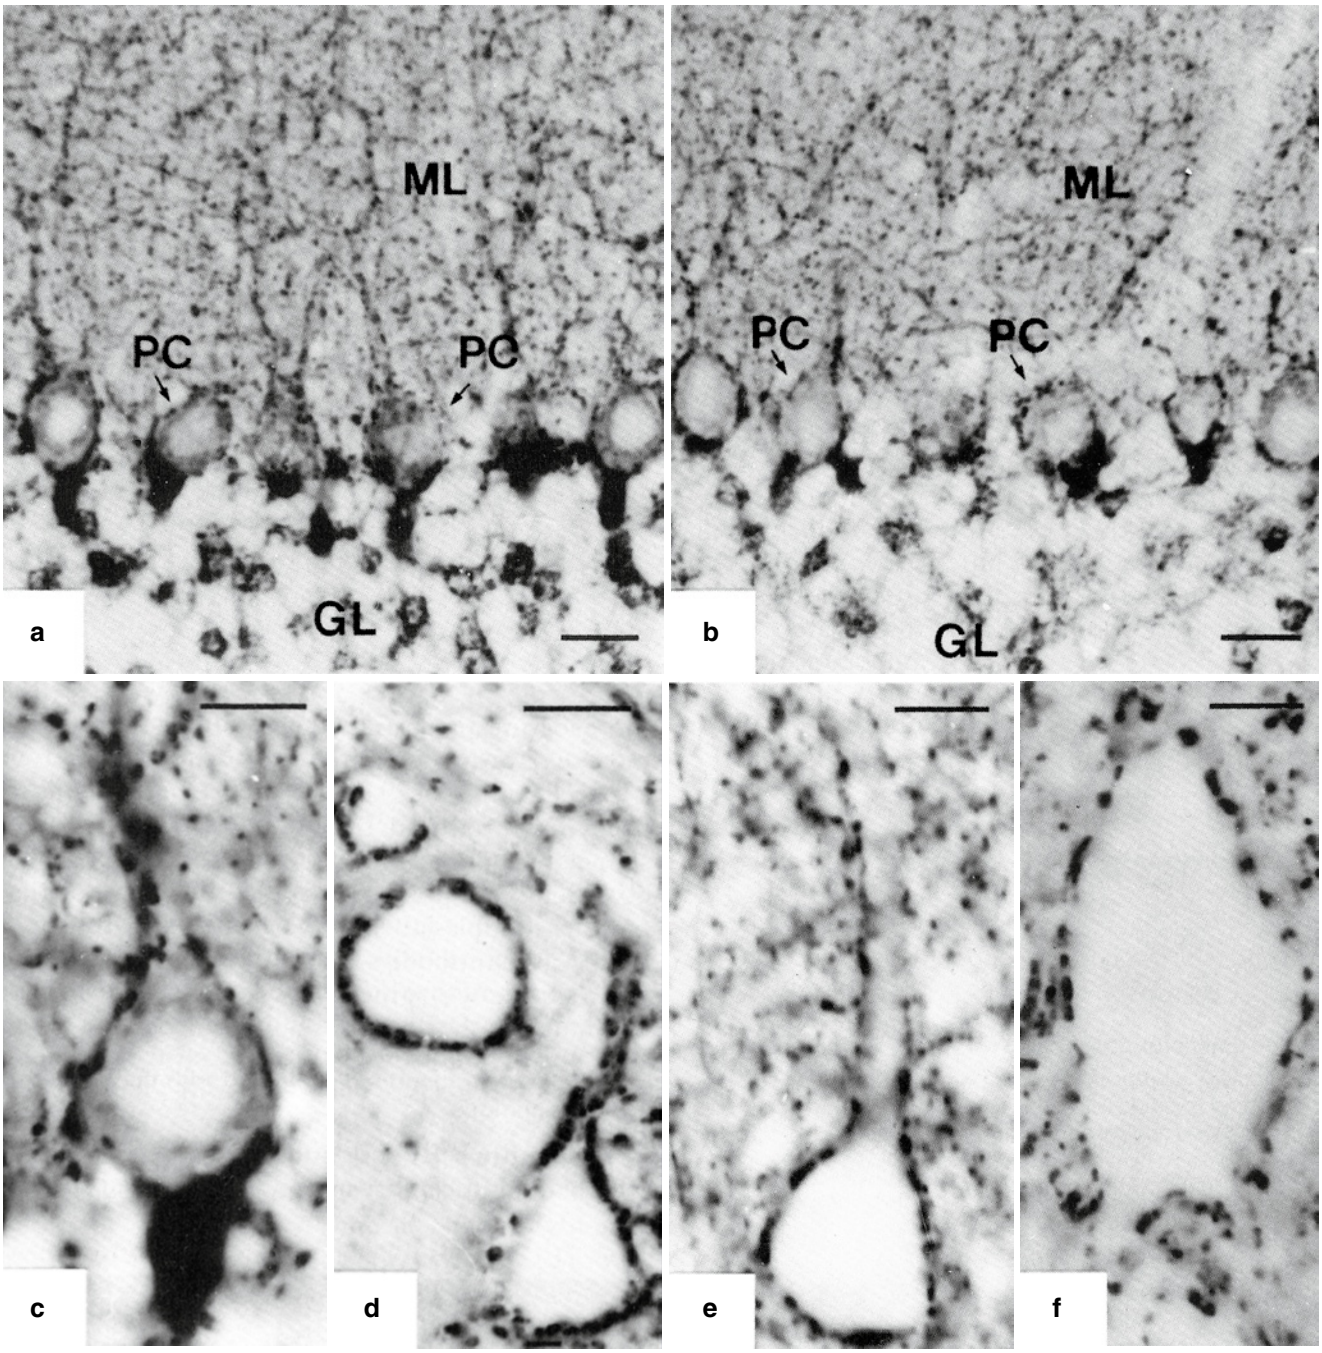

Fig. 72.1 Immunoperoxidase staining of rat brain regions by cerebrospinal fluid (CSF) (**a**, **c**–**f**) and serum (**b**) of a patient with stiff-man syndrome. Immunoreactivity is represented by the *dark areas*. Panels **a** and **b** show similar fields of the cerebellar cortex immunostained with CSF and serum, respectively; the identity of both patterns is striking. Panel **c** shows a higher magnification of a Purkinje cell. Note the dense accumulation of immunoreactivity at the axon hillock and the abundance of the immunoreactive puncta that outline the perikaryon and the proximal portion of its dendritic tree. Note also the weak immunoreactivity of the Purkinje cell cytoplasm. Panel **d** shows two large neurons of the deep cerebellar nuclei. Their surface is outlined by densely apposed immunoreactive puncta. Panel **e** shows a layer of V pyramidal cells of the cerebral cortex, and panel **f** shows a brain stem motor neuron. These cells are also outlined by immunoreactive dots. Scattered puncta are visible in a surrounding neuropil. No immunoreactivity is visible in the cytoplasm of the cells shown in panels **d**–**f** (compare with the cytoplasm of Purkinje cells visible in **c**) (*PC* Purkinje cells, *ML* molecular layer, *GL* granule cell layer) (*Bars* in panels **a** and **b** denote 20 μm, and those in **c**–**f**, 10 μm) (Reprinted with permission from Solimena et al. [25])

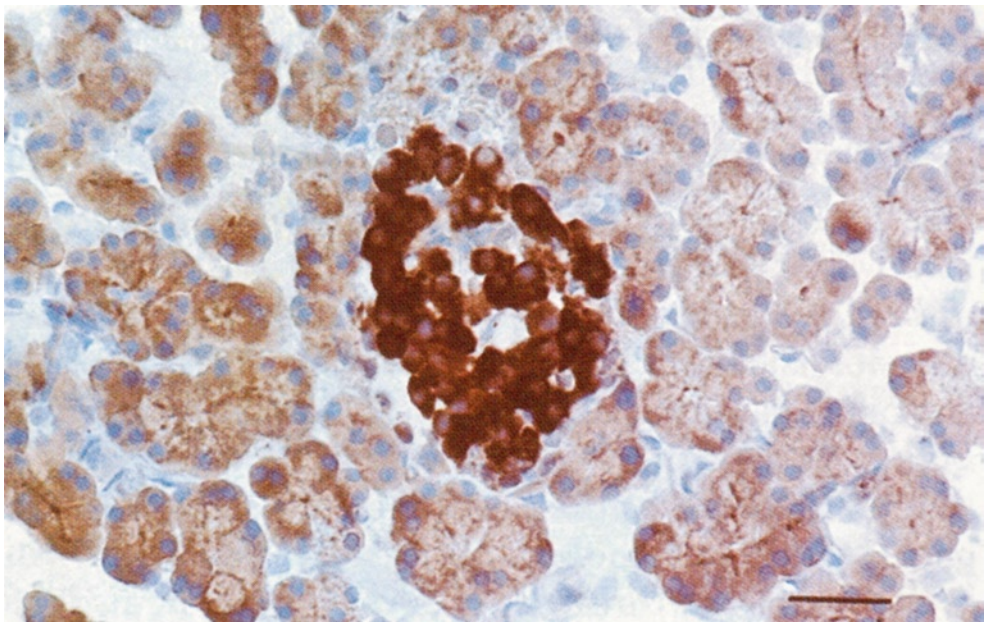

Fig. 72.2 Immunoperoxidase staining of rat pancreas with the serum of a patient with stiff-man syndrome (SMS). The histological section of rat pancreas was counterstained with hematoxylin and immunostained SMS patient sera and detected with peroxidase. β-cells of Langerhans islets are heavily stained (Reproduced with permission from Solimena et al. [4]. Copyright 1990 Massachusetts Medical Society. All rights reserved)

was detectable in the cytoplasm of the perikarya of known GABA-ergic neurons (i.e., Purkinje cells; Fig. 72.1c), while the cytoplasm of non-GABA-ergic neurons was not immunoreactive (Fig. 72.1d–f). The staining patterns produced in all of the brain regions were reminiscent of the patterns produced by antibodies directed against glutamic acid decarboxylase (GAD), the enzyme responsible for the biosynthesis of GABA including localization to nerve terminals [43, 44, 46–48].

Outside the central nervous system, GAD and GABA are found in pancreatic β-cells, male germ cells, the oviduct, and the ovary [48–51]. Accordingly, the serum and CSF of patients with SMS react with rat pancreatic β-cells (Fig. 72.2) [4]. Immunoprecipitation and western blotting experiments conducted on a large series of patients demonstrated that 60 % of patient sera reacted with GAD 65kD/GAD 67kD isoforms [3]. In this series of patients, 30 % of patients positive for anti-GAD antibodies were also affected by type 1 diabetes mellitus, and almost all patients in the anti-GAD positive group had clinical or serological evidence of other organ-specific autoimmune diseases (Fig. 72.3, panels a and b) [3]. Other investigators confirmed these observations [8, 40, 52–56].

The demonstration that GAD is a major autoantigen in SMS also led to the demonstration that the 64 kD protein, identified as a major autoantigen in type 1 diabetics, was in fact GAD [57]. SMS is associated with HLA phenotypes predisposing to type 1 diabetes and organ-specific autoimmunity [25, 58, 59]. Anti-GAD immunoreactivity identifies patients at risk for developing type 1 diabetes mellitus, years before the development of clinical symptoms [60, 61]. Autoantibodies directed against GAD are also found in late-onset cerebellar degeneration associated with endocrine disorders and palatal myoclonus [62, 63].

In vivo confirmation of the involvement of the inhibitory GABA-ergic pathways in the SMS pathogenesis came out from MR spectroscopy studies that reported decrease in GABA levels in several brain regions of patients with disease compared with control subjects [64].

Moreover in vivo evidence of central GABA-A receptors dysfunction in SMS has emerged by studies conducted with a [^{11}C]flumazenil (FMZ) positron emission tomography (PET) [65, 66]. FMZ is a radioligand to the postsynaptic central benzodiazepine receptor which is co-localized with the GABA-A receptor, and its derangements in SMS patients may be related to the motor symptoms. In the first study with PET conducted in two patients with SMS, the authors demonstrated a reduction of FMZ binding potential in motor-premotor cortex and increased FMZ binding potential in the cerebellar nuclei [65]. As reported above, this is consistent with MRI spectroscopy data [64]. These data were confirmed by another study that has demonstrated a global reduction of cortical FMZ binding in a female patient with SMS compared to nine healthy individuals [66].

Stiff-Man Syndrome Associated with Breast Cancer

In some patients, SMS is associated with cancer, in particular breast cancer [7, 8, 67–72]. Immunohistochemistry employing serum and CSF of these patients demonstrates

immunoreactivity co-localization with synaptic-vesicle-associated proteins (Fig. 72.4) [7, 73, 74]. The serum and CSF antibodies of these patients recognized a non-intrinsic membrane protein of 128 kD, which is expressed at high levels in the central nervous system and at lower levels in the testis and endocrine tissues [7]. The 128 kD autoantigen proved to be amphiphysin [75]. Autoantibodies directed against amphiphysin I and amphiphysin II are also present in other paraneoplastic nervous system disorders [75–79].

Psychiatric Disorders Associated with Stiff-Man Syndrome

Anxious symptoms and other psychiatric manifestations are found frequently in patients with SMS [35–37, 80, 81]. Evidence suggests that anxiety disorders are related to disturbances in the GABA-ergic system in cortico-limbic pathways and disruption of the GABA systems could explain the frequent association of SMS with psychiatric manifestations [81, 82]. A woman with SMS and profound anxiety underwent a PET scan analysis showing reduced ^{11}C-FMZ binding potential in the limbic region, amygdale, and hippocampus, and these findings were supported by previous reports of decreased GABA levels in the amygdale region measured with MRI spectroscopy [41, 64, 65] (Fig. 72.5).

Moreover to explore the pathogenic role of antibodies against GAD 65 on psychiatric symptoms of SMS, the authors passively transferred the patient IgG fraction intrathecally into rats and demonstrated that anxiety can be reproduced in rat, suggesting a probable pathogenic action of IgG autoantibodies (Fig. 72.6). Furthermore, rat sections of CNS incubated with purified SMS patient IgG displayed a pronounced immunoreactivity in particular in structures associated with emotional control, such as amygdale, hippocampus, and frontal cortex, and similar staining patterns were observed in the human autopsy CNS material [41].

Clinical Presentation

SMS is a rare disorder characterized by fluctuating, progressive muscle stiffness, and painful spasms of the trunk [1, 2, 23, 40, 54, 83–85]. The onset is insidious usually in the fourth and fifth decades. The incidence of SMS is slightly greater in women than men; however, the exact incidence and prevalence of SMS are unknown.

The initial complaints are usually muscular tightness, stiffness, rigidity, and painful spasms of the lower back [1, 2, 53, 83]. Patients describe the pain as a dull, cramping feeling with severe muscle fatigue. Muscle rigidity first presents as symmetrically predominantly affecting the axial muscles, such as the neck, lumbar paraspinal, and abdominal muscles (Fig. 72.3, panels c and d). Axial rigidity progresses slowly over months or years causing a characteristic hyperlordosis of the lumbar region. Proximal limb muscles are involved later and the lower extremities are affected greater than the upper leading to difficulty in walking. In severely symptomatic cases, the distal musculature may be affected. SMS has a slow progression of manifestations associated with impairment of walking. Respiratory, swallowing, and facial muscles may be involved in advanced patients. The disease has usually a chronic course, but patients tend to stabilize after months or years. Neurological examination reveals normal strength and sensation. Deep tendon reflexes are often increased. The affected muscles are tight and rock-hard with a board-like consistency. Muscles supplied by the cranial nerves are rarely involved, and trismus does not occur. Examination shows truncal rigidity and there is a characteristic lumbar hyperlordosis in established cases. The gait is slow, laborious, and stiff. Passive or voluntary movement precipitates severely painful spasms of all involved musculature [1, 2, 23, 54, 83, 86–88].

SMS is usually an acquired condition; however, a hereditary form of SMS is described in several families

Fig. 72.3 Clinical characteristics of a typical stiff-man syndrome (SMS) patient with autoantibodies against glutamic acid decarboxylase (GAD). A 53-year-old woman with a past medical history notable for onset of vitiligo at age 33 (panels **a** and **b**), Graves' disease at age 38, and type 1 diabetes mellitus at age 51 was treated with thyroid hormone replacement and insulin. She complained of muscle rigidity, cramps, and painful spasms of 1-year duration. These symptoms involved mainly the axial musculature (panels **c** and **d**) but also the proximal portion of lower and upper limbs. She also noticed that these symptoms were partially ameliorated by low doses of diazepam. On the basis of clinical examination, a diagnosis of probable SMS was made. The patient underwent laboratory and electromyographic investigations. HLA phenotype was A3/30(19), B8/13, BW4/BW6, CW6, DR7/17(3), DR52/53, DQ2. An organ-specific autoimmunity screening of the serum demonstrated the following: thyroid-stimulating hormone receptor autoantibodies 97 U/L (normal value, 0–10), thyroid microsomal autoantibodies 1:102,400 dilution (normal value, absent), islet cell antibodies weakly positive (normal value, negative), GAD autoantibodies 63.1 U (normal value, 0–3 U), and autoantibodies directed against GABA-ergic synapses by immunohistochemistry on rat cerebellar sections. Autoantibodies directed against GAD were also present in the CSF. Needle electromyography demonstrated continuous motor unit activity at rest (rectus abdominis), which was exacerbated by hand clapping (* in panel **e**) and abolished by 10 mg intravenous diazepam (*arrow* in panel **f**). A diagnosis of SMS was made and the patient treated with diazepam 20 mg/day, with partial remission of muscular stiffness and painful cramps (Folli F, Galardi G, unpublished observations, 2000)

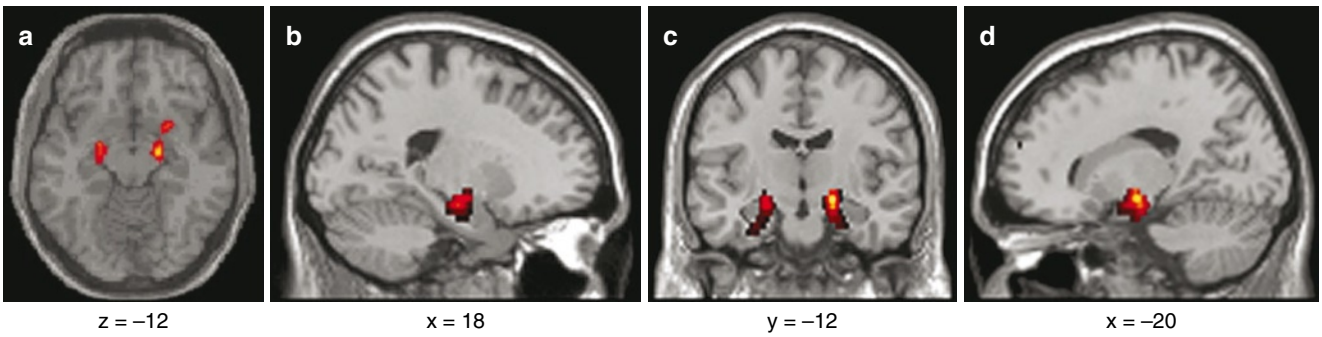

Fig. 72.5 Bilateral reductions of (11)C-FMZ binding potential in amygdala regions in the SMS patient. This figure shows the results of the PET scan analysis with statistical parametric mapping (SPM) with voxel-based analysis and thus the comparison of GABA-A receptor binding potential in a 53-year-old woman with SMS and anxiety. The (11)C-FMZ binding potential is significantly reduced bilaterally in the patient's limbic region when compared to normal controls (Reproduced with permission from Geis et al. [41])

[84, 85]. Hereditary SMS differs from acquired forms with stiffness present at birth but resolving by 3 years of age. Stiffness reappears at adolescence, often precipitated by sudden movement or cold, but remains mild when compared with the sporadic condition. The pattern of inheritance appears autosomal dominant, but X-linkage cannot be excluded in some families.

Differential Diagnosis

Conditions that cause continuous motor-unit activity at rest, rigidity, reflex, and action-induced spasms should be considered in the differential diagnosis of SMS. Focal lesions of the spinal cord, encephalomyelitis, corticobasal degeneration, or tetanus may at times be confused with SMS.

Variants of SMS are described and, on clinical and electrophysiological grounds, are divided into five groups of patients (Table 72.1). The first is typical SMS. The second variant is progressive encephalomyelitis with rigidity: a very rare rapidly deteriorating condition that may present with clinical features similar to those of the SMS. The clinical course is severe and progressive, often resulting in death within a few months [89–96]. The third variant is stiff-limb syndrome characterized by rigidity, abnormal fixed posturing, and painful spasms, usually of the distal lower limb. About half of the patients go on to develop sphincter or brainstem involvement. Half of patients become wheelchair bound. The patients partially respond to GABA-ergic drugs [97–100]. The fourth variant is SMS associated with antibodies to the synaptic vesicle protein amphiphysin II. This is a form of paraneoplastic SMS described in a small number of women with breast and lung cancer, characterized by different clinical features, partially responsive to benzodiazepines at high dose and with a significant response to tumor excision and chemotherapy [65, 73, 78, 101, 102]. The fifth variant is jerking stiff-man syndrome, in which myoclonic jerking is a prominent additional feature [103–105].

Fig. 72.4 Immunoreactivity of serum from a patient with stiff-man syndrome (SMS) against rat cerebellum and brain stem. Patients 1, 2, and 3 were affected by SMS and breast cancer, and a control patient was affected by SMS with autoantibodies against glutamic acid decarboxylase. In panels **a**–**i**, immunoperoxidase staining was used (immunoreactive areas are *black*), and in panels **j** and **k**, immunofluorescence staining was used (immunoreactive areas are *white*). (**a**) Sagittal section of cerebellum stained with serum from patient 1 shows staining of all regions containing synapses in the cerebellar cortex and the deep cerebellar nuclei (*DCN*). The dense staining of the molecular layer (*ML*) and the patchy staining of the granular layer (*GL*) correspond to the known distribution of the synapses in the two layers. (**b**) Cerebellar cortex stained with serum from patient 3 shows widespread immunoreactivity on synapses. (**c**) Cerebellar cortex stained with serum from the control patient shows only a few immunoreactive synapses, corresponding to "γ-aminobutyric acidergic synapses". These include synapses made by basket cell axons around the axon hillocks of Purkinje cells (*arrow*). (**d**–**f**) Adjacent sections of cerebellar cortex stained with serum samples from patients 1, 2, and 3, respectively, have identical patterns of immunoreactivity. This pattern is very similar to that produced by rabbit antibodies directed against a nerve-terminal marker, synapsin I (**g**). (**h**, **i**) Adjacent sections of deep cerebellar nuclei stained with serum samples from patients 1 and 3, respectively, show localized immunoreactivity in the cytoplasm of neuronal perikarya (*P*) and dendrites, as well as in the nerve terminals that form synapses at their surfaces (*arrows*). (**j**) Double immunofluorescence labeling of a brain stem section with serum from patient 3 and (**k**) antibodies directed against synaptophysin, a synaptic vesicle marker, shows nerve terminals filled with synaptic vesicles (with puncta). The profiles of neuronal perikarya and dendrites (*arrows*) are apparent. The *scale bar* measures 0.25 μm in **a**, 25 μm in **b** and **c**, 50 μm in **d–g**, and 25 μm in **h**–**k** (Reprinted with permission from Folli et al. [7])

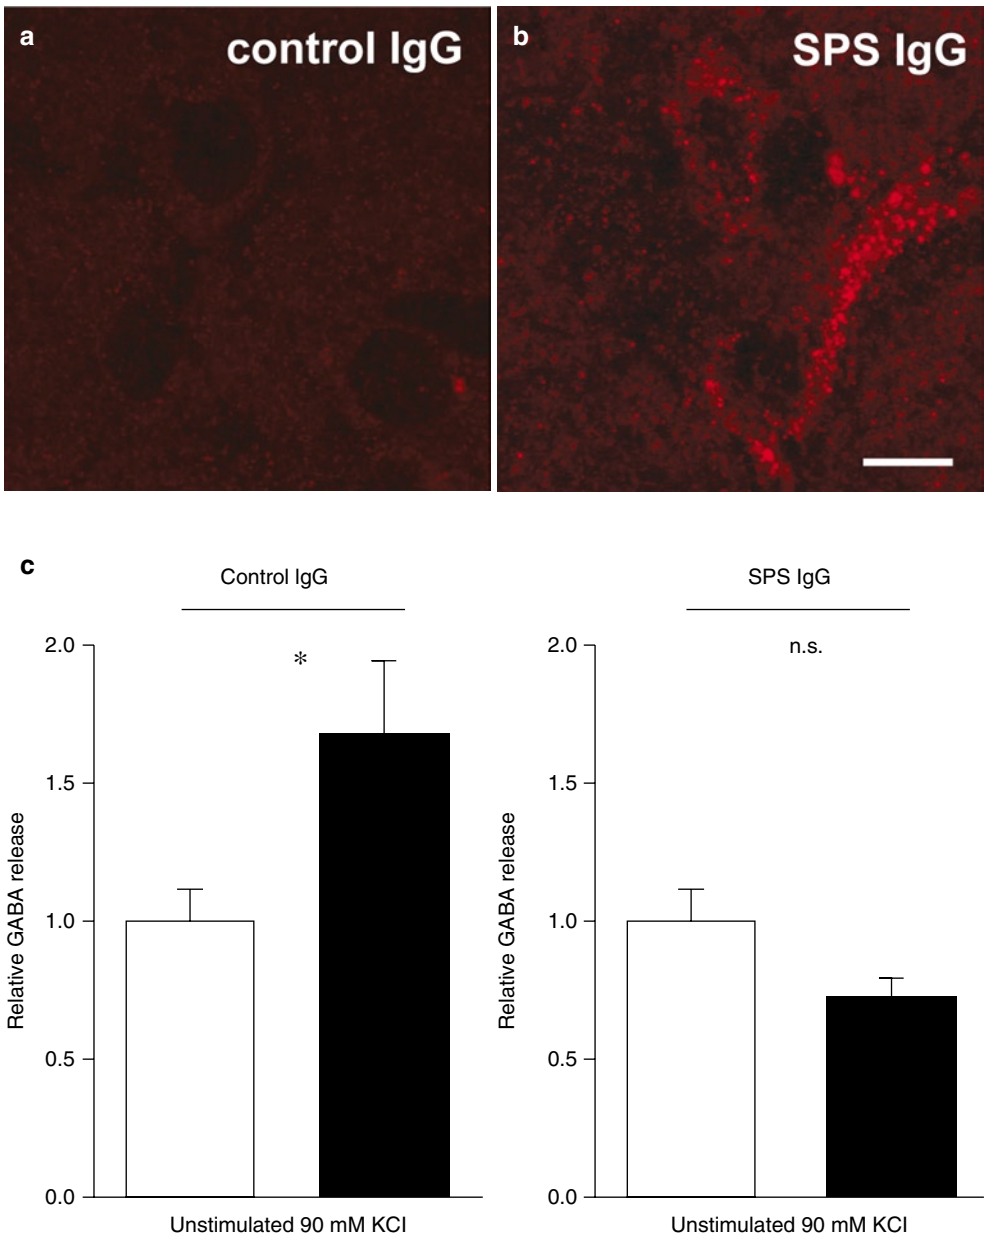

Fig. 72.6 SMS IgG accumulates in interneurons of rat amygdala complex and reduces GABA release from hippocampal neurons. In rats treated intrathecally with SMS IgG (**a**) but not in those treated with control IgG (**b**), immunoreaction against human IgG showed positive staining of neurons in the amygdala complex (*scale bar*, 10 mm). (**c**) Dissociated hippocampal neurons from E18 mouse embryos were incubated with SMS or control IgG. The increase of GABA release into the supernatants induced by stimulation with 90 mmol KCl was absent in SMS IgG-treated neuronal cell cultures as demonstrated by HPLC analysis (*p, 0.05, student's t-test) (Reproduced with permission from Geis et al. [41])

Evaluation and Diagnosis

Electromyography and muscle examination are critical to make a clear diagnosis and to understand pathophysiological mechanisms underlying SMS [2, 33, 34, 39, 40, 106]. Routine nerve conduction studies for both sensory and motor nerves are normal. The needle electromyographic pattern, although not unique to the disease, is present in virtually all patients with SMS with evidence of continuous motor-unit activity, especially in the paraspinal and abdominal muscles. The activity is continuous during wakefulness, diminished during sleep, exacerbated by sensory stimuli, and abolished by intravenously administered diazepam (Fig. 72.3, panels e and f) [2]. It is detectable, with needle or surface electrodes, particularly in abdominal and thoracolumbar muscles. Limb muscles are involved too but less severely than truncal muscles. Motor-unit activity is more prominent in lower limbs than upper limbs, and the severity of muscle involvement decreases with a proximo-distal gradient.

Electromyographic activity in SMS resembles the electromyographic pattern observed in voluntary muscle contraction. It is composed by motor-unit action potentials (MUAPs) of normal morphology, which fire tonically at rest. The number of MUAPs and the firing rate are higher in the thoracolumbar than in the limb muscles producing different electromyographic patterns, ranging from full interference pattern to single MUAPs, corresponding to the severity of involuntary muscle contraction. Although not specific for

Table 72.1 Clinical characteristics and laboratory findings of stiff-man syndrome (SMS) and its variants

	SMS	Progressive encephalomyelitis with rigidity	Stiff-limb syndrome	Paraneoplastic SMS/stiff-limb syndrome	Jerking SMS

SMS, measurement of the silent period may be helpful. The physiology of the silent period is complex [107, 108]. After a brief latency following a painful cutaneous stimulus, motor-unit activity is suppressed for a short period (i.e., the silent period). This reflex is mediated via spinal intraneural inhibition. The silent period can be useful in differentiating motor-unit activity of lower motor neuron or peripheral origin (e.g., tetanus, where the silent period is short or absent) from an upper motor neuron or central origin (e.g., SMS, where the silent period is normal) [108].

The continuous motor-unit activity of SMS is responsible for the abnormal lordotic posture and the gait abnormalities. It affects both agonists and antagonists muscles without asymmetry, and it is unresolved by attempts of voluntary relaxation or by stretching the stiff muscles.

The presence of superimposed episodic spasms on continuous motor-unit activity is another fundamental aspect of the final diagnosis of SMS. Muscle spasms might be spontaneous or induced by acoustic, somatosensory, or emotional inputs. They are electromyographically characterized by a sudden increment of the tonic motor-unit firing and a progressive return to the basal continuous motor activity.

Recent studies point to the possibility that hyperexcitability of the motor cortex in SMS plays a role in the pathogenesis. This could be explained by impairment of supraspinal GABA-ergic neurons leading to impaired balance between inhibitory and excitatory circuitry [98, 109].

There are no specific clinical laboratory findings in SMS, i.e., routine laboratory investigations are usually normal. GAD antibodies are present in serum in up to 80 % of patients with non-paraneoplastic form of SMS and are present in CSF as well. A high proportion of patients (>80 %) have other autoimmune diseases including insulin-dependent diabetes mellitus [110, 111]. Autoimmune thyroid disease, pernicious anemia, and vitiligo are also common. Epilepsy in the stiff-man syndrome occurs in about 10 % of patients (see Fig. 72.3) [3, 8, 25, 53, 112]. Five percent of patients have autoantibodies against amphiphysin and have an associated breast cancer [7, 8, 75].

Clinical and Laboratory Criteria

Diagnostic criteria for the SMS are the following [1, 2, 23]:

1. Stiffness and rigidity in axial muscle, progression of the stiffness to the proximal limb muscles, making volitional movements including walking difficult.
2. Abnormal axial posture, most often lordosis, resulting from continuous contraction of paraspinal and abdominal muscles.
3. Superimposed spasms precipitated by voluntary movement, noise, emotional upsets, and unexpected auditory and somatosensory stimuli.
4. Normal muscle strength and sensory examination.
5. Absence of brainstem; pyramidal, extrapyramidal, and lower motor neuron signs; and sphincter disturbance.
6. Normal intellect (epilepsy may occur).
7. Continuous motor-unit activity in at least one axial muscle with typical EMG findings.
8. Favorable response to the oral or intravenous administration of diazepam.
9. Diagnosis is supported by the finding, in association with the above clinical and electrophysiological criteria, of anti-GAD antibodies (65–67 kD doublet in western blot

on total brain homogenate or GABA-ergic synaptic pattern by indirect immunohistochemistry on rat cerebellar sections). They are found in 70 % of patients in blood and CSF. In about 5 % of patients, anti-amphiphysin II antibodies in blood and CSF are found by western blot using total brain homogenate. A substantial proportion of patients have oligoclonal bands in the CNS or abnormal Link/Tourtellote index, which is further indication of immune system activation in the CNS [3, 7, 113, 114].

Treatment

Therapy for stiff-man syndrome is based on knowledge of the pathophysiology of the disease: (1) drug-potentiating GABA-ergic transmission and (2) immunosuppressive agents.

Drug-Potentiating GABA-ergic Transmission

Diazepam is the initial treatment for SMS patients. High dosages of up to 100 mg/day are usually required. The majority of patients respond to diazepam to a certain extent, and the dramatic clinical improvement after administration of the drug helps to confirm the diagnosis [2, 20, 27, 31]. However, the high doses of diazepam are not easily tolerated, and other agents are often necessary to control manifestations. Clonazepam may be employed as an alternative to diazepam (up to 6 mg/day) [31]. Other drugs affecting GABA transmission, such as vigabatrin (which decreases GABA catabolism, up to 3,000 mg/day), tiagabin (which interferes with GABA uptake), and sodium valproate (up to 2,000 mg/day) may be helpful [32, 115–117]. Baclofen (up to 60 mg/day) increases GABA activity and may be helpful [21]. In a double-blind, placebo-controlled trial of three patients, 50 μg intrathecal baclofen improved electrophysiologic findings more than placebo; however, there is only slightly improved physical symptoms of one patient [118]. Most recent case reports confirm treatment improves symptoms and quality of life [119, 120].

Immunosuppressive Agents

There is evidence from expert opinion, nonrandomized historical controls, and case reports that plasmapheresis is beneficial in the treatment of SMS, although it is not uniformly effective [59, 121–125]. Plasma exchange for SMS is considered investigational by the Therapeutic and Technology Assessment Subcommittee of the American Academy of Neurology [125]. Prednisone, high-dose intravenous immunoglobulin, and cyclosporine are reported to be effective for some patients [121, 126–130]. Based on one randomized placebo-controlled trial [131], noncontrolled studies [132, 133], and several case reports [134], in patients with SMS and a poor response to initial GABA-potentiating therapy, the use of intravenous immunoglobulin at a total dose of 2 g/ kg is recommended [135].

Support for use of immunosuppressive therapies comes from the demonstration of high titers of GAD autoantibodies among SMS patients and that these autoantibodies inhibit GABA synthesis in vitro, suppress cerebellar GABA-ergic transmission, and are directed against the enzymatic active site of the protein [12, 41, 136, 137].

Prognosis

The prognosis of SMS in association with autoantibodies against GAD is usually good for long-term survival and maintenance of independence in activities of daily living. However, five percent of patients may develop frequent attacks of muscle spasms with severe paroxysmal autonomic dysfunction resulting in sudden death [1, 6, 38, 53–55, 72, 100]. The prognosis of patients affected by stiff-limb syndrome differs. The disease is chronic (decades), but at variance with SMS, approximately half of patients become wheelchair bound [97]. Encephalomyelitis with rigidity follows a subacute course leading to death within 3 years [55, 92, 94–96, 100]. The prognosis of the patients affected by the paraneoplastic forms of SMS is dependent on cure of the underlying cancer.

Tetanus

73

Jayashri Srinivasan and Thomas D. Sabin

Introduction

Tetanus is a neurological disorder caused by a potent neurotoxin, tetanus toxin (tetanospasmin), elaborated by *Clostridium tetani*, a gram-positive, spore-forming obligate-anaerobic bacillus found normally in the mammalian gut as well as soil and animal excrement. Reported cases of tetanus have declined greater than 95 %, and mortality has declined by greater than 99 % in the USA since 1947 with a case fatality rate of 13.2 % [1]. Incidence is higher among persons over 65 years of age, Hispanics, intravenous drug users, and diabetics. Tetanus toxin abolishes inhibitory spinal reflex arcs, allowing excitatory reflexes to predominate, thus resulting in increased muscle tone and spasms that are the cardinal manifestations of the disease. Tetanus is predominantly seen in neonates and children in the developing world, where immunization programs remain inadequate. In the Western world, where immunization with tetanus toxoid is universal, tetanus is most often encountered in patients over 65 years of age, often after a trivial injury acquired outdoors, and in drug addicts. Tetanus occurs in several distinct clinical forms including localized, generalized (including neonatal), and cephalic disease.

Etiology

Clostridium tetani are gram-positive, spore-forming, motile, obligate anaerobes that are found worldwide; the spores are formed terminally, giving the organism a distinctive drumstick-like appearance. The spores are relatively resistant to drying and various disinfectants. Phenol (5 %), formaldehyde (3 %), and chloramine (1 %) generally require more than 15 h to kill the spores, while autoclaving, aqueous iodine and 2 % glutaraldehyde at pH 7.5–8.5 are lethal. The spores of *C. tetani* are ubiquitous and survive many years, especially in soil cultivated by manure. Spores may also be found in animal and human feces and in house and operating room dust.

Under appropriate anaerobic conditions, particularly in wounds associated with necrosis and foreign bodies, the spores germinate into the vegetative form that elaborates two exotoxins, tetanolysin and tetanospasmin. Tetanolysin is an oxygen-sensitive hemolysin that may have some role in establishing infection, but is not otherwise thought to be involved in the pathogenesis of tetanus. Tetanospasmin, a zinc metalloprotease, is formed under plasmid control as a single 1315-amino acid 150 kD polypeptide chain. It is cleaved by bacterial protease, papain, resulting in a nontoxic C fragment (carboxy terminal of heavy chain) and an A–B fragment (light chain and amino terminal of the heavy chain) to form a heterodimer joined by a disulfide bond [2, 3]. The heavy chain is responsible for specific binding to neuronal cells and for cell penetration of the light chain which blocks transmitter release. When tetanospasmin is released in infected wounds, the C fragment binds to specific axonal membrane gangliosides (GD1b and GT) at the neuromuscular junction predominantly at the terminals of alpha motor and to lesser extent autonomic neurons [4, 5]. The C-terminal H (CC)-domain interacts with complex polysialo-gangliosides, such as GT1b and a synaptic vesicle protein receptor via two neighboring binding sites, resulting in highly specific uptake of the neurotoxins at synapses of cholinergic motor neurons [6–8]. The toxin is internalized inside the lumen of synaptic vesicles following vesicle reuptake and is translocated from the endosomes to the

DOI 10.1007/978-1-4614-6567-6_73, © Springer Science+Business Media New York 2014

cytosol [6, 7]. Their multistep mode of mechanism can be ascribed to their multidomain three-dimensional structure. It is then transported by retrograde transsynaptic axonal transport to the cell bodies of inhibitory interneurons in the spinal cord and brainstem [8, 9]. In the inhibitory neurons in the spinal cord, the light chain fragment causes proteolytic cleavage of the SNARE (synaptosomal-associated protein receptor) complexes, particularly the synaptobrevin/vesicle-associated membrane protein, and prevents neurotransmitter release (glycine in the spinal cord and gamma-aminobutyric acid [GABA] in the brain) [9]. This disinhibition results in uncontrolled excessive efferent discharge of motor and autonomic neurons resulting in muscle rigidity, spasms, and autonomic dysfunction characteristic of tetanus. The amino acid structures of the two most powerful toxins known, botulinum and tetanospasmin, are partially homologous; the estimated human lethal dose of tetanospasmin is less than 2.5 ng/kg [10].

Epidemiology

Tetanus is a sporadic disease which only affects non-immunized and partially immunized persons or immunized individuals who fail to maintain adequate immunity with booster doses of vaccine. Tetanus causes substantial morbidity and mortality in developing countries. The World Health Organization estimated that about 277,400 deaths from neonatal tetanus alone occurred in 1997 [11]. Improved hygiene and childbirth practices, improvements in wound care, and active immunization have led to substantial reductions in tetanus in developed countries.

Tetanus surveillance in the USA between 1995 and 1997 yielded a total of 124 cases, giving an annual incidence of 0.15 cases per 1,000,000 population. Sixty percent of patients were aged 20–59 years, 35 % were aged ≥ 60 years, and 5 % were aged <20 years, including one case of neonatal tetanus. Tetanus among intravenous drug users compromised 11 % of all cases [12].

Of 67 cases of tetanus reported in California during 1987–1997, a total of 27 (40 %) occurred in injecting drug users (IDUs); injection technique information was available in 14 persons, all of whom had used the subcutaneous route ("skin popping"), and specific drug use information in ten persons revealed heroin use in all [13].

There is evidence that following natural disasters such as earthquakes and tsunamis in Haiti, Indonesia, and Kashmir, there have been clusters of outbreaks of tetanus. In a population where immunization is inadequate, following crush injuries, there is contamination of wounds by spore-containing soil resulting in tetanus [14].

Rarely, tetanus may be seen in spite of adequate immunization; the reason for this not known [15].

Pathogenesis

Spores of *C. tetani* usually gain access to the body by wound inoculation and the spores are converted to the toxin-producing vegetative forms. An anaerobic milieu or a local reduction in oxidation-reduction potential, as in wounds with devitalized tissue, foreign bodies, or active infection, causes vegetative organisms to produce the toxins tetanospasmin and tetanolysin. Calcium appears to increase local necrosis and may enhance germination in wounds contaminated with soil. *C. tetani* by itself does not provoke a significant inflammatory response so the infection may remain localized and inconspicuous.

The transport of tetanospasmin, released at the site of injury, to the central nervous system is complex. Although the toxin gains access to the systemic circulation and enters the central nervous system (CNS) with the highest efficiency of any known protein, tetanospasmin does not appear to cross the blood-brain barrier. The portal of entry appears to be through binding of the toxin to peripheral alpha motor neuron terminals. Binding to a specific ganglioside-containing receptor is followed by internalization of the toxin by endocytosis and retrograde axonal transport to cell bodies in the brainstem and spinal cord [16]. The toxin then migrates across the synapse to presynaptic terminals, where it blocks release of the inhibitory neurotransmitters glycine and GABA. The resultant disinhibition of the spinal reflex arcs leads to an increase in the resting firing rate of the alpha motor neuron, producing rigidity. Agonists and antagonists may be recruited rather than inhibited, thereby producing tetanospasms. The clinical picture is similar to strychnine poisoning, which acts by competitively binding to postsynaptic glycine receptors at the motor neurons. Loss of inhibition may also affect preganglionic sympathetic neurons in the lateral gray matter of the spinal cord mediated by protease activity of the light chain on synaptobrevin [17], producing sympathetic hyperactivity and high circulating catecholamine levels.

In localized tetanus, only the nerves supplying the affected muscles are involved. Generalized tetanus occurs when toxin released in the wound enters the bloodstream and is spread to other nerve terminals; if intra-axonal transport time, approximately 75–250 mm/day, is assumed to be equal for all nerves, short nerves are likely to be affected before long nerves. This may explain the sequential involvement of nerves of the head, axial trunk, and extremities in generalized tetanus [4].

Clinical Manifestations

The incubation period for tetanus varies from 3 days to 3 weeks and is usually 8 days after an acute injury. The incubation period varies directly with the distance of the injury

Fig. 73.1 Risus sardonicus. Note the spasm of the facial muscles, producing a grimace or sneer on the baby's face (Photo courtesy of the World Health Organization)

Fig. 73.2 Opisthotonus. Note the severe contraction of the extensor back muscles (Photo courtesy of the Centers for Disease Control)

from the CNS. Injuries to the lower extremities are likely to be associated with longer incubation periods than injuries to the head and neck; the shorter the incubation period, the greater the possibility of death. Some 15–25 % of patients with tetanus have no evidence of a recent wound.

Tetanus may take one of three clinical forms: localized, generalized, and cephalic. *Localized tetanus* is limited to painful muscular spasms in a confined area close to the site of injury. These contractions may persist for weeks to months before spontaneously subsiding. Localized tetanus is uncommon in humans and is generally mild, with death-to-case ratios of less than 1 %. However, it may be the first manifestation of generalized tetanus, which portends a more dire outcome. Most patients have *generalized tetanus* with widespread signs and symptoms. In approximately 50 % of patients, the illness starts with spasm of the muscles of mastication – the classical *trismus* or *lockjaw*. Dysphagia, stiffness, and pain in the neck, shoulder, and back muscles appear soon thereafter. Symptoms progress to involve the abdominal muscles producing a rigid abdomen and proximal limb muscles; the hands and feet are relatively spared. Sustained contraction of the facial muscles produces a grimace or sneer (*risus sardonicus*) (Fig. 73.1) and contraction of the extensor back muscles produces an arched back (*opisthotonos*) (Fig. 73.2). Some patients develop *tetanospasms* – paroxysmal, generalized, painful, tonic muscle contractions that occur repetitively and are spontaneous or provoked by even minor stimulation. Distention of the bowel or bladder, mucus plugs in the bronchi, or slight noises may trigger tetanospasms.

A constant threat during generalized spasms is reduced ventilation or apnea secondary to laryngospasm. Tetanospasms occur intermittently, irregularly, and unpredictably, persisting from a few seconds to minutes. Initially mild and separated by periods of relaxation, the paroxysms tend to become more frequent, severe, painful, and exhausting as they continue. Dysphagia or ileus may preclude oral feeding. The degree of illness may be mild (muscle rigidity and few or no spasms), moderate (trismus, dysphagia, rigidity, and spasms), or severe (frequent explosive spasms). The patient may have a mild fever; cognitive testing and sensory examination are usually normal; deep tendon reflexes may be increased.

Autonomic dysfunction commonly complicates severe cases and is characterized by labile or sustained hypertension, tachycardia, arrhythmias, hyperpyrexia, profuse sweating, peripheral vasoconstriction, and increased plasma and urinary catecholamine levels. Periods of bradycardia and hypotension may also occur and may require pacemaker insertion. "Autonomic storms", characterized by episodes of sinus tachycardia and severe hypertension followed within hours by profound bradycardia and hypotension, may occur. These are often a harbinger of cardiac arrest, which remains the single most dreaded complication of tetanus. It usually occurs under conditions of marked cardiovascular instability secondary to wildly fluctuating sympathetic and parasympathetic activity. Cardiac arrest may also be secondary to excessive vagal activity during suctioning of the pharynx and trachea, severe hypoxia due to prolonged muscular and laryngeal spasm, hyperpyrexia causing cardiovascular collapse, or massive pulmonary embolism.

Maternal and neonatal tetanus are important causes of morbidity and mortality, claiming 187,000 lives every year mostly in Asia and Africa [18]. Neonatal tetanus occurs as a generalized form and has a high mortality. It develops in the first 2 weeks of life in children born to inadequately immunized mothers, frequently after non-sterile treatment of the umbilical cord stump. Infants present with poor feeding, rigidity, and spasms.

Cephalic tetanus is rare and follows lesions of the head and face (e.g., otitis media), especially in the distribution of the facial nerve. It is characterized by unilateral facial paralysis, trismus, facial stiffness on the nonparalyzed side, nuchal

rigidity, pharyngeal spasms causing dysphagia, and frequent laryngeal spasms with risk of death from asphyxia. Cephalic tetanus may be associated with paresis involving the glossopharyngeal, vagus, and rarely the oculomotor nerves. The disease has a short incubation period and may graduate to generalized tetanus.

Other complications include rhabdomyolysis, fractures, muscle rupture, deep venous thromboses, pulmonary emboli, atelectasis and pneumonia, sepsis, decubitus ulcers, gastric ulcers, fecal impaction, and urinary retention.

Differential Diagnosis

The differential diagnosis of tetanus depends on the clinical pattern of presentation. Spasm of the masseter (trismus) may be seen in patients with dental caries, tonsillitis, peritonsillar abscess, temporomandibular joint dysfunction, and parotitis. Trismus and muscle spasms may occasionally be seen in purulent meningitis and encephalitis but are associated with characteristic clinical and cerebrospinal fluid (CSF) abnormalities. Rabies may cause muscle spasms, particularly in the muscles of respiration and deglutition. However, the accompanying encephalitis is characterized by hallucinations, hydrophobia, mania, stupor, and tonic-clonic seizures.

Hypocalcemic tetany may superficially resemble tetanus. However, it is accompanied by Chvostek's and Trousseau's signs, affects the extremities more than the trunk, and is not associated with trismus. Tetany is confirmed by low serum calcium levels.

Drug-induced dystonia such as those due to dopaminergic blocking agents such as phenothiazines may produce oculogyric movements, characterized by eye deviation and head and neck movements; this usually responds to benztropine unlike tetanus. Malignant neuroleptic syndrome may also mimic tetanus, but the history of medication use and the presence of altered mental status differentiate this condition from tetanus.

Strychnine poisoning produces an almost identical clinical presentation to tetanus. However, trismus is either absent or appears late in strychnine poisoning and is impersistent. Also, body temperature is normal, muscle rigidity between spasms is absent, and symptoms and signs usually develop much more rapidly than with tetanus. A history suggestive of poisoning may be obtained and the diagnosis can be confirmed by detecting strychnine in the gastric contents or urine.

Stiff person syndrome has an insidious onset, tends to cause minimal symptoms in facial and jaw muscles, does not have the characteristic loss of the silent period in the electromyography (EMG), and may be associated with antibodies to glutamic acid decarboxylase (GAD) or, in rare cases, to amphiphysin, glycine receptor or gephyrin.

Conversion reactions may also mimic tetanus, but patients with hysteria are more likely to relax when distracted, and the EMG shows no loss of the silent period.

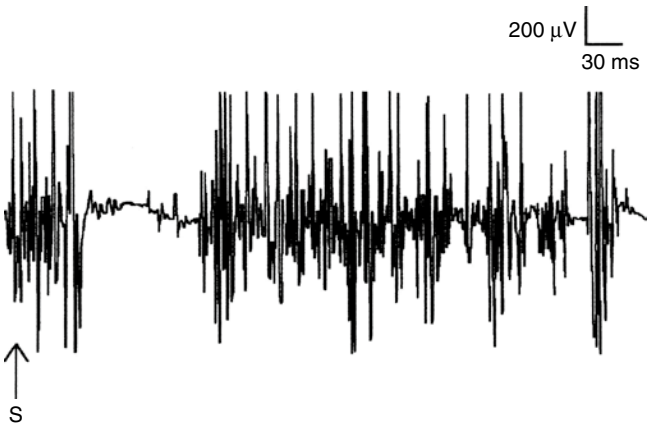

Fig. 73.3 Normal silent period. During sustained voluntary contraction or spontaneous motor unit activity from a central origin, a supramaximal mixed nerve or cutaneous stimulus (*S*) will inhibit motor unit activity, resulting in the silent period. The silent period normally occurs 50–100 ms after a supramaximal stimulus and is most pronounced with a painful stimulus. The silent period is absent in tetanus

Cephalic tetanus may be confused with Bell's palsy or trigeminal neuralgia; however, cephalic tetanus is frequently associated with multiple cranial nerve palsies, trismus, and nuchal rigidity.

Evaluation and Diagnosis

The diagnosis of tetanus is largely made on the basis of clinical findings. The absence of a wound does not exclude tetanus. Tetanus is less likely if a reliable history of primary immunization with appropriate booster doses is obtained or if serum antitoxin levels are 0.01 unit/ml or higher. However, there are reports of tetanus developing in fully immunized patients [15]. Anaerobic cultures of wound specimens should be done although *C. tetani* is isolated only in approximately a third of cases. A positive wound culture is not diagnostic of tetanus as the organism may be grown from wounds of patients who do not have tetanus. Laboratory tests are of little value; the leukocyte count may be mildly elevated and serum creatine kinase may be moderately elevated in generalized tetanus. Cerebrospinal fluid (CSF) examination is usually normal though in severe cases, CSF protein and immunoglobulins may be elevated.

Electrodiagnostic studies in cephalic tetanus may show abnormal blink reflex [19]. Needle EMG recording from muscles in spasm may show continuous discharges of motor unit action potentials, like those recorded during forceful voluntary contraction. A characteristic feature of tetanus on EMG is shortening or absence of the silent period normally seen 50–100 ms after supramaximal nerve stimulation (Fig. 73.3). The silent period is mediated partially through recurrent inhibition of the alpha motor neurons by the Renshaw cells, the inhibitory neurons in the spinal cord.

Neurotransmitter release from these inhibitory neurons is blocked by tetanus toxin. The loss of the silent period may be demonstrated in an affected muscle in localized tetanus and in the masseter in generalized tetanus [20]. After discharges following F waves have been observed in mild tetanus [21]. Single-fiber EMG of the affected muscle may show increased jitter and blocking in a significant proportion of the recorded units [22].

Treatment

Treatment strategies are directed toward the following goals: elimination of the source of toxin; neutralization of circulating, unbound toxin before it reaches the nervous system by the early administration of specific antitoxin; exploration, careful cleansing, and thorough debridement of wounds; and adequate immunization to prevent infection.

General Measures

General supportive measures include expert intensive medical and nursing care in a dimly lit room where environmental stimuli are minimized, ideally in an intensive care, where adequate cardiopulmonary, caloric, fluid, and electrolyte balance monitoring can be maintained. In addition, patients usually require prophylaxis against venous thrombosis and stress gastric ulcers, adequate treatment of fevers, stool softeners to prevent fecal impaction, and urinary catheterization if retention develops. Since tetanus is a catabolic illness, caloric intake of 3,500 cal with at least 100 g of protein is essential and is often given by nasogastric feeding. Physical therapy should be initiated as soon as the spasms are controlled to prevent contractures from prolonged immobility.

Antitoxin

Human tetanus immunoglobulin (TIG) should be given immediately at the time of diagnosis to prevent further spread of the circulating unbound toxin. The dose is 3,000–6,000 units injected intramuscularly; part of the dose may be infiltrated around the wound for the theoretical, but unproven, objective of neutralizing the toxin at the site of its production. Tetanus antitoxin does not cross the blood-brain barrier and has no effect on toxin already bound to nervous tissue. Intrathecal antitoxin administration is not recommended in the United States. However, a study done in Brazil suggested that intrathecal tetanus immunoglobulin may be of benefit; the duration of spasm, hospital stay, and period of respiratory assistance was shorter [23] and a meta-analyses from Kenya also confirmed that intrathecal tetanus immunoglobulin may be beneficial [24].

Wound Care and Antibiotics

After administration of antitoxin, the wound should be debrided, necrotic tissue must be excised, and foreign objects removed. The wound should be bathed and irrigated with 3 % hydrogen peroxide at least three times a day. Antibacterial therapy is routinely used to prevent the growth and multiplication of bacteria in the wound, though there are no controlled trials to show that antibacterial therapy is clearly beneficial. Metronidazole 500 mg is given intravenously every 6–8 h in adults and 20–30 mg/kg/day in three divided doses in children. Crystalline penicillin G 100,000 units/kg/day given in four divided doses is also widely used in developing countries. In mixed infections, intravenous cephalosporins such as a cefazolin, cefuroxime, or ceftriaxone may be used.

Sedatives and Muscle Relaxants

This is an important aspect of the treatment of tetanus and the aim is to reduce rigidity and control spasms. Diazepam is widely used in doses of 0.5–10 mg/kg/day given either as an infusion or in divided doses. Higher doses have been used but are invariably associated with respiratory depression. An alternative agent is midazolam 5–15 mg/h as an intravenous infusion. Chlorpromazine is also used though there is small risk of dystonic reactions and the malignant neuroleptic syndrome. Baclofen, a GABA B agonist, is a potent muscle relaxant that can be given by the intrathecal route with a bolus of 300–500 μg and continued at a steady rate of 500–1,000 μg/day [25]. Intrathecal baclofen has the advantage of treating spasms but preserving voluntary movement and respiration. Dantrolene, a direct muscle relaxant, has also been used to treat spasms [26]. Propofol, an intravenous sedative agent, is used in patients who are artificially ventilated. There has been a recent reemergence of the practice of using magnesium sulfate intravenously to reduce spasms without compromising respiratory function. However, studies suggest that although magnesium sulfate may reduce the medications used for cardiovascular instability, there is no definite evidence it reduces the need for mechanical ventilation [27].

Tracheostomy, Neuromuscular Blockade, and Ventilatory Support

Tracheostomy is mandatory in severe tetanus as prolonged laryngeal spasm can result in significant hypoxia and death; it is also recommended in mild to moderate cases where it may assist in artificial ventilation. The use of neuromuscular blockade with pancuronium or vecuronium is often necessary, particularly when spasms do not respond to conservative treatment with sedatives and muscle relaxants.

Table 73.1 Routine diphtheria, tetanus, and pertussis immunization schedule summary for children <7 years of age

Dose	Customary age	Age/interval	Product
Primary 1	2 months	6 weeks old or older	DTaP[a,b]
Primary 2	4 months	4–8 weeks after first dose[c]	DTaP[a,b]
Primary 3	6 months	4–8 weeks after second dose[c]	DTaP[a,b]
Primary 4	15–18 months	9–12 months after third dose[c]	DTaP[a,b]
Booster	4–6 years old, before entering kindergarten or elementary school (not necessary, if fourth primary immunizing dose administered after fourth birthday)		DTaP[a,b]
Additional boosters	Every 10 years after last dose		Td

[a]Whole-cell DTP is an acceptable alternative if DTaP is not readily available
[b]Use DT if pertussis vaccine is contraindicated. If the child is 1 year of age or older at the time that dose three is due, a third dose 6–12 months after the second completes primary immunization with DT
[c]Prolonging the interval does not require restarting series

Treatment of Autonomic Circulatory Derangement

Management of the complex autonomic disturbances seen in tetanus may be very difficult. Hypotension can be treated with fluid load and if needed inotropic support with dobutamine or dopamine. Hypertensive episodes can be treated with beta blockers such as an intravenous infusion of labetalol. Intravenous magnesium sulfate can also be used to treat autonomic dysfunction, and some authors recommend this as a first-line therapy for spasms [27]. Epidural bupivacaine may be useful to treat episodes of severe circulatory disturbances [28].

Prevention

Since tetanus spores cannot be removed from the environment, the goal of tetanus prevention consists of adequate immunization. The Maternal and Neonatal Tetanus Elimination Initiative of the World Health organization assists countries where tetanus has not been eliminated by providing immunization to expectant mothers. Immunization of pregnant women or women of childbearing age with at least two doses of tetanus toxoid is estimated to reduce mortality from neonatal tetanus by 94 % [29].

Active Immunization

Primary tetanus immunization, usually with combined DTaP (diphtheria and tetanus toxoid and acellular pertussis) or DTP (diphtheria and tetanus toxoid and pertussis) vaccine, is recommended for all children 6 weeks to 7 years of age without contraindications to vaccination (Table 73.1). A minimum of 4 weeks (typically 6–8 weeks) should separate the first, second, and third doses of tetanus toxoid. The fourth dose of the primary series should be given no less than 6 months after the third dose.

For active immunization of infants and children, the recommendation is to receive the first dose at 2 months of age, two further doses at 1–2 month intervals, the fourth dose at 15–18 months of age, and a fifth dose at 4–6 years of age. Thereafter, the adult formulation should be given every 10 years. Combined adsorbed tetanus and diphtheria toxoid for adult use (Td) rather than single-antigen tetanus toxoid is preferred for persons over 7 years of age. In addition to decennial booster doses of tetanus and diphtheria toxoids during adult life, the Advisory Committee on Immunization Practices (ACIP) recommends review of vaccination history for adolescents at age 11–12 years and for adults at age 50 years to enable health-care providers to administer any required vaccine.

All partially immunized and unimmunized adults should receive vaccine, as should those recovering from tetanus. The primary series for adults consists of three doses: the first and second doses are given 4–8 weeks apart, the third dose is given 6–12 months after the second, and a booster dose is required every 10 years.

Immunization After Wounds

Proper wound management requires consideration for passive immunization with TIG (tetanus immunoglobulin) and active immunization with vaccine. For active immunization, in children <7 years of age, DTaP (diphtheria, tetanus toxoid, and acellular pertussis) or DT, if pertussis vaccine is contraindicated, is preferred to tetanus toxoid alone. For children ≥7 years and adults, Td (tetanus toxoid, diphtheria) is preferred to tetanus toxoid alone; DTaP may be given if the patient has not previously been vaccinated with Tdap.

For clean, minor wounds, Td is administered to persons who have unknown tetanus immunization histories, received less than three doses of adsorbed tetanus toxoid, or received three or more doses of adsorbed vaccine but 10 years or more have elapsed since the last dose.

The recommendations for contaminated or severe wounds are identical, except that vaccine should be given if more than 5 years have elapsed since the last booster dose. TIG is not recommended for clean, minor wounds but is given for all other wounds if the immunization history indicates unknown or incomplete immunization. The dose of TIG for passive immunization is 250 units intramuscularly (deltoid or lateral thigh) in adults and children >7 years old; in children <7 years old, the dose is 4 units/kg. This is thought to produce a protective antibody level in the serum for at least 4–6 weeks. Vaccine and tetanus antitoxin should be administered at separate sites in separate syringes.

Preventive efforts of neonatal tetanus include maternal vaccination, including vaccination during pregnancy, measures to increase the number of in-hospital births, and training for nonmedical birth attendants.

Adverse Effects of Tetanus Toxoid

Tetanus toxoid is well tolerated. There is no evidence that tetanus toxoid use is associated with Guillain-Barre syndrome or any other significant adverse effect [30].

Prognosis

The prognosis is influenced by various factors, including age, immunization status, underlying illness, and quality of supportive care. The most important factor determining outcome is the quality of intensive care. Mortality rates are low in countries where good quality intensive care units are available. In developing countries, with poor access to supportive care mortality rates as high as 50 % may be seen [18]. The outcome is poor in neonatal tetanus, in the elderly, and in those with a short incubation or a short period from onset of symptoms to the first spasm. In the 124 cases reported in the USA between 1995 and 1997, fatalities ranged from 2.3 % for persons aged 20–39 years to 16 % for persons aged 40–59 years to 18 % for persons over 60 years [12].

The clinical course of tetanus extends over 4–6 weeks, and patients may require ventilatory and intensive care support for up to 3 weeks during this period. Increased tone and minor spasms can last for months, but recovery is usually complete. Most patients will benefit from physical therapy in a rehabilitation unit prior to discharge home.

Neuroleptic Malignant Syndrome

74

Prachi Mehndiratta, Yonatan Spolter, Blessing Igboeli, Martha Sajatovic, and Peter F. Buckley

Introduction

Neuroleptic malignant syndrome (NMS) is a condition characterized by altered mental state, muscular rigidity, autonomic dysfunction, and hyperpyrexia occurring most often (but not invariably) during treatment with antipsychotic and other psychotropic medications [1–4]. NMS remains an enigmatic condition. Despite its decreasing frequency over the last two decades, it is still a cause for concern among psychiatrists and neurologists alike.

The first descriptions of the syndrome ("syndrome malin des neuroleptiques") originated in France [5, 6]. Building upon earlier observances in their clinic, Delay and Deniker described a constellation of signs (temperature elevation, rigidity, delirium) which were associated with a severe and life-threatening neurotoxicity to neuroleptic therapy [5]. Thereafter, reports of NMS appeared with increasing frequency in the literature, and the syndrome was described in relation to treatment with other psychotropic medications (e.g., antidepressants, lithium) and in other conditions such as postoperatively or with dehydration [4, 7–9]. The occurrence of NMS in patients with neuropsychiatric conditions associated with compromised dopamine function (e.g., Wilson's disease, Parkinson's disease, and Huntington's chorea) [9–11] provided impetus to the notion that NMS was due to acute hypodopaminergia. Also, these reports heightened concern that NMS could occur in a variety of pathological states and that NMS would not be limited in risk merely to persons with serious mental illness who are treated with antipsychotic medications (Table 74.1).

Epidemiology

The true incidence of NMS is unknown. Attempts to determine its frequency have been thwarted by diagnostic imprecision, shifts over time, and variance across several diagnostic criteria which have inevitably resulted in divergent formulations of this syndrome and a focus on distinct (psychiatric) patient populations rather than a broader, epidemiologically based approach which looks at drug use and adverse effects across diverse patient populations [1]. That said, it is certain that NMS is considerably less common now than the high incidence figures which were cited in earlier psychiatric

Table 74.1 Conditions in which NMS occurs in the absence of antipsychotic medications

Table 74.2 Commonly prescribed antipsychotic medications

Agent	Trade name	Daily dosage range (mg)[a]
Typical		
Haloperidol	Haldol	1–30
Perphenazine	Trilafon	4–32
Thioridazine	Mellaril	25–1,800
Mesoridazine	Serentil	25–300
Chlorpromazine	Thorazine	25–800
Molindone	Moban	25–250
Thiothixene	Navane	5–30
Atypical		
Clozapine	Clozaril	12.5–900
Risperidone	Risperdal	1–6
Olanzapine	Zyprexa	2.5–20
Quetiapine	Seroquel	100–800

[a]Representative of the effective doses which are generally used in clinical practice for the treatment of psychotic, nonpsychotic, and neurological conditions

studies [1, 9, 12]. For example, in one of the first studies of the epidemiology of NMS, Pope and colleagues estimated a 1.4 % incidence of NMS in the psychiatric population [13]. Another study found a 12.2 % rate of NMS [14]. Subsequent studies cited a much lower incidence of NMS at 0.07–0.15 % [15–17]. Several factors, alone or in combination, are likely to account for the falling incidence of NMS. First, the diagnostic stringency has improved over time [1, 2]. Second, clinicians are wary of this condition and, consequently, are apt to discontinue antipsychotic medications and to institute supportive measures promptly so as to avert the full-blown syndrome. Third, prescribing practices with antipsychotic medications have changed: Doses have decreased over time, the practice of "rapid neuroleptization" is now obsolete, and the typical antipsychotics have been replaced by new, "atypical" antipsychotics in many psychiatric settings. Table 74.2 illustrates representative compounds in the typical (older) antipsychotic and atypical (newer) class. The atypical antipsychotics appear less likely to induce NMS [18, 19]. Finally, it cannot be discounted that some other factors of pathogenic importance (e.g., low serum iron or genetic predisposition to NMS) may have declined in frequency. While NMS is less common than in previous decades, it remains as one of the most acute and serious of the neurologic side effects of antipsychotic therapy.

Etiology and Pathogenesis

There remain large gaps in our understanding of the etiology and pathophysiology of NMS [20]. Various competing theories are postulated. Most of them are speculative without any robust evidence. Some theories try to integrate dysregulation among the various neurotransmitter systems, including γ-aminobutyric acid (GABA), acetylcholine (Ach), norepinephrine, and serotonin, as contributing to the development of NMS. There are also etiologic hypotheses related to endorphin dysregulation [21] and to prostaglandin receptor sensitivity [22]. Current theories, however, do not explain why NMS develops only in a small minority of patients exposed to the offending agents. Other cofactors need to be invoked to explain the idiosyncratic occurrence of NMS [9, 23, 24].

Genetic Factors

Family studies are difficult in NMS because they would involve treating family members with a drug which may not be medically indicated; however, without family studies of drug exposure, the possibility of a genetic basis for NMS cannot be ruled out. So far only few reports of familial NMS have appeared in the literature [25–27]. Deuschl and colleagues reported the occurrence of unrecognized NMS in the twin brother (concordant for schizophrenia) of an index case with schizophrenia and NMS [25]. The twin brother had at least one documented episode with otherwise unexplained fever, tachycardia, and rigidity, suggesting the occurrence of unrecognized NMS. Otani and colleagues described a Japanese family consisting of a mother and her two daughters, all of whom experienced NMS on therapeutic or subtherapeutic doses of neuroleptics [26]. The authors advise extreme caution in starting neuroleptic treatment in a patient with a family history of NMS. Manor and colleagues reported two Ashkenazi Jewish siblings suffering from GM2 gangliosidosis with similar neurological and psychiatric manifestation who developed NMS while on low to very low doses of neuroleptics [27]. Lazarus and colleagues diagnosed possible NMS without rigidity in a mentally retarded patient with an inverted duplication of chromosome 15 [28]. Association between NMS and polymorphisms in the 5HT1A and 5HT2A receptor genes was excluded in a recent study [29]. Analogous to Parkinson's disease, polymorphism of CYP2D6 has been suggested as a possible marker of susceptibility to the NMS [30].

NMS may show a genetic overlap with malignant hyperthermia (MH). However, data from family studies [31], from in vitro muscle contracture testing [32], and from association studies [33] indicate that NMS patients do not share a genetic defect with malignant hyperthermia patients. Six mutations in the skeletal muscle ryanodine receptor (RYR1) gene (associated with MH) were investigated in unrelated NMS patients by single strand conformation polymorphism, and none were detected [33]. Though MH and NMS are similar clinically, they are pharmacologically distinct, implying that cross-reactivity between triggering agents is unlikely to occur.

Dopamine-Blockade Hypothesis

Dopamine hypoactivity is perhaps the most widely favored as a plausible explanation for the occurrence of NMS [34]. There are several lines of evidence linking dopamine hypoactivity to key physical signs important for diagnosis of this complex syndrome.

Firstly, blockage of D2 receptors in the nigrostriatal and hypothalamic pathways is responsible for the clinical signs of muscular rigidity and impaired thermoregulation, respectively [35]. Jauss et al. reported a patient with NMS who underwent single-photon emission computed tomography scan (SPECT) that demonstrated no binding of iodobenzamide tracer to D2 receptors in the striatum during the acute phase of NMS [36], thereby providing experimental evidence highlighting the involvement of the nigrostriatal pathway. Secondly, clinical features of NMS have been seen not only with use of antipsychotics and antiemetics that have dopamine receptor antagonistic properties but also have been reported following withdrawal of dopaminergic medications [37, 38].

Studies measuring dopamine metabolites in cerebrospinal fluid (CSF) also add support to the dopamine hypoactivity hypothesis. Nisijima et al. studied monoamine metabolites of dopamine in the CSF [39] and demonstrated a decrease in homovanillic acid (HVA) levels and increased concentrations of norepinephrine in the CSF of NMS patients versus controls. The study by Nisijima supported not only the dopamine-blockade hypothesis but also hinted at a potential role of noradrenergic hyperactivity in the pathogenesis.

Genetic studies have identified a number of functional polymorphisms in the dopamine D2 receptor gene. A TaqI A genotype A1 allele identified by Suzuki et al. [40] is particularly important. A1 allele carriers have been shown to be prone to developing drug-induced NMS due to lower D2 receptor gene density in the basal ganglia and diminished dopaminergic activity [41]. Finally, favorable therapeutic response in NMS to dopaminergic agents, for example, bromocriptine and lisuride, lends further support to a primary role for dopaminergic mechanisms in the pathogenesis of NMS.

Dopamine–Serotonin Interactions

NMS has often been compared and contrasted with serotonin syndrome (SS) due to a considerable overlap in their clinical manifestations. In the past, these two clinical entities have been thought by some to represent "a spectrum of the same disorder," whereas others have called it "a common end point for two pathophysiological processes" [42, 43]. While NMS is caused by antipsychotic medications, resulting in dopamine hypofunction, SS is attributed to serotonin hyperfunction, due to ingestion of serotonin-enhancing agents [39, 44, 45]. Gomez-Esteban et al. reported a patient who developed NMS with haloperidol, followed by SS associated with fluoxetine use 6 years later [46]. They suggested a common fundamental pathogenic mechanism underlying the two disorders. DSM IV criteria, however, define NMS and SS differently. The American Psychiatry Association DSM IV criteria considered NMS an unpredictable idiosyncratic drug reaction, while SS a predictable consequence of excess serotonergic activity [47].

Serotonergic agents, such as lithium and clomipramine, have also been shown to result in the development of NMS in cases where multiple psychotropic medications are used simultaneously and by mechanisms other than dopamine blockade [48, 49]. There is also evidence to suggest that some of the atypical antipsychotics, that is, aripiprazole, ziprasidone, clozapine, and quetiapine, behave as partial agonists of the 5-HT1A receptor. This partial agonist action is suggestive of a serotonin-mediated pathway in the causation of NMS.

There is, however, a paucity of biochemical evidence to support this serotonin-mediated hypothesis, with only a handful of prospective studies available in literature.

Spivak et al. performed a small prospective study of eight patients with acute NMS and measured serum plasma levels of dopamine, serotonin, and norepinephrine. They demonstrated a statistically significant increase in serotonin/dopamine ratio ($p = 0.015$) in the acute phase of NMS, suggesting that this imbalance of neurotransmitters is crucial to the development of NMS [50]. In contrast, Nisijima et al. demonstrated no significant differences in CSF levels of serum 5-hydroxy indole acetic acid (5-HIAA) – a major metabolite of serotonin – between NMS patients and controls [51].

NMS and SS are thus perhaps best described as simultaneously discrete yet similar syndromes. There is a greater need for biochemical evidence to support the diagnosis of NMS, as the current observations differentiating it from SS are inconsistent [52].

Cholinergic Hyperactivity Hypothesis

Deuschl et al., in 1987, hypothesized that cholinergic hyperactivity is a mechanism for altered consciousness, as demonstrated by a patient with NMS experiencing prompt return to consciousness with utilization of biperiden, an anticholinergic agent [25]. There is however a paucity of subsequent literature that lends support to this mechanism. Tanii et al. reported a 43-year-old male who developed NMS 2 weeks after discontinuation of olanzapine and an anticholinergic agent and switching to perospirone [52]. Although the authors attributed the development of NMS to anticholinergic withdrawal, there is evidence to suggest that partial serotonergic agonists such as perospirone can also cause NMS [53].

In addition, cholinergic hyperactivity fails to account for the clinical symptoms and signs of NMS such as hyperthermia, tachycardia, and labile hypertension. The role of cholinergic excess in NMS is hence best described as controversial.

Opioid GABAergic and Glutamatergic Hypotheses: Slim Evidence for Implication in NMS

The role of the opioid system in NMS is speculative at best. Sandyk reviewed evidence of opioid system involvement in thermoregulation and how this might relate to other symptoms of NMS [21]. At present, opiate antagonists, naloxone, have no role in the management of hyperthermia or muscle rigidity in NMS.

Although not widely endorsed, it is possible that a relative GABAergic deficiency may have a primary pathogenic role in NMS or, alternatively, occur secondary to enhanced dopaminergic turnover reported during NMS [54]. Since diazepam is known to facilitate GABA transmission, it could potentially exert indirect dopaminergic effects mediated by GABAergic feedback loops within nigrostriatal and mesolimbic centers. Indeed, diazepam-responsive NMS has been suggested as a subtype of NMS, given the association of good response to diazepam [54, 55]. On the other hand, the temporal association between clonazepam withdrawal and the induction of NMS in one patient suggests that clonazepam withdrawal may have contributed to induction of NMS [56]. In another patient, the addition of zopiclone to the benzodiazepine nitrazepam produced an NMS-like picture [57].

Based on successful treatment of acute akinetic catatonic patients with intravenous infusion of amantadine, an N-methyl-D-aspartate (NMDA) receptor antagonist, Northoff and colleagues [58] have postulated glutamatergic dysfunction in catatonia as well. There is a paucity of studies showing glutamatergic abnormalities in NMS.

Sympathoadrenal Hyperactivity: A More Central Role?

In contrast to the neurotransmitters above, sympathetic hyperactivity has often been reported in NMS [59]. Increased levels of noradrenaline (NA) and adrenaline in urine and blood have been noted during the active phase of NMS [60, 61]. Schibuk and Schachter suggest that tricyclic antidepressants could predispose neuroleptic-treated patients to NMS by causing an excess of norepinephrine relative to dopamine [62]. Similarly, a tricyclic-induced hyperadrenergic state, compounded by neuroleptic-induced dopamine receptor blockade, has been proposed as a putative mechanism of NMS [60]. Urinary catecholamines and their metabolites are positively correlated with blood creatine kinase (CK) levels in acute phase of NMS, but other clinical features are not [61]. CSF levels of NA were significantly higher in NMS patients than those of controls and returned to normal after recovery [63]. Compared with control levels, CSF levels of 3-methoxy-4-hydroxy-phenylglycol (MHPG), a metabolite of NA, showed no significant change, either during the active phase or NMS or after recovery, although the values showed a tendency to be higher during the active phase than after recovery. These results support a secondary role for increased sympathetic activity during the acute phase of NMS [63].

Gurrera suggests that dysregulated sympathetic nervous system hyperactivity could be responsible for many features of NMS. A predisposition to more extreme sympathetic nervous system activation and/or dysfunction in response to emotional or psychological stress may even confer vulnerability for NMS [59]. Gurrera cogently articulates how a hyperadrenergic state, in combination with variables like dopamine receptor antagonism or psychological stress, would produce the clinical syndrome of NMS [59]. At the very least, the relative mutual independence of neural and adrenal segments of the sympathetic nervous system and the differential effects of norepinephrine and epinephrine at adrenoreceptors may contribute to the unpredictable course and fluctuating signs that characterize NMS. The therapeutic implications of this remain uncertain.

Hypoferremia and Acute Phase Reaction

Acute phase reaction in NMS is a complex physiological reaction involving activation of leukocytes and cytokine-mediated thermoregulatory, neuroendocrine, and metabolic changes. Hypoferremia, or low serum iron, was described by Rosebush et al. to be an epiphenomenon in the acute phase of NMS. Rosebush and Mazurek found that 95 % of patients who developed NMS had reduced iron levels. This seemed to accompany rather than precede the development of the syndrome, and the levels returned to normal upon resolution of NMS [64–66]. The exact mechanism for this serum iron reduction is not clear. Weiss et al. demonstrated that anti-inflammatory cytokines, such as IL-4 and IL-13, caused uptake of iron by activated macrophages [67, 68]. Others have suggested the role of hepcidin – an anti-inflammatory molecule induced by the liver during the acute phase that mediates iron homeostasis [69].

There is a body of evidence that implicates low serum iron levels in increasing risk for NMS. In a study from Australia, Lee et al. studied 55 patients with catatonia during a 3-year period. They measured serum iron in 39 patients and found it to be low in 44 %. Patients with low iron and normal serum iron were then retrospectively compared. Low serum iron levels were found to be associated with malignant catatonia, excited catatonia, and a poor response to benzodiazepines [55]. In their study, a total of five patients with malignant catatonia developed NMS and each of these had received neuroleptics. Patients with malignant catatonia, on neuroleptic medications with low serum iron levels, were at high risk of developing NMS. This study suggested that hypoferremia might predict development of NMS in patients on concurrent neuroleptics for catatonia.

Similarly, Peralta et al. reported 40 patients with catatonia compared with 40 non-catatonic patients. Catatonics had significantly lower mean serum iron than non-catatonics.

Serum iron <50 μg/dl was significantly more prevalent in the catatonic (35 %) than in the non-catatonic (7.5 %) group. Severity of catatonic symptoms was inversely correlated with level of serum iron ($r = -0.34$, $p = 0.002$) [70].

The observation that low serum iron occurs in NMS and non-NMS malignant catatonia, and the evolution of the latter into NMS following exposure to neuroleptics, provide support to the hypothesis that NMS could be a form of malignant catatonia and that the two conditions may share similar pathophysiology. Although low serum iron is found to be associated with catatonia and NMS, its role as a causative factor needs further investigation.

Postmortem Changes

There do not appear to be consistent pathologic changes of brain structures based on postmortem NMS reports. One autopsy study of NMS has implicated anterior and lateral hypothalamic nuclei in NMS, with preservation of remaining hypothalamic nuclei [71]. These findings, however, were not confirmed in other pathologic studies of NMS patients [72–75]. A finding in several postmortem studies was that of cerebellar degeneration, with particular involvement of the Purkinje cell layer. This finding was postulated by several investigators to reflect the effects of hyperthermia rather than any underlying pathophysiology of NMS [73, 75]. Slettedal et al. demonstrated similar findings in two patients with the serotonin syndrome [76]. Similar cerebellar changes have been demonstrated on autopsy in patients with severe hyperthermia from other causes [75].

Postmortem studies of three patients with NMS-like syndromes demonstrated decreased levels of norepinephrine, catechol-o-methyltransferase (COMT), and homovallinic acid (HVA) in all three patients [73]. The investigators used these findings to suggest that cholinergic depletion may have contributed to dopamine blockade in these patients. Gabellini et al. [72] reported a case of an AIDS patient with two clinical episodes of NMS induced by antipsychotics and antiemetics, respectively. In this patient, there was a marked loss of dopaminergic neurons in the substantia nigra. While this pathologic finding is typical of AIDS, the authors postulate that a relative dopaminergic loss made the patient more susceptible to dopamine blockade by pharmacologic agents. In a study of both brain and muscle tissues following a resolved case of NMS, investigators noted prominent myopathic changes in muscle tissue but normal brain tissue [74]. They used these findings to suggest that the primary effects of NMS may be exhibited in the muscle rather than the brain.

Animal Models

There have been a number of studies that investigated animal models of NMS. Swine susceptible to porcine stress syndrome, a genetic disorder of swine characterized by hyperthermia, muscle rigidity, and autonomic dysfunction, were identified as a possible animal model for NMS. The administration of both haloperidol and lithium produced the syndrome in two of three susceptible swine, but only one of three non-susceptible ones [77]. The syndrome was only induced by administering both agents simultaneously and was not prevented by pretreatment with bromocriptine. The swine animal model has also been used to support the role of serotonin in the development of NMS. When mutant and wild-type swine were exposed to the serotonin-2 agonist 1-(2,5 dimethoxy-4-iodophenyl)-2-aminopropane hydrochloride (DOI), both groups developed NMS symptoms. The susceptibility of wild-type swine to DOI demonstrates the potential role of serotonin in the development of NMS [78].

Tanii et al. [79] demonstrated a model of an NMS-like syndrome in genetically normal rabbits that was reversible with the administration of dantrolene. Symptoms of fever, muscle rigidity, and elevated CK were induced in the rabbits after administration of haloperidol, atropine, and exposure to elevated ambient temperatures. The investigators used this model to propose the interaction between dopamine blockade, cholinergic deficiency, and exposure to risk factors as necessary to produce NMS symptoms. Another study demonstrated the importance of dopamine activity in the perifornical–lateral hypothalamus (pfLH) in thermoregulation in rats [80]. Based on their observations, the investigators proposed that dopamine activity in the pfLH plays a central role in NMS pathophysiology.

Etiology and Pathogenesis: Conclusions

As yet, no clear theory of etiology or a unified model of pathogenesis of NMS exists. Part of the problem lies in how the syndrome is defined, whether it is a unitary syndrome or a heterogeneous conglomeration of various iatrogenic conditions [1]. If the boundaries of the syndrome are broad and over-inclusive, it will be difficult to arrive at a single theory or model of etiopathogenesis. It is apparent that a dysregulation or imbalance of various neurotransmitter systems may be involved. Such imbalances may be aggravated by noradrenergic or serotonergic actions of drugs which are co-administered with neuroleptics or, alternatively, by physiologic changes involving these neurotransmitters associated with psychosis [20].

The dopaminergic theory needs to be revised in view of the recent advances in cloning of various dopaminergic receptors. Instead of focusing on D2 receptor blockade alone, we need to consider involvement of both D2/3/4 and D1/5 subfamilies of dopamine receptors and their interactions with other neurotransmitter receptor systems. Alterations in second messenger system functioning and state-dependent changes in receptor sensitivity and function also need to be taken into account. The availability of in vivo receptor imaging using positron emission tomography (PET) or SPECT may help elucidate the changes in receptor occupancies in

various CNS regions which may be involved in the pathogenesis of NMS.

Clinical Presentation

There has been a significant increase in recognition and management of NMS in the last decade due to the proliferation of literature in this field [81, 82]. The severe and potentially life-threatening nature of this idiosyncratic reaction makes it critical for physicians and nursing staff to recognize it early and appropriately direct clinical interventions. Clinical presentations vary from mild to severe and often present along a continuum. Woodbury and Woodbury described five stages of NMS spectrum-related symptoms that include (1) stage I, drug-induced parkinsonism; (2) stage II, drug-induced catatonia; (3) stage III, mild, early NMS; (4) stage IV, moderate NMS; and (5) stage V, severe NMS [83]. Treatments are determined based upon severity as well as duration and characteristics of symptoms present.

Drug-Induced Parkinsonism

The symptoms of NMS classically evolve over 24–72 h. Caroff et al. reported onset of NMS within 24 h in 16 % patients and within a week in 66 % of patients after initiation of antipsychotic medications [84, 85].

Due to the basal ganglia dopaminergic involvement, the first features to develop are tremor and cogwheeling rigidity. A case study by Addonizio [86] demonstrated that the development of rigidity preceded hyperthermia in 91 % of the patients. The subsequent development of bradykinesia results in progression to a parkinsonian phenotype. Withdrawal of the offending agent at this time results in regression of symptoms.

Drug-Induced Catatonia

Dystonia or abnormal posturing, mutism, dysarthria, and involuntary movements can occur in the parkinsonian subtype of NMS. This stage may be confused with a host of neurologic, psychiatric, or metabolic disorders. Thus, the differential presents a challenge for the treating clinician [87]. Acute lethal catatonia is a life-threatening neuropsychiatric emergency that mimics NMS and must be ruled out. Initial features such as psychosis, automatisms, and negativism often precede the onset of motor symptoms in patients with lethal catatonia. Posturing with waxy flexibility is also unique to acute lethal catatonia and is not seen in patients with NMS [88, 89].

Mild, Early NMS

The prodrome of drug-induced parkinsonism and catatonia progresses to full-blown NMS if neuroleptics are continued. Hyperthermia and autonomic changes follow the changed mental status and rigidity. Typically body temperature exceeds 39 °C; however, occasional case reports have been reported without fever [90]. This stage very quickly progresses to moderate or severe NMS if left untreated. In an analysis of 340 cases, mental status changes were followed by rigidity, hyperthermia, and autonomic dysfunction, respectively, in 70 % of patients [90].

Moderate to Severe NMS

Moderate and severe NMS are characterized by a variety of symptoms and sometimes can be differentiated only by fluctuations in severity. Severe rigidity, coma, hyperthermia, tachycardia, and blood pressure fluctuations are a hallmark of this disease process. Blood pressure typically shows increases in both systolic and diastolic pressures. Harsch [91] reported a mean systolic increase of 42 mmHg and a mean diastolic increase of 36 mmHg with a mean pulse of 136 (range 112–180) beat/min. Other autonomic abnormalities include diaphoresis, sialorrhea, and urinary incontinence.

Individuals with NMS have characteristic abnormalities on laboratory testing, most prominently elevated creatine kinase levels (CK). Mean CK elevation is usually in the range of 3700–5,000 units/l; however, levels are not consistently related to the degree or duration of rigidity [92].

In addition to abnormal CK, white blood cell count is also often elevated and peaks at 24–48 h, with a range of 10,000–40,000 cells/ml. Hyperthermia results in the development of severe dehydration that leads to abnormalities in serum electrolytes. Rigidity can cause accelerated rhabdomyolysis and renal failure. Myoglobinuria, proteinuria, hyaline casts, and white and red blood cells in the urine are often seen. Urine volume may drop to less than 500 ml/day, with a urine/plasma creatinine ratio of more than 40 or urine osmolality of higher than 500 mosmol/kg [24]. Other nonspecific abnormal laboratory values may include an increase in serum transaminases, lactic dehydrogenase, alkaline phosphatase, and aldolase.

Complications and Residual Symptoms

NMS is associated with a variety of medical complications. Muscle rigidity and rapid breakdown with rhabdomyolysis is one of the most frequently encountered complications and is an important predictor of mortality. Adequate hydration, urine alkalization, and monitoring serial renal function panels can prevent the development of renal failure.

Deep venous thrombi and pulmonary embolism often result from protracted immobility and severe rigidity that impair venous return. Respiratory failure may also occur due to decreased chest wall mobility and autonomic dysfunction. In addition, altered mental status may increase the risk for aspiration pneumonia in about 20 % of patients [93]. Autonomic dysfunction can also predispose to cardiac arrhythmias and myocardial ischemia that might be lethal [94].

Early recognition and treatment of NMS is critical in preventing long-term and residual symptoms. Patients with underlying structural brain disease are particularly susceptible to residual catatonic and parkinsonian symptoms [95].

Follow-up studies (of sufficient sample and duration of observation), to accurately determine the occurrence and pattern of residual symptoms after NMS, are lacking. Hyperthermia, which is a cardinal feature of NMS, may lead to cerebellar neuronal degeneration and permanent cerebellar ataxia [3]. Individuals who are on concomitant lithium therapy when NMS occurs may be particularly prone to risk of pancerebellar damage [96]. This may occur even at lithium levels that are within "therapeutic range." A variety of chronic neurological abnormalities persist after resolution of NMS, including mutism and cognitive impairments [97]. Generally, cases of residual cognitive impairment are also associated with elevated temperature as a component of NMS.

Diagnosis and Evaluation

NMS was first described by Delay and Deniker [98] as a syndrome of pallor and hyperthermia. They described three main groups of symptoms: (1) hyperpyrexia with temperature of between 38 and 40 °C within 24–48 h; (2) akinesia, stupor, hypertonicity, or dyskinesias; and (3) pulmonary symptoms, for example, congestion or infarcts accompanied by dyspnea and signs of asphyxia. NMS continues to be a descriptive syndrome, and the absence of concrete criteria has led to its misdiagnosis and confounding by other syndromes which are of a superficially similar clinical profile.

There currently exists no "gold standard" technique to diagnose NMS. Several diagnostic criteria have been established over the years by formal consensus and expert review which include classifications by Kurlan et al. [99], Levenson [100], Sachdev et al. [24], and Adityanjee et al. [1], and the DSM IV consensus [47]. The most prominent and widely accepted of these until recently were the DSM IV criteria that required the presence of severe muscle rigidity and hyperthermia, and two or more associated symptoms which include impaired consciousness, mutism, tremor, dysphagia, incontinence, diaphoresis, elevated blood pressure, increased white count, and raised CK levels [47].

Most recently a study by Gurrera et al. [81] established an international NMS consensus regarding diagnostic criteria using the Delphi technique. Their 2011 study assigned scores to each diagnostic feature in order of its importance relative to others. In contrast to prior scores, these criteria provided critical cutoffs for temperature, CK elevation, blood pressure elevation and fluctuation, hypermetabolism, and changes in respiratory rate.

Although these criteria require validation prior to application in clinical settings, they do reflect a step forward in the field, as they highlight the relative importance of individual elements, include critical values that provide more objective guidelines for evaluation of these patients, and represent a consensus of worldwide experts in the field.

A high index of suspicion should always be maintained for NMS, particularly in patients on neuroleptics and those in whom dopaminergic medications were recently tapered. Evaluation must be prompt and aimed at excluding other neurologic, toxic, infectious, or metabolic conditions that can masquerade as NMS (see section on Differential Diagnosis). A medical evaluation also helps to identify concurrent medical illnesses and complications of NMS. A thorough physical examination, including a detailed neurological evaluation, should guide the clinical evaluation. For the sake of uniformity, extrapyramidal symptoms should be serially assessed on standardized extrapyramidal symptom rating scales such as the Simpson–Angus neurological rating scale [101], catatonic symptoms on the Francis–Bush catatonia scale [82, 102], and altered consciousness should be assessed on the Glasgow coma scale [103]. Careful vital signs monitoring and telemetry is essential to detect any autonomic instability.

Laboratory evaluation must include complete blood counts, serum electrolytes, CK levels, urine microscopy, protein, and myoglobin testing. A lumbar puncture and brain imaging, such as non-contrast CT and MRI, are often necessary to exclude infection and structural brain disease. Electroencephalography (EEG) is often performed in keeping with the presence of altered mental status and demonstrates mild to moderate diffuse encephalopathy. Whenever indicated, other optional tests such as toxicology screen, lithium levels, arterial blood gases, and coagulation studies should be ordered. SPECT or PET scan for receptor occupancy is not indicated but may be performed in the research setting.

Differential Diagnosis

While NMS has a classic tetrad of symptoms of altered mental status, rigidity, hyperthermia, and autonomic instability, a wide array of disorders can present with similar symptoms. As NMS is considered a diagnosis of exclusion [37], it is essential to consider a broad array of diagnostic possibilities prior to arriving at a diagnosis of NMS. As noted in Table 74.3, various categories of disease can lead to an NMS-like picture. Other medication-induced disorders may mimic

NMS. These include malignant hyperthermia, neuroleptic heat stroke, serotonin syndrome, parkinsonism-hyperpyrexia syndrome, and either abuse or withdrawal of several drugs.

Table 74.3 Differential diagnoses of neuroleptic malignant syndrome

Infection
Central nervous system
Encephalitis, meningitis, rabies, tetanus
Systemic
Sepsis secondary to localized infection
Drug-Induced States
Adverse effects of psychotropic drugs
Neuroleptic heat stroke, serotonin syndrome, central anticholinergic syndrome
Other medication effects
Malignant hyperthermia
Medication withdrawal
Parkinsonism-hyperpyrexia syndrome, baclofen withdrawal
Drugs of abuse and toxins
Ecstasy, strychnine toxicity (heroin, pesticides)
Autoimmune
Encephalitis lethargica
Stiff man syndrome
Metabolic conditions
Mitochondrial disease
Inherited disorders of catecholamine production
Psychiatric conditions
Acute psychosis, with agitation
Catatonia

Table 74.4 illustrates clinical and laboratory differences that might be anticipated with NMS versus serotonin syndrome.

A variety of infectious causes may present with an NMS-like syndrome, including systemic sepsis and central nervous system infection such as meningoencephalitis, rabies, and tetanus. Autoimmune encephalitis and nonconvulsive status epilepticus are other neurological diagnoses to consider in such patients. Finally, metabolic conditions such as Leigh's disease, mitochondrial disorders, and inherited disorders of catecholamine production may lead to acute dystonias that resemble NMS [104]. Given the broad range of potential diagnoses, critical features of the history, physical exam, laboratory, and imaging studies must be sought to corroborate the diagnosis. Nonetheless, considerable uncertainty may remain regarding the final diagnosis in a patient with NMS features and exposure to neuroleptic medications. Consideration is given here to conditions that are life threatening, common, and bear the most resemblance to NMS.

Infections

When assessing a patient with the classic features of fever, rigidity, altered mental status, and autonomic instability, one of the most important diagnoses to rule out is that of acute infection [37, 104]. Both central nervous system infection and other localized sources of infection with associated sepsis can present with fever and altered mental status. Patients presenting with these symptoms in the setting of neuroleptic medication use may present a diagnostic dilemma to the clinician [64]. A careful survey of the patient for common sources of infection, such as pneumonia, urinary tract

Table 74.4 Clinical and laboratory test features that help to distinguish NMS from serotonin syndrome

Features	Neuroleptic malignant syndrome	Serotonin syndrome
Inciting agents	Typical and atypical antipsychotics	SSRI's, MAO inhibitors, tricyclic antidepressants, meperidine
Time to development	1–3 days	<12 h
Clinical features		
(a) Neuromuscular symptoms	Tremor and rigidity	Tremor, rigidity, shivering, ataxia, myoclonus, hyperreflexia, ankle clonus
(b) Gastrointestinal symptoms	Typically not seen	Nausea, vomiting, diarrhea
(c) Mental status changes and autonomic dysfunction	Hyperthermia, labile blood pressure	Mild hyperthermia (not as severe as in NMS)
Laboratory studies – general	Leukocytosis, metabolic acidosis, elevated CK, myoglobinuria, electrolyte imbalances, rhabdomyolysis	Similar laboratory abnormalities but not as severe as in NMS
Laboratory studies – urine metabolite levels	Elevated urine dopamine, epinephrine, norepinephrine, metanephrine, and nonmetanephrine	No elevation in urine levels of 5-hydroxy indole acetic acid (5-HIAA)
Prognosis and recovery	Higher mortality, recovery can take up to 3–4 weeks after withdrawal of offending agent	Benign and patients recover 1–7 days after withdrawal of offending agent

infection, catheter-associated infections, and abdominal cavity infections, must be undertaken.

The initial evaluation should include a careful history and physical examination searching for signs and symptoms of infection. Physical examination should focus on identifying signs of localized infection, such as skin and soft tissue swelling, changes in breath sounds, abdominal tenderness, suprapubic tenderness, or abnormal appearance of indwelling lines and catheters. Detailed neurological examination is essential to evaluate for focal neurologic deficits indicative of a central nervous system (CNS) infection. Additionally, signs of meningeal irritation, such as nuchal rigidity or photophobia, should be elicited. Laboratory evaluations should include complete blood count, blood cultures, and serum lactate, in addition to serum CK. Additional investigations such as specific cultures, chest and abdominal radiographs, lumbar puncture, and neurological imaging should be obtained based on clinical suspicion. If CNS infection is suspected based on history and physical exam, a lumbar puncture is essential to evaluate for inflammatory cells in the cerebrospinal fluid and identify the nature of infection. In NMS, CSF studies may show elevated protein with normal cell counts and glucose [64], and neurological imaging is usually normal [64, 100]. While hypoxia and resulting metabolic acidosis may be present in severe cases of NMS, the only consistently elevated laboratory values are serum CK and white blood cell count which are present in most, but not all, cases [64, 100]. Such elevations may also occur in the setting of sepsis, which may lead to confusion in establishing the diagnosis.

In addition to sepsis and meningoencephalitis, other less common forms of CNS infection may present with an NMS-like picture. Tetanus, the clinical syndrome caused by infection with the bacterium *C. tetani,* causes patients to have tetanic spasms of both axial and appendicular muscles. In late stages of the disease, the tetanic activity is sustained and therefore may resemble NMS [104]. As treatment of tetanus is different from that of NMS, prompt recognition is important in order to improve patient outcome. Similarly, rabies infection may mimic NMS in its early stages with the common symptoms of fever, rigidity, autonomic instability, and altered mental status [104]. Distinguishing features of rabies include a history of animal bite, insidious onset, and the presence of hallucinations. Finally, encephalitis lethargica, a noninfectious, autoimmune form of encephalitis, presents with dyskinesias and neuropsychiatric features that may mimic NMS [104, 105]. This syndrome is responsive to high-dose intravenous steroids and therefore must be distinguished from NMS [106].

Drug–Drug Interactions

While NMS should be considered in patients on antipsychotics medications who present with fever and muscle rigidity, there are other drug-induced neurotoxicities and drug–drug interactions which should also be taken into account as part of the differential diagnosis. This becomes especially important for patients with serious mental illness, treated with multiple psychotropic medications, who are particularly vulnerable to neurological adverse effects. Also, patients with schizophrenia or other serious mental illnesses may be on other systemic medications for comorbid physical ailments, and the high rates of polypharmacy across different drug classes predisposes to drug–drug interactions and toxicities.

Given the broad features of current NMS diagnostic criteria, it is conceivable that some published case reports may have been misattributed to NMS. Hasan and Buckley analyzed published reports of NMS due to the atypical antipsychotic medications (risperidone and clozapine) and found that, not only was NMS misdiagnosed in 50 % of the cases, the rates varied when different diagnostic criteria were applied [18]. Differential diagnoses included known adverse effects of the atypical antipsychotics, drug–drug interactions, drug withdrawal syndromes, seizures, and systemic infections. Strict diagnostic criteria like the ones proposed by Gurrera and colleagues might help to decrease the inconsistencies and misdiagnoses of NMS [81].

Adverse Effect of Atypical Antipsychotics

As a class, the atypical antipsychotics have been characterized by lower rates of extrapyramidal symptoms and muscle rigidity that are commonly associated with the older, typical antipsychotics [107]. This has contributed to some case reports of clozapine-induced NMS to be diagnosed without the cardinal NMS feature of muscle rigidity, though clozapine is virtually without extrapyramidal side effects. It is still unknown if the clinical presentation of NMS differs with atypical antipsychotic medications; however, it is our position that the stringent diagnostic criteria for NMS be maintained to decrease incidences of misdiagnosis or overdiagnosis of the syndrome. For patients on atypical antipsychotics where characteristics of NMS are present, the diagnosis of NMS should only be considered if the complete criteria are met.

Another reason for retaining the established NMS diagnostic criteria is that the side effects profile of the atypical antipsychotics can overlap with many features of NMS. For example, approximately 3 % of patients on clozapine develop a benign hyperthermia during the first 10 days of treatment. Approximately 20 % of patients starting therapy with an atypical antipsychotic will show some signs of autonomic instability, that is, tachycardia, postural hypotension, and instability of vital signs. Thus, clinicians should be conservative in diagnosing NMS when atypical antipsychotics are prescribed.

Contributing to the divergence on NMS criteria may be the overemphasis on CK elevation as a diagnostic criterion. CK elevation is seen in many psychiatric conditions and contexts, including acute psychosis, agitation, following seclu-

sion or restraint, and with the use of intramuscular psychotropic (antipsychotic and other) medications. There have also been reports of isolated CK elevation during treatment with atypical antipsychotics medications, including clozapine, olanzapine, risperidone, and quetiapine, without the development of NMS. In some cases, the CK elevation has been of the magnitude of 13,000 U/L without pathological sequelae of NMS or ill outcome; thus, the increase in CK seen after the initiation of atypical antipsychotic treatment may be benign. Currently, the mechanism and significance of this effect and its frequency with each new drug is undetermined.

Catatonia and Malignant Hyperthermia

There are overlaps in clinical presentations between NMS and catatonia, as well as NMS and malignant hyperthermia (MH). Catatonia is a rare form of psychosis, which presents as a subtype of schizophrenia. When catatonia is diagnosed, it is usually associated with underlying CNS lesion. Characteristics unique to catatonia include a past history of similar presentations, a gradual onset of illness, a predominance of motor signs, the presence of features typical of catatonia (flexibilities cera, ambitendency), and the presence of other clinical signs which are associated with an underlying organic pathology. Unlike NMS, fever is a late effect of catatonia.

MH is a disorder of skeletal muscle calcium regulation. It occurs usually in genetically susceptible patients receiving halogenated inhalation anesthetics or depolarizing muscle relaxants (see Chap. 54). NMS and MH share many clinical features and were once thought to have a common pathophysiological basis; however, research has shown this to be unlikely (see Etiology and Pathogenesis section). In MH, the calcium channel dysfunction in the sarcoplasmic reticulum has been attributed to abnormalities in the ryanodine receptor complex, a receptor system that has been linked to ryanodine receptor gene on chromosome 19. There has not been any significance of this receptor gene for NMS in previous animal studies. There is also no associated increase in anesthetic complications either in patients with NMS or any of their first degree relatives. Furthermore, electroconvulsive therapy (ECT) has been given as a form of treatment to patients with NMS without either the development of MH or exacerbation of NMS.

Treatment and Management

Treatment of NMS or suspected NMS is based upon symptom severity, character, and duration. Both Woodbury and Woodbury [83] and Velamoor and colleagues [108] suggested guidelines for management of NMS, based on a hierarchy of symptom severity. This approach has merit, considering the oftentimes nonspecific presentation of NMS particularly in its early stages. This remains a major challenge for the field [109]. Accurate diagnosis is another challenge [81]. Given the serious and potentially rapidly progressing course of NMS, all individuals with suspected NMS should be monitored in closely supervised settings, usually in a hospital. Individuals who meet criteria for full-blown NMS should be treated in a medical intensive care unit for initial care [3].

Prodromal Phase

Individuals who are being treated for acute psychosis and who exhibit agitation, catatonia, or disorganization should be closely observed, as is good practice for all acutely ill patients. Regular monitoring of vital signs, including temperature (which is not consistently done in some psychiatric settings) should occur. This becomes particularly important in situations where restraints are utilized or when the patient receives injectable antipsychotic medication. Disorganized or catatonic patients may have reduced fluid intake, and this should be closely monitored, encouraging oral fluids and initiating intravenous fluids if the patient becomes dehydrated and is unable to drink. Blood pressure measurements should evaluate for orthostasis. Dosing of antipsychotic medications should be moderate, with adjunctive benzodiazepines utilized for sedation or the management of acute agitation, if possible.

Early/Mild NMS

The most critical intervention in the treatment of early NMS is discontinuation of antipsychotic agents [108, 110]. Benzodiazepines, for example, lorazepam 1–2 mg, may be substituted to manage agitation, and good fluid intake should be assured. The notion that benzodiazepines may prevent NMS from occurring, or may treat mild NMS, has been suggested by some investigators [94], although controlled studies of risk factors have not consistently supported this hypothesis [64]. Discontinuation of lithium is also generally recommended. Lithium has been implicated in the re-induction of NMS among patients with a prior history of NMS [3], although a case-controlled study by Keck and colleagues did not show that the use of lithium was associated with development of NMS [23]. Dopamine agonist medications, such as amantadine, should be continued if already in use, as withdrawal of these agents may worsen NMS [3]. In addition to physical examination and routine laboratory studies, sequential serum CK and CBC with differential should be performed, as well as urinalysis.

Management of full-blown NMS consists of supportive measures and active, specific treatments.

Supportive Measures

Patients should be treated in an intensive care unit with continued vital sign and cardiac monitoring. General measures, such as the use of cooling blankets and antipyretics, may reduce hyperthermia [111]. This is an important objective in the acute care of patients with NMS. Intravenous fluids should be instituted if dehydration has occurred or is imminent [112]. In cases of severe hypertension, short-acting antihypertensive agents such as nifedepine may be utilized [3]. Intensive, skilled nursing care for patients confined to bed, with attendant physical therapy, will prevent the development of decubitus ulcers, which may delay recovery from NMS. Where gag reflex is absent or swallowing is impaired, patients should receive parenteral nutrition to prevent aspiration pneumonia until swallowing improves [3, 92]. Respiratory failure may occur due to decreased chest wall compliance. These patients may require oxygen or intubation and mechanical ventilation in severe cases [92]. Subcutaneous heparin should be initiated to prevent pulmonary embolism and deep venous thrombosis triggered by prolonged immobility. Caroff reviewed 60 cases of NMS and found that supportive therapy was the predominant treatment modality with a mortality rate of 20 % [113]. Later reviews have suggested that improved outcome may be obtained with the addition of specific treatments for NMS [92, 114, 115].

Specific Treatments

In patients who do not appear to be responding adequately to supportive treatment, specific medications should be considered. Clinical conditions that would suggest that specific treatment should be implemented include refractory hyperthermia, persistent rigidity, and rising CK levels. The decision to start specific therapies is usually made after 1–3 days of observation and support [3]. There are a number of treatment options available [115]. Because of the rarity of NMS, the literature on effectiveness of various somatic treatments is not based on prospective, controlled trials but is generally from case series.

Dopamine agonists such as *bromocriptine* and *amantadine* have been utilized effectively to treat NMS [92, 115]. It has been suggested that neuroleptic-induced dopamine antagonism is the primary cause of NMS, and thus dopamine agonists may reverse this effect in the brain [20]. Bromocriptine is one of the most often utilized dopamine agonists for NMS and may be the dopamine agonist of choice [4]. Dosing should be initiated at 2.5 mg bid or tid and increased by up to 7.5 mg/day with no serious side effects [3, 92]. Rosenberg and Green reported that bromocriptine decreased response to treatment time from 6.8 days with supportive treatment alone to 1.03 days with bromocriptine ($p<0.0005$) [92]. Time to complete resolution of NMS was 10 days with bromocriptine, compared to 15.8 days with supportive therapy alone, although this did not reach statistical significance ($p=0.09$). Sakkas reviewed over 700 published cases of NMS and found that mortality was 21 % for supportive treatment alone and decreased to 10 % with bromocriptine [116]. Amantadine is another dopamine agonist that is fairly commonly utilized for treatment of NMS. Sakkas reported that the use of amantadine reduced mortality in NMS from 21 % with supportive treatment alone to 3 % with amantadine.

Based on clinical similarity of NMS to malignant hyperthermia, *dantrolene* has been utilized for the treatment of NMS. Dantrolene can be given intravenously or orally. Tsutsumi and colleagues used a mean dose of dantrolene of 0.97 mg/kg/day for a mean duration of 8.3 days [117]. Rosenberg and Green reported that use of dantrolene reduced treatment response time to 1.72 days with dantrolene, compared to 6.8 days with supportive treatment [92]. Sakkas reported that mortality from NMS treated with dantrolene was reduced to 10 % compared to 21 % with supportive care alone [116]. Greenberg and Gorelick [118] recommend the concomitant use of dantrolene with bromocriptine for some patients. Their protocol includes giving dantrolene 0.25 mg/kg intravenously tid, until rigidity and hyperthermia resolve, and bromocriptine tid for 10 days, which is gradually withdrawn over the next week.

Benzodiazepines may also be used with other agents to treat NMS and are beneficial for the treatment of agitation during NMS [115]. Other more speculative drug treatments that have been utilized for NMS include pancuronium [119], levodopa [100], apomorphine and lisuride [3], and vitamin E [120]. Iron supplementation is proposed as having a protective effect; however, this has not been well supported [3].
Finally, electroconvulsive therapy (ECT) is reported to be an effective treatment for NMS where pharmacotherapy fails [121–123]. Fink proposed that ECT should be utilized as second-line therapy for NMS, after failure of benzodiazepines [121]. Davis and colleagues reported that mortality rates for NMS with ECT were half that of supportive treatment alone [122]. When ECT is utilized, multiple seizures may be required for best response [123]. On the other hand, the use of succinylcholine during the ECT procedure is implicated in causing hyperkalemia and cardiac arrhythmias in patients with rhabdomyolysis or autonomic abnormality [124]. Thus, other muscle relaxants during ECT should be used if rhabdomyolysis is severe.

Post NMS

After the resolution of an episode of NMS, patients often continue to have severe psychiatric illness and are in need of continued pharmacologic care. These patients present a

challenge to the treating clinician, in that recurrence of NMS is a continued risk. Wells and colleagues reported that the risk of reoccurrence of NMS diminishes if at least 5 days had elapsed from recovery from NMS to neuroleptic rechallenge [125]. Rosebush and colleagues recommend a waiting period of 2 weeks between NMS recovery and neuroleptic rechallenge [126]. Harsch [91] recommended that guidelines for restarting neuroleptic drugs include (1) normal CK, (2) state of good hydration, and (3) inpatient monitoring. Use of adjunctive agents such as benzodiazepines, valproate, carbamazepine, and verapamil may help manage behavioral manifestations and allow for lower dosages of antipsychotic medication [23]. For patients who show resolution of the hypermetabolic state, but remain catatonic, ECT may be a useful option. The use of an atypical antipsychotic is preferred for individuals with a history of NMS who require antipsychotic therapy. While atypical antipsychotics have the potential to induce NMS, clozapine may be a strong choice when rechallenging patients with an NMS history. This remains one area of great therapeutic uncertainty, and clinicians should proceed cautiously. A second opinion can be helpful in such circumstances.

Prognosis

In accordance with its title [6], NMS was once considered to carry an ominous prognosis. In adults, early reports cited a mortality rate of 15–25 % [110, 127]. Subsequent reports provide a more favorable outcome with a mortality rate of below 5 % [3]. The decline in mortality reflects more judicious prescribing practices, heightened awareness, prompt diagnosis of NMS, and the success in managing this condition aggressively with supportive measures and with pharmacotherapy [115]. Outcome is better with atypical compared to typical antipsychotics [128].

In general, the prospect of a favorable outcome is greatly enhanced by early diagnosis and prompt management. There are isolated reports of persistent cognitive impairment following an episode of NMS [129, 130]. This adverse effect appears uncommon but has not been systematically studied. It appears that most patients recover from NMS without complications.

Paraneoplastic Neuromuscular Disorders

75

Betul Gundogdu, Myrna R. Rosenfeld, and Stacy A. Rudnicki

Introduction

Neuromuscular dysfunction in a cancer patient usually represents the side effect of neurotoxic therapy, infiltration of nerves or spinal roots by the tumor, or metabolic or nutritional deficits. Paraneoplastic disorders (PND) may also lead to neuromuscular dysfunction. These cancer-associated syndromes are largely mediated by immune mechanisms. Many PND of the central nervous system are associated with the presence of specific anti-neuronal antibodies in cerebrospinal fluid and serum that serve as markers of the paraneoplastic origin of the disorder (Table 75.1) [1]. For neuromuscular syndromes, the only two antibodies that define a disorder as paraneoplastic are anti-Hu and anti-CRMP5. Patients with Lambert–Eaton myasthenic syndrome (LEMS), myasthenia gravis, neuromyotonia, and stiff-person syndrome may have antibodies against voltage-gated calcium channels (VGCC), the acetylcholine receptor (AChR), Caspr2, or amphiphysin, respectively; however, these antibodies are also found in the non-paraneoplastic forms of these disorders. Identification of these antibodies confirms the neurologic diagnosis but not that of a cancer association. Therefore, the diagnosis of a paraneoplastic neuromuscular disorder is strongly based on clinical history and findings. In patients with a known cancer, the major differential diagnoses must always include the more common mechanisms noted above. For example, mononeuropathies and plexopathies in cancer patients are most often secondary to compression of nerves by tumor or hemorrhage, and infarction secondary to infiltration by leukemia. Tumors that express neuroendocrine proteins such as small-cell lung cancer (SCLC) or that effect immunoregulatory organs (e.g., thymus) or immunoglobulin-producing cells (plasma or B cells) are more commonly associated with PND, and thus, the development of neurologic dysfunction in a patient with one of these disorders should alert one to the possibility of a PND. In patients without a known tumor, one should suspect that a neuromuscular disorder might be paraneoplastic when there is the acute to subacute development of symptoms, when the patient presents with a syndrome known to be frequently associated with cancer or if a specific anti-neuronal antibody is found in serum or cerebrospinal fluid.

In general, the approach to treatment for paraneoplastic neuromuscular dysfunction is the same as for the non-cancer-associated disorder. In all cases, identification and treatment of the associated tumor should be the first concern [2]. For disorders such as LEMS in which the antibodies are pathogenic, therapy to remove the antibodies is often successful. In disorders with stiffness or cramping, pharmacological interventions can be useful. Immunosuppressive interventions are largely empiric with their use based on the presumed immune-mediated pathogenesis and clinical trials with non-paraneoplastic disorders.

Paraneoplastic Sensory Neuronopathy

In contrast to sensory neuropathies, sensory neuronopathies are rare with the two most common causes being paraneoplastic and Sjögren's syndrome. Rather than the distally predominant pattern of symptoms seen in a length-dependent neuropathy, paraneoplastic sensory neuronopathy (PSN) patients have patchy and asymmetric presentation which may mimic a radiculopathy or multiple mononeuropathies. Onset of symptoms is subacute, and frequently, the upper extremity is the site of initial involvement; over weeks or months, symptoms spread and may involve all limbs as well

Table 75.1 Paraneoplastic neuromuscular disorders: immune and cancer associations

Disorder	Antibody association	Cancer when associated	Comments
Sensory neuronopathy	Anti-Hu	SCLC, others	Often in association with PEM
Motor neuron disease	None	Breast (upper motor neuron syndrome) Hodgkin's, non-Hodgkin's, SCLC (lower motor syndrome)	About 20 % of patients with PEM have predominant motor neuron dysfunction
Stiff-person syndrome	Anti-amphiphysin, anti-GAD	SCLC, thymoma, breast	Anti-GAD antibodies are mostly associated with non-paraneoplastic cases
Acute necrotizing myelopathy	Anti-amphiphysin, CRMP5, Hu	Lung, breast	
Polyradiculoneuropathy	None	Hodgkin's, non-Hodgkin's	
Chronic sensorimotor neuropathy	CRMP5, Hu None	Lung, others Plasma cell dyscrasia	
Sensorimotor neuropathy associated with malignant monoclonal gammopathies	Autoantibodies targeting peripheral nerve antigens	MGUS, Waldenström's macroglobulinemia, amyloidosis, multiple myeloma, osteosclerotic myeloma, POEMS, Castleman's, any disorder with a paraproteinemia	Includes anti-MAG in 50 % of patients with IgM MGUS
Vasculitic neuropathy	None	Lymphoma, leukemia, SCLC	May be part of PEM
Peripheral nerve hyperexcitability	Anti-Caspr2, likely others	SCLC, thymoma	Morvan's syndrome when there is additional CNS involvement
Myasthenia gravis	AChR, titin, RyR, MuSK	Thymoma	MuSK antibodies rarely associate with thymoma
Lambert–Eaton myasthenic syndrome	VGCC, Sox1	SCLC	Sox1 antibodies strongly support the presence of SCLC
Dermatomyositis	Anti-synthetase, signal recognition particle, anti-translation factor, anti-Jo-1	Ovarian, breast, pancreatic, lymphoma, others	
Necrotizing myopathy	None	Solid tumors	

SCLC small-cell lung cancer, *PEM* paraneoplastic encephalomyelitis, *GAD* glutamic acid decarboxylase, *CRMP5* collapsin response mediator protein, *MGUS* monoclonal gammopathy with undetermined significance, *Caspr2* contactin-associated protein-like 2, *AChR* acetylcholine receptor, *RyR* ryanodine receptor, *MuSK* muscle-specific kinase, *VGCC* voltage-gated calcium channel

as the trunk and face [3]. Pain and/or paresthesias are reported, but the most disabling feature is often proprioceptive loss, resulting in a sensory ataxia [4]. When the loss is severe, patients may have choreiform movements of the hands and feet and may become wheelchair bound from profound proprioceptive loss in the legs. On examination, patients also have impaired vibration sensation; there may be loss of pain or temperature, though typically not as severe as proprioceptive and vibratory loss. Reflexes are depressed or absent [5]. Poor proprioception may make it difficult to fully evaluate strength. However, some patients may also have involvement of not only the dorsal root ganglia but also the ventral horns or the sensory and motor peripheral nerves [6, 7]. Cranial neuropathies which may result in signs and symptoms such as facial paresthesias, impaired taste or hearing, and tonic pupils are felt to be associated with concurrent PEM involving the brainstem [8, 9].

Symptoms of PSN may occur in isolation or as part of paraneoplastic encephalomyelitis (PEM). Additional clinical features may include cognitive impairment, psychiatric symptoms, seizures, cerebellar ataxia, opsoclonus, myoclonus, and dysautonomia of the gut [3, 6, 10].

Anti-Hu antibodies in the serum of a patient with subacute sensory neuronopathy are highly suggestive of a paraneoplastic disorder. In a study of such patients with prolonged follow-up, only 3 % did not have an underlying malignancy identified. There were no clinical features predictive of patients more or less likely to have a cancer [11]. In contrast to the PSN picture associated with Hu antibodies, anti-CRMP5 antibodies and anti-amphiphysin are more likely to be associated with a sensory motor neuropathy [12, 13].

The CSF may show increased proteins and a mononuclear pleocytosis at the onset of PSN or only increased proteins at later stages. Oligoclonal bands and intrathecal synthesis of IgG or anti-Hu antibodies are common findings. Other laboratory studies are usually normal or nondiagnostic.

In a true isolated sensory neuronopathy, one expects to see small or absent sensory nerve action potentials with normal motor nerve conduction studies (NCS) and electromyography in a non-length-dependent pattern. Though clinically apparent motor involvement in patients with PSN is infrequent, electrophysiologic studies in patients with Hu antibodies have found changes not only on sensory NCS but also on abnormal motor NCS, albeit less frequently. Rarely, pure

motor or motor-predominant abnormalities are found. Reduced amplitudes supporting axonal and/or neuronal loss are typical, but mild slowing of conduction velocities in addition to amplitude loss in some suggests there may also occasionally be a mixed axonal/demyelinating process at play [14, 15].

The most commonly associated tumor is SCLC [3]. Other associated tumors include cancer of the breast, cancer of the ovary, non-SCLC, and Hodgkin's and non-Hodgkin's lymphoma, but almost any type of malignancy has been reported. Symptoms usually precede the diagnosis of the tumor by several months to 2 years, although longer periods may occur.

Since dorsal root ganglia cannot regenerate, treatment tends to be ineffective once these cells have been lost. Therefore, early recognition of the syndrome, leading to identification and treatment of the underlying cancer, is the best therapy. Studies of patients with SCLC and anti-Hu-associated PSN and PEM demonstrated that patients whose tumors completely responded to therapy were more likely to have neurologic stabilization or improvement compared to patients whose tumors were untreated or that did not respond to therapy [6, 16].

Other non-cancer-related causes of a sensory neuronopathy include exposure to toxins (chlorobiphenyl), pyridoxine overdose, antibiotics, and immune-mediated disorders, including primary biliary cirrhosis, chronic active hepatitis, anti-ganglioside antibodies, and Sjögren's syndrome [17]. Chemotherapeutic agents, such as paclitaxel, docetaxel, cisplatin, and oxaliplatin, can result in a predominant or pure sensory neuropathy [18, 19]. Thalidomide used to treat multiple myeloma also results in a length-dependent sensory more so than motor axonal neuropathy [20]. An idiopathic form of sensory neuronopathy has been described, which may respond to treatment with immunoglobulins. Chronic sensory ataxic neuropathy associated with IgM anti-disialosyl ganglioside antibodies against GD1b, GQ1b, GT1c, and GD3 should also be considered in the differential diagnosis. Because of its association with eye movement abnormalities, the acronym CANOMAD, or chronic ataxic neuropathy ophthalmoplegia M protein agglutination disialosyl antibodies, has been suggested [21]. Other features may include bulbar signs, facial weakness and paresthesias, and optic neuropathy; both demyelinating and axonal features have been described on electrophysiologic studies [5, 21, 22].

Motor Neuron Disease

Motor neuron disorders (MND) have been reported in some patients with cancer, but for many this is most likely a coincidental finding. Most population-based studies have failed to show any increase incidence in cancer in those with amyotrophic lateral sclerosis (ALS) [23, 24], though a recent report found a slightly higher incidence of cancer, predominantly breast and lung, in patients with ALS than expected [25]. Reports of stabilization or remission of motor neuron symptoms in some patients, and unusual pathological findings such as inflammatory changes in others, also suggest that some cases may have a paraneoplastic origin.

Predominant motor neuron dysfunction, sometimes resembling ALS, occurs in about 20 % of patients with anti-Hu-associated PEM, although with time other areas of the nervous system will become involved. Pure lower motor neuron syndromes which have at least in part improved following treatment of the associated cancer have been reported in patients with renal cell carcinoma and breast cancer [26–28]. Breast cancer has also been found in women with primary lateral sclerosis, a pure upper motor neuron disorder [29]. Improvement of signs and symptoms of MND has been reported following resection of a parathyroid adenoma in some but not all patients [30–32]; patients with typical ALS may not improve and in most the relationship is likely coincidental [32, 33].

Since patients with primary hyperparathyroidism can develop weakness in a pattern similar to ALS, it is possible that some cases were misdiagnosed [34]. Feature that distinguishes PHP-related weakness includes distal loss of pain and vibration senses and the association with changes in mentation and personality [32].

Stiff-Person Syndrome

The stiff-person syndrome (SPS) is characterized by the development of progressive rigidity of the skeletal muscles with superimposed painful spasms. The spasms are severe and can lead to limb deformities and bone fractures. Three subtypes have been described: (1) stiff-limb syndrome with symptoms limited to a limb, typically the distal leg; (2) stiff-person syndrome with stiffness in the trunk and proximal legs; and (3) rapidly progressive and fatal encephalomyelitis associated with rigidity [35]. Both antibodies to glutamic acid decarboxylase (GAD) and amphiphysin have been described in SPS. GAD antibodies can be seen in type 1 diabetes mellitus and may be associated with other neurological manifestations including cerebellar ataxia, limbic encephalitis, epilepsy, and encephalomyelitis [36]. Rarely, paraneoplastic SPS with GAD antibodies has been described in patients with breast cancer, multiple myeloma, and thymoma [37–39]. Amphiphysin antibodies are not uniquely associated with SPS; other neurological symptoms may occur including neuropathy, encephalopathy, myelopathy, and a cerebellar syndrome; when the antibody is present, there is a high rate of cancer found, particularly small-cell lung and breast cancer [40]. In women with SPS and amphiphysin

antibodies, there was a high rate of breast cancer (10/11) and stiffness in the cervical region. There was good response to treatment with high-dose benzodiazepine, steroids, and cancer-specific therapy [41].

Nerve conduction studies in patients with SPS are normal, and EMG may show either continuously firing normal-appearing motor units or grouped units firing in bursts [35].

Response to symptomatic and immunosuppressive therapy is mixed for SPS patients with or without cancer. Paraneoplastic SPS may respond to treatment of the tumor and steroids [37, 40]. Benzodiazepines, baclofen, gabapentin, and levetiracetam may offer symptomatic relief [35, 42, 43]. Intravenous immunoglobulins (IVIg) is useful in patients with non-paraneoplastic SPS and may be effective in the paraneoplastic form of the disorder though perhaps less so when amphiphysin antibodies are present [44, 45].

Acute Necrotizing Myelopathy

Paraneoplastic myelopathy usually occurs in association with dysfunction at other level of the nervous system as in encephalomyelitis or cerebellar degeneration. Isolated paraneoplastic myelopathy is rare and most often described in association with lung or breast cancer. The more commonly associated antibodies are anti-amphiphysin, CRMP5, and Hu. The onset is insidious or subacute and, in more than half of patients, precedes the cancer diagnosis. In one series, CSF abnormalities including lymphocytic pleocytosis and elevated protein and oligoclonal bands were found in many cases [46]. In this series, 23 % of patients were initially diagnosed with primary progressive multiple sclerosis, in part due to the presence of these CSF abnormalities. These authors also found that the presence of symmetric longitudinally extensive tract or gray matter-specific changes on spinal MRI was characteristic of paraneoplastic myelopathy.

Tumor treatment and immunotherapy may provide mild improvement or temporary stabilization, but the majority of patients fail to respond and become wheelchair dependent within 1 year of onset.

The Peripheral Neuropathies

Polyradiculoneuropathy

An acute to subacute polyradiculoneuropathy indistinguishable from the Guillain–Barré syndrome (GBS) appears to occur at a higher-than-expected frequency in patients with cancer, most commonly Hodgkin's and non-Hodgkin's lymphoma. Patients present with the acute onset of a rapidly progressive sensorimotor or pure motor neuropathy. The protein and one pathologic study demonstrated perivascular lymphocytic infiltration of the peripheral nerves and inflammatory infiltrates in Schwann cells [47, 48]. Electrophysiological studies most commonly demonstrate an acquired demyelinating sensorimotor neuropathy typical for GBS, but acute motor axonal neuropathy and acute motor and sensory axonal neuropathy may also be seen. The disorder may occur during active disease, remission, or prior to tumor relapse, and the course of the neuropathy is independent of the lymphoma. Similar to GBS, some patients with paraneoplastic polyradiculoneuropathy respond to plasmapheresis or IVIg, though mortality in patients with cancer and GBS is higher than seen in isolated GBS [48]. Rarely, patients develop weakness and sensory symptoms secondary to motor and sensory neuronopathy that mimics axonal Guillain–Barré syndrome (GBS) [49].

In patients with cancer, the differential diagnosis of acute or subacute polyradiculoneuropathy should include leptomeningeal carcinomatosis, or infiltration of nerve roots and peripheral nerves by leukemia or lymphoma (neurolymphomatosis). In most metastatic infiltrations of leptomeninges and nerves, symptoms are asymmetric, usually associated with pain, and do not evolve acutely.

Chronic Sensorimotor Neuropathy

In many cases, when patients with cancer develop a chronic neuropathy, it occurs after the cancer diagnosis and is more likely related to the side effects of chemotherapy, metabolic dysfunction (such as from failing liver or kidneys), or poor nutrition. Patients present with symmetric, distal paresthesias, sometimes associated with pain. There is loss of deep tendon reflexes and, with time, atrophy of the distal musculature. Cranial nerves are usually spared [50]. In most patients, symptoms will be slowly progressive with weakness developing late. More rarely, some patients may have remitting and relapsing symptoms. There is no associated antibody, and the relationship to the underlying cancer is uncertain.

Electrodiagnostic and pathologic studies demonstrate axonal degeneration, segmental demyelination, and, less commonly, a combination of both. The diagnosis of chronic sensorimotor neuropathies in patients with cancer is usually complicated by superimposed neuropathies secondary to treatment.

A length-dependent sensorimotor axonal neuropathy may precede the identification of cancer in patients with CRMP5 antibodies. Some of these patients have not only a neuropathy but also cerebellar dysfunction [13]. Small-cell lung carcinoma and thymomas are the common associated tumors; time to find a tumor may be longer in patients with CRMP5 antibodies and neuropathy compared to those with anti-Hu-associated neuropathy. Despite this,

patients with CRMP5 antibodies have longer median survival compared to Hu patients [12].

A chronic demyelinating sensory motor neuropathy (similar to CIDP) has been reported in conjunction with breast cancer and CRMP5 antibodies. The neuropathy preceded the cancer diagnosis by 2 years and improved after the breast cancer was treated with wide local excision, chemotherapy, and radiation therapy [51].

Sensorimotor Neuropathy Associated with Malignant Monoclonal Gammopathies

Approximately 10 % of patients with a chronic sensorimotor neuropathy of unknown etiology will have a paraproteinemia including benign monoclonal gammopathy, multiple myeloma, Waldenström's macroglobulinemia (WM), primary systemic amyloidosis, and POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M spike, and skin changes).

Although the exact pathogenetic mechanism is not known, neuropathy can be secondary to the monoclonal proteins targeting neural antigens as in the case of IgM antibodies binding to myelin-associated glycoprotein in nerves. The relationship of the IgG or IgA monoclonal gammopathy with polyneuropathy is less clear. The neuropathy subtype can have variable clinical and electrophysiologic presentations depending on the associated serum paraproteins and the underlying hematologic process.

Treatment for the neuropathies associated with malignant monoclonal gammopathies is not standardized. Due to the slow progression of many of the neuropathies, older age of the patients, lack of randomized trials to determine efficacy, and adverse events associated with different therapies, many reserve treatment for those patients with progressive functional impairment. In general treatment is aimed at the underlying disorder, thus removing the cells that produce the paraprotein or by directly removing the paraprotein from the circulation.

Monoclonal Gammopathy with Undetermined Significance (MGUS)

MGUS is the most common hematologic disorder associated with a peripheral neuropathy. It is a premalignant condition that affects more than 3 % of the general population over the age of 50 and carries a 1 % per year persistent risk of malignant transformation [52]. The most common neuropathy is described as "distal acquired demyelinating symmetric" (DADS) sensory and motor neuropathy. It is very slowly progressive, with the prominence of sensory loss and ataxia, little or no weakness initially, and frequent tremor [53]. In about 50 % of patients with IgM MGUS, the monoclonal protein binds to myelin-associated glycoprotein (MAG), a constituent of normal peripheral nerve myelin. This results in a characteristic change in peripheral nerve myelin, consisting of widening of myelin lamellae demonstrated in electron microscopy, and is likely responsible for the nerve damage [54–56]. The neuropathy with anti-MAG antibodies typically affects older men in their 60s–70s, who develop insidious paresthesias of the distal lower extremities that gradually extend proximally over a period of 10–20 years [57]. Gait ataxia, tremor, and loss of vibratory and position sense are also frequently present. Overall prognosis is good but half of patients will become disabled by 15 years after onset [58].

Electrophysiologically, the findings are consistent with a primarily demyelinating process with absent or markedly reduced sensory nerve action potentials. Motor nerve conduction velocities are significantly slowed, but the degree of distal slowing, and hence prolongation of the distal motor latency, is much greater.

Less commonly, patients with IgM MGUS have antibodies to other peripheral nerve antigens such as ganglioside GM1, chondroitin sulfate, and sulfatide. The phenotype of the neuropathy varies with the antibody. High titers of anti-GM1 IgM are associated with a pure lower motor neuron syndrome with multifocal motor conduction block, while anti-chondroitin sulfate or sulfatide IgM associates with a predominantly sensory neuropathy [59]. Anti-GM1 IgM antibodies are not associated with underlying plasma cell dyscrasia. In the subgroup of patients with IgM MGUS without anti-MAG or other antibody activity, the neuropathy has features of a chronic inflammatory demyelinating polyneuropathy [60].

Waldenström's Macroglobulinemia

Waldenström's macroglobulinemia (WM) is a rare disease defined as having an IgM paraproteinemia and bone marrow (BM) infiltrated by lymphoplasmacytic lymphoma. Associated clinical features are anemia, hepatosplenomegaly, lymphadenopathy, and hyperviscosity, but these are not required for diagnosis [61, 62]. Older series suggested a low occurrence of neuropathy in WM; however, when targeted evaluations are done, a neuropathy is found in almost 50 % of patients [63, 64]. Clinical signs and symptoms suggest small- and large-fiber sensory involvement; on examination, patients may have trouble with tandem walking even with relatively good strength and proprioception. The electrophysiology may demonstrate a sensory axonal neuropathy or a sensorimotor demyelinating neuropathy with associated axonal loss. The former may be associated with anti-sulfatide antibodies and the latter with anti-MAG antibodies. Patients

with the demyelinating features on nerve conduction study tend to have more significant findings on exam [64]. Amyloid and cryoglobulinemia associated with WM may also produce neuropathy in some patients.

Primary Systemic Amyloidosis

Primary systemic amyloidosis is due to the overproduction and organ deposition of immunoglobulin light chains (predominantly lambda). It is also known as immunoglobulin light chain amyloidosis (AL). Clinical features vary according to the organs affected and can include macroglossia, organomegaly (hepatomegaly and/or splenomegaly), cardiomyopathy, or nephrotic syndrome [65]. About 20 % of patients with AL present with a peripheral neuropathy [66]. The neuropathy is predominantly sensory, symmetric, and slowly progressive and more commonly affects the distal lower extremities. There is often prominent involvement of small fibers that results in autonomic dysfunction and pain [67]. Uncommon presentations have been reported such as a multifocal, large-fiber process affecting the upper limbs [68].

Electrophysiologic studies usually show a primarily axonal sensorimotor neuropathy, with decreased compound muscle action potential amplitudes, decreased to absent sensory nerve action potentialss, and normal or mild decreases in conduction velocities with signs of denervation on EMG.

The diagnosis can be confirmed by nerve biopsy is positive for amyloid deposition in most cases with a clinically symptomatic sensory neuropathy. The prognosis of amyloidosis has improved from a median survival of less than 18 months in the 1990s to a 2-year survival of 82 % with autologous stem cell transplant [69, 70].

Multiple Myeloma

One-third of patients with multiple myeloma have electrophysiologic signs of peripheral neuropathy, but only 5–10 % develop clinical symptoms that usually precede the diagnosis of myeloma. The neuropathy is heterogeneous and attributed to perineural or perivascular immunoglobulin deposition, specifically IgM or IgG kappa, with or without associated amyloid infiltration. Patients may develop a mild sensorimotor axonal neuropathy, a pure sensory neuropathy, or a subacute monophasic or relapsing and remitting neuropathy with evidence of demyelination on electrophysiologic and morphologic studies. For the evaluating neurologist, it is important to keep in mind that treatment-related peripheral neuropathies are currently the most frequent cause of symptomatic polyneuropathy in patients with multiple myeloma [71].

Osteosclerotic Myeloma and POEMS Syndrome

The term osteosclerotic myeloma has been used for many years to describe an unusual form of myeloma characterized by single or multiple plasmacytomas that manifest as sclerotic bone lesions. The lesions involve ribs, vertebrae, pelvic bones, and proximal long bones and usually spare skull and distal extremities. The serum M protein is IgG or IgA subtype and almost always lambda light chain restricted. POEMS syndrome is a syndrome defined by the presence of polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes and has also been called Crow–Fukase or Takatsuki syndrome. Almost all patients with POEMS have sclerotic bone lesions, and whether there is a true distinction between osteosclerotic myeloma and POEMS is under debate, and the clinical course of patients with osteosclerotic myeloma is similar whether they meet some or all POEMS criteria [72]. Additionally, almost all patients defined as having POEMS will have coexisting Castleman's disease (see below).

In all cases, peripheral neuropathy is the dominant symptom**.** In contrast to the neuropathy associated with multiple myeloma, the neuropathy in osteosclerotic myeloma/POEMS is fairly homogeneous and recognizable as a chronic, distal, and large-fiber sensorimotor neuropathy, with symmetric proximal spread. The disorder resembles a chronic demyelinating polyneuropathy (CIDP) but has less marked prolongation of the motor distal latencies, has more marked motor amplitude loss in the lower extremities, and is less likely to have conduction block [73]. Nerve biopsy shows mixed primary demyelination and axonal degeneration and uncompacted myelin lamellae [74].

For those patients with single or a few osteosclerotic lesions, a limited field radiation can be effective. For those with widespread lesions, systemic therapy is necessary, although there are no standardized approaches to therapy. Autologous peripheral blood stem cell transplant has become the treatment of choice, particularly in younger patients. Other treatment options include high-dose melphalan, lenalidomide, thalidomide, anti-VEGF monoclonal antibody, and cyclophosphamide [75].

Castleman's Disease

There are several subtypes of this disorder including an asymptomatic localized (unicentric) mediastinal lymphadenopathy as originally described by Castleman [76]. Plasmablastic multicentric Castleman's disease is an aggressive variant that is associated with immunosuppression and HHV-8 infection and is increasingly being described in persons living with HIV infection [77].

Patients may develop several types of neuropathies, including painful sensorimotor deficits, a chronic relapsing

sensorimotor neuropathy, and a predominantly motor neuropathy. Nerve biopsy may show demyelination and axonal loss. The finding of capillary proliferation and endothelial hypertrophy in the epineurium and endoneurium supports the concept that a diffuse vasculopathy may contribute to the neuropathy [78].

Vasculitic Neuropathy

Paraneoplastic systemic vasculitis is a nonsystemic vasculitis that involves small vessels of the skin and, rarely, the nerve. Skin rash or a necrotic skin ulcer may provide a clue to the underlying vasculitis. It is most often but not exclusively described in association with lymphomas, leukemias, and SCLC. Symptoms may precede the cancer diagnosis and often start as a painful, asymmetric sensorimotor neuropathy or as multiple mononeuropathies [79]. Nerve biopsy shows Wallerian degeneration with perivascular infiltrates of the epineurium or endoneurium. Muscle biopsy reveals neurogenic changes and rarely demonstrates microvasculitis as well [80, 81].

Electrophysiological studies may demonstrate a diffuse axonal sensorimotor axonal neuropathy or multiple mononeuropathies [80, 82]. The CSF frequently shows an elevated protein with mild pleocytosis but negative cytology [80, 83].

Paraneoplastic vasculitis of nerve and muscle can develop in association with other paraneoplastic syndromes, such as PEM with or without PSN [80]. There are reports of responses to treatment of the tumor and immunosuppressants (steroids, cyclophosphamide) [83, 84].

Peripheral Nerve Hyperexcitability (PNH)

PNH is a heterogeneous disorder with a constellation of symptoms that may include cramps, fasciculations, spasms, myokymia, neuromyotonia paresthesias, muscle atrophy, and weakness [85, 86]. It is also called Isaacs' syndrome [87], and when neuropsychiatric and autonomic symptoms are present, it carries the eponym Morvan's syndrome [88]. The disorder is characterized by spontaneous and continuous muscle fiber activity of peripheral nerve origin, which can be triggered by voluntary muscle contraction (Fig. 75.1). In approximately half of the patients with PNH, an axonopathy is present. In one-third of these, there is a known inherited or acquired disorder of the motor neuron or axon, while in the remainder no recognizable cause for the axonopathy is found. Electrophysiology shows that the axonopathy may be a pure motor or sensorimotor axonal neuropathy or multiple mononeuropathies [89].

A minority of patients with PNH have an associated cancer (11–13 %) with SCLC and thymoma most commonly found [86, 89]. Patients with paraneoplastic PNH are older, less likely to have sensory complaints, more likely to have proximal muscle weakness, less likely to have muscle atrophy, and are less likely to have an axonal neuropathy on nerve conduction studies and have abundant myokymia [89].

Antibodies erroneously described as targeting voltage-gated potassium channels have been described in 5–54 % of patients with PNH [86, 89, 90]. Recent studies have shown that the potassium channel is not the target antigen but rather an antigen that interacts with the potassium channel including contactin-associated protein-like 2 (Caspr2) [91]. Caspr2

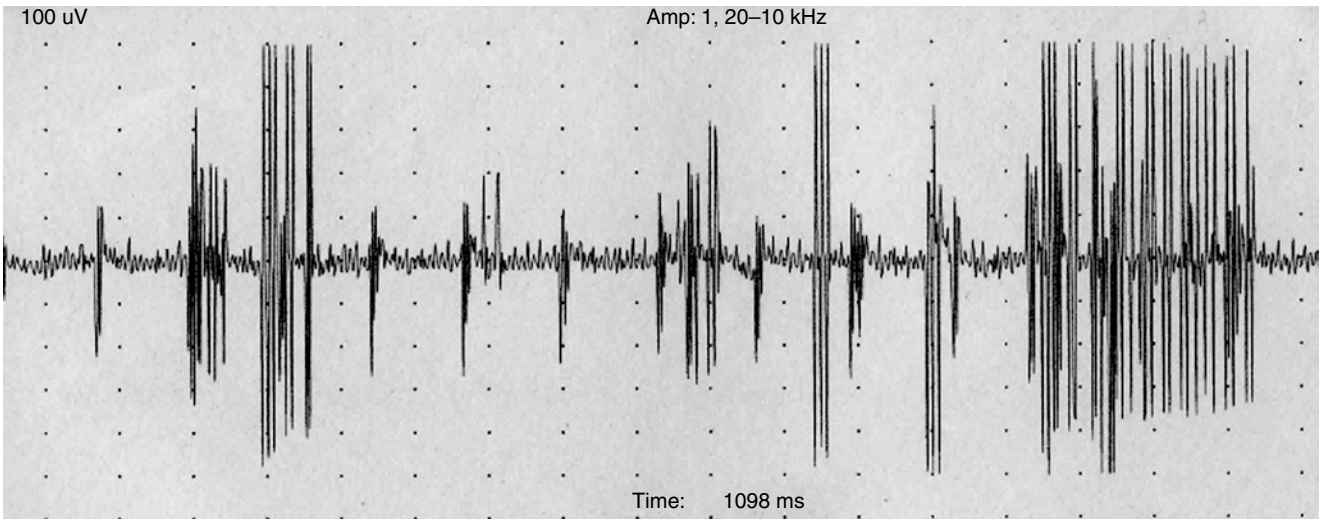

Fig. 75.1 A 34-year-old woman with a recent diagnosis of thymoma develops seizures, hallucinations, and difficulties with short-term memory. Her examination reveals limb stiffness with muscle twitching. EMG of the frontalis muscle demonstrates neuromyotonia with bursts of spontaneous high-frequency discharges. The combination of neuromyotonia and central nervous system dysfunction in encephalitis is known as Morvan's syndrome. Serology evaluation revealed the presence of anti-Caspr2 antibodies

antibodies have been found in patients with thymoma but are also found in patients without cancer. Some patients with Caspr2 antibodies have additional central nervous system dysfunction representing Morvan's syndrome [91, 92]. Patients with Caspr2-associated symptoms are likely to have other immune-mediated disorders such as myasthenia gravis. The combination of symptoms related to the PNH and those due to other autoimmunities such as fasciculations and muscle atrophy has resulted in some patient with Caspr2-associated symptoms being misdiagnosed as having motor neuron disease. The detection of Caspr2 antibodies helps identify a disease that may respond to immunotherapy [91].

In PNH, the spectrum of motor symptoms may range from cramps and fasciculations to neuromyotonia (NMT) with the latter defined by specific electromyographic features. These include bursts of doublets, triplets, and multiplets with maximum intraburst frequency between 40 and 350 Hz. Fasciculations are frequently seen, but fibrillations and positive sharp waves are not. NMT discharges can arise spontaneously or be provoked by nerve stimulation and are more commonly found distally than proximally [93]. Motor nerve conduction studies may show repetitive discharges following the expected compound muscle action potential with waning amplitude following a single stimulus [94, 95]. In contrast to neuromyotonia, myotonic discharges wax and wane in amplitude and have a characteristic dive bomber or revving motorcycle sound. Myotonia is only rarely reported as paraneoplastic in patients with lung cancer; before making this diagnosis, patients should be examined carefully for signs of myotonic dystrophy, myotonia congenita, or paramyotonia congenita [96].

Myasthenia Gravis (MG)

Myasthenia gravis (MG) is an autoimmune disorder characterized by fatigable weakness of skeletal muscles due to antibodies directed against components of the neuromuscular junction, frequently the acetylcholine receptor (AChR) and less often against muscle-specific kinase (MuSK), a surface membrane muscle enzyme. The clinical manifestations may be highly variable in patients; some have purely ocular symptoms (ptosis and diplopia), while others will have generalized disease. Patients with generalized disease may have not only the ocular symptoms but also proximal greater than distal extremity weakness, nasal voice or dysarthria, dysphagia, and shortness of breath. Symptoms may become more apparent with use of the muscle involved; for example, with sustained up gaze, a lid may become droopy or an eye may come down [97].

When MG is suspected, acetylcholine receptor antibodies (AChR) are obtained, and electrophysiologic testing performed. AChR antibodies are found in up to 59 % of patients with ocular only symptoms and in up to 82 % of patients with generalized disease [98]. Routine nerve conduction studies are normal, and with slow rates of stimulation, a decremental response exacerbated by exercise is found. Single-fiber EMG demonstrates increased jitter and blocking [99, 100].

Patients diagnosed as having MG need to have chest imaging as 10–15 % of patients with MG have a thymoma. In addition, MG occurs in up to 45 % of patients with thymoma [101, 102]. MG patients with a thymoma nearly always have detectable AChR antibodies in serum and tend to be less responsive to treatment than those without thymoma [103].

Striational antibodies, which react with epitopes on the muscle proteins titin and ryanodine receptor (RyR), are frequently found in MG patients with thymoma [104]. The presence of titin and RyR antibodies is associated with more severe disease in thymoma-associated MG and in late-onset MG [105]. Muscle-specific kinase (MuSK) antibodies may be found in up to half of the patients with MG without AChR antibodies, and these patients rarely have an associated thymoma [106].

When the diagnosis of a thymoma in a MG patient is established, the neoplasm should be removed. Thymectomy can be performed transternally or through a video-assisted thoracoscopic approach, usually with similar outcome [107]. Almost all patients will have some response to anticholinesterase drugs, but this is rarely complete. Additional immunosuppressive and immunomodulatory therapies are often required with corticosteroids the most commonly used. Steroid-sparing immunosuppressant therapies used to treat MG include azathioprine, cyclophosphamide, and cyclosporine as well as several novel strategies such as the use of antisense oligonucleotides that affect the efficacy of AChR activation [108, 109].

Lambert–Eaton Myasthenic Syndrome

Lambert–Eaton myasthenic syndrome (LEMS) is a presynaptic disorder of neuromuscular transmission. Proximal leg muscle weakness is usually the first symptom reported by patients followed by weakness of the arms. The symptoms usually are insidious progressing over months or years before the diagnosis is made. Ptosis and diplopia are seen in about 25 % of patients. The oropharyngeal and ocular muscles are affected but usually not to the same extent or severity as in myasthenia gravis. About 80–90 % of LEMS patients have some degree of autonomic dysfunction, usually characterized by dry mouth that may be the initial presenting symptom. Other symptoms of autonomic dysfunction include constipation, urinary retention, pupillary constriction, sweating, dry eyes, and postural hypotension. Respiratory muscle weakness is uncommon but may be present in patients with generalized weakness and rarely may be the presenting symptom [110]. Reflexes usually are reduced or absent in LEMS. They can be elicited by the patient actively contracting the muscle group in question for 10 s prior to reflex

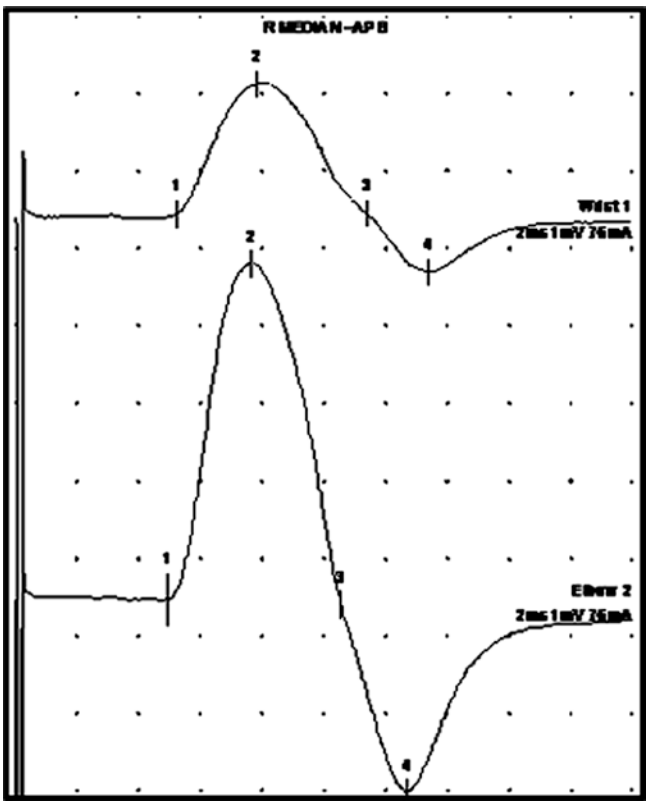

Fig. 75.2 A 57-year-old man is being evaluated for complaints of generalized weakness and difficulty walking for several months. He reports dizziness upon standing and has had several near syncopal episodes. His examination reveals proximal weakness of all extremities and areflexia. *Top tracing*: Right median compound muscle action potential (Compound muscle action potential) at rest which is small in amplitude. *Bottom tracing*: The Compound muscle action potential following 10 s of exercise, demonstrating greater than 100 % increment that is diagnostic for a presynaptic neuromuscular junction defect. The patient was an active smoker and CT of the chest was abnormal. Bronchoscopy revealed SCLC

testing. This increase in reflex activity or muscle strength for a short term after muscle contraction is a characteristic phenomenon called postexercise facilitation.

Repetitive nerve stimulation is the electrophysiological study of choice to diagnose LEMS. The first compound muscle action potential (Compound muscle action potential) amplitude is typically low in these patients; however, high-frequency stimulation (50 Hz) or, preferably, stimulation after brief (10 s) exercise can induce an increase in Compound muscle action potential amplitude (increment) greater than 100 % (Fig. 75.2). Ten-second postexercise stimulation has a sensitivity of 84–96 % and is 100 % specific for LEMS [111]. High-frequency stimulation has comparable sensitivity but is very painful and should be avoided if possible.

Most reports estimate that between 50 and 60 % of patients with LEMS have an associated cancer, most commonly SCLC. However, other malignancies have been reported including prostate carcinoma, thymoma, and lymphoproliferative disorders [112–114]. In most patients the symptoms

Table 75.2 LEMS tumor association prediction score

	Present	Absent
Dysarthria, dysphagia, masticatory, bulbar, or neck muscle weakness	1	0
Erectile dysfunction (women score 0)	1	0
Loss of weight ≥ 5 %	1	0
Active tobacco use	1	0
Age ≥ 50	1	0
Karnofsky Performance Status ≤ 60	1	0

Adapted from [120]
Patient scores directly correlate with increasing risk of having an associated SCLC. Patients with scores of 0–1 have little to no risk, while those with a score of 6 have close to 100 % risk

of LEMS develop before or coincident with the cancer diagnosis. In tumor-associated cases of LEMS, the most common age for the appearance of symptoms is 60 years and 65 % of patients are men. Non-tumor-associated cases can be seen in all ages, more commonly after 35 years with almost an equal frequency in men and women [115].

Patients with older age, male sex, weight loss, and smoking history should be screened with thoracic CT and 18F-fluorodeoxyglucose (FDG)-PET. Screening detected 91 % of SCLC within 3 months and 96 % within 1 year of diagnosis of LEMS. If negative, subsequent screenings with thoracic CT or FDG-PET should be done every 3–6 months, until 2 years after the diagnosis [116].

Antibodies to P-/Q-type voltage-gated calcium channel (VGCC) are responsible for the clinical symptoms of LEMS. These antibodies have been detected in 85–90 % of patients with LEMS, and some studies report a percentage close to 100 % in LEMS patients with SCLC [117, 118]. The antibodies impair the calcium entry to motor nerve terminals and, therefore, decrease the number of quanta released by a nerve impulse. Similarly, the antibodies result in a reduction in the density and distribution of active zone particles, thought to be the morphological representation of the VGCC. Parasympathetic, sympathetic, and enteric neurons are all affected.

In addition to VGCC antibodies, almost two-thirds of patients with LEMS and SCLC have antibodies to SOX1, a developmental transcription factor [119]. SOX1 antibodies are found in less than 5 % of those without SCLC, and thus, their presence is useful in alerting the physician to an underlying tumor in a patient with LEMS. Taking the presence or absence of SOX1 antibodies into consideration, along with several clinical and demographic features such as age of LEMS onset and smoking history, a LEMS tumor association prediction score has been developed that accurately discriminates LEMS with and without SCLC with high accuracy (Table 75.2) [120].

In addition to treatment of the associated cancer, the first choice for symptomatic treatment of patients with LEMS is 3,4-diaminopyridine. The results of four randomized controlled trials reported a significant improvement in muscle strength score or Compound muscle action potential

amplitude after treatment [121]. The drug blocks voltage-gated potassium channels, prolonging the action potential at the motor nerve terminals and lengthening the opening time of the VGCC. In general, 3,4-diaminopyridine is well tolerated; the common side effects reported are perioral tingling and digital paresthesias and gastrointestinal symptoms. The most frequent serious adverse events are seizures; this risk seems to be dose dependent and is described at doses of around 100 mg/day. Supraventricular tachycardia and prolongation of the QT interval are other possible adverse effects of the drug. Some patients with LEMS reported benefits from adding pyridostigmine to 3,4-diaminopyridine [122–124]. If symptoms remain, long-term treatment with prednisone and azathioprine should be considered. Prednisone, given most often in combination with azathioprine, was found to be effective in a retrospective study but its use is supported by the positive results of the combined treatment in myasthenia gravis [125, 126]. Acute treatment with IVIg, plasmapheresis, or additional immunosuppressive agents is rarely needed [127]. One crossover trial reported significant improvement in limb strength after treatment with IVIg [128]. Rituximab was effective in three LEMS patients with severe weakness [129, 130].

Dermatomyositis

About 20–25 % of patients with dermatomyositis develop cancer that is usually diagnosed shortly before the onset of neurological symptoms. The clinical symptoms of dermatomyositis are similar in patients with and without cancer, and except for older age, there are no symptoms or laboratory markers that indicate a paraneoplastic origin. In patients with dermatomyositis, a characteristic reddish or purplish skin rash often precedes the appearance of proximal muscle weakness. The pharyngeal muscles, neck flexors, and respiratory muscles may be involved, leading to dysphagia and rarely ventilatory failure. Reflexes and sensation are unaffected. Other manifestations include arthralgias and contractures, myocardial inflammation leading to congestive heart failure, and interstitial lung disease. Electrophysiological studies show features of myopathy, including motor unit action potentials of brief duration and low amplitude that are often polyphasic. Typically, the levels of serum creatine kinase are elevated and may change with disease activity; normal serum creatine kinase does not rule out dermatomyositis.

About 20-40 % of patients with dermatomyositis have anti-synthetase, anti-signal recognition particle, and anti-translation factor antibodies. An antibody against histidyl-tRNA synthetase (anti-Jo-1) is present in about 80 % of adult patients with dermatomyositis who have associated interstitial lung disease [131, 132].

The most common cancers are ovarian, breast, pancreatic, lung, gastrointestinal, and lymphomas. In one review, the risk for lymphoma was only raised the first year after diagnosis of dermatomyositis, while for the other tumors, the risk of developing cancer was the highest within the first year of follow-up and then dropped substantially in subsequent years but still remaining higher than expected. It has been recommended that patients with a new diagnosis of dermatomyositis undergo cancer screening annually for the first 3 years after diagnosis and then as required for new signs or symptoms suggesting a possible cancer.

Treatment of dermatomyositis is the same for patients with or without cancer. It often responds to corticosteroids and, if refractory, to IVIg.

Paraneoplastic Necrotizing Myopathy

Myopathies with little or no inflammatory infiltrate but extensive muscle fiber necrosis have also been associated with malignancies. Since its first description by Smith in 1969, no systemic studies have been done to assess the overall risk of cancer in patients with this condition [133]. Necrotizing myopathy has been more commonly associated with gastrointestinal tumors, small-cell lung cancer, and breast cancer. The myopathy can precede the diagnosis of myopathy or be discovered within 3 years of the diagnosis [134]. Histopathological findings in paraneoplastic necrotizing myopathies have been reported to be heterogeneous, with a picture ranging from sparse, segmental necrotic lesions to massive necrosis [135, 136]. The hallmark histological feature of a necrotizing myopathy in contrast to an inflammatory one, however, is sparse inflammatory cells confined to damaged, necrotic muscle fibers. Clinically, patients develop a subacute, progressive, and symmetric weakness of proximal muscles. The reported outcomes vary considerably from fast progression with no remission to complete recovery [137]. The severity of the condition does not always parallel tumor progression. Since the pathophysiology of the disease is not well established, treatment of the underlying cancer seems to be the mainstay of therapy. Additional treatment with corticosteroids, IVIg, or other immune modulators may be of benefit to some patients. More studies on the pathophysiology and treatment of paraneoplastic necrotizing myopathy are warranted, as the condition is severe and outcome differs dramatically among patients.

Acute Neuromuscular Weakness in the Intensive Care Unit

76

David Lacomis and Ahmed El-Dokla

Introduction

Over the last three decades, the following scenario has become increasingly common: a patient is noted to have generalized flaccid limb weakness with – and sometimes without – diaphragm weakness while undergoing treatment of a non-neurologic critical illness [1]. The onset of weakness is usually difficult to pinpoint because of prior sedation, pharmacologic paralysis, or encephalopathy. Furthermore, the weakness or failure to wean from the ventilator usually does not become a concern until the underlying critical illness improves. Rarely, it is determined that the weakness is due to "unmasking" of an underlying neuromuscular disorder such as myasthenia gravis or motor neuron disease. Occasionally, the patient may have a new disorder, such as Guillain–Barré syndrome, that typically presents outside the ICU. Much more frequently, the patient is manifesting features of an acute, ICU-acquired, neuromuscular disorder that is related to either the critical illness, its treatment, or both. Indeed, in most hospitals, it is now much more common for patients to develop newly acquired neuromuscular weakness while in the ICU than it is for patients to be admitted to the ICU for treatment of a neuromuscular disorder [2].

Since ICU patients with newly acquired neuromuscular weakness all tend to have attenuated tendon reflexes and unreliable sensory examinations due to sedation, encephalopathy, or both, it is usually difficult to totally delineate whether the weakness is due to a disorder of anterior horn cells, nerves, muscles, or neuromuscular junctions without ancillary testing. In many patients, several of these components of the motor unit, especially muscle and nerve, may be injured simultaneously [3, 4]; and, in others, central nervous system disorders may coexist with the neuromuscular weakness making diagnosis even more challenging.

Utilizing electrodiagnostic techniques in the ICU in spite of the electrically unfriendly environment has led to better characterization of these processes, and subsequent histopathologic studies of muscle and nerve as well as analysis of animal models have also enhanced our understanding of the major ICU-acquired neuromuscular disorders. These disorders are somewhat broadly categorized as *critical illness polyneuropathy* (CIP), *critical illness myopathy* (CIM), and *prolonged neuromuscular junction* (NMJ) *blockade*. Prolonged NMJ blockade has become less common, likely due to the reduced use of paralytic agents in ICUs, while reports of combined CIM and CIP have increased. These three disorders will be the focal points of this chapter which will relate their clinical, electrodiagnostic, and pathologic features as well as discuss pathogenesis and controversies. However, potential subgroups of the three major disorders and the differential diagnosis of weakness in the ICU patient will also be discussed.

The Spectrum of Weakness in the ICU

It is very difficult to assemble a large prospective study of the various causes of neuromuscular weakness that lead to admission to the ICU or arise while in the ICU. In a retrospective study of 92 ICU patients who underwent EMG from our center, newly acquired disorders were more than twice as common as disorders such as Guillain–Barré syndrome that led to ICU admission. Acute myopathy (mostly CIM) was found to be three times as common as acute axonal sensorimotor polyneuropathy (mainly CIP) [2]. In that study,

prolonged NMJ blockade was seen only in one patient who also had CIM. On the other hand, there are a large number of studies that prospectively evaluate neuromuscular disorders arising in the ICU. Methodologies vary, but in general, it is known that 25–34 % of patients treated for critical illness develop neuromuscular weakness due to myopathy, neuropathy, or both. Electrodiagnostic studies are abnormal in up to 80 % in some studies [5–10].

The proportions of patients having critical illness myopathy and neuropathy also vary in these studies, possibly due to the types of disorders treated and an overrepresentation of CIP alone if comprehensive electrodiagnostic testing and judicious use of muscle biopsy were not utilized as diagnostic tools in differentiating CIP from CIM or in identifying CIM in addition to CIP.

Etiology and Pathogenesis: Epidemiology

Critical Illness Polyneuropathy

"Sepsis," a clinical response to infection that is also termed the systemic inflammatory response syndrome (SIRS), and multiple organ dysfunction syndrome (MODS) are common problems in the ICU [11]. Bolton and colleagues noted that up to 70 % of prospectively studied ICU patients treated for SIRS or MODS have electrophysiologic evidence of an acute axonal sensorimotor polyneuropathy (PN) they termed CIP, and half of these have clinical evidence of PN [12]. The neuropathy ranges from mild to severe and tends to occur in ICU patients who are hospitalized for at least one and usually more than 2 weeks. The neuropathy occurs as a preexisting "septic" encephalopathy is often resolving [13]. Although there is an association with hypoalbuminemia and hyperglycemia, these metabolic changes could simply reflect the presence and severity of SIRS or MODS [14, 15]. However, hyperglycemia could be a true risk factor, since its intensive treatment in the ICU may be associated with a decreased incidence in newly acquired neuromuscular disorders (discussed again later) [16–20].

CIP may also be triggered by mechanical or thermal injury as well as infection [21].

Critical Illness Myopathy

Patients with CIM, also previously called acute necrotizing myopathy of intensive care, thick filament myopathy, acute myopathy with myosin loss, acute quadriplegic myopathy, and critical care myopathy, are often exposed to high doses of intravenous corticosteroids (IVCS) sometimes in combination with neuromuscular junction blocking agents (NMBAs) [22]. The disorder was first reported in 1977 in a patient treated for status asthmaticus [23], and many subsequent studies involved status asthmaticus patients [24–44]. Thereafter, other critically ill patients, such as organ transplant recipients, and patients with acute respiratory distress syndrome, pneumonia, and chronic obstructive pulmonary disease were commonly noted to develop CIM [45–52]. Children as well as adults may be affected.

There has been an evolution regarding consideration of risk factors. First, it was noted that occasional patients were exposed to NMBAs without IVCS [47]. In fact, there may be a correlation with the dose of NMBA and likelihood of developing CIM [38]. It had also been noted that patients who had received IVCS got high doses, at least a total dose of 1,000 mg of methylprednisolone or its equivalent [22, 32], but some patients had lower corticosteroid exposures. It was then noted that few patients also have coexisting SIRS or MODS, although many status asthmaticus patients who develop CIM do not [44]. Propofol administration [53], severe disuse, and myasthenia gravis [54] in combination with IVCS have also been associated with CIM. Increasingly over the past decade, patients with SIRS or MODS who are not exposed to either corticosteroids or NMBAs were noted to develop the syndrome [55, 56].

One of the more recent larger prospective studies of both CIP and CIM found that there was increased risk for corticosteroids as well as females, duration of ventilation, and organ dysfunction [6]. Other studies of mixed CIM and CIP populations that generally included patients with SIRS or MODS did not clearly identify corticosteroids as a risk factor [7–9, 57, 58]. Risk factors included the severity of illness and the presence of SIRS [8]. Of note, muscle biopsies were either not performed or did not demonstrate myosin loss.

A more recent prospective study utilizing muscle membrane inexcitability as a diagnostic tool in screening 40 patients for CIM during the early course of critical illness also concluded that systemic inflammation appears to be the main risk factor in developing CIM. Risk factors did not include either adjunctive hydrocortisone treatment in septic shock or administration of neuromuscular blocking agents or aminoglycosides [59]. Muscle histopathology was not examined.

There are only several other prospective studies of CIM alone. Up to two-thirds of patients treated for status asthmaticus develop elevations in serum creatine kinase, and one-third have clinical features of myopathy [38]. There was a 34.6 % incidence of CIM in patients with severe chronic obstructive pulmonary disease exacerbations. Biopsies in a subset confirmed CIM. Risk factors included total corticosteroid dose and illness severity as well as sepsis [52]. Approximately 7 % of liver transplant patients develop severe CIM after transplantation [48]. In the liver transplant patients, associated risk factors include higher severity index of critical illness according to APACHE-II (acute physiology

and chronic health evaluation) [60] scores, presence of renal failure, and higher corticosteroid doses [48]. Retrospective studies noted 19–44 % incidences in status asthmaticus patients [32, 41, 44].

Some patients with suspected CIM may actually have *rhabdomyolysis* from infection or pharmacologic agents other than IVCS or NMBAs [61–69]. Rarely, an underlying inherited metabolic myopathy [70] could present in the ICU with rhabdomyolysis. Rhabdomyolysis can also occur in ICU patients or lead to ICU admission following illicit drug use, extreme overexertion, or limb ischemia [58–62, 71–75] with compartment syndrome; these disorders can be differentiated clinically and by toxicology screening. It is uncertain whether rhabdomyolysis or muscle necrosis histologically in association with NMBAs should be categorized separately from CIM. We do not consider it as a separate entity in this chapter. Differentiating rhabdomyolysis from CIM with thick filament loss may be impossible without muscle histologic examination, and even the pathologies may overlap. In patients with presumed rhabdomyolysis, we recommend waiting for at least a month from onset of the attack to obtain a muscle biopsy because early histologic examination will show necrosis regardless of the etiology of the rhabdomyolysis, and selective loss of thick filaments, which may be seen with CIM, may not be seen prior to 2 weeks of onset anyway [22].

A catabolic or *cachectic myopathy* may also manifest in the ICU in some chronically ill patients. The incidence is unknown. This disorder is discussed later in this chapter.

Prolonged Neuromuscular Junction Blockade

Prolonged neuromuscular junction (NMJ) blockade is a very rare cause of prolonged weakness; it tends to occur in patients treated with high doses of vecuronium or pancuronium [49, 76–78]. Affected patients usually also have renal failure. Although these drugs are deacetylated in the liver, they are secreted in the urine [79], and their active metabolites (e.g., 3-desacetyl-vecuronium) accumulate in the setting of renal dysfunction [76]. The first reported patient with prolonged NMJ blockade received gallamine, and that patient also had renal failure [80]. Female sex, acidosis, and hypermagnesemia were also associated risk factors in one study [76]. Hepatic failure [49] and medications with neuromuscular junction blocking properties may also increase susceptibility. The roles of associated sepsis and corticosteroid use in affected patients are unresolved. Some affected patients also have superimposed CIM [47, 49]. Since electrophysiologic and pathologic studies in some reported cases are limited, it is unclear how often these superimposed processes are present and, if so, if they are the actual primary cause of weakness.

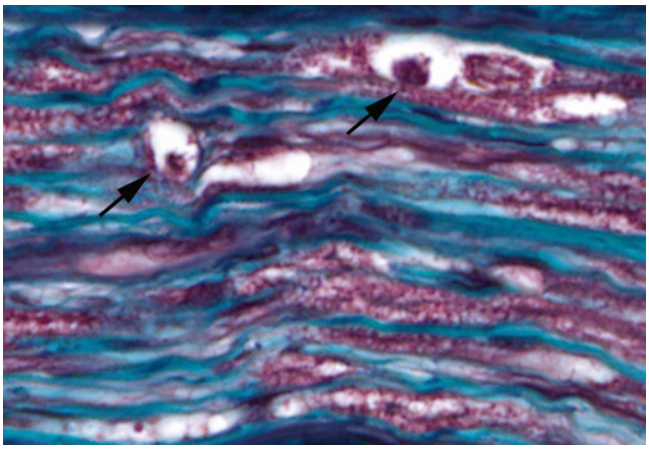

Fig. 76.1 Critical illness polyneuropathy. This sural nerve specimen was obtained at autopsy from a 43-year-old woman who succumbed from anaerobic septicemia and renal and hepatic failure after 34 days in the ICU. She had new-onset weakness, respiratory failure, and a remote history of multiple myeloma. The specimen reveals myelin ovoids (*arrows*) which are indicative of acute axonal degeneration. Elastic trichrome

Pathology and Pathogenesis

The pathogenesis of *critical illness polyneuropathy* is uncertain. Autopsy and surgical pathologic studies reveal (noninflammatory) acute degeneration of sensory and motor axons [15, 81] (Fig. 76.1). It is controversial whether CIP can be a pure motor neuropathy [82]. Careful exclusion of CIM is necessary in such cases. Muscle necrosis is also occasionally noted histologically in some patients with CIP. However, muscle necrosis may be an incidental finding in many ICU patients [83]. Typically, muscle histopathology in CIP reveals angulated atrophic fibers of both fiber types, whereas, in CIM, the atrophy is usually worse in type 2 fibers, and one must look carefully for evidence of myosin loss (described below); otherwise histopathologic features of CIM could be misdiagnosed as neurogenic atrophy.

If CIM is a consideration, biopsy of a proximal muscle might have a higher yield than a distal muscle biopsy as is typically performed along with a nerve when both tissues are biopsied. In our opinion, electrophysiologic and muscle histopathologic findings are complementary in establishing a diagnosis of combined critical illness myopathy and polyneuropathy, but they are not often performed together in clinical practice. In patients who cannot activate motor units, EMG may not differentiate myopathy from axonal neuropathy or if there is motor axonal regeneration with small "nascent" motor unit potentials simulating myopathy. In these situations, muscle biopsy may be particularly useful in determining the presence of myopathy rather than or in addition to CIP. Clinical judgment is needed to determine whether the prognostic implications are useful, since CIM usually improves faster than CIP (discussed later).

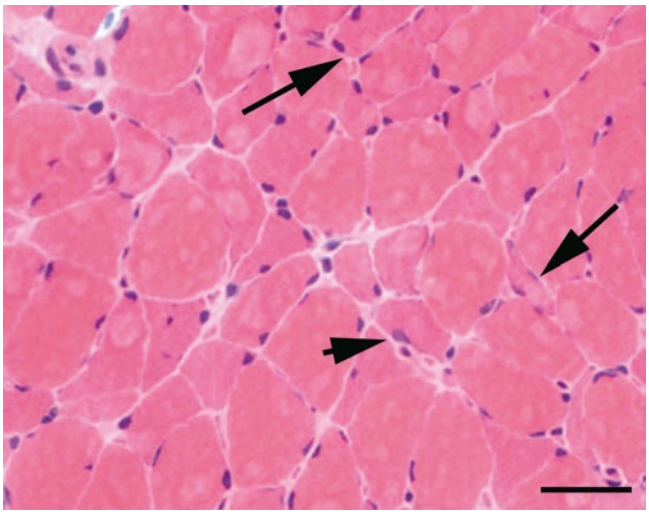

Fig. 76.2 Critical illness myopathy. A hematoxylin and eosin-stained cryostat section of skeletal muscle reveals atrophic myofibers that have abnormal basophilic stippling (see *long arrows*). The lighter *pink* regions in the sarcoplasm of many fibers correspond to myofibrillar disruption. The *short arrow* depicts an atrophic myofiber with an enlarged nucleus (bar = 50 μ)

In CIP, it has been postulated that cytokines and free radicals associated with the SIRS or MODS may adversely affect the microcirculation and ultimately cause endoneurial hypoxia and axonal degeneration [13, 21]. The central nervous system is usually affected as well. Numerous possible causes of axonal dysfunction are yet to be investigated. Malnutrition associated with SIRS and MODS may have a role, but no specific nutritional deficiencies have been identified. Hyperglycemia may play a role, and its treatment reduces the incidence of polyneuropathy and possibly myopathy in the ICU, but the reported risk reduction is likely to be an overestimation of the treatment effect due to the limited diagnostic methods used [84].

A humoral factor (identity undetermined) has also been noted in CIP patients and shown to be toxic to rat spinal cord neurons, but its significance is unknown [85, 86].

Although the cause of *critical illness myopathy* is also uncertain, a number of pathologic changes and "triggering factors" are now well known. Histologically, there is a spectrum of abnormalities [87]. Myofiber atrophy, especially involving type 2 fibers, is very common, and myofiber necrosis and regeneration are present in varying degrees [28, 37, 47]. However, necrosis may be absent. On cryostat sections, the atrophic fibers may have a stippled basophilic appearance (probably reflecting myofibrillar disorganization) with hematoxylin and eosin. Nuclei may be enlarged in some atrophic fibers (Fig. 76.2). The atrophic fibers also tend to stain darkly (purplish) with Gomori trichrome (Fig. 76.3). The intermyofibrillar network often also appears disrupted with the NADH-TR reaction (Fig. 76.4). These features should alert the muscle pathologist that the atrophy is not "neurogenic." Gutman et al. also reported a variant of CIM associated with acute atrophy and regeneration of only type 2 fibers [88]. *The histopathologic hallmark is loss of myosin.* It is most easily detected on the myosin-ATPase stain, but it can be subtle. Myosin-ATPase reactivity is usually patchy, sometimes core-like, or completely absent in some to many non-necrotic fibers studied at alkaline and acid pHs especially if the biopsy is obtained more than 12 days after the likely onset of weakness [34, 37, 56] (Figs. 76.3, 76.5, and 76.6). There may be a subpopulation of fibers that stain less intensely than the lighter normal type 1 fibers at an alkaline pH in which the type 2 fibers are usually dark and type 1 fibers are of medium intensity (Fig. 76.6). The loss of myosin may be confirmed immunohistochemically (Fig. 76.5), biochemically [89], or ultrastructurally (loss of thick filaments with preservation of thin filaments and Z bands) (Fig. 76.7). Myosin loss may preferentially affect type 2 fibers or atrophic fibers [90] in some cases, but both fiber types and atrophic and non-atrophic are usually affected. Loss of thick filaments, although characteristic, is not specific to CIM and has been noted focally in other disorders such as dermatomyositis, thrombotic thrombocytopenia purpura, human immunodeficiency virus infection, and congenital myopathy. Furthermore, in CIM, other structural proteins, such as titin, nebulin, and actin, are also reduced but to a lesser degree than myosin [56].

Myosin loss may be related to a decreased transcription rate or loss of myosin mRNA [91]. In addition, the atrophic fibers of CIM often express fetal myosin and desmin consistent with regeneration [56]. There is also evidence of increased expression of calpain, a calcium-activated protease [56] suggesting that changes in cellular calcium homeostasis play a role in pathogenesis, and calpain may degrade myosin [56]. The calpain expression was noted predominantly in atrophic fibers. Calpain expression was also noted in a dermatomyositis disease control in perifascicular fibers [56]. There is also increased apoptosis [92] as well as upregulation of the transforming growth factor-b/mitogen-activated protein kinase pathway [93]. It is unclear whether or not the ubiquitin–proteasome pathway is upregulated [56, 92].

Intravenous corticosteroids, especially in conjunction with either pharmacologic (NMBA-mediated) or structural denervation, seem to precipitate the process of myosin thick filament loss [22]. In disuse states (including ICU hospitalizations), glucocorticoid receptors are upregulated [94], perhaps rendering critically ill patients more vulnerable to corticosteroid myotoxicity. Likewise, nicotinic acetylcholine receptors are increased in patients receiving NMBAs as they are with denervation perhaps rendering such patients more vulnerable to NMBA toxicity [95]. Interestingly, a mouse neuropathy model suggests that the state of innervation regulates myosin isoforms [96]. Activity levels also influence myosin isoform expression [97], and disuse may also cause end-plate alterations. Single-fiber EMG demonstrates

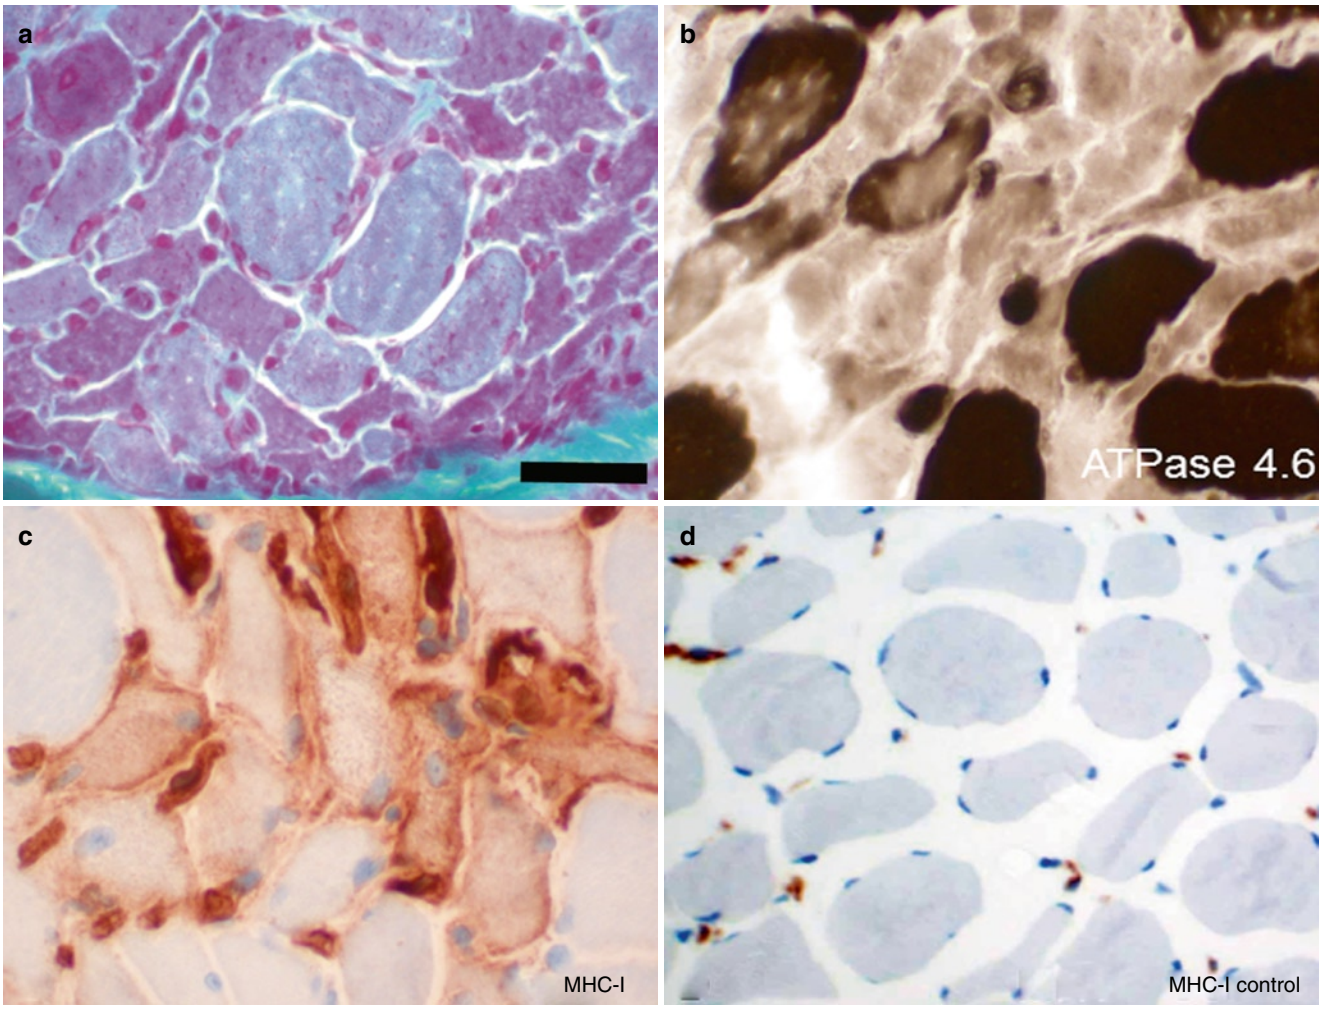

Fig. 76.3 Additional histopathologic features that may be seen in critical illness myopathy. (**a**). Atrophic myofibers often stain abnormally *purple* with Gomori trichrome (bar = 50 μ). (**b**). Typical patchy and homogenous reductions in myosin-ATPase reactivity are also shown in this patient. (**c**). In addition, there is upregulation of major histocompatibility complex type 1 seen as the brown reaction product mainly in the sarcolemmal membranes. Normally, myofibers are nonreactive, but capillaries stain as seen in the normal control (panel **d**)

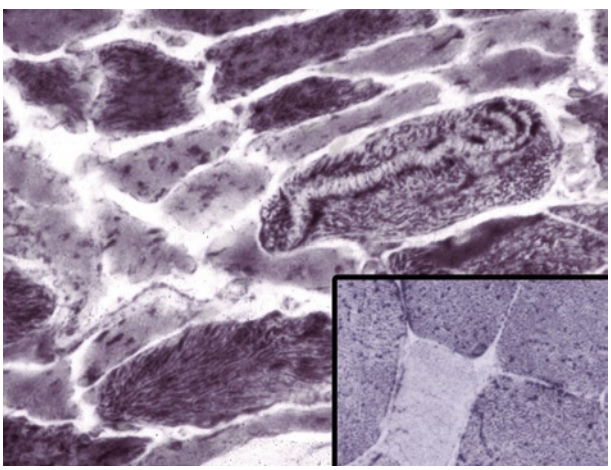

Fig. 76.4 Critical illness myopathy. This NADH-TR-reacted cryostat section illustrates, abnormal, nonhomogeneous staining due to disruptions in the myofibrillar architecture. In particular, the light, atrophic fibers have abnormal clumping of NADH-TR reactivity. The inset reveals normal homogeneous NADH-TR reactivity

a transient increase in mean consecutive differences in muscles subjected to disuse [98].

The roles of SIRS and MODS which often accompany CIM are unclear. Some asthma patients with CIM do not have SIRS or MODS; on the other hand, other patients with CIM have SIRS or MODS without either IVCS or NMBA exposure and develop CIM with thick filament loss [55, 56]. It is uncertain how SIRS or MODS (with disuse) precipitates myopathy in these patients. Sepsis alone may produce a hypercatabolic state resulting in loss of muscle energy stores [99], but it is difficult to explain a relatively selective loss of thick filaments [55, 56]. In patients with SIRS or MODS who receive IVCS with or without NMBAs, these toxins (IVCS and NMBAs) may have enhanced effects due to increased capillary permeability caused by SIRS or MODS [21].

Evidence of inflammation in the form of inflammatory cells is not seen in biopsy specimens, but abnormal upregulation of major histocompatibility complex type 1 is

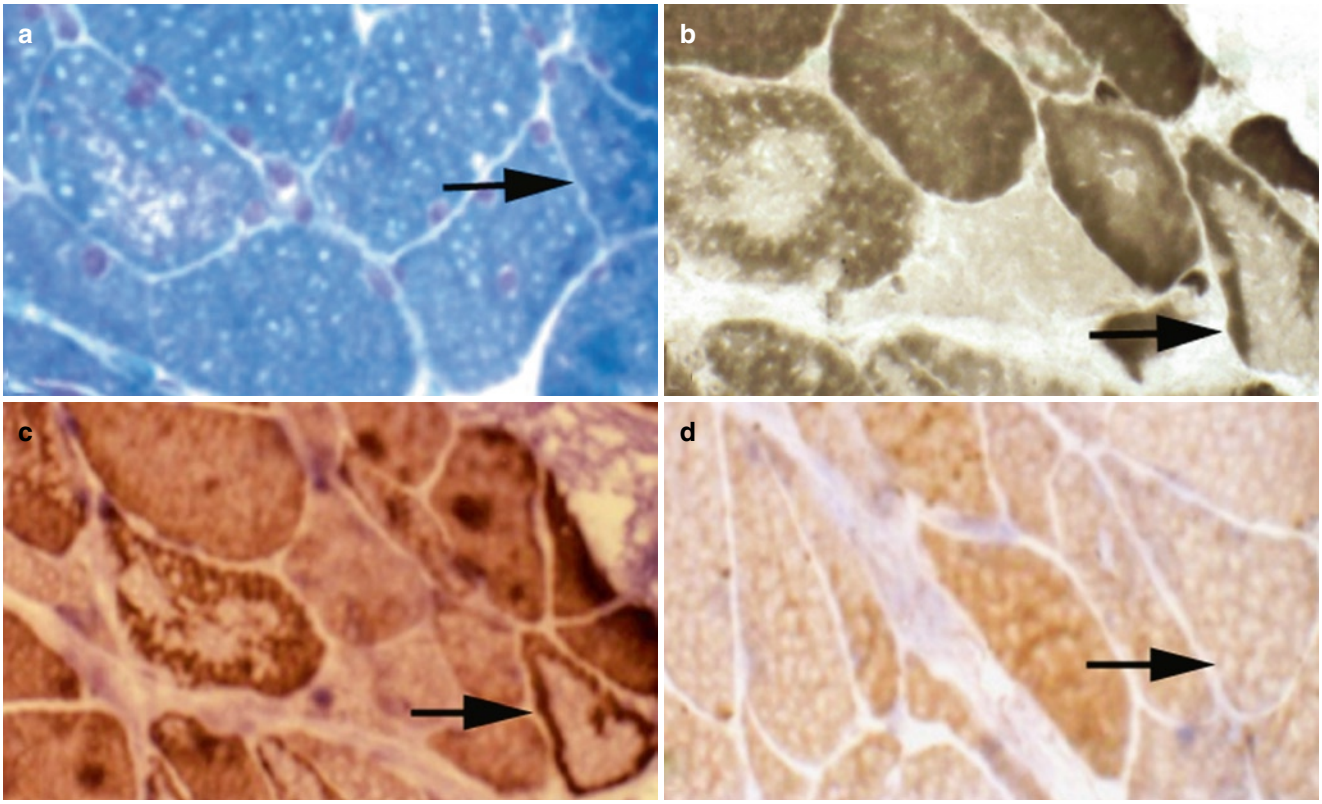

Fig. 76.5 Histologic features of critical illness myopathy from serial cryostat sections. Follow the *arrows* to see the same myofiber in each panel. (**a**). There is an abnormal variation in myofiber sizes without necrosis (Gomori trichrome). (**b**). A myosin-ATPase-reacted section (pH 4.6) reveals reduced or absent central staining in several myofibers and completely absent staining in the fiber at the back of the *arrow*. The abnormal reactivity was also present at pHs 9.4 and 4.3. (**c**). Pan-myosin heavy chain immunoreactivity is absent or reduced in a pattern similar to that illustrated in b. (**d**). Actin immunoreactivity is preserved in this deeper section (bar = 50 μ)

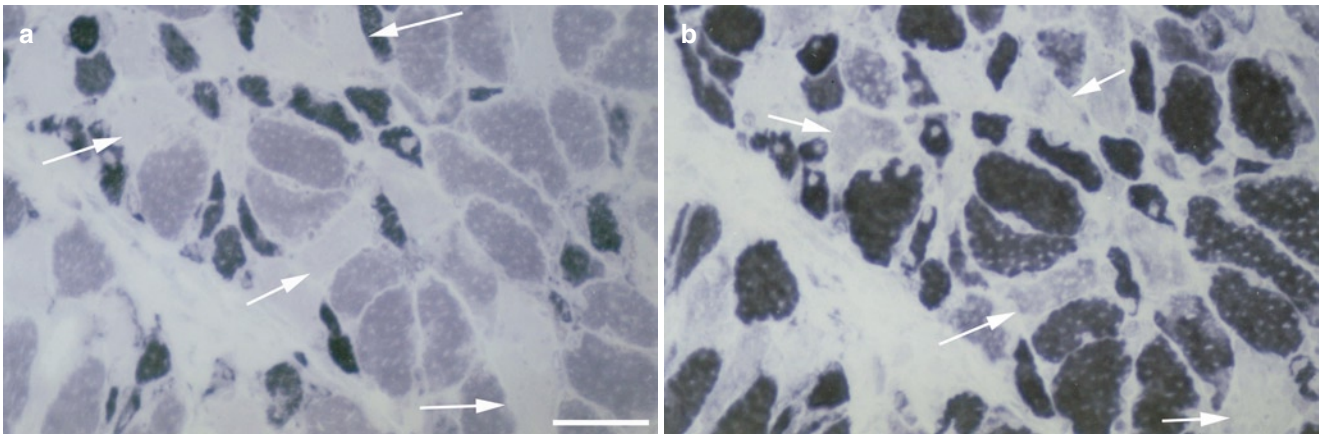

Fig. 76.6 Serial ATPase-reacted sections illustrate myofibers with reduced or absent reactivity at pH 9.4 (**a**) and 4.6 (**b**). At pH 9.4, the abnormal myofibers stain less intensely than the normal light type 1 fibers (see *arrows* for examples of fibers with reduced ATPase reactivity in both panels). Bar = 40 μ

occasionally noted (Fig. 76.3). However, the effects of systemic inflammation on muscle may not be apparent structurally. There is clear evidence of reduced or absent muscle membrane excitability in CIM [100–103]. Perhaps the early effects are on the muscle membrane and involve cytokines and factors such as interleukin-6, insulin-like growth factor (IGF), and IGF-binding protein-1 (IGFBP-I) with impairment of growth-factor-mediated insulin sensitivity [59], and later effects lead to myosin loss. Evidence from animal models points toward abnormal sodium current as the cause of inexcitability [102]. There is relatively increased chloride conductance associated with changes in chloride channel

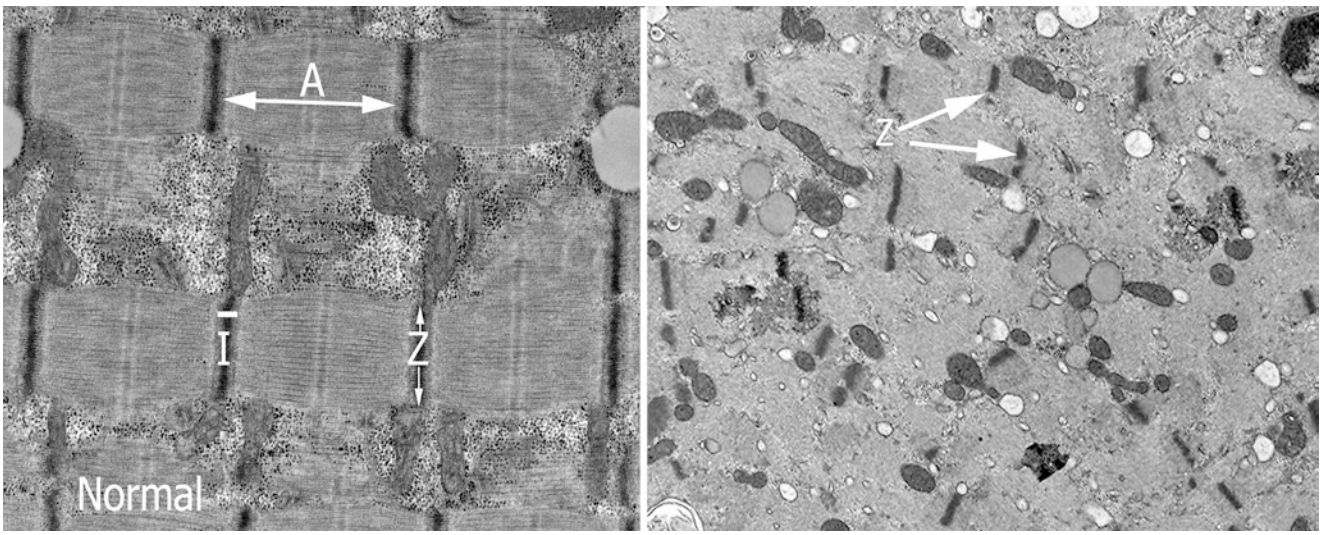

Fig. 76.7 An electron photomicrograph from a patient with critical illness myopathy (*right*) illustrates relatively selective loss of myosin thick filaments and *A* bands with preservation of *Z* lines and *I* bands compared to the normal control on the *left*

mRNA expression. Thus, there is decreased sarcolemmal depolarization when sodium channels open. Sodium current is also reduced, but sodium channel mRNA is increased rather than decreased suggesting that the changes in sodium current are secondary or posttranscriptional and not due to reduced upregulation of Na channels. Others have suggested that calcium ions have a role, but data are conflicting [104, 105]. Oxidative stress may also play a role. It has been hypothesized that loss of sarcolemmal nitric oxide synthase 1 leads to muscle fiber inexcitability by reducing nitric oxide release at the muscle membrane [106]. In septic patients, an increase in muscle nitric oxide synthase 2 mRNA and protein has been associated with peroxynitrate formation and reduced contractile strength [107].

The animal model mentioned above utilizes traumatic soleus denervation and treatment with corticosteroids [108, 109]. After about 7 days of CS exposure, the denervated soleus develops myosin loss. (The animals are otherwise healthy.) If the sciatic nerve is only crushed and allowed to regenerate, the myopathy reverses. Thus, only denervation and CS are required to cause myosin loss as well as sodium channelopathy in this model [91, 102, 108, 109]. Another model using rabbits also provides evidence of negative effects of high doses of intramuscular methylprednisolone on diaphragm muscle function. In the animals, there was a decline in diaphragm maximum muscle tension, myofibrillar disarray, suppression of insulin growth factor type 1, and overexpression of muscle atrophy F-box mRNA as well as activation of the ubiquitin–proteasome pathway [110].

Thus, membrane proteins as well as thick myofilaments and other structural proteins are altered in CIM. Although controversial, it seems that IVCS, functional or structural denervation (NMBAs, denervation-IVCS animal model), critical illness, systemic inflammation, cytokines, possibly disuse, and calpain overexpression have roles in CIM; it is not certain exactly how they trigger myosin loss or incite the pathologic cascade which also involves sarcolemmal ion channels and other structural proteins. Furthermore, it is possible that there are two categories of critical illness myopathy, one with myosin loss triggered by IVCS and one with muscle necrosis only, and that the risk factors differ.

In addition to a thick filament myopathy, the syndrome of CIM may overlap with acute myopathies from *rhabdomyolysis* and with a "catabolic" or *cachectic myopathy* related to chronic illnesses. These disorders warrant separate discussion since they can present in ICU patients. Toxic myopathies that do not result in rhabdomyolysis rarely present in the ICU and are discussed briefly in the "Differential Diagnosis" section of this chapter and extensively in Chap. 68.

The pathogenesis of *rhabdomyolysis* from illicit or pharmacologic drugs, such as cocaine, heroin, and amphetamines [69], is usually unknown. Part of the final common pathway of myocyte injury appears to involve an increase in free sarcoplasmic or mitochondrial calcium with activation of proteolytic enzymes that damage the sarcolemmal membrane [64]. Calcium-related abnormalities may also be shared with CIM and hypermetabolic syndromes associated with rhabdomyolysis (see "Differential Diagnosis" section). Secondary mitochondrial injury could also lead to oxidative cellular damage [65]. Similarly, carbon dioxide gas, when used as an arteriography contrast agent, can also cause rhabdomyolysis, presumably due to tissue hypoxia [111].

Importantly, one particular sedative drug, propofol, that is used in the ICU may cause rhabdomyolysis and has been reported to do so especially in the setting of treatment of nonconvulsive status epilepticus [62]. The pathogenesis is uncertain, but it is important to mention this occurrence, because CIM, prolonged NMBA blockade, and other problems with nondepolarizing NMBAs have led to reduced use of NMBAs and increased use of propofol sedation. Propofol has desirable pharmacokinetic properties (short half-life) and a relatively low incidence of side effects, but at least some physicians recommend that it not be first-line therapy in the pediatric population [62]. In addition to rhabdomyolysis, other reported adverse events include cardiac toxicity, anaphylaxis, movement disorders, seizures, metabolic acidosis, hypoxia, and hypotension. However, it may be difficult to determine if propofol alone or other drugs or associated illnesses cause such adverse events in complicated ICU patients. Nevertheless, it is important to keep in mind that ICU patients receiving propofol who develop weakness may have propofol-induced rhabdomyolysis and not CIM with thick filament loss with which it is also associated [53]. Although the mechanisms of these myopathies may differ, they may be difficult to differentiate without muscle histologic evaluation.

Rhabdomyolysis may also develop in patients with an underlying undiagnosed or known inherited glycogen or lipid storage myopathies in the ICU during stress or fasting. The mechanism of rhabdomyolysis in these disorders is also incompletely understood, but ultimately increased calcium sensitivity of contractile proteins and elevated intracellular calcium lead to muscle injury [112, 113].

As mentioned, rhabdomyolysis may also be caused by viral or bacterial infections. Infections may account for about 5 % of cases of rhabdomyolysis [63], and they certainly may present in the ICU patient. The cause is again uncertain, but lymphocytic or viral invasion of myofibers and cytokine-induced damage (via tumor necrosis factor alpha and interleukin-1 (IL-1)) are possible mechanisms [64].

The mechanism of rhabdomyolysis from vascular compromise and compartment syndrome, which can also occur in the ICU, appears to be "pressure-related." However, some authors noted that patients may retain their pulses and postulated that the compartment pressure may not have to be high enough to completely compromise arterial supply yet it still can cause muscle necrosis [71].

Regardless of the cause, the pathologic changes in rhabdomyolysis range from subtle, scattered myofiber necrosis to severe panfascicular necrosis without selective thick filament loss.

Cachectic myopathy, a vague and poorly described entity, has received more study in medical disciplines other than neurology. Although it is a chronic condition, patients with cachectic myopathy are usually medically fragile and may end up in the ICU with the mildest intercurrent illness. Cachectic myopathy is a known complication of cancer and cardiovascular disease that usually has a component of severe congestive heart failure [114]. It also occurs with severe chronic obstructive lung disease and infections like human immunodeficiency virus. Usually the severe associated medical conditions overshadow any functional limitations due to the myopathy, but sometimes the weakness is the rate-limiting step in discharging the patient from the hospital.

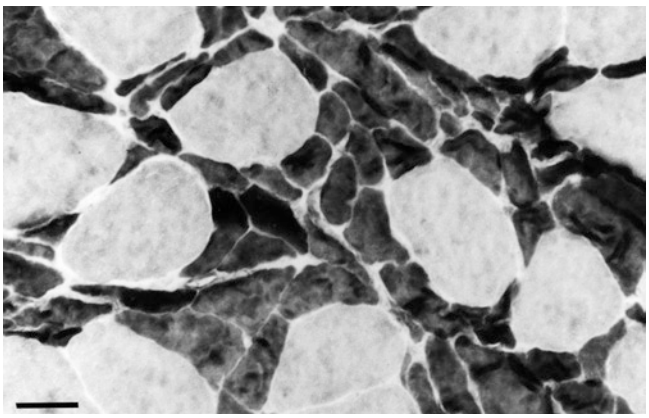

Fig. 76.8 A myosin-ATPase-reacted cryostat section (pH 9.4) reveals prominent atrophy of the dark type 2 fibers in this congestive heart failure patient who was in the intensive care unit for months and was diagnosed with cachectic myopathy (bar = 25 μ)

The exact etiology of cachectic myopathy is unknown. Like many of the entities discussed in this chapter, some authors advocated that cytokines are important precipitating factors. There are also animal models in which cachectic myopathy could be induced by cachectin or IL-1 [115]. In addition, some tumors are reported to secrete cachectin, and both cachectin and IL-1 elevations are thought to lead to cachectic myopathy in humans with malignancies. Myogenic differentiation factor D, which plays an important role in regulating muscle differentiation, may be involved in cachectic as well as in CIM. Myogenic differentiation factor D and other myogenic regulatory factors influence the activity of a number of muscle-specific genes [116].

Even though the mechanisms proposed to cause cachectic myopathy are similar to those proposed to cause CIP and CIM, cachectic myopathy can usually be differentiated from CIM pathologically. In cachectic myopathy, there is no loss of thick filaments and only type II fiber atrophy is seen (Fig. 76.8). In addition, cachectic myopathy is a chronic condition and, therefore, likely has a unique yet incompletely understood etiology. However, until the true pathogenesis of both CIM and cachectic myopathy are delineated, the distinction becomes arbitrary.

The pathophysiology of *prolonged neuromuscular junction blockade* from vecuronium or pancuronium is related to prolongation of circulating drug metabolites usually in the

setting of renal failure [76]. In most cases, it is controversial and unproven as to whether patients with very prolonged weakness (lasting weeks) develop a terminal motor axonopathy or end-plate disorder as the cause of prolonged weakness or whether they have superimposed critical illness polyneuropathy or myopathy. There are few pathologic studies of motor end plates in humans with this disorder. Subtle changes (regeneration) have been noted [117]. Animals with prolonged NMBA exposure may develop subtle end-plate damage with regeneration [118]. In addition, acetylcholine sensitivity may be increased after prolonged NMBA administration [119], and AChR number increases (upregulation) akin to denervation [95].

Clinical Presentation

Patients with *critical illness polyneuropathy* usually present after 1–2 weeks of SIRS or MODS with failure to wean from mechanical ventilation or with diffuse limb weakness, or both [12–14, 47, 120–122]. The exact onset may be difficult to pinpoint given the common associations of encephalopathy and sedation. The disorder is often overlooked unless clinical suspicion is high. Occasionally, the weakness is more pronounced distally. The face is rarely weak, and extraocular muscle weakness is not expected. Tendon reflexes are usually attenuated or lost, but sometimes they are preserved [21]. Distal sensation may be impaired, but sensation is often difficult to assess in the ICU patient. Patients may grimace with painful stimulation but not withdraw limbs. Muscle atrophy, especially in the distal extremities, commonly occurs over weeks.

Patients with *critical illness myopathy* usually also present with failure to wean, flaccid generalized weakness, or both [22]. The disorder is usually recognized days to weeks after exposure to IVCS with or without NMBAs. Sometimes proximal and rarely distal muscles are predominantly affected. The degree of weakness varies from mild to severe. Only with rare exception is the weakness asymmetric [123]. Neck flexor, facial, and diaphragm muscles are also commonly affected, and rarely extraocular muscles are involved [36, 45, 47]. Tendon reflexes are usually reduced or lost, but they may be normal. Sensation is normal if it can be assessed. Encephalopathic patients with CIM usually only grimace to pain since they are too weak to withdraw noxiously stimulated limbs. In addition, muscle wasting is sometimes present [24, 55].

Patients with *rhabdomyolysis* usually have proximal more often than diffuse weakness, but weakness can be diffuse. About 50 % have muscle swelling and myalgias that may be the predominant symptoms. Focal pain and swelling from compartment syndromes may be present. Tendon reflexes and sensation are normal. Other symptoms and signs can be protean and include hyperthermia, bleeding from coagulopathy, malaise, fever, tachycardia, abdominal pain, nausea, vomiting, and encephalopathy from the high levels of urea. Inadequate ventilation, hypoxemia, and respiratory acidosis may also occur. There may be metabolic acidosis from the release of sulfate and phosphate ions from muscle cells. Potential major complications include cardiac conduction abnormalities and arrest, compartment syndrome, and acute renal failure.

Cachectic myopathy may present in a chronically ill appearing patient. There may be acute to subacute progressive proximal weakness and a history of more chronic painless proximal weakness with associated diffuse muscle atrophy.

Prolonged *neuromuscular junction blockade* also presents as flaccid generalized weakness with failure to wean and areflexia that persists (usually for days) after NMBAs are discontinued [76, 77]. Cranial muscles may be affected, and the presence of significant extraocular muscle involvement should alert the clinician to this diagnosis since it is uncommon in CIM and not reported in CIP [124]. Patients recover over hours to days unless there is an associated terminal motor axonopathy, CIM, or CIP.

Differential Diagnosis of Weakness in the Intensive Care Unit (Table 76.1)

In the ICU patient, both prolonged ventilator dependence (in the absence of pulmonary disease [125–127] or phrenic nerve trauma) and acute flaccid generalized weakness are usually of peripheral nervous system origin, but central nervous system processes such as septic or toxic encephalopathy, an ischemic or hemorrhagic brainstem stroke, or central pontine myelinolysis should be considered as causes or contributors to weakness. Acutely, upper motor neuron signs may or may not be present. We have also found, however, that it is not uncommon for patients to have concurrent encephalopathy and weakness, the latter being of neuromuscular origin. In such instances, neuromuscular weakness may be overlooked. It is unlikely for septic or toxic encephalopathy alone to cause severe flaccid weakness.

Cervical myelopathy from tumor, trauma, inflammation, or ischemia may also produce flaccid quadriplegia acutely usually with sphincter dysfunction and a sensory "level." Nerve conduction studies are normal in such patients. Needle electrode findings may be normal except for reduced recruitment; however, fibrillation potential activity may be present simulating a lower motor neuron disorder [128].

In addition to CIP, other acute polyneuropathies to consider include Guillain–Barré syndrome (GBS) and rarely porphyric, toxic, vasculitic, paraneoplastic, and nutritional neuropathies. Axonal GBS (acute motor sensory axonal

neuropathy or AMSAN) may be particularly difficult to differentiate from CIP, but axonal GBS is unlikely to present while the patient is in the ICU for treatment of another disorder. In addition, many patients with axonal GBS have an antecedent, usually diarrheal, illness from *Campylobacter jejuni*; and, as opposed to CIP, they tend to lack spontaneous activity on EMG at the time of initial diagnosis [120]. Acute motor axonal neuropathy (AMAN) often follows Campylobacter infection also and presents like AMSAN but without sensory involvement.

A motor axonal neuropathy or terminal motor axonopathy from NMBAs has been reported; however, it has not been proven that this entity is a separate disorder because some of these patients may have actually had CIM – no muscle pathology reviewed – or CIP. An experimental model is needed to determine if this condition exists. Limited animal data (frog) only reveal subtle changes at the motor end plate after long-term curare exposure [118].

Motor neuron diseases (amyotrophic lateral sclerosis or viral poliomyelitis including West Nile virus) can present with respiratory failure precipitating ICU admission; however, such processes only very rarely present during an ICU admission for another disorder. It is thought that patients may also rarely develop diffuse anterior horn cell injury acutely after hypoperfusion or hypotension [129].

Neuromuscular transmission defects can be precipitated by aminoglycosides, lithium, anesthetic drugs, and hypermagnesemia and can unmask myasthenia gravis. Lambert–Eaton myasthenic syndrome can also result in respiratory failure requiring ICU treatment. Lastly, botulism, especially wound botulism, can occur in the ICU patient.

Myopathies other than CIM and rhabdomyolysis are rarely diagnosed in the ICU and are usually responsible for respiratory failure or aspiration which results in ICU admission. They include polymyositis, dermatomyositis, viral myositis, acid maltase deficiency, mitochondrial myopathy, and muscular dystrophies. Pyomyositis rarely develops in "septic" patients. It is also conceivable that trichinosis or sarcoid myopathy could be severe enough to lead to ICU admission. Hypophosphatemic and hypokalemic myopathies may also develop in the ICU [99].

Nonsteroidal toxic myopathies that do not cause overt rhabdomyolysis may rarely present in the ICU and may be difficult to identify in the setting of multiple medical problems or multiorgan dysfunction. These disorders may cause some muscle necrosis and present in either an acute or subacute fashion with proximal more often than diffuse weakness and sometimes with myalgias and muscle tenderness. As causes of ICU weakness, their true incidence is uncertain, but it is probably low [61]. Therefore, the neurologist consulted for evaluation of proximal weakness in the setting of MODS or SIRS would probably consider CIM as the first diagnostic choice, but toxic myopathy should be considered if the patient is receiving a potentially myotoxic medication especially in the setting of MODS or changes in medications which can slow drug metabolism.

Two toxic drugs that warrant specific mention are colchicine and hydroxychloroquine. Colchicine can affect transplant patients who are often in the ICU [130]. We specifically noted colchicine neuromyotoxicity in heart transplant patients taking multiple drugs including cyclosporin and with renal insufficiency [130]. Cholesterol-lowering drugs may also increase the risk of colchicine myotoxicity in addition to causing myopathy by themselves. The ultimate cause of most toxic myopathies is usually unknown, but colchicine toxicity is probably due to disruption of microtubules involved in lysosomal processing. Hydroxychloroquine can cause a vacuolar myopathy that causes ventilatory failure as well as limb weakness, leading to an ICU admission [131].

As discussed earlier in this chapter, rhabdomyolysis can also cause ICU weakness. In addition to the aforementioned

drugs and infections, there are also several specific hypermetabolic states that cause rhabdomyolysis. They may occur in the ICU or lead to ICU admission. These syndromes are rare and are not easily confused with other causes of ICU weakness because they usually also affect the central nervous system. These hypermetabolic or hyperexcitable syndromes include malignant hyperthermia (MH), neuroleptic malignant syndrome (NMS), central anticholinergic syndrome, heat stroke, and serotonergic syndrome [132, 133]. The illicit drug "ecstasy" can also cause a hyperthermia syndrome with seizures, tachycardia, and rhabdomyolysis [134]. Malignant hyperthermia is reviewed in Chap. 54. Neuroleptic malignant syndrome is thought to occur due to a central disorder of dopaminergic blockade affecting hypothalamic thermal regulation. It is also associated with hyperthermia, encephalopathy, muscle rigidity, tachycardia, leukocytosis, and autonomic dysregulation and usually evolves hours to days after initiation or increased doses of neuroleptic medication or rarely during withdrawal of dopaminergic medications used to treat Parkinson's disease. It can occur in treated Parkinson's disease patients who are admitted to the ICU and have their oral medications discontinued.

Central anticholinergic syndrome (from anticholinergic toxicity) can be associated with rhabdomyolysis and also consists of dry mouth, dilated pupils, urinary retention, and increased body temperature. It can overlap with heat stroke which is due to thermoregulatory failure in spite of a normal set point for temperature. Exertional heat stroke occurs in normal individuals after significant exercise, possibly in extreme conditions such as warm humidity. While this condition might be in the differential weakness in the ICU, classic heat stroke is more common and occurs in patients who develop a usually acquired inability to dissipate heat due to medical problems such as obesity, alcohol, illicit drugs (amphetamines), or medications, such as anticholinergics, that reduce sweating [133]. There can be an associated mild leukocytosis and dehydration with hyponatremia. In addition to rhabdomyolysis, renal failure, liver damage, and disseminated intravascular coagulation can also occur. Interestingly, cold temperatures can also produce rhabdomyolysis, perhaps from vasoconstriction and excessive energy demands.

Serotonergic syndrome, which is associated with the use of serotonergic reuptake inhibitors and Eldepryl, includes agitation, disorientation, confusion, and occasionally coma. Frequently, there are autonomic instability and leukocytosis in addition to rhabdomyolysis. This syndrome is felt to progress more rapidly and with less rigidity and myoclonus than NMS although there is overlap. There is also overlap in the supported pathogenetic mechanisms of these syndromes, and some appear to share a final common pathway.

Patients with these hypermetabolic syndromes all tend to have associated encephalopathy and rhabdomyolysis along with the features noted above; thus, they could easily be confused with septicemia or SIRS, and the patient could be diagnosed with associated CIM. It should be noted that elevated cytokines (like in so many of these disorders) have been reported to be the mechanism of muscle cell injury in these patients.

Evaluation and Diagnosis

Laboratory and Electrophysiologic Studies (Table 76.2)

In critical illness polyneuropathy, the cerebrospinal fluid and the serum creatine kinase (CK) are usually normal [47]. Electrophysiologic studies are consistent with a diffuse sensorimotor axonal polyneuropathy manifest as reduced sensory and motor amplitudes with no or minimal conduction slowing. The findings are usually noted in a week or two after ICU admission, but they may occur earlier. In a population of septic patients with CIP and CIM, low motor

Table 76.2 Summary of features and diagnostic criteria for CIM and CIP

Both CIM and CIP
Following onset of critical illness, the patient develops generalized, flaccid weakness with or without difficulty weaning from mechanical ventilation in the absence of another neuromuscular disorder
Absence of decremental response with 2–3 Hz repetitive stimulation
CIM[a]
Normal or minimally reduced sensory nerve amplitudes
Low motor responses with broad, long-duration CMAPS *or* low-amplitude CMAPs and early recruitment of short-duration motor unit potentials on EMG with or without fibrillation potentials, *or* low CMAP amplitudes and direct muscle stimulation consistent with reduced muscle membrane excitability (nerve-evoked to muscle-evoked CMAP ratio >0.5) *or* muscle biopsy demonstrating myosin loss
CIP
Low-amplitude CMAPS *and* sensory responses *or* low-amplitude CMAPS responses and the lack of myosin loss on muscle biopsy or direct muscle stimulation findings consistent with neuropathy (nerve to muscle ratio <0.5)
Absence of prolonged F-waves, conduction block, and substantial slowing of conduction velocities
EMG revealing reduced recruitment of normal MUPs and fibrillation potentials early in the course or high-amplitude long-duration MUPs later

[a]Elevated serum creatine kinase level is a supportive feature

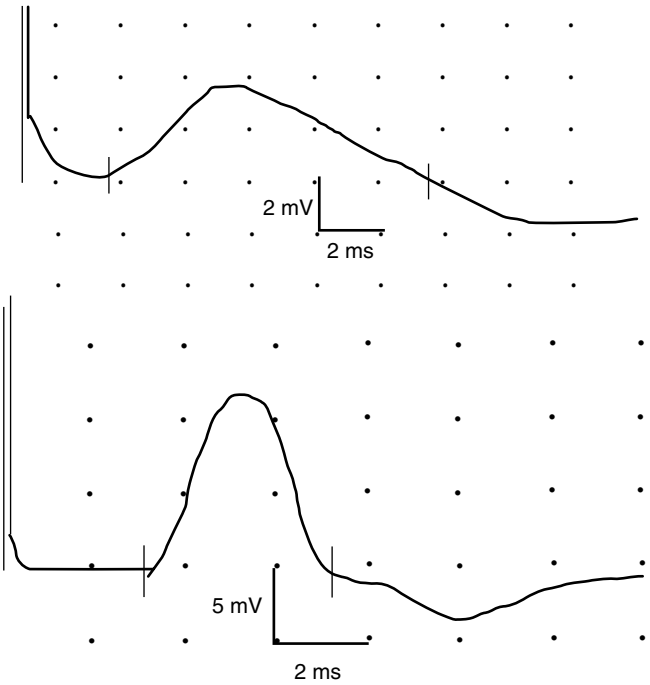

Fig. 76.9 The *top panel* illustrates a low-amplitude, broad, long-duration CMAP from a patient with CIM. The *bottom panel* is a normal for comparison

responses were seen within 72 h of admission in 63 %, and the findings were predictive of mortality. Twenty-one percent went on to have mostly mixed CIP and CIM [7].

Needle electrode examination usually reveals widespread spontaneous activity (positive waves and fibrillation potentials) [12, 14, 47, 120, 135]. Voluntary motor unit potentials (MUPs) are reduced in number and may be small and polyphasic during early reinnervation [15]. If studied, the phrenic nerve amplitudes are often reduced, and the diaphragm needle examination may reveal fibrillation potentials [127].

It is controversial as to whether CIP patients can have normal sensory responses [82, 135, 136]. Careful correlation with histopathologic examinations that at least exclude myopathy is necessary to resolve this issue. In particular, myosin loss should be excluded. Serial electrophysiologic studies or direct needle stimulation (discussed below) may also be useful. Sophisticated electrophysiologic studies have shown a predominance of myopathy in mixed cases of critical illness myopathy and neuropathy [137]. Additionally, a more recent study of 33 ICU patients with marked weakness prospectively assessed by electrodiagnostic testing and percutaneous muscle biopsy also showed that myopathy was highly predominant over the neuropathic impairment [138]. Therefore, some authors suggest that muscle biopsy should be performed more frequently as it establishes the diagnosis of at least a component of CIM in many patients especially since EMG can be technically difficult in ICU setting [139]. In our experience, CIP alone is uncommon, and most of the cases are associated with CIM.

In at least half of patients with *critical illness myopathy,* the creatine kinase is elevated especially early in the course. Usually, the elevation is less than 50-fold, but some patients have higher elevations. CK is usually normal later in the course of the disease. Prospectively studied and one group of retrospectively studied status asthmaticus patients with CIM all had an elevated CK [38, 44]. Thus, it is possible that the CK elevations may be missed in some patients because the CK has fallen by the time the diagnosis is suspected. This occurrence relates to the fact that patients become weak while they are sedated or pharmacologically paralyzed. In fact, Douglass et al. prospectively noted that the CK peaks at 3.6 ± 1.5 days and the elevation lasts 9.8 ± 6 days [38]. This elevation pattern is similar to that seen with rhabdomyolysis. We often see patients not diagnosed with CIM until weeks after probable onset of weakness, and their CK is usually normal.

In CIM, magnetic resonance imaging of skeletal muscle may demonstrate nonspecific, diffuse high-intensity signals on both T2-weighted images and the short-tau inversion recovery (STIR) sequence with isointense signals on T1-weighted images in both proximal and distal muscles [140].

Nerve conduction studies in CIM frequently reveal low motor amplitudes with normal conduction velocities. Occasionally, motor amplitudes are normal. CMAP durations may also be increased in multiple nerves in varying degrees due to slow conduction through the muscle membrane [103, 141–143] (Fig. 76.9). Sensory amplitudes are usually normal or mildly reduced compared to motor responses [47]. (Patients with low sensory responses may have superimposed CIP, a preexisting PN, or edema at recording sites.) Only rarely is there a transient decremental response with 2–3 Hz repetitive stimulation of motor nerves consistent with superimposed neuromuscular junction blockade [49]. Serial studies showed an increase in motor and sometimes sensory amplitudes during recovery [47]. Needle electrode examination reveals widespread positive waves and fibrillation potentials in 56–100 % of patients [22, 38, 44, 46–48, 53]. The fibrillation potential activity is variable in degree. Complex repetitive discharges [42, 44] and rarely myotonia [48] may be present. Abnormal spontaneous activity can be seen as early as 7 days after treatment with IVCS and NMBAs [42]. Motor unit potentials may not be recruited in very weak patients. Occasionally, only a few MUPs may be transiently recruited. In milder cases, there may be normal to more often, early recruitment of short-duration, often low-amplitude, and polyphasic MUPs. These "myopathic" motor unit potential changes become more apparent during recovery while spontaneous activity disappears [42]. In patients who cannot recruit MUPs well, it may not be possible to differentiate a motor axonopathy (possible variant of CIP)

from CIM without a muscle biopsy. In these patients especially, there is utility for the technique of direct muscle stimulation (DMS).

Rich et al. noted that some muscles in patients with CIM were inexcitable to direct electrical stimulation, whereas denervated muscles maintained normal excitability despite atrophy [100, 101]. These investigators then noted that needle-evoked (nerve-stimulated) compound muscle action potential (neCMAP) amplitudes were reduced in both myopathy and neuropathy but that the compound muscle action potentials obtained with direct needle stimulation of muscle (dmCMAP) were lower in myopathy patients [101]. Thus, a nerve/muscle ratio of the neCMAP/dmCMAP is close to 0 or at least <0.5 in patients with neuropathy and close to 1 if the patient has myopathy. (Both absent responses equal a ratio of 1.) They also noted that a patient undergoing vecuronium neuromuscular junction blockade had a preserved dmCMAP despite an absent neCMAP excluding acute neuromuscular junction blockade as a cause of the high neCMAP/dmCMAP ratio in CIM. Furthermore, a patient with periodic paralysis (membrane inexcitability) had findings similar to those of patients with CIM supporting the contention of membrane inexcitability in CIM [101]. Others have confirmed these results and also used DMS to demonstrate slowing of muscle fiber conduction as well as reduced muscle fiber excitability by DMS and by using paired stimuli [103]. In addition, velocity recovery cycles of muscle action potentials have also been used for assessment of muscle membrane properties in CIM. In ten patients, velocity recovery cycles were recorded from the brachioradialis muscle by DMS. Muscle fibers were depolarized likely because sodium channel inactivation was increased [144].

Utilizing all the known clinical, laboratory, and electrodiagnostic features described above, clinicians and researchers have proposed diagnostic criteria for CIM and CIP [145–147] (modified in Table 76.2). Differentiating these entities is critical for research studies that especially address risk factors and pathogenesis. In clinical practice, differentiation may be less critical, but it does provide prognostic as well as diagnostic information. (Patients with CIM tend improve faster than those with CIP as discussed below.)

Laboratory abnormalities associated with *rhabdomyolysis* include a highly elevated CK, increased or reduced potassium, reduced phosphate, increased creatine, and reduced calcium. Blood urea nitrogen and creatinine will be elevated if there is secondary renal injury. However, visible myoglobinuria is not always present; renal failure may or may not occur. A rise in serum myoglobin precedes the increase in CK, and CK peaks within 1–3 days and can decline by 3–5 days; therefore, if a CK is not assessed during this interval, rhabdomyolysis cannot be excluded by a normal CK obtained later. Urine chemistries may reveal hyperuricemia, myoglobinuria, or pigmented granular casts. Nerve conduction studies are usually normal, and fibrillation potentials of varying degrees may be present in a patchy or generalized fashion. However, EMG findings may be normal [148].

In *cachectic myopathy*, the CK is normal. The electromyogram may reveal motor unit potential changes consistent with myopathy but usually without associated significant spontaneous activity.

Reported electrophysiologic studies in patients with *prolonged neuromuscular junction blockade* are often limited to train of four (TOF) stimulation which shows a reduction or absence of twitches. In a few cases, 2–3 Hz repetitive nerve stimulation also revealed a decremental response [47, 49, 50, 76]. Inexcitable nerves were reported in another patient [77]. The use of stimulated single-fiber EMG has not been reported. Needle electrode examinations in a few patients revealed spontaneous activity [76]. Short-duration motor unit potentials may also be present [50].

Treatment, Management, and Prognosis

General Principles

All critically ill patients, including those with neuromuscular weakness, require adequate nutritional intake, correction of underlying metabolic disorders such as hypokalemia and hypophosphatemia, and aggressive treatment of underlying infections since all of these metabolic abnormalities can aggravate weakness.

Since paralyzed limbs are susceptible to deep venous thrombosis, prophylaxis via either subcutaneous heparin or pneumatic devices is warranted. Frequent turning and padding of pressure points is important to avoid development of decubitus ulcers or nerve entrapments.

If the patient is not yet receiving mechanical ventilation, the risk of and likelihood of respiratory compromise must be assessed by serial assessment of vital capacity and negative inspiratory force and monitoring their clinical signs and symptoms to determine if and when tracheal intubation is required.

Patients with neuromuscular respiratory failure may require prolonged ventilatory support. If the clinical and electrodiagnostic findings are consistent with significant neuromuscular respiratory weakness, early tracheotomy is indicated to improve pulmonary toilet.

Initially, physiotherapy is generally limited to range of motion and bracing to prevent contractures (especially at the ankles). As patients recover, inpatient rehabilitation is often required [24]. A recent study showed that the majority of patients discharged from the ICU with critical illness polyneuropathy and myopathy and treated in a neuro-rehabilitation setting had a good functional outcome. The mean length of

inpatient rehabilitation stay was 76.2 ± 28.1 days. At discharge, 57.1 % of patients achieved good recovery [149]. A small minority required long-term care. Due to residual deficits in some, ankle foot orthoses may be required long term as well as other assistive devices for ambulation. Rehabilitation for patients with CIP/CIM should be started as soon as possible after diagnosis, because the improvement in function decreases as the time from established diagnosis to the start of rehabilitation increases [150].

Critical Illness Polyneuropathy

Aside from the general principles noted above, there are no proven specific therapies. The use of intravenous immunoglobulin (IVIG) has generated interest, but it has not been well studied. A small pilot study showed no obvious improvement in PN with IVIG [151]. A prospective, uncontrolled study of 33 patients with MODS (16 with gram-negative septicemia) suggested that 0.9 g/kg of IVIG given over 3 days may prevent CIP in patients with septicemia or SIRS [152], but a prospective controlled trial is necessary to make that determination.

In CIP, there is a high mortality rate (up to 50 %) due to the underlying disease [21]. However, survivors tend to recover partially (severe PN) or fully (mild to moderate PN) over months, and milder forms may "resolve" in weeks [21, 149]. About 22 % of patients with CIP have severe residual handicaps at 1 year [153], and, as with most axonopathies, distal leg weakness is the most common residual effect.

Critical Illness Myopathy

There is no specific treatment for CIM, but the general principles noted above apply. Prevention is ideal if possible. Limiting intravenous corticosteroids or paralytic agents in ICU patients is recommended in order to make occurrence less likely, and these agents should generally not be used without proof of utility. In particular, avoidance of continuous or high-dose recurrent NMBAs is suggested. The use of train of four monitoring and serial assessments of serum creatine kinase during use of paralytic agents may also help reduce the incidence of CIM theoretically. Some investigators recommend the use of non-aminosteroid NMBAs such as atracurium; however, atracurium is also clearly associated with CIM, and there is no proof that this more expensive agent leads to a lower incidence of CIM. Patients could also be monitored for CIM as well as CIP by serial peroneal motor responses. A unilateral peroneal CMAP reduction of more than two standard deviations of normal value was sensitive (100 %) and moderately specific (67 %) in diagnosing critical illness neuromuscular weakness in one study, and all patients developed the electrophysiological findings within 13 days of ICU admission [154].

Once CIM is identified, corticosteroids should be tapered or discontinued if possible. Rechallenge with IVCS should be avoided, if possible, since CIM may recur [28]. There is conflicting data about the beneficial effect of strict glucose control and the duration of mechanical ventilation in CIP and CIM [84]. In our opinion, the beneficial effect has not been fully proven, and more studies need to be done before we reach a final conclusion.

Patients with CIM who do not succumb to their underlying disorder usually recover over weeks to months, and most recover fully. However, there is considerable morbidity and increased medical costs associated with CIM. For example, the mean time to ambulation is about 8 weeks, and in one study of liver transplant patients with CIM, the time in the ICU was 49 ± 36 days (mean ± SD) vs. 14 ± 14 days for those without CIM [48]. Although patients with CIM are generally in poorer health overall, failure to wean from CIM is a major contributor to prolonged ICU stays.

Patients with *mixed CIM and CIP* tend to recover more like patients with CIP. In those patients, CIM tends to occur before CIP, and the addition of CIP likely prolongs ICU stays and delays the recovery [155].

In patients with *rhabdomyolysis*, intravenous hydration with alkaline diuresis is recommended to avoid renal failure [71]. Analgesics can be used for myalgias. Medical complications, such as hyperthermia, coagulopathy, hypoxemia, and acidosis, may also require treatment. Compartment syndromes require orthopedic evaluation for possible fasciotomy.

In patients with *cachectic myopathy*, there has been a treatment paradigm proposed using branched chain amino acids (BCAAs). BCAAs did not alter muscle protein catabolism, but they did increase intracellular amino acid nitrogen pools. The clinical significance of this finding is unknown [114]. The prognosis of cachectic myopathy is likely different than in CIM or CIP in that it almost entirely depends on treatment of the underlying condition so that normal activity can be resumed.

Prolonged Neuromuscular Junction Blockade

This disorder is self-limited; therefore, prevention is optimal. It is felt, but not proven, that the process can be avoided by paying careful attention to train of four monitoring. In general, avoidance of continuous infusions of NMBAs or recurrent boluses is advised, and one should consider alternative therapies such as propofol or other sedatives. However, propofol use has also been associated with rhabdomyolysis [62] and CIM (in association with IV corticosteroids) [53]. Once prolonged NMJ blockade is identified, administration

of neostigmine or edrophonium may transiently reverse the weakness; but, generally, it persists for days until the metabolites are excreted. Patients with prolonged weakness, which can be due to CIM, CIP, or end-plate myopathy, may then require rehabilitation.

Floppy Infant

77

Bassam A. Bassam

The floppy infant syndrome (FIS) is characterized by prominent generalized hypotonia. Hypotonia manifests with diminished muscle tone and resistance to passive movements, excessive joint mobility, abnormal infant postures, and a variable degree of weakness. Hypotonia at birth, or during the first 6 months of life, is a nonspecific sign because it may be encountered with many illnesses.

The first step in the differential diagnosis is a detailed clinical history, including developmental milestones, and a physical examination, with careful observation for dysmorphic features that might suggest chromosomal abnormalities or syndromic patterns. Examination for hypotonia is usually carried out with the infant at rest, the head in midline position, and the limbs moved passively (Fig. 77.1). The truncal tone is assessed by suspending the infant with the abdomen held on the examiner's hand. A normal, full-term infant assumes a posture with straightened back, flexed limbs, and straight head; a hypotonic infant drapes over the examiner's hand "inverted U sign." The shoulder-girdle tone may be assessed by suspending the infant vertically while supporting the axillae. A full-term infant adducts the arms and fixes the shoulders, whereas a hypotonic infant tends to slip through the examiner's hands "scarf sign." Laboratory tests, including muscle enzymes, electrodiagnostic (EDX) studies, and muscle biopsy with histochemical stains and electron microscopy, are helpful in the diagnosis of peripheral neuromuscular disorders that may cause FIS.

The differential diagnosis of FIS includes a wide variety of causes that may be related to the central nervous system (CNS), anterior horn cell, peripheral nerve or muscle disorders, as well as connective tissue disorders, mitochondrial disorders, or systemic illness (Table 77.1 and Fig. 77.2) [1]. In some disorders, both the CNS and neuromuscular system are simultaneously involved. Analysis of three clinical series showed that chromosomal disorders accounted for 31 % of the elucidated diagnosis (CNS anomalies were present in 13 %, myopathies in 5 %, congenital myotonic dystrophy in 4 %, spinal muscular atrophy in 2 %, muscular dystrophy in 2 %, and inborn errors of metabolism in 3 %) [2]. When only one limb is affected, traumatic neuropathy, or more commonly brachial plexus palsy, should be considered.

Central Nervous System Disorders

Approximately 80 % of floppy infants have primary acute or chronic CNS diseases. Usually, the clinical diagnosis is readily recognized by the neurologist, and neither EDX studies nor muscle biopsy is necessary. Despite prominent hypotonia, these infants often have better muscle strength than tone and may have normal strength or only transient weakness early in life. Increased tendon reflexes, seizures, obtundation, or delayed intellectual and language milestones suggest a CNS disorder (Table 77.2).

Acute Central Nervous System Diseases

Acute CNS causes of FIS include perinatal hypoxia, sepsis and meningitis, birth trauma, intracranial hemorrhages, intoxication, drug withdrawal, inborn errors of metabolism, and acquired metabolic disturbances of glucose, calcium, and electrolytes. *Hypoxic-ischemic encephalopathy* is by far the most common cause of all hypotonia in newborns. Acute CNS diseases, such as birth trauma, intraventricular hemorrhage, or asphyxia, may have prominent hypotonia and decreased reflexes early in life, which change to hyperreflexia in early childhood.

DOI 10.1007/978-1-4614-6567-6_77,

Fig. 77.1 An infant with infantile spinal muscular atrophy (SMA I, Werdnig-Hoffman disease) lies flat and floppy, with the legs spread in a "frog leg" position and the arms externally rotated with the elbows flexed (**a**). Note also the triangular mouth and facial expression consistent with bifacial weakness. On sitting, the infant cannot sustain his head upright (**b**), and the head falls back when he is pulled by the arms (**c**). While held supine, there is no active truncal tone and the head and limbs drop by force of gravity (**d**) (Reprinted from Bradley et al. [48])

Chronic Central Nervous System Diseases

Chronic CNS diseases associated with FIS include neural tube defects, microcephaly, cerebral and cerebellar malformations, congenital infections, cerebral lipidoses, chromosomal disorders, and dysmorphic syndromes. Long-term follow-up study showed that *cerebral palsy* and *mental retardation* are common chronic CNS causes of FIS [3]. Hypotonia associated with ataxia is often seen in disorders of the cerebellum and with choreoathetosis in basal ganglia dysfunction. Spinal cord malformations or injuries, such as those seen in a difficult breech delivery, may be associated with hypotonia, weakness, and a sensory level, with normal muscle strength and tone above the involved level. Among the dysmorphic syndromes known to be associated with hypotonia are Prader-Willi syndrome, Cohen syndrome, Zellweger

syndrome, Lowe's syndrome, and Down syndrome. In many of these syndromes, hypotonia is an early manifestation at birth, and children develop the more classic signs of the syndrome over time. Chromosomal studies are confirmatory with a limited but ever-increasing number of conditions and are indicated in evaluating the hypotonic infant with dysmorphic features. In genetically determined conditions with a metabolic defect resulting in hypotonia and various physiologic and mental impairments, such as storage disorders and phenylketonuria, the diagnosis relies exclusively on laboratory analysis of certain enzymes or metabolic products. Additionally, the high-resolution imaging technology and unprecedented advances in genetic technology in the last decade have increased our abilities to establish a specific diagnosis for a significant number of genetic disorders.

Motor Unit Disorders

Approximately 20 % of patients with FIS have neuromuscular diseases, including anterior horn cell disorders, neuropathies, neuromuscular junction disorders, and myopathies (Table 77.3). Infants with lower motor neuron disorders usually have profound weakness proportional with the severity of hypotonia, decreased or absent tendon reflexes, and abnormalities on muscle enzymes, EDX studies, edrophonium (Tensilon®) test, or muscle biopsy. Examination of the child's mother in suspected neonatal myasthenia gravis or congenital myotonic dystrophy may render additional diagnostic evaluation unnecessary. The following is a brief discussion of motor unit disorders associated with FIS.

Table 77.3 Motor unit disorders associated with the floppy infant syndrome

Anterior horn cell disorders
Spinal muscular atrophy
Spinal muscular atrophy I (Werdnig-Hoffmann disease)
Spinal muscular atrophy II (intermediate form of SMA)
Glycogen storage type II (Pompe's disease)
Enterovirus infection (Coxsackie, ECHO, polio)
Organic aciduria (biotin-responsive carboxylase deficiency)
Peripheral neuropathies
Guillain-Barré syndrome
Toxic (heavy metals)
HMSN type III (Dejerine-Sottas disease)
Congenital hypomyelinating neuropathy
HMSN type I variant (rare)

Anterior Horn Cell Disorders

Most neurogenic cases of severe weakness and hypotonia in infancy are secondary to spinal muscular atrophy (SMA) type I (acute infantile or Werdnig-Hoffmann disease). Rare cases are due to organic aciduria or glycogen storage type II (Pompe's disease) or are associated with enterovirus infections.

The SMAs are a group of heterogeneous disorders characterized by degeneration of motor neurons within the anterior horn of the spinal cord and in the motor nuclei of the brain stem (see Chap. 21). They may arise in the newborn, during childhood, adolescence, or adult life. The infantile form of SMA is the most severe among the group, but less severe chronic forms of infantile SMA are well known [4]. *Acute infantile SMA* (*type I*, *Werdnig-Hoffmann disease*) is an autosomal-recessive disease that usually presents at birth or during the first few months of life. The infant has hypotonia, areflexia, and severe generalized weakness, including bulbar and respiratory muscles. Facial expression, strength, and ocular movements are preserved, and the infant looks fully alert and is often smiling. Tongue fasciculations may be observed. EDX studies reveal normal motor conduction velocity for age, low-amplitude CMAPs, widespread fibrillations, diminished number of motor unit action potentials (MUAPs); some are of long duration and polyphasic potentials. However, early EDX studies may give ambiguous results. Muscle biopsy is essential for the diagnosis, often showing mixed atrophic with hypertrophic fascicles (Fig. 77.3). Most infants die within the first 2 years of life due to aspiration pneumonia and respiratory failure [5]. In the *chronic infantile form of SMA* (*type II*, *intermediate*), the infant looks normal at birth. Weakness and hypotonia usually appear between 6 and 18 months of age. The pelvic girdle is

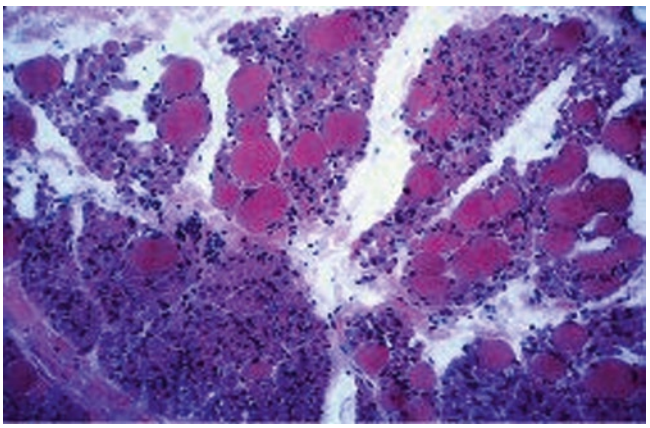

Fig. 77.3 Muscle biopsy in spinal muscular atrophy (SMA I, Werdnig-Hoffman disease). Typically, the severe form of SMA exhibits markedly hypertrophic fibers among atrophic fascicles of myofibers. While both fiber types undergo atrophy, the majority of hypertrophic fibers are type I fibers

often weaker than the shoulder girdle and the face and bulbar muscles are spared. The weakness may stabilize or in some cases may improve. Usually patients attain sitting ability; however, these children often are never able to achieve independent ambulation. Progressive respiratory insufficiency, joint contractures, and scoliosis are common complications. Life expectancy is variable, with some individuals surviving into early adulthood [5]. Muscle biopsy and EDX finding are similar to those seen in SMA I. Diagnosis of SMA can be adequately confirmed in the vast majority of SMA cases by a positive peripheral blood gene study for a DNA mutation of the motor neuron survival gene [6].

Infants with the *biotin-responsive carboxylase deficiency* present with weakness, hypotonia, areflexia, and lethargy and may be diagnosed by urine screening for organic acidurias. The classic form of *Pompe's disease* usually presents with hypotonia, accompanied by cardiomegaly and hepatomegaly, but variant forms with prominent hypotonia and no cardiac involvement are described. The diagnosis of suspected Pompe's disease can be established by muscle biopsy and deficient acid maltase activity in leukocyte or fibroblasts. Acute *acquired enterovirus infections*, including Coxsackie virus, enteric cytopathogenic human orphan virus, and, especially, poliomyelitis virus, may be associated with asymmetric flaccid paralysis. However, poliovirus infections have been nearly eradicated in Western societies with immunization programs (see Table 77.3).

Peripheral Neuropathies

Several neuropathies may present in very early life with weakness and hypotonia (see Table 77.3 and Fig. 77.4). The symptoms may be predominantly motor, sensory, autonomic, or a combination. Areflexia or hyporeflexia is found in most neuropathies. EDX studies confirm the diagnosis and characterize the neuropathy as axonal versus demyelinating. Nerve biopsy may provide a specific diagnosis in some cases. Examination of family members is important when hereditary neuropathies are suspected. The disease course may be acute, subacute, or chronic.

Acute inflammatory demyelinating polyneuropathy (*Guillain-Barré syndrome*) is probably the most common acute acquired neuropathy of childhood. It should be considered in young infants with subacute onset of hypotonia because the youngest reported case is 4.5 months old [7]. The weakness is symmetric and reaches a peak in 2 weeks, associated with a high cerebrospinal fluid protein level and slow nerve conduction velocities. A complete recovery is expected in the majority of these infants. Acute or subacute neuropathies due to heavy metal poisoning, toxins, or drugs may present with severe weakness, and a history of exposure should be investigated.

Hereditary neuropathies with symptom onset in infancy are rare. *Hereditary motor and sensory neuropathy type III* (*HMSN III*, *Dejerine-Sottas disease*) has an earlier onset and more profound weakness than HMSN type I. HMSN III usually presents during the first year of life with hypotonia, areflexia, and predominant distal severe weakness. Enlargement of the peripheral nerves, persistently elevated CSF protein level, and markedly decreased nerve conduction velocities are characteristic features (see Chap. 26) [8]. DNA-based molecular leukocyte testing for mutations in the PMP22, PO, and ERG2 genes are commercially available and may establish a specific diagnosis. A rare severe *congenital hypomyelinating neuropathy* (*CHN*) has been described, characterized by profound neonatal hypotonia, slow nerve conductions, thin myelin sheaths, and absence of onion-bulb formation, setting this disorder apart from HMSN III. These infants usually die within the first few months of life due to respiratory and bulbar dysfunction. Mutations of PO, PMP22, and ERG2 are all reported in CHN [9, 10]. *Krabbe's disease*, *metachromatic leukodystrophy*, and *giant axonal neuropathy* affect both the central and peripheral nervous systems (see Chap. 27). However, some infants with Krabbe's disease may present with polyneuropathy manifested by weakness and hypotonia instead of hypertonia. Leukocyte enzyme assay shows a reduced galactosylceramidase ß-galactosidase level. Patients with the infantile variant of metachromatic leukodystrophy develop normally for 1 or 2 years before developing hypotonia; however, some cases present before the age of 6 months, with neuropathic weakness as the dominant clinical feature and the diagnosis confirmed by arylsulfatase A assay of lymphocytes or fibroblasts [11]. Giant axonal neuropathy is an autosomal recessive disorder, localized to chromosome 16q24. The primary features of this disorder include rapidly progressive polyneuropathy, initial hypotonia before developing spasticity, kinky hair, and a variable CNS involvement. EDX studies show axonal

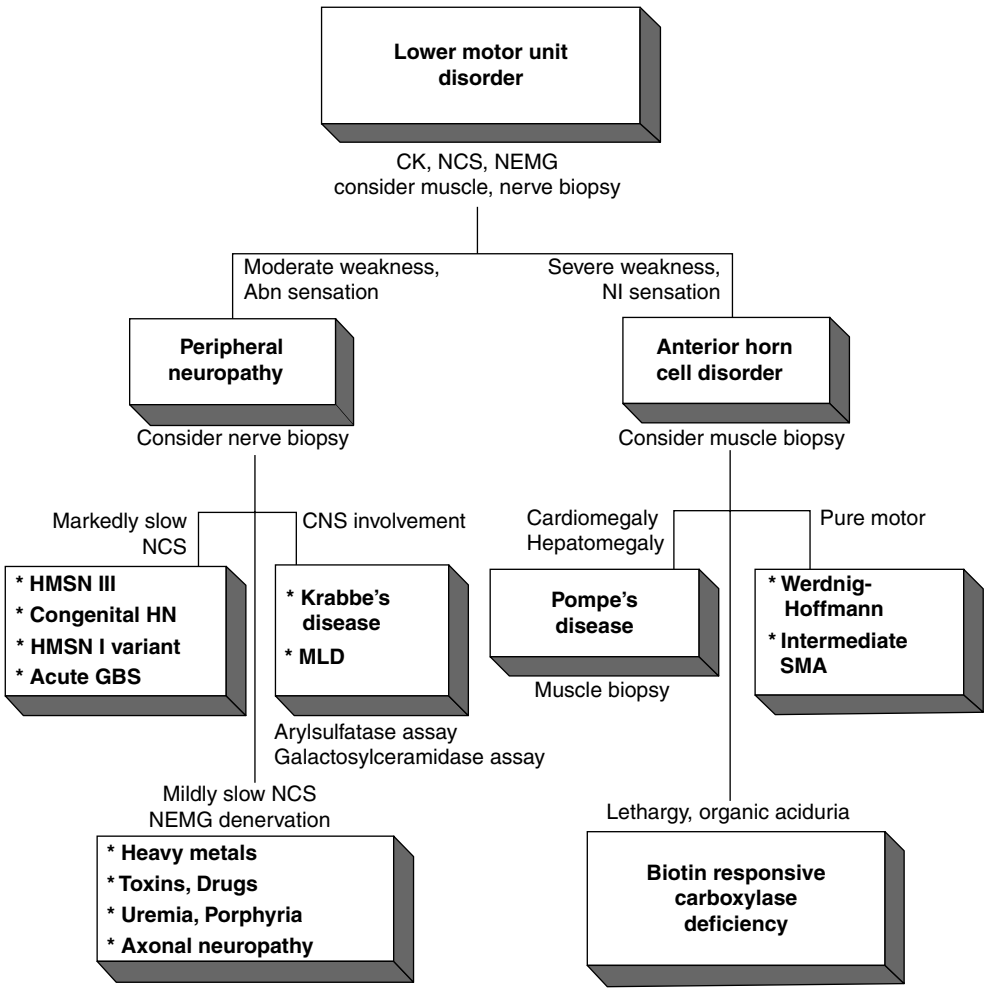

Fig. 77.4 Diagnostic approach algorithm of motor unit disorders associated with the floppy infant syndrome (part 1) (*CK* creatine kinase, *NCS* nerve conduction studies, *NEMG* needle electromyography, *Abn* abnormal, *NL* normal, *CNS* central nervous system, *HMSN III* hereditary motor sensory neuropathy type III (Dejerene-Sottas disease), *HN* hypomyelinating neuropathy, *HMSN I* hereditary motor sensory neuropathy type I (Charcot-Marie-Tooth disease type I), *GBS* Guillain-Barré syndrome, *MLD* metachromatic leukodystrophy, *SMA* spinal muscular atrophy)

neuropathy, and nerve biopsy demonstrates distended axons with filamentous inclusions and axonal loss [12].

Neuromuscular Junction Disorders

Neuromuscular junction disorders that may present in the newborn include neonatal myasthenia gravis, congenital myasthenic syndromes, and infantile botulism (see Table 77.3 and Fig. 77.5).

Neonatal myasthenia gravis occurs in approximately 10–15 % of infants born to women with seropositive myasthenia gravis. Infants develop transient myasthenia, which usually resolves completely in 3–6 weeks. Symptoms develop after birth, or within few days, and include feeding difficulty, weak cry, facial and generalized weakness, and hypotonia [13]. The disease is caused by passive transfer of acetylcholine receptor (AChR) antibodies from mother to child, and symptoms severity correlates with antibody concentration. The diagnosis is suspected by family history and supported by a Tensilon test and decrement response on repetitive motor nerve stimulation. Elevated serum AChR antibodies are detected in 80–85 % of these infants. When the disease is severe, treatment with neostigmine or pyridostigmine is indicated, along with supportive measures until recovery.

Congenital myasthenic syndromes (*CMS*) are a group of genetic disorders characterized by neuromuscular junction dysfunction. Engel described the clinical, ultrastructural, and neurophysiologic features of the congenital myasthenic syndrome subtypes, which comprise several discrete ultrastructural presynaptic, synaptic, and postsynaptic abnormalities [14]. The mother does not have myasthenia gravis, but there may be a family history of similarly affected siblings, consistent with autosomal-recessive inheritance. The clinical symptoms present at birth or within the first year of life, of variable severity, include hypotonia, muscle weakness, ptosis, ophthalmoparesis, and often dysphagia (see Chap. 51) [15]. Hypotonia at birth, respiratory difficulty, and episodes of apnea may occur in severe cases, whereas only intermittent hypotonia and increased fatigue are seen in mild cases. EDX studies demonstrate decremental response of the

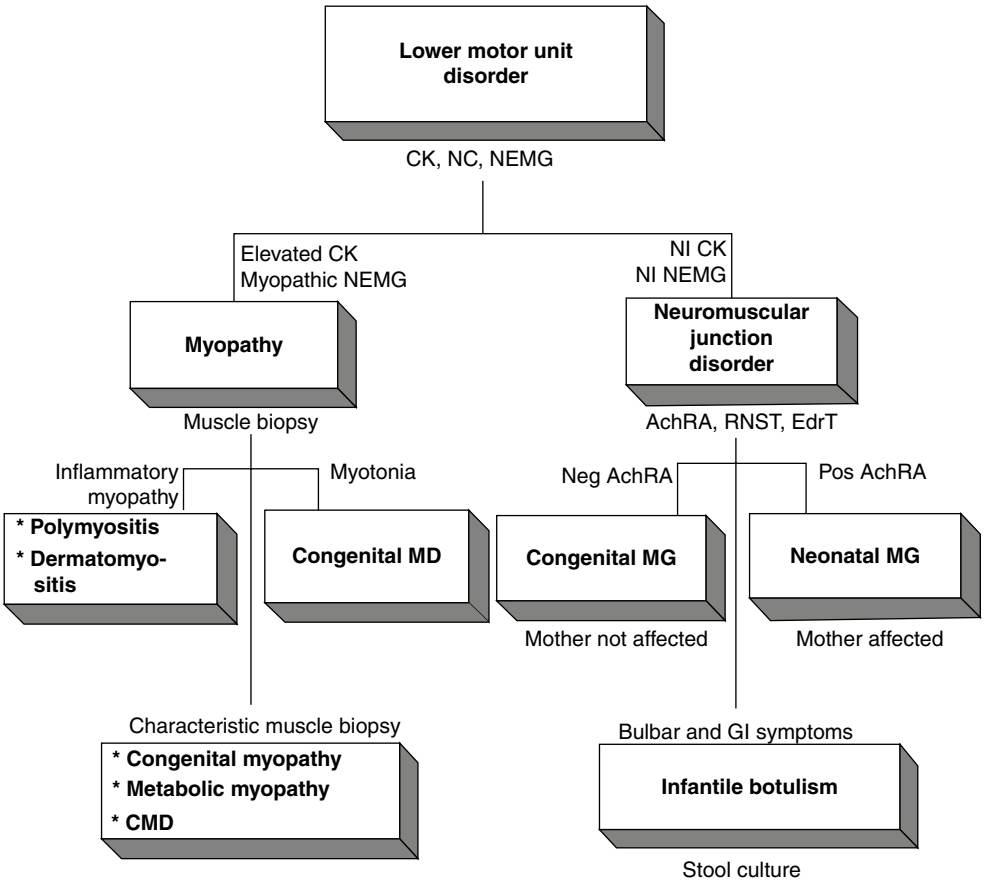

Fig. 77.5 Diagnostic approach algorithm of motor unit disorders associated with the floppy infant syndrome (part 2) (*CK* creatine kinase, *NCS* nerve conduction studies, *NEMG* needle electromyography, *Abn* abnormal, *AchRA* acetylcholine receptor antibodies, *RNST* repetitive nerve stimulation test, *EdrT* edrophonium test, *MG* myasthenia gravis, *CMD* congenital muscular dystrophy)

compound muscle action potential (CMAP) on repetitive motor nerve stimulation, but AChR antibodies are absent. Clinical symptoms improve with acetylcholinesterase inhibitor (AchE-I) drugs administration, however, not in CMS subtypes with AchE deficiency.

Infantile botulism manifesting as hypotonia is not uncommon presynaptic neuromuscular junction disorder. It is caused by absorption of *Clostridium botulinum* toxin from the intestine. Symptoms appear between 6 weeks and 9 months of age. Constipation is a common initial symptom, followed by a descending paralysis of cranial muscles, upper and then lower extremities. The infant has marked hypotonia, prominent facial weakness, ophthalmoplegia with pupillary abnormality, feeding difficulty, and limb weakness (see Chap. 52) [16]. Weakness may progress to respiratory failure requiring mechanical ventilation. Most laboratory tests are negative. Repetitive motor nerve stimulation is useful, showing an incremental response of the CMAP to rapid stimulation rates (20–40 Hz) ranging from 30 to 100 %. The initial CMAP has a small amplitude and short duration. The diagnosis is confirmed by isolation of the organism from stool samples. Treatment is supportive, including feeding and mechanical ventilation when necessary, and full recovery is common.

Myopathies

Myopathy, in a strict sense, refers to pathology primarily involving muscle fibers. Clinical examination, family history, needle electromyography (EMG), serum enzyme levels, and muscle biopsy usually define a specific diagnosis of myopathy. Infants with congenital myopathies, metabolic myopathies, congenital myotonic dystrophy, congenital muscular dystrophy, and a few other myopathies are hypotonic at birth and have weakness of limbs, trunk, or facial muscles (see Table 77.3 and Fig. 77.5).

Congenital myopathies are a group of primary muscle diseases, clinically and genetically heterogeneous, defined according to microscopic structural changes or, in some cases, abnormalities in the proportion or size of one fiber type (see Chap. 62). These disorders include central core disease, nemaline myopathy, myotubular myopathy, congenital fiber-type disproportion, and a few other less common conditions (Figs. 77.6 and 77.7). The clinical manifestations usually start in the neonatal period with hypotonia, limb and facial weakness, decreased movements, and poorly developed musculature. Associated skeletal abnormalities, such as elongated faces, hip dislocation, scoliosis, high arched palate, and pes cavus, are variably seen.

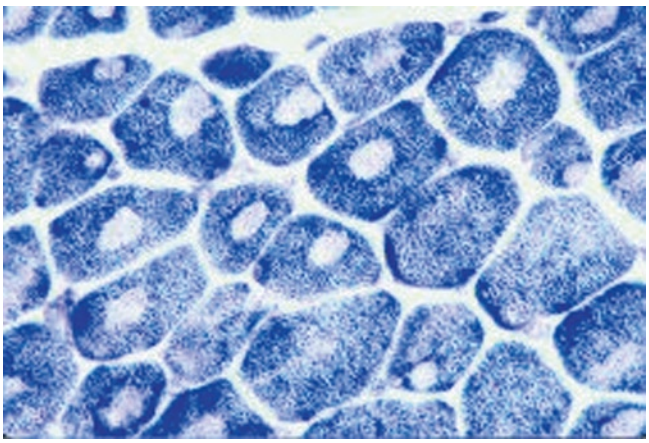

Fig. 77.6 Muscle biopsy in central core disease. Characteristic changes of central core disease are observed in this illustration. Roughly rounded regions with absent NADH diaphorase activity are seen toward the center of the affected myofibers. These features reflect disarray of cytoskeletal elements in the sarcomere

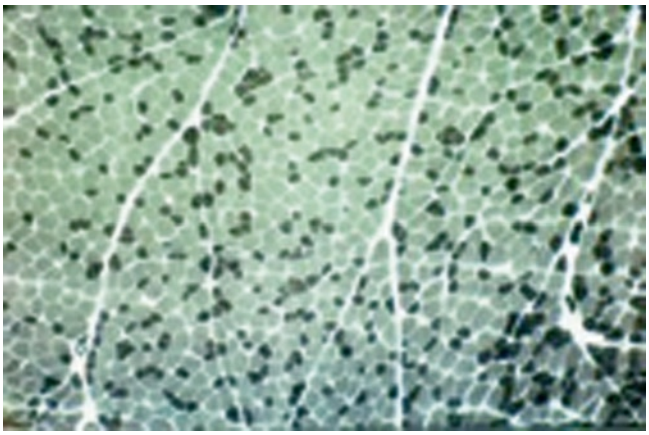

Fig. 77.7 Muscle biopsy in congenital fiber type disproportion. As shown in this typical case, most type I fibers are smaller than type II fibers. Frequently, these changes are a consequence of increased diameters of type II fibers

Serum CK is usually normal, but needle EMG often reveals short-duration, low-amplitude and polyphasic MUAPs in the hands of an electromyographer with experience in pediatric EMG. Specific diagnosis is made on the basis of the muscle biopsy histological findings. The disease course is usually nonprogressive or only slowly progressive; however, some individuals are severely weak and may die from respiratory failure [17, 18].

Metabolic myopathies usually present in childhood and, occasionally, in infancy. The diagnosis is made by muscle biopsy showing excess glycogen or lipid storage and, in some forms, by enzymatic analysis. Infantile acid maltase deficiency (Pompe's disease) is the most frequent metabolic myopathy presenting in infancy as FIS, with severe hypotonia, weakness, respiratory difficulty, cardiomegaly, hepatomegaly, and macroglossia. The enzyme deficiency is systemic, and the heart, liver, kidneys, and CNS are also involved. Needle EMG examination reveals short-duration, low-amplitude, and polyphasic MUAPs and, often, myotonia-like discharges. The diagnosis is best established by leukocytes, fibroblasts, or muscle enzyme assay. Enzyme replacement therapy with recombinant alpha-glucosidase intravenously is currently available [19].

Infantile phenotype of debranching enzyme deficiency (Cori-Forbes disease) presents early in life with hypoglycemia, hypotonia and weakness, and liver dysfunction. Diagnosis can be established by enzyme assay of erythrocytes, muscle, or liver biopsy [20]. Rare cases of myophosphorylase deficiency (McArdle's disease) may present as FIS and follows a rapidly progressive fatal course [21]. Isolated infantile muscle phosphorylase-b-kinase deficiency presenting with severe FIS and respiratory failure have been reported [22]. Glycogen storage disease type IV (branching enzyme deficiency) is a rare disease that can present at different ages, characterized by myopathy, alone or in combination with liver or heart involvement, and is increasingly being recognized as a cause of severe congenital hypotonia [23]. Carnitine deficiency rarely presents in infancy as FIS and is diagnosed by muscle biopsy [24]. A small number of patients with cytochrome C oxidase (COX) deficiency may present in infancy with hypotonia, muscle weakness, feeding and respiratory difficulty, and lactic acidosis and recover in few years [25]. However, the majority of COX deficiency cases have associated multiple CNS and ophthalmologic manifestations, and death often occurs within 2 years of onset.

Congenital myotonic dystrophy is among most common muscle diseases presenting with FIS. Approximately 20 % of infants with myotonic dystrophy have hypotonia in the neonatal period (see Chap. 59) [26]. In congenital cases, the disease is inherited from the mother, and the pregnancy is often complicated by polyhydramnios and prolonged labor. Often these children display inadequate diaphragm and respiratory muscle function and require assisted mechanical ventilation for several weeks. In addition to marked hypotonia, these infants have facial diplegia, feeding difficulty, gastrointestinal dysfunction, mental deficiency, and, often, joint contractures. A facial appearance with tented upper lip, drooping of the eyelids, and wasting of temporalis muscle is a characteristic appearance. Cardiomyopathy and cardiac arrhythmia are frequently encountered and may contribute to early death along with respiratory failure and aspiration. If the infant survives the respiratory failure and swallowing difficulty gradually resolves over a few years, then the disease follows the course of myotonic dystrophy, with delayed motor development and mental retardation. The diagnosis is achieved by neurologic and needle EMG examination of the mother, which reveals myotonic discharges, although the mother may be unaware of her disease, and confirmed by leukocytes analysis for unstable DNA trinucleotide repeat on chromosome 19. Myotonic discharges are usually absent in affected infants and become evident only later in childhood [27].

Congenital muscular dystrophies are a rare and heterogeneous group of muscular dystrophies with benign and severe types, most of which has autosomal-recessive inheritance. Infants present with hypotonia at birth and proximal muscle weakness. Joint contractures, delayed motor milestones, and a clinical picture of arthrogryposis are common. Needle EMG examination shows myopathic features, and serum CK level is variable. Diagnosis of congenital muscular dystrophy is usually achieved by muscle biopsy, which shows dystrophic changes, with no specific histologic abnormalities. Laminin 2 chain (formerly named merosin) is among a family of large extracellular trimeric glycoproteins that surrounds muscle fibers. Patients with merosin-negative immunofluorescent stain of muscle biopsy (merosin deficiency) present with profound hypotonia, severe weakness, often remain unable to ambulate independently, and have associated neuropathy [28]. A detailed large clinical and pathologic study showed that patients with merosin-positive congenital muscular dystrophy characteristically have milder weakness and hypotonia, less severe joint contractures, and a relatively benign course [29]. Fukuyama form of congenital muscular dystrophy is primarily seen in Japan and presents with severe muscular dystrophy, arthrogryposis, mental retardation, and associated CNS abnormalities [30]. The disease is secondary to Fukutin deficiency, an essential extracellular protein, expressed in various tissues. Serum CK is increased in the early stages only. Needle EMG examination shows myopathic features, and the muscle biopsy reveals a dystrophic pattern. The family history is consistent with autosomal-recessive inheritance, although many cases are isolated [31].

Benign Congenital Hypotonia

The term *benign or essential congenital hypotonia* is applied to a group of infants with mild hypotonia and good muscle strength, well-preserved or hypoactive tendon reflexes, and no other clinical manifestations. The prevalence of benign congenital hypotonia is around 3–4 % of hypotonia causes in hypotonic series, and the diagnosis is reached by exclusion of other specific disorders. EMG studies and serum CK are invariably normal. Muscle biopsy may not be warranted in all cases and is usually normal or may show only nonspecific minor abnormalities, such as small fibers of both histochemical types. Muscle tone eventually improves to within the broad limits of normal, usually around the age of 8–10 years [32].

Other Causes of Hypotonia

Hypotonic infants due to systemic diseases represent a large number of FIS causes; thus, assessment of the floppy infant general health as the first step is essential. Several systemic disorders that influence the CNS, such as sepsis, heart failure due to significant congenital heart disease, and some metabolic and endocrine disorders, can be associated with significant hypotonia in infancy (Table 77.4). Hypothyroidism, malnutrition, malabsorption, and renal tubular acidosis are among the more common conditions. These infants usually have severe hypotonia, with only marginal weakness, but they usually have other features of their systemic illness. Infants who have suffered significant hypoxic-ischemic insult often have hypotonia for weeks or months before they develop increased muscle tone. Connective tissue disorders, such as Marfan syndrome or Ehlers-Danlos syndrome, often are associated with hypotonia at birth or during early childhood. These infants manifest significant hypotonia, normal strength and reflexes, and hypermobility of the joints. Infants with inborn errors of metabolism may be hypotonic and can be diagnosed by metabolic screens.

Table 77.4 Systemic causes of hypotonia

Sepsis
Congenital heart disease
Endocrine (hypothyroidism)
Nutritional (malabsorption, malnutrition)
Metabolic (renal tubular acidosis, hypercalcemia)
Hypoxic-ischemic insult
Connective tissue disorders (Marfan and Ehlers-Danlos syndromes)
Maternal medications (psychotropics, benzodiazepines)

Certain drugs administered during pregnancy may cause hypotonia in neonates. Psychotropic drugs taken during late pregnancy may cause neonatal symptoms, including withdrawal symptoms and a floppy infant [33]. Because of rapid placental transfer and slow fetal elimination, benzodiazepines taken in high doses during late pregnancy and labor may cause FIS [34].

Arthrogryposis Multiplex Congenita

Arthrogryposis multiplex congenital (AMC) is a descriptive syndrome characterized by multiple congenital joint contractures, alone or in association with other conditions. In 1841, Otto first described this entity, and in 1923, Stern coined the term arthrogryposis multiplex congenital [35, 36].

AMC is a rare condition with an incidence of 1 in 5,000–10,000 live births. It appears to result from a number of disorders, with a common factor of decreased fetal movements during embryonic formation of joints. Several major causes of AMC are identified, including CNS developmental defects, motor unit disorders, connective tissue abnormalities, space limitations within the uterus, intrauterine vascular insults, and maternal diseases (Table 77.5). AMC may also be a manifestation of specific syndromes, including chromosome trisomy 18 and 21, Möbius, prune belly, and Zellweger syndromes [37]. In addition, there is a group of inherited

Tumors, deformities, vascular insult
Maternal diseases
Diabetes, viral infections, drugs

disorders, with phenotypic variation and overlap, known as distal arthrogryposes. They are characterized by multiple congenital contractures of the distal limbs alone or associated with other discrete anomalies but without primary neurologic or neuromuscular disease that affects limb function [38].

CNS developmental defects known to be associated with arthrogryposis include migrational brain disorders, severe hypoplasia of the cerebellum, pyramidal tract degeneration, ischemic brain damage, cortical frontal atrophy, and cerebral abnormalities associated with congenital myopathies. Seizures and severe learning disorders are commonly associated with arthrogryposis secondary to a brain disorder [39–41].

When AMC is associated with *motor unit disorders*, they are usually of the neurogenic rather than myopathic type, among which SMA I is a common cause. Other SMA variants, such as the autosomal-recessive form and dysgenesis of the anterior horn cells, may be associated with neurogenic arthrogryposis [42]. Arthrogryposis has been described in a few patients suffering with hereditary peripheral neuropathy [43]. Congenital muscular dystrophy, nemaline myopathy, central core disease, and various other congenital myopathies are sometimes associated with AMC [44]. Arthrogryposis is also reported in isolated cases of mitochondrial myopathies and congenital myasthenic syndromes. Muscle biopsy and EDX studies are very useful in establishing the diagnosis [45, 46].

Connective tissue abnormalities, including developmental abnormalities of the tendons and joints, pterygium syndrome, and congenital contractural arachnodactyly, may result in limited fetal movements and AMC [47]. Oligohydramnios, intrauterine tumors (especially fibroids), and uterine deformities may limit the space and cause decreased intrauterine fetal movements with subsequent higher incidence of arthrogryposis. Arthrogryposis also is reported in association with impaired vascular supply, maternal diabetes mellitus, hyperthermia, various viral infections, and certain drugs during pregnancy. Armyoplasia is a sporadic syndrome characterized by an absence of limb muscles, which are replaced by fibrous and fatty tissue. The newborn has multiple limb abnormalities and joint contractures.

Joint contractures may be diagnosed prenatally by ultrasound. Careful prenatal and perinatal history, clinical examination, and relevant investigations are needed to determine the etiology of arthrogryposis, as the prognosis and genetic implications vary. The mainstay of treatment for affected infants is physiotherapy, splinting, and orthopedic surgery, along with optimizing medical care.

Rhabdomyolysis and Myoglobinuria

78

Devanshi Jadhav and Henry J. Kaminski

Introduction

Rhabdomyolysis (lysis of skeletal muscle cells) is a potentially lethal syndrome with a broad spectrum of clinical and biochemical findings. Myalgia, pigmenturia, and elevated activity of serum creatine kinase (CK) are the common features. Fulminant rhabdomyolysis may be associated with severe metabolic disturbances and involvement of other organ systems. Cardiac arrest, compartment syndrome, and acute renal failure are the major complications. The first cases of death secondary to rhabdomyolysis appear in the Book of Numbers; Israelites died after eating quail, which had been fed on hemlock (a reported cause of rhabdomyolysis) [1, 2]. The prevention of life-threatening complications of rhabdomyolysis strongly depends on early diagnosis and adequate therapy. Since the repair mechanism of striated muscle functions very well, the prognosis of appropriately treated rhabdomyolysis is excellent.

Rhabdomyolysis denotes an acute or subacute event, which leads to necrosis of striated muscles. The clinical features vary widely from moderate muscular symptoms to life-threatening complications. Rhabdomyolysis occurs in a wide array of settings: alcohol abuse, drug addiction, excessive exercises, severe physical trauma, and attempted suicide. Neurologists deal with the clinical complications of rhabdomyolysis in several clinical scenarios. Patients with severe rhabdomyolysis may be comatose and subsequently develop significant metabolic disturbances involving the central and peripheral nervous systems. Other patients with mild or recurrent rhabdomyolysis may present with exercise-related neuromuscular manifestations requiring a search for an underlying metabolic defect, while rhabdomyolysis may also develop as a sequelae of seizures or withdrawal of antiparkinsonian medications [3, 4]. The chapter reviews the present state of knowledge of the clinical and biochemical diagnosis of rhabdomyolysis; its pathophysiology, classification, provocative factors, and associated diseases; and the management of patients including diagnostic and therapeutic guidelines. The authors acknowledge the work of the original authors, Aad Verrips, Petra Poels, and JM Gabreëls, upon which much of the present contribution is based [5].

Definition

Rhabdomyolysis is defined as a clinical and biochemical syndrome resulting from skeletal muscle injury that alters the integrity of the muscle cell membrane sufficiently to allow the release of muscle cell contents, including myoglobin, creatine phosphokinase, potassium, aldolase, lactate dehydrogenase, and glutamic oxaloacetic transaminase into the blood. Rhabdomyolysis may cause visible pigmenturia as a result of myoglobin in the urine, which leads to myoglobinuria often used as a synonym for rhabdomyolysis. Bowden et al. suggested the term rhabdomyolysis to highlight that the fundamental problem in myoglobinuria concerns the muscle and is not primarily related to either myoglobin or renal failure [6]. In fact, myoglobinuria does not exist without rhabdomyolysis, but rhabdomyolysis does not necessarily result in visible myoglobinuria, and many other constituents of muscle are released into the blood.

No strict criteria exist for the diagnosis of rhabdomyolysis, probably due to the diversity of its clinical presentation, but we offer the following as criteria based on existing literature:

1. An event of muscle destruction with manifestations confined to the muscles or with involvement of other systems, resulting in general weakness or specific organ

diseases such as cardiomyopathy, neuropathy, encephalopathy, or nephropathy.
2. An increase in serum levels of skeletal muscle enzymes, particularly CK. The degree of elevation of serum CK level is arbitrary but should be at least fivefold normal (>975 IU/l) [7].
3. An increase in the level of serum and urinary myoglobin.

Pathogenesis

Rhabdomyolysis is the result of a direct muscle injury or an altered relationship between energy production and energy consumption in muscle. The development of muscle cell necrosis is thought to start at the plasma membrane, including the sarcolemma and T-tubule, where several adenosine triphosphate dinucleotide-consuming ion transport systems are located (Fig. 78.1).

The balance between the intra- and extracellular calcium concentration is of crucial importance for muscle cell integrity [8]. In the intact muscle fiber, there is a steep calcium gradient across the plasma membrane, the extracellular calcium concentration being manyfold higher than the intracellular concentration. The binding of calcium with high affinity to a large number of cellular components is one efficient mechanism to keep the intracellular free calcium concentration at low levels [9]. The sodium/potassium pump is critical for calcium homeostasis and muscle cell integrity. The sodium/potassium pump at the plasma membrane regulates the active transport of sodium out of the cell and potassium into the cell. The activity of this pump appears to be regulated by sodium potassium-activated adenosine triphosphatase (sodium/potassium -ATPase) and is dependent on sufficient ATP supply. When the Na^+/K^+ pump malfunctions because of energy depletion or direct injury to the plasma membrane, an influx of sodium chloride and water into the cell occurs [10]. Osmotic swelling then leads to muscle cell injury. Subsequently, an exchange of sodium for calcium ions, via a protein carrier exchange mechanism, promotes increased influx of calcium ions across the membrane and subsequent activation of calcium-dependent proteases, contributing to muscle injury.

Calcium ions are sequestered by the sarcoplasmic reticulum (SR) that contains different calcium-transporting systems for the uptake of calcium and the release of calcium back to the cytosol (Fig. 78.2). Once the integrity of the muscle membrane and SR membrane is lost, an increased influx of calcium ions overloads the mitochondria. The mitochondria have an impressive capacity for calcium uptake and will store excess calcium for a relatively long time. However, when the level of mitochondrial calcium loading becomes intolerable to the organelle, the excess calcium is released from the mitochondria into the cytosol. The functional and structural damage of the mitochondria and the ensuing lack of energy create a vicious cycle as less energy becomes available for pumping calcium out of the cell (Fig. 78.2).

The elevated level of intracellular calcium activates phospholipase-A_2 resulting in the accumulation of lysophospholipids in the muscle cell and raises the activity of neutral proteases to a level that becomes destructive to the muscle cell. The elevated cytoplasmic calcium level will enhance the interaction of actin and myosin filaments leading to

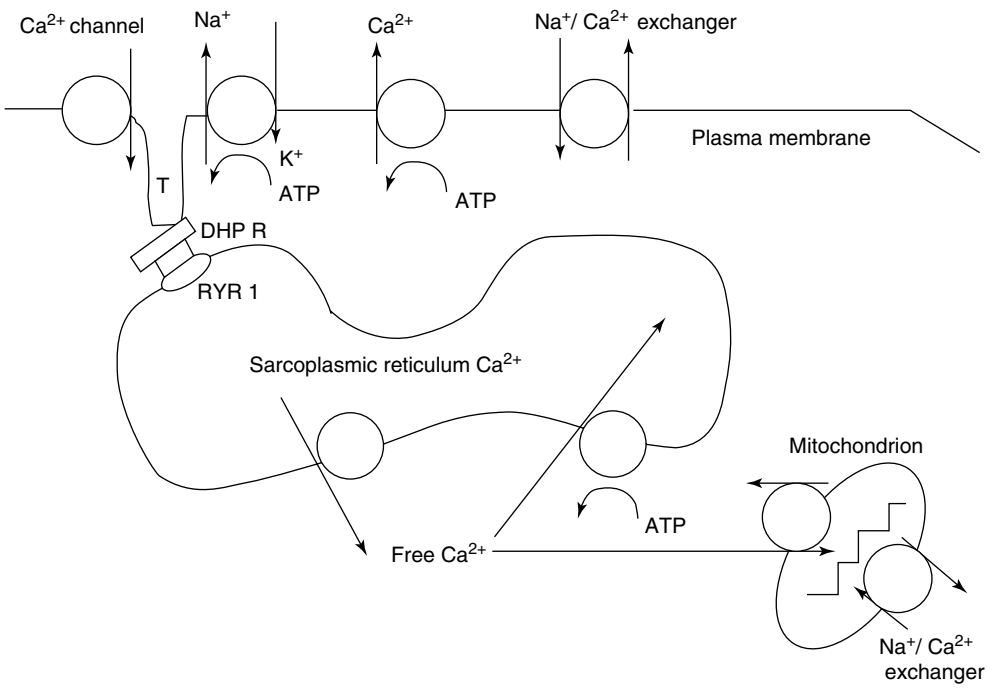

Fig. 78.1 Schematic representation of calcium release and uptake by the muscle cell and its organelles (Reproduced from Poels and Gabreëls [160])

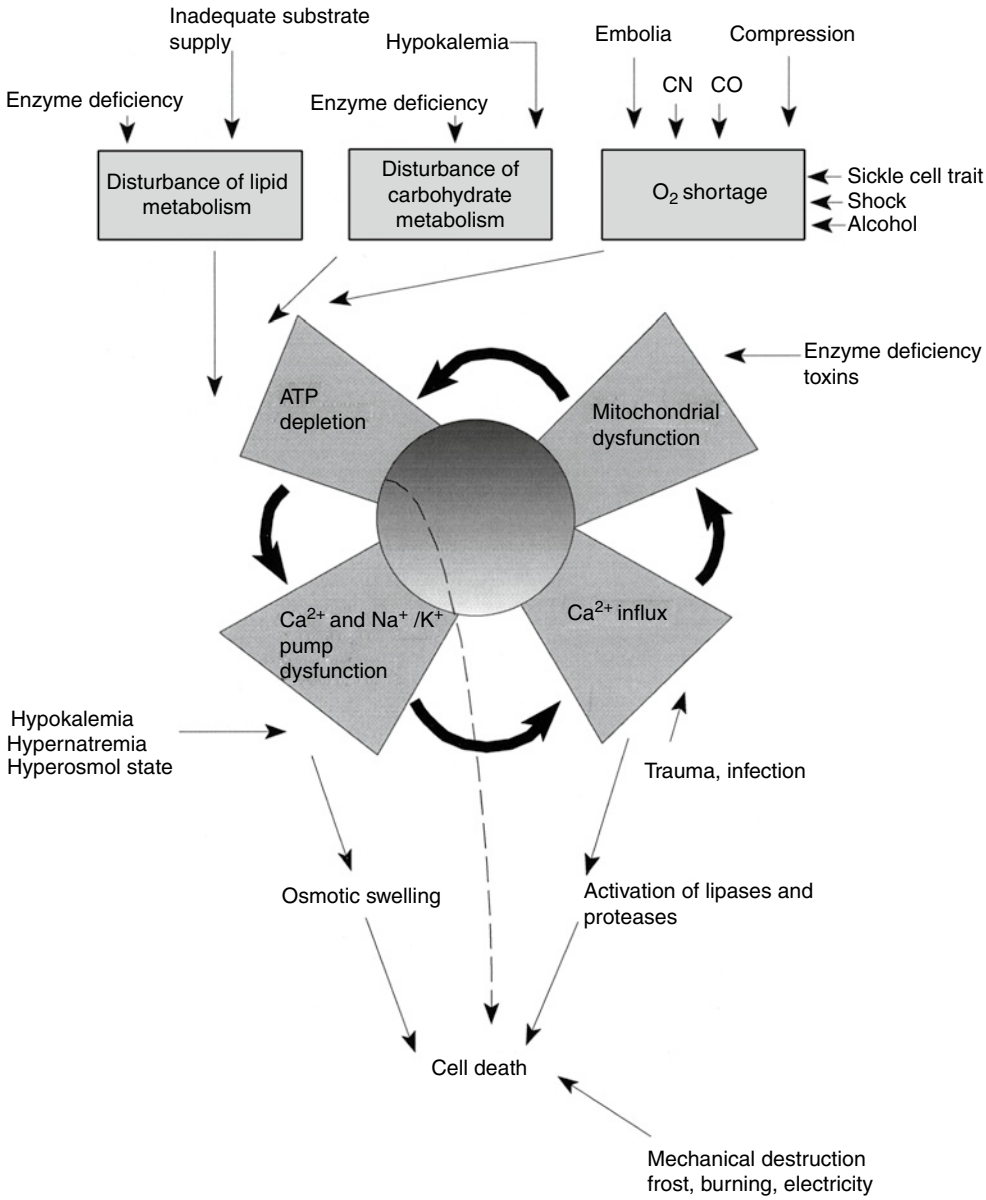

Fig. 78.2 Schematic representation of the process of muscle cell necrosis and its causative factors (Reproduced from Poels and Gabreëls [160, p. 178])

myofibrillar hypercontractures and, if the calcium level is critically high, to damage of the muscle cell [11].

Biochemical Features

Myoglobin

Myoglobin functions as an oxygen store and carrier, important in maintaining the ability of skeletal muscles to consume oxygen and generate contraction. This small protein (17,800 kDa) is rapidly filtered through the renal glomeruli. Myoglobinuria (leading to tea colored urine) is estimated to cause 5–25 % [12] of cases of renal failure with serum levels above 300 μg/l and develops in most patients excreting more than 1,000 μg/l [13]. A rise in serum myoglobin level precedes an increase in serum CK. The concentration of myoglobin in serum returns to normal 1–6 h after cessation of muscle injury due to the rapid clearance of myoglobin by both renal excretion and metabolism to bilirubin [13]. Therefore, determination of myoglobin in serum and urine is helpful only for the early diagnosis of rhabdomyolysis, and the absence of elevated levels of serum myoglobin does not eliminate the diagnosis of rhabdomyolysis.

Pigmenturia may also occur in patients with hemoglobinuria or porphyria, but the clinical presentations differ. The combination of a positive o-toluidine test, gold–brown pigmented casts in urine, the absence of erythrocyturia, colorless serum, and a normal haptoglobin level confirms the diagnosis myoglobinuria. Assay methods using specific antibodies against myoglobin are the most sensitive tests since antibodies to myoglobin do not cross-react with hemoglobin. Radioimmunoassay and enzyme-linked immunoassay have

a sensitivity high enough to measure normal contents of myoglobin in serum and urine [14].

Serum Creatine Kinase

CK plays an important role in metabolism by catalyzing the reversible transfer of the terminal phosphate group of ATP to creatine to form phosphocreatine. The laboratory abnormality most suggestive of rhabdomyolysis is an elevation of serum CK to at least fivefold normal. Destruction of about 200 g of muscle causes an elevation of serum CK.

Human tissues contain three isoenzymes of CK: MM, MB, and BB. The predominant sources of CK-MM isoenzyme are skeletal and cardiac muscle. The CK-BB isoenzyme is found in brain tissue and CK-MB isoenzyme mainly in cardiac but also in skeletal muscle. In rhabdomyolysis, an elevation of total CK, especially of CK-MM isoenzyme, is found, accompanied by an increase of myoglobin in serum and urine. Involvement of myocardium is likely if the isoenzyme CK-MB exceeds 5 % of the total CK activity [15].

Serum CK concentration begins to rise 2–12 h after onset of muscle injury, peaks in 1–3 days, and declines within 3–5 days after muscle injury ceases. Serum CK levels remain elevated longer than myoglobin levels because of its relatively slow clearance with a serum half-life of about 1.5 days. The elevation of serum CK level in acute attacks of rhabdomyolysis is transient and may reach a level of 100,000 IU/l, being many times higher than in most other conditions. Persistently and moderately elevated serum CK levels are also present in many common myopathies and other disorders, including hypothyroidism, but are not accompanied by massive muscle necrosis with pigmenturia.

Carbonic Anhydrase III

For diagnostic purposes, serum CK and myoglobin are generally used to demonstrate skeletal muscle damage in rhabdomyolysis. Carbonic anhydrase III is an even more specific marker of skeletal muscle injury than are myoglobin and serum CK, as it is not present in myocardium [16, 17].

Potassium, Calcium, and Phosphate

When the integrity of muscle cell membrane is disrupted, other protein and nonprotein cellular components are also released into the circulation. Clinically critical biochemical findings in rhabdomyolysis are hyperkalemia, hypocalcemia, and hyperphosphatemia. Muscle necrosis of about 150 g will release in excess of 15 mmol potassium, sufficient to acutely elevate serum and extracellular fluid potassium concentrations [7]. The resulting hyperkalemia may lead to cardiac arrhythmias. Hypocalcemia in the initial phase of rhabdomyolysis is attributed to deposition of calcium salts in necrotic muscle [18]. This appears to result from the release of large amounts of organic and inorganic phosphate into the circulation, elevating the calcium phosphate product with subsequent deposition of calcium salts into muscle and other tissues [18]. Another cause of the initial hypocalcemia may be a fall in plasma levels of 1,25-dihydroxycholecalciferol due to hyperphosphatemia [19]. During the later stage, an excessive rise in calcium may occur, when calcium is mobilized from damaged muscle again. Another cause of hypercalcemia is attributed to secondary hyperparathyroidism, triggered by hyperphosphatemia [11, 20]. Other laboratory findings include elevated serum levels of aminotransferases, aldolase, lactate dehydrogenase, creatinine, urea, hydroxybutyrate, and uric acid. Hyperuricemia is the result of enhanced cellular release of purine precursors, which are converted to uric acids by the liver. The uric acid concentration, in general, is correlated with the serum CK level [11].

Clinical Presentation

There is great heterogeneity in the clinical presentation of rhabdomyolysis, which is probably due to the diversity of its etiological factors [21]. The clinical features are divided into (a) muscular manifestations accompanied by pigmenturia, (b) systemic disturbances, and (c) complications resulting from involvement of other organ systems.

Muscular manifestations consist of muscle pain, swelling, tenderness, stiffness, contractures, and weakness. However, in one study, only 50 % of the patients with rhabdomyolysis presented with muscular signs and symptoms [7]. Rhabdomyolysis may involve all striated muscles diffusely or focally. Usually the postural muscles of the thighs, calves, and the lower back and the muscles of the arms are painful and weak. When edema develops, the muscles become stiff and tender to palpation. Muscle swelling of the calves may result in contractures and loss of ankle jerks. Rhabdomyolysis may also extend to the muscles of the chest, abdomen, palate, and throat and to the masticatory muscles. In general, the muscle repair mechanisms seem to function extremely well, as the permanent damage to muscle that results from traumatic and non-traumatic events is surprisingly minimal. Usually, the muscle disorder is self-limited and leads to complete recovery within days or weeks.

Systemic disturbances may be prominent in fulminant rhabdomyolysis, leading to general malaise, fever, tachycardia, abdominal pain, nausea, and vomiting. High levels of urea may result in encephalopathy with impaired consciousness, agitation, and confusion. Depression of cerebral metabolism is followed by hypoventilation, leading to hypoxia and respiratory acidosis. The major complications of rhabdomyolysis are cardiac arrest, compartment syndrome, and acute renal failure.

Fulminant rhabdomyolysis associated with severe hyperkalemia and hypocalcemia may induce a life-threatening complication of cardiac arrest. Hyperkalemia is cardiotoxic,

which may be potentiated by hypocalcemia. The development of the compartment syndrome is another complication of severe rhabdomyolysis in which the muscle swelling may produce compression of adjacent vessels and nerves within tight fascial compartments. When the compartmental pressure exceeds the arterial pressure, secondary ischemic necrosis and muscle destruction result. Compartment syndrome in non-traumatic rhabdomyolysis is usually subsequent to prolonged coma or immobilization following overdose of various drugs, where the patient's own body weight may raise the external pressure on muscles. The direct toxicity of alcohol and heroin on muscles is very likely to be of additional importance.

Acute renal failure may be life threatening and the most frequently reported complication of rhabdomyolysis. The frequency of acute renal failure in rhabdomyolysis is not known, but it is described in a third to nearly half of patients in large case series [10, 22]. Why this complication develops in only some patients is not known. Renal insufficiency may develop in patients who are compromised in some manner that influences renal function [23] or may be related to the quantity of myoglobin released into the circulation. The major theories that have been advanced to explain its development include factors related to renal circulation and direct tubular injury:

- Back leak of filtrate through the damaged tubular epithelium to the peritubular circulation [24].
- Renal ischemia as a result of vasoconstriction of renal arterioles due to intravascular hypovolemia.
- Associated shock with impaired renal flow and decreased glomerular filtration rate.
- Tubular obstruction by precipitation of pigmented casts in the ultra filtrate. The formation of intraluminar casts in combination with the renal tubular secretory Tamm–Horsfall protein is facilitated by the acid pH of the tubular fluid.
- Tubular injury by direct toxicity of myoglobin in itself or indirect toxicity by the heme pigments released from myoglobin in the presence of hypovolemia and aciduria. The overwhelming quantities of free iron cannot be stored into ferritin and facilitate the generation of free radicals [25, 26].
- Release of neutral proteases or vasoactive kinins from injured skeletal muscle cells that may directly damage the kidney [27].

Classification and Etiology

Rhabdomyolysis may be categorized in several ways: traumatic and non-traumatic forms or endogenous and exogenous types and hereditary and acquired forms. Any classification, however, has its limitations, as there is often more than one trigger for an attack of rhabdomyolysis. In some patients, genetic causes overlap with nongenetic causes. Recurrent attacks of rhabdomyolysis in patients with hereditary metabolic myopathies are usually induced by exercise, but exercise may also induce rhabdomyolysis in patients without known genetic disorders. Rhabdomyolysis associated with drug-induced coma may be caused by trauma, immobilization, hypoventilation, shock, or metabolic acidosis. A study of 77 patients with recurrent attacks of rhabdomyolysis found known muscle enzyme defects in half. This would suggest that the remaining patients harbored as yet unidentified genetic disorders [28].

Table 78.1 Causes of hereditary rhabdomyolysis

Deficiencies of glycogenolytic enzymes
Myophosphorylase (McArdle's disease)
Phosphorylase kinase
Phosphofructokinase (Tarui's disease)
Phosphoglycerate kinase
Phosphoglycerate mutase
Lactate dehydrogenase
Abnormal lipid metabolism
Carnitine palmitoyltransferase deficiency I and II
Carnitine deficiency
Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency
Short-chain 3-hydroxyacyl-CoA dehydrogenase deficiency
Late-onset medium-chain 3-hydroxyacyl-CoA dehydrogenase deficiency
Very long-chain acyl-coenzyme A dehydrogenase deficiency
Various genetic disorders
Idiopathic rhabdomyolysis
Autosomal dominant myoglobinuria
Myoadenylate deaminase deficiency
Malignant hyperthermia
Monocarboxylate transporter
Neuroleptic malignant syndrome
Dystrophin-associated muscular dystrophies
Mitochondrial mutations

Hereditary Causes of Rhabdomyolysis

Hereditary causes of rhabdomyolysis include disorders of glycogen and lipid metabolism, other genetic diseases such as malignant hyperthermia [29], and endogenous disorders without identified causes (Table 78.1) [1, 30]. In hereditary disorders associated with rhabdomyolysis, the number of recognized metabolic defects has increased during the last two decades and will increase as genetic diagnosis improves.

Recurrent rhabdomyolysis is characteristic of a number of inherited glycogen storage diseases of muscle. Defects in enzymes of glycogenolysis associated with rhabdomyolysis are myophosphorylase, phosphorylase kinase,

phosphofructokinase (PFK), phosphoglycerate kinase (PGK), phosphoglycerate mutase (PGAM), and lactate dehydrogenase (LDH). Exercise is the most important triggering factor in patients with glycogenolytic enzyme defects. The metabolic block in glycogenosis causes a disturbance in energy production early during intense exercise.

Intense exercise of normal skeletal muscle produces intracellular acidosis and increases intracellular inorganic phosphate levels, both of which reduce the calcium sensitivity and tension-generating capacity of the contractile proteins [31]. In skeletal muscles with impaired myoglycolysis or impaired myoglycogenolysis, intense exercise, particularly if performed under ischemic conditions, produces electrically silent muscle contractions called contractures. Experiments in an animal model of impaired myoglycolysis and impaired myoglycogenolysis demonstrated that the initial metabolic abnormalities causing contractures are elevated ADP levels, depletion of creatine phosphate, and elevated intracellular Ca^{+2} levels combined with no change in intracellular pH and only a small increase in intracellular inorganic phosphate. At the onset of contracture, the level of ATP was not reduced. The tension present in contracture resulted from a combination of elevated intracellular Ca^{+2} and increased sensitivity of the contractile proteins to Ca^{+2}. Depletion of creatine phosphate prevents conversion of ADP to ATP and ATP levels drop [32]. When ATP levels fall below a critical level, cellular metabolism is disrupted. This results in loss of integrity of membranes and muscle necrosis, especially of the type 2 fibers, which depend primarily on glycolysis [33]. Exercise intolerance, muscle cramps, and pigmenturia are the primary manifestations of glycogenolytic disorders.

In most patients, the first symptoms begin before the age of 20 years, and the attacks of rhabdomyolysis are intermittent and exercise induced. In glycogenolytic disorders, the inheritance is usually autosomal recessive, except for PGK deficiency, which is X-linked. Serum CK is persistently increased 5- to l0-fold. In certain of the disorders during the ischemic forearm test, the normal rise of lactate in venous blood is small or completely absent [34]. Histological examination shows an accumulation of glycogen beneath the sarcolemma and histochemical staining for the abnormal glycogenolytic enzyme is negative. The activity of the individual glycogenolytic enzyme and its content may also be biochemically measured in muscle tissue.

Myophosphorylase deficiency (*McArdle's disease*) was identified in 1959 [35]. Exercise intolerance is most prominent during the first 10 min of intensive exertion. After brief rest, the patient may resume exercise; this so-called second wind phenomenon is characteristic of myophosphorylase deficiency [36]. In a review of patients with McArdle's disease, slightly over 50 % had overt myoglobinuria and elevated serum CK levels, indicative of rhabdomyolysis [36]. In half of patients, the rhabdomyolytic attacks occurred once or twice, while the others more frequently. Exercise was the main precipitating factor. Acute renal failure developed in 6–8 % of patients, who eventually all recovered. Tonin et al. [28] screened muscle biopsies of 30 patients with exercise intolerance without myoglobinuria and found myophosphorylase deficiency in 17. Therefore, as myoglobinuria is not an obligatory consequence of McArdle's disease, many patients with only exercise intolerance may not be identified with the disorder. McArdle's disease is the second common disorder of muscle metabolism, after carnitine palmitoyltransferase (CPT) deficiency, causing exercise-induced rhabdomyolysis.

Phosphorylase kinase deficiency, a cause of benign hepatomegaly in infancy, is rarely reported to cause rhabdomyolysis [37]. However, in 77 muscle biopsies of patients with rhabdomyolysis, Tonin et al. found phosphorylase kinase deficiency in four [28] and concluded that the importance of this enzyme defect as a cause of rhabdomyolysis is underestimated.

Phosphofructokinase (*PFK*) *deficiency* (Tarui's disease), which was described in 1967 [38], has only rarely been associated with rhabdomyolysis [39]. The clinical picture is identical to that of myophosphorylase deficiency: a lifelong intolerance to strenuous exercise with pain and stiffness of exercising muscles. However, a few patients with PFK deficiency are reported with onset in older age with progressive limb weakness and therefore should be considered in the differential diagnosis of late-onset myopathy [28].

Three defects of terminal glycolysis are PGK deficiency, PGAM deficiency, and LDH deficiency [40, 41]. PGAM deficiency and lactate dehydrogenase (LDH) deficiency are clinically characterized by exercise intolerance, muscle cramps, and recurrent rhabdomyolysis but with no fixed weakness. They do not cause a complete block of the glycolytic pathway and do not result in severe glycogen accumulation on muscle biopsy. Phosphoglycerate kinase (PGK) deficiency was first described by DiMauro in a 14-year-old boy with rhabdomyolysis and renal failure after intense exercise [41]. The enzyme defect is also expressed in erythrocytes, in fibroblasts, and muscle cultures. PGK deficiency is an X-linked recessive trait and usually associated with hemolytic anemia, mental retardation, and seizures.

Recurrent rhabdomyolysis is also a characteristic feature of disorders of lipid metabolism including carnitine palmitoyl transferase (CPT) II deficiency, carnitine deficiency, short-/medium-/long-/very long-chain and multiple acyl-coenzyme A dehydrogenase deficiencies, electron transfer flavoprotein (ETF) deficiency, ketoacyl CoA thiolase deficiency, and trifunctional enzyme deficiency [12]. Carnitine palmitoyltransferase (CPT) I and II deficiency, a disorder of lipid metabolism. CPT I and II deficiency [38] proved to be the most common hereditary disorder causing rhabdomyolysis in the patients studied by Tonin and colleagues [28]. CPT I

and II are responsible for the transport of long-chain fatty acids across the mitochondrial membrane, before which the fatty acids must be esterified with carnitine. In patients with CPT I and II deficiency, muscle pain and rhabdomyolysis develop after strenuous exercise for a prolonged time without adequate intake of food or during prolonged stress, in contrast to rhabdomyolysis in glycogenolytic disorders, which occurs in the initial phase of exercise. In CPT I and II deficiency, attacks of rhabdomyolysis may be successfully prevented by maintenance of adequate intake of carbohydrates during long periods of exercise.

The high frequency of rhabdomyolysis in CPT deficiency is in contrast with its rarity in mitochondrial myopathies [42], acid maltase deficiency [39], and in systemic carnitine deficiency [43]. Deficiency of CPT results in recurrent rhabdomyolysis, while deficiency of the substrate carnitine predominantly causes lipid storage myopathy [44]. The reason for the difference in clinical presentations is not clear. Recurrent attacks of rhabdomyolysis have been described in only three patients with myopathic carnitine deficiency [45–47] and in one patient with a secondary carnitine deficiency syndrome due to long-chain acyl-CoA dehydrogenase deficiency [48].

Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency (LCHAD) is a defect of mitochondrial fatty acid beta-oxidation that may induce rhabdomyolysis. These deficiencies may become manifest during infancy with hypoglycemic coma, hepatic steatosis, and hypocarnitinemia. Another manifestation is cardiomyopathy. In addition, LCHAD deficiency has specific features, including peripheral neuropathy and chorioretinopathy. Female carriers of LCHAD deficiency are prone to preeclampsia-related pregnancy complications. Diagnosis is suggested by 3-hydroxylated acylcarnitine species in blood [49].

Tein et al. described a 16-year-old girl with short-chain L-3-hydroxyacyl-coenzyme A dehydrogenase deficiency resulting in juvenile-onset recurrent myoglobinuria, hypoketotic hypoglycemic encephalopathy, and hypertrophic/dilated cardiomyopathy [50].

Very long-chain acyl-coenzyme A dehydrogenase deficiency (VCHAD) is an adult-onset myopathy very similar to CPT II deficiency, caused due to a mutation in the acyl-coenzyme A dehydrogenase, very long-chain (ACADVL) gene. It is characterized by rhabdomyolysis and myoglobinuria after exercise or fasting and detected by immunohistochemistry. Voermans et al. reported two patients who were otherwise healthy with episodic exercise-induced rhabdomyolysis [51].

A family with "autosomal dominant myoglobinuria" has been reported, in which ten individuals of both sexes in four successive generations suffered from myoglobinuria, precipitated by a febrile illness. Four individuals suffered acute renal failure, which in two was reversed only after dialysis. In one, a mitochondrial disorder was suspected, but no mutation in the mitochondrial DNA was identified. The authors suggested that the myoglobinuria in this family was caused by a nuclear-encoded mutation affecting the respiratory chain [52].

Myoadenylate deaminase (*MAD*) *deficiency* was first described in 1978 in five patients with exertional myalgia [53]. MAD is involved in purine nucleotide breakdown by catalyzing the irreversible deamination of adenosine monophosphate to inosine monophosphate while ammonia is formed. This reaction is active during muscle contraction, especially during ischemic exercise. The clinical features are rapid fatigue and weakness or cramping following vigorous exercise. In some patients, exertional rhabdomyolysis was described [53–55]. The normal rise in ammonia in venous blood is small or absent during the ischemic forearm test. In the study of Tonin et al. [28], three patients with rhabdomyolysis had an isolated MAD deficiency. As MAD deficiency is often associated with other well-defined disorders, for example, amyotrophic lateral sclerosis [55], hypokalemic periodic paralysis [56], dermatomyositis [57], and progressive systemic sclerosis [58], a coincidental association of MAD deficiency with other causes of rhabdomyolysis cannot be excluded. Although its pathogenic significance in muscle disorders has not been clearly defined [34], MAD deficiency does impair energy production [59]. Verzijl et al. demonstrated the same underlying molecular defect, a C34T transition, in inherited and acquired MAD deficiency in a Dutch population and found the same frequency of the mutant MAD allele in the general population as in patients with neuromuscular complaints. Their conclusion was that secondary MAD deficiency is merely a "coincidental" finding and that MAD deficiency is a harmless genetic variant [60].

In addition to metabolic causes, recurrent rhabdomyolysis is attributed to a number of incompletely characterized genetic defects. Mitochondrial mutations in genes encoding succinate dehydrogenase/complex II deficiency, complex III deficiency, coenzyme Q10 deficiency, cytochrome Q10 deficiency, and cytochrome c oxidase deficiency have been identified in association with clinical features suggestive of mitochondrial disease, such as progressive external ophthalmoplegia [12].

In two brothers with recurrent rhabdomyolysis, a defect of the mitochondrial energy-transducing system due to multiple deletions of mitochondrial DNA was reported [61]. Monocarboxylate transporter 1 (MCT1) mutations (the gene for the red cell lactate transporter also expressed in skeletal muscle) were described in patients with subnormal erythrocyte lactate transport plus manifestations of muscle injury on exercise and heat exposure [62].

Malignant hyperthermia (MH) is a life-threatening form of rhabdomyolysis [63], which is characterized by a

hypermetabolic state of skeletal muscle, associated with extreme muscle rigidity and rhabdomyolysis, rapidly rising body temperature to 41°C or and above, metabolic acidosis, cardiac arrhythmia, and disseminated coagulopathy. A genetic defect in the ryanodine receptor gene, *RYR1* (MHS1 locus) on chromosome 19q13.2, has been identified as a cause of 70–80 % of patients. Mutations in the *CACNA1S* (MHS5 locus) that encode the α_1-subunit of the skeletal muscle dihydropyridine receptor L-type calcium channel account for 1 % of all cases. Three additional loci have been mapped, but the genes have not been identified: MHS2, linked to chromosomal locus 17q11.2-q24; MHS4, linked to chromosomal locus 3q13; and MHS6, linked to chromosome 5p. In a single family, MHS3, linked to chromosomal 7q21-q22, has been associated with a mutation in the calcium channel alpha-2 gene but it has not been found to have an association with MHS in other studies [64]. MH is almost always observed after administration of volatile anesthetics, for example, halothane, and depolarizing muscle relaxants such as succinylcholine. Isolated episodes of rhabdomyolysis are described and induced by physical or emotional stress [29, 65].

The clinical manifestations of MH are similar to the neuroleptic malignant syndrome (NMS). Patients receiving neuroleptics may also develop a potentially lethal disorder, characterized by moderate hyperthermia, instability of the autonomic nervous system, muscle rigidity, and myoglobinuria accompanied by an increase in serum CK [66]. All neuroleptic medications, synthetic narcotics, and tricyclic antidepressants may induce NMS [67, 68]. Different from MH, however, is the gradual development of signs and symptoms in NMS. Another difference is the central disorder in NMS and the presumed sarcolemmal defect in MH. There has been no genetic defect associated with NMS.

Acquired Causes of Rhabdomyolysis

The majority of patients who develop rhabdomyolysis have no underlying neuromuscular disease but are exposed to a range of inciting factors or events (Table 78.2). Genetic susceptibility is not considered to be responsible for the development of rhabdomyolysis: any human who is stressed sufficiently, exposed to drugs or toxins, or suffers from metabolic disorders or infectious diseases may develop rhabdomyolysis.

In large series of patients with rhabdomyolysis [7, 69], alcoholism and drug abuse are responsible for the majority of cases. Ethanol itself may have a direct toxic effect on muscles [70] and interfere with muscle metabolism [71]. In contrast to alcohol-induced rhabdomyolysis, which is marked by muscle pain, acute hypokalemia myopathy observed in alcoholics is characterized by rapidly developing painless muscle weakness [72]. A subclinical chronic myopathy may proceed to acute muscle necrosis after a sustained period of alcohol abuse and starvation [72]. Involvement of the heart muscle, resulting in cardiomyopathy, has been described [73]. Chronic alcoholism leads to muscle atrophy, primarily of type 2 fibers [74]. Histological analysis reveals necrosis and invasion of degenerated fibers by leucocytes and macrophages [75]. At an ultrastructural level, there is dilatation of sarcoplasmic reticulum, increased fat and glycogen, and distorted mitochondria [70].

Table 78.2 Causes of acquired rhabdomyolysis

Toxic
Alcohol, drugs, and toxins (see Table 78.3)
Excessive muscle exercise
Sports and military training
Status epilepticus, convulsions, prolonged myoclonus, status asthmaticus, acute dystonia
Direct muscle injury
Crush, burning, freezing, electric shock, lightning stroke, prolonged immobility, compartment syndrome
Ischemic injury
Compression, vascular occlusion, sickle cell trait
Metabolic disorders
Diabetic ketoacidosis, nonketotic hyperosmolar coma, hypothyroidism, hypophosphatemia, hyponatremia, hypokalemia, hypocalcemia
Infections
Bacterial, viral
Heat-related syndromes
Toxic shock syndrome, heat stroke, hypothermia
Inflammatory myopathies
Polymyositis, dermatomyositis
Other
Anticholinergic syndrome, withdrawal of L-Dopa

Four patients have been described with end-stage renal failure on hemodialysis who developed rhabdomyolysis after major surgery [76]. This possibly underappreciated complication was manifest by extreme hyperphosphatemia, hypocalcemia, and elevated CK. The possible precipitating factors included opiates used for anesthesia and postoperative pain control, anesthetic agents, and surgical position. As treatment options, the authors suggested increasing dialysis to control hyperphosphatemia and hypocalcemia [76]. Surgery itself, particularly in a prolonged position, may be a causative factor for rhabdomyolysis [77–79].

Rhabdomyolysis has developed in patients exposed to a great variety of *drugs and toxins* with a direct effect on muscle, including heroin [80], cocaine [81], amphetamine [82], phencyclidine [83], theophylline [84], antihistamines [85], antihyperlipidemics [86], barbiturates, antibiotics, beta-blockers, and several other myotoxic drugs (Table 78.3) [1, 87–91]. Some drugs and toxins exert a direct toxic effect

Table 78.3 Drugs and toxins associated with rhabdomyolysis

Drugs
Acetaminophen, amphetamines, amphotericin B, antibiotics (several), antihistamines, azathioprine, bactrim, barbiturates, bezafibrate, caffeine, clofibrate, cocaine, epsilon aminocaproic acid, ethanol, glycyrrhetinate (licorice, carbenoxolone), β-HMG-CoA reductase inhibitors, imatinib mesylate, iron dextran, isoniazid, lamotrigine, lithium, LSD, marijuana, meprobamate opiates, mineralocorticoids, phencyclidine, phenytoin neuroleptics, rohypnol, serotonin reuptake inhibitors, strychnine, succinylcholine suxamethonium, theophylline, vasopressin, zidovudine
Toxins
Carbon monoxide, *C. Diff* toxin, gasoline, Haffs fish, plasmocid, staphylococcal toxin, streptococcal toxin, tetanus toxin, toluene, typhoid toxin

on muscles, but in many others, the underlying mechanisms are not clear. Neuroleptics may primarily affect the central nervous system. The abrupt withdrawal of L-dopa medication in parkinsonian patients [92] may lead to clinical features similar to NMS and the central anticholinergic syndrome, consisting of dry mouth, dilated pupils, urinary retention, increased body temperature, and rhabdomyolysis. Overdose of certain drugs such as heroin and barbiturates is associated with rhabdomyolysis, which may be due to secondary factors like muscle compression in coma, delirium, and hyperthermia. Rhabdomyolysis has frequently been observed after chronic ingestion of compounds and drugs associated with hypokalemia, including licorice, carbenoxolone, laxatives, and diuretics [93, 94].

Several case reports of rhabdomyolysis describe envenomation by snakes, hornets, spiders, and scorpions containing myotoxins, probably phospholipases, that proved to cause rhabdomyolysis [95]. Two large epidemics of acute attacks of rhabdomyolysis occurred after ingestion of contaminated fish [96]. Eating quails, fed with hellebore or hemlock, has also been associated with fatal outbreaks of rhabdomyolysis [2, 97].

Rhabdomyolysis may occur due to *strenuous exercise*, especially in untrained individuals [98]. A lack of heat acclimatization, profuse sweating, insufficient intake of salts and high ambient temperature, resulting in hemodilution and hyponatremia, contribute to the development of rhabdomyolysis [99]. Extreme muscle activity with pathological conditions, such as generalized convulsions [100], status epilepticus [101], and status asthmaticus [102]; prolonged myoclonus [103]; severe dystonia [104]; or acute psychosis [105] may result in rhabdomyolysis.

Heat stroke is a disorder manifested by rhabdomyolysis and metabolic encephalopathy, anhydrosis, and hyperthermia. Heat-related syndromes are reported in users of phenothiazines, which may impair temperature regulation [106]. Heatstroke may develop in older individuals secondary to exhaustion [107], amphetamine abuse [82], and in patients with sickle cell trait [108]. Heat-related syndromes may be complicated by disseminated coagulopathy.

Direct muscle injury occurs in crush [109], ischemic injuries [110], burns, frostbite [111], electric shock, or lightning stroke [112]. Prolonged immobility during surgery [113] and pressure palsies in comatose patients seem also to interfere with the energy metabolism of muscles, resulting in rhabdomyolysis.

Metabolic depression may directly affect muscles or indirectly disturb energy metabolism. Diabetic ketoacidosis [114], nonketotic hyperglycemia [115], and hypothyroidism [116] are the primary disorders affecting muscle cell integrity or distorting cellular energy processes. Rhabdomyolysis induced by hypokalemia is associated with the intake of several medications and compounds but is also observed in miscellaneous disorders like anorexia nervosa [117]. Bartter's syndrome [118], renal tubular acidosis [119], total parenteral nutrition [120], and electrolyte disturbance following small-bowel resection [121]. Hyponatremia, due to water intoxication, as a cause of rhabdomyolysis was described in a patient with psychogenic polydipsia [122].

Inflammatory muscle diseases, such as polymyositis and dermatomyositis, are frequently associated with rhabdomyolysis [123]. Patients with chronic inflammatory myopathy also appear more susceptible to attacks of rhabdomyolysis [124].

Rhabdomyolysis occurs in a variety of systemic infections [125] and may be related to fever [126], the effect of toxins, or a direct injury of skeletal muscle by infectious agents. Rhabdomyolysis is described secondary to bacterial infections including typhoid fever [127], *Staphylococcus* [128], Streptococcus pneumonia [129, 130], and infection by *Shigella*, *Salmonella*, *Herbicola lathery*, and *Escherichia coli* [131]. Legionnaires' disease [132], leptospirosis [133], and *Clostridium perfringens* infection [134] are also reported in association with rhabdomyolysis. Rhabdomyolysis may play a role in the toxic shock syndrome [135] due to toxin production or from dehydration, rigors, and fever. It is associated with staphylococcus aureus and Group B streptococcus, and cases have been reported with Group C streptococcus [136] and characterized by hypotension, fever, encephalopathy, erythematous rash, liver disease, and renal failure.

Influenza is the most common trigger for developing virus-induced rhabdomyolysis [137]. Many viruses may cause rhabdomyolysis, including Epstein–Barr [138], coxsackie [139], herpes [140], adenovirus [141], enterovirus, and echoviruses [142] as well as in association with human immunodeficiency viral infection [143].

The primary etiologies of *acute rhabdomyolysis in children* are associated with anoxic–ischemic encephalopathy (including sudden infant death, near drowning [144, 145], and other life-threatening events), electrolyte disorders, severe hyperthermia, poisonings, and hereditary myopathies.

Non-traumatic rhabdomyolysis must be suspected in these circumstances, requiring blood CK measurements. In children, clinical signs are variable and nonspecific [146].

Diagnosis

The diagnostic procedures recommended depend on the clinical presentation, the severity of the muscular manifestations, the presence of complications, and the presumed etiological factors. In general, the diagnostic pathway may be divided into three main steps:

1. Confirmation of the diagnosis of rhabdomyolysis and its common pathogenic causes
2. Estimation of the risk for developing acute renal failure and prevention of other complications in the acute phase
3. Search for an underlying metabolic disorder or genetic defect

The diagnosis of rhabdomyolysis is suspected from the patient's presentation and may be confirmed by an increased serum CK and myoglobin. In the initial phase, myoglobin in the urine may be established by radioimmunoassay.

Careful evaluation of the patient's history and laboratory data will promote prompt treatment and minimize the complications associated with rhabdomyolysis. Analyses of arterial blood for pH, P_{CO2}, and P_{O2} should be performed and measurement in serum should be made of sodium, potassium, chloride, CO_2 content, calcium, phosphate, albumin, uric acid, lactate dehydrogenase, aspartate aminotransferase, bilirubin, alkaline phosphatase, urea, and creatinine. The urinary output and pH of the urine should be quantitated. Attention must be paid to exogenous toxins, such as illicit drugs, alcohol, and prescribed drugs, the most common cause of rhabdomyolysis [22].

When the underlying pathogenesis is not clear, and especially with recurrent rhabdomyolysis, the patient should be assessed for a genetic disorder of muscle metabolism [22]. Evaluation of the medical history must be directed to the familial occurrence of muscular symptoms, exercise intolerance, anesthesia-induced muscle problems, and the presence of the second wind phenomenon (see Chap. 63).

Physical examination usually reveals no abnormalities and only rarely slight muscle atrophy or weakness. Computed tomography and particularly gadolinium enhanced magnetic resonance imaging may be helpful in determining the extent of muscle damage [147]; however, their clinical value has not been assessed.

Biochemical assessment consists of measuring the activities of glycogenolytic enzymes in erythrocytes and of CPT I and II in leucocytes and serum carnitine and organic acids in urine. Electromyography is only of value in the acute phase of rhabdomyolysis when myopathic findings may be present. On muscle biopsy, light-microscopic findings of necrosis of muscle fibers are rather nonspecific and of little value in differential diagnosis. Histochemical examination, however, may reveal glycogen accumulation or increased lipid deposits indicating a glycogenolytic enzyme deficiency or disorder of lipid metabolism. Enzyme histochemical examination may reveal deficiency of glycogenolytic enzymes or MAD. Biochemical investigation of muscle biopsy may yield important information about carnitine content and CPT I and II activity, oxidation of fatty acids, pyruvate oxidation, and mitochondrial metabolism. The activity of glycogenolytic enzymes may be measured in muscle tissue biochemically or determined by chromatographic or electrophoretic examination, or their contents may be determined by immunological methods.

Treatment

Management of rhabdomyolysis includes two aspects: supportive medical care in the acute stage and treatment or elimination of the underlying cause.

Acute Management

Renal Failure

The treatment in the acute phase of rhabdomyolysis consists of maintenance of adequate circulating blood volume and sufficient diuresis to prevent acute tubular necrosis. Intravenous administration of 4–11 l of normal saline solution may be necessary to maintain blood pressure and urine output. Volume expansion is essential to increase urinary output and to dilute the concentration of myoglobin. While there is evidence that supports prompt intravenous volume expansion, there is no adequate evidence to support one particular crystalloid. There is no significant benefit to forced diuresis with either loop diuretics or osmotically active agents; however, the one study did not stratify by disease and included all etiologies for acute renal failure in addition to rhabdomyolysis [148]. Because an acidic urine favors myoglobin-induced nephrotoxicity, alkalinization of the urine by adding sodium bicarbonate to the intravenous fluids has been advocated [149]. But two independent investigations failed to demonstrate a difference between resuscitation with saline versus a bicarbonate solution in the prevention of rhabdomyolysis-induced renal failure [1]. The use of sodium bicarbonate is controversial as very large quantities of bicarbonate may aggravate hypocalcemia [10]. Alkalinization of the proximal tubular fluid pH by the administration of the carbonic anhydrase inhibitor acetazolamide is not beneficial [150].

Treatment with an iron-chelating agent such as dysferoxamine awaits clinical validation. The radical scavenging

agent glutathione may further deplete intracellular ATP stores and thus contribute to the proximal tubular injury. The hyperuricemia may respond to saline diuresis. Xanthine oxidase inhibitors may not prevent hyperuricemia acutely, if there is ongoing muscle necrosis [150].

If oliguria persists and medical treatment is not sufficient to overcome renal failure, dialysis may be necessary to manage hyperkalemia, acidosis, or volume overload. Uremic encephalopathy may be an indication for dialysis as well. Intravenous glucose and insulin help drive the extracellular potassium into the intracellular compartment. Hemodialysis and continuous (arteriovenous or venous–venous) hemofiltration restore fluid and electrolyte balance more quickly than peritoneal dialysis. Peltonem et al. suggests patients treated with hemodiafiltration and forced alkaline diuresis had a much higher clearance of the plasma myoglobin than that of patients receiving forced alkaline diuresis alone [151]. There are advantages and dangers of commonly suggested drugs used in acute renal failure (see Reference [149]).

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) should be treated with fresh frozen plasma, clotting factors only if there is a bleeding. Epsilon aminocaproic acid, an antifibrinolytic drug, should be avoided as treatment because of rhabdomyolysis as a potential adverse effect [152].

Compartment Syndrome

Prevention of compartment syndrome may be achieved by careful clinical or intracompartmental pressure monitoring followed by urgent decompressive fasciotomy when necessary. Nerves are damaged by external pressure, ischemia, and increased intracompartmental pressure. Tissue pressure measurements possibly aid in the decision of whether or not surgical intervention is indicated. If the interstitial muscular pressure during 8 h exceeds 35 mmHg, fasciotomy is recommended.

Hypocalcemia

Infusion of calcium salts to counteract the effects of hyperkalemia is not recommended in the presence of hyperphosphatemia, as it may cause calcium phosphate deposition in soft tissue. Unless there is a threat of hyperkalemic cardiac rhythm disturbance, calcium infusion is not indicated [153].

Treatment or Elimination of the Underlying Cause

In acquired recurrent rhabdomyolysis, withdrawal of the toxic drug or compound is the treatment of choice. Eventually, oral ingestion of the causative agent may be treated with gastric lavage or activated charcoal or elimination may be forced by diuresis, hemofiltration, or hemodialysis [152].

In the case of a glycogenolytic enzyme deficiency or a disorder in lipid metabolism, advice should be given about adequate intake of food in relation to exercise. In MH and NMS dantrolene, sodium is the medication of choice to prevent muscle necrosis. Since MH is almost always observed after administration of volatile anesthetics, for example, halothane, and depolarizing muscle relaxants such as succinylcholine, these anesthetic agents must be avoided in these patients. A combination of cooling, hydration, and intravenous administration of dantrolene sodium are the therapy of choice and may be life saving.

Several therapies have been tried to improve exercise tolerance in glyco(geno)lytic disorders and to prevent attacks of rhabdomyolysis. Oral supply of glucagon or glucose has no long-lasting effect. In PFK deficiency, glucose has a negative effect on exercise tolerance as it cannot be used as energy supply and even impedes lipolysis. Wagenmakers et al. [154] suggested that especially physical training would stimulate the mitochondrial oxidative processes and improve exercise tolerance in myophosphorylase deficiency.

Patients with disorders of lipid metabolism (CPT I, II, LCHAD, SCHAD deficiency) should receive frequent, low-fat, high-carbohydrate meals and should never skip meals. Prolonged exercise should be avoided and intravenous glucose should be provided early in any illness associated with a diminished oral intake [155].

Conclusion

Rhabdomyolysis is common. The clinical manifestations vary widely from mild myalgia to severe muscle weakness with involvement of other organ systems. Measuring serum CK and myoglobin should confirm the diagnosis. The subsequent metabolic disturbances may be life-threatening factors. Cardiac arrest, acute renal failure, and the compartment syndrome are the major complications of severe rhabdomyolysis. The etiologic factors of rhabdomyolysis are numerous and of diverse origin. Alcoholism, drugs and toxins, strenuous exercise, infections, and metabolic disorders are the most common etiologies in acquired rhabdomyolysis.

For some patients, rhabdomyolysis may be prevented. An accurate history may reveal patients with MH or other neuromuscular disorders in whom specific anesthetic management is mandatory. In other high-risk patients groups, that is, patients with end-stage renal failure or alcoholics, an unsuspected factor, like surgery, may trigger the onset of rhabdomyolysis. Physicians must be made aware of the occurrence of drug interactions, for example, β-hydroxy methylglutaryl coenzyme A reductase inhibitors (statins) with erythromycin [156], cyclosporine [156–158], or ketoconazole [159], which increase the risk

of rhabdomyolysis. Clinicians should also be vigilant in taking a careful history for hereditary disorders, especially in those with a suggestion of skeletal muscle involvement, that may place a patient at risk for rhabdomyolyis.

Eosinophilia-Myalgia Syndrome, Eosinophilic Fasciitis, and Related Fasciitis Disorders

79

Jeffrey A. Allen and John Varga

The fasciitis disorders represent a diverse group of chronic, frequently progressive diseases characterized by inflammation and excessive accumulation of collagen in the subcutaneous tissue. The pathogenesis of the fasciitis disorders is still mysterious. To a smaller or larger degree, these disorders share clinical and histopathological features with systemic sclerosis (SSc), the prototype systemic fibrosing disorder. The fibrosing disorders have in common marked fascial fibrosis that often occurs as part of a systemic disorder affecting multiple organ systems. This heterogeneous category of conditions include eosinophilia-myalgia syndrome (EMS), the toxic oil syndrome (TOS), and eosinophilic fasciitis (diffuse fasciitis with eosinophilia, DFE), as well as a broad group of localized or systemic disorders. Some of these are listed in Table 79.1. Patients with these disorders may seek medical care from a variety of specialists, including rheumatologists, neurologists, and dermatologists.

Eosinophilia-Myalgia Syndrome (EMS)

Introduction

In 1989, an outbreak of the eosinophilia-myalgia syndrome (EMS) [1, 2], a previously unknown illness with the abrupt onset of constitutional symptoms, myalgia, and marked peripheral eosinophilia, was recognized. While more than 1,500 patients were reported to the Centers for Disease Control and Prevention (CDC), there are estimates that many more cases occurred [3, 4]. Among its multisystem manifestations, EMS was associated with prominent neuromuscular involvement.

Etiology and Pathogenesis

Epidemiological studies revealed a strong association between the use of L-tryptophan (LT)-containing products and EMS [5]. In almost all cases, the source LT was traced to a single manufacturer [6–8]. In late 1989, the US Food and Drug Administration (FDA) issued a nationwide recall of LT-containing products. With the removal of tryptophan from consumer markets, the number of new EMS cases diminished rapidly [9]. Detailed analysis of implicated LT revealed more than 60 trace impurities, 6 of which were associated with EMS [10, 11]. The best characterized of these is 1,1′ethylidenebis (L-tryptophan) (EBT) [12, 13]. EBT studies have duplicated some, but not all, EMS-like features, including stimulation of fibroblast proliferation and eosino-

phil modulation [14–16]. Nonetheless, the role of EBT in EMS remains uncertain [17]. Later studies identified other EMS-associated impurities, including 3-(Phenylamino)alanine or PAA [18–20]. PAA shares chemical properties with 3-(N-phenylamino)-1,2-propanediol (PAP) linked to the 1981 toxic oil syndrome (TOS) epidemic in Spain and thus generated particular interest. PAP can undergo biotransformation to PAA and both can be converted into quinone imine intermediate metabolites by similar bioactivation pathways. These compounds are reactive toward nucleophiles present on many biological molecules [21]. In addition to EBT and PAA, other recognized EMS-associated LT impurities include 2-(3-indolylmethyl)-L-tryptophan, 3a-hydroxy-1,2,3,3a,8,8a-hexahydropyrrolo-(2-3b)-indole-2-carboxylic acid, and 2-(2-hydroxy indoline)-Trp [22, 23].

Despite the strong association between EMS and LT ingestion, 2 % of individuals with EMS reported no history of LT use and other cases antedated the 1989 epidemic when LT products were not available [3]. In 2005, the FDA lifted the LT import alert and LT was once again available in US markets. In 2011, a new patient with EMS was identified [24]. This patient developed the classic clinical and histopathological features of EMS following LT exposure.

The incidence of EMS even among epidemic LT users was very low [6–8, 25, 26]. Risk factors included larger doses of LT and increasing age [26]. Polymorphisms in immune response genes also seem to be important. HLA-DRB1 and DQA1 allele typing performed on patients with documented LT ingestion showed that HLA-DRB1*04 and DQA1*0601 were EMS risk factors, whereas DRB1*07, DQA1*0501, and DQA1*0201 were protective [27, 28]. These observations indicate a role for genetic factors in regulating susceptibility for EMS in exposed individuals.

The major pathological processes in EMS are inflammation and fibrosis. The primary findings are (1) mononuclear inflammatory cells with occasional eosinophils in the subcutaneous fat, septa, fascia, around blood vessels and nerves, and in the muscle perimysium and epimysium (Fig. 79.1); (2) endothelial cell swelling; and (3) collagen accumulation in subcutaneous areas with fibrosis [29–32]. Although intact eosinophils may be absent in affected tissues, the eosinophil degranulation products major basic protein and eosinophil derived neurotoxin are often prominent. The histopathological findings in EMS are distinctive but not unique [33–44].

The pathogenesis of EMS is thought to involve exposure to certain preparations of LT in a genetically susceptible host that trigger acute inflammation and eosinophil activation with resulting chronic tissue fibrosis [45–56]. Dysregulated cellular immunity appears to play an important role in the acute phase. This is supported by recognition of inflammatory cell infiltration in patients with active EMS [57], altered ratios of T-cell phenotypes of peripheral blood monocytes, lack of local complement activation, a paucity of B cells, and absence of immunoglobulin reactivity [58]. The etiologic agent(s) may act directly on mononuclear cells, possibly mediated via the toll-like receptor innate immune receptors leading to production of inflammatory cytokines and chemokines, which could then activate tissue eosinophils and convert them to a hypodense phenotype. Once activated, eosinophils can release additional cytotoxic molecules and cytokines such as interleukin-4 [54], granulocyte-macrophage colony-stimulating factor (GM-CSF) [55, 56], interleukin-5 [59], and transforming growth factor-beta (TGF-ß) [60]. TGF-β is considered to be paramount in inducing fibrogenesis [24, 60, 61]. Gene expression profiling of lesional EMS tissues has demonstrated activation of TGF-ß pathways, with consequent upregulation of collagen genes associated with extracellular matrix production and remodeling [24, 60, 62, 63]. These findings suggest that eosinophil-derived TGF-ß may drive the chronic fibrotic response in EMS.

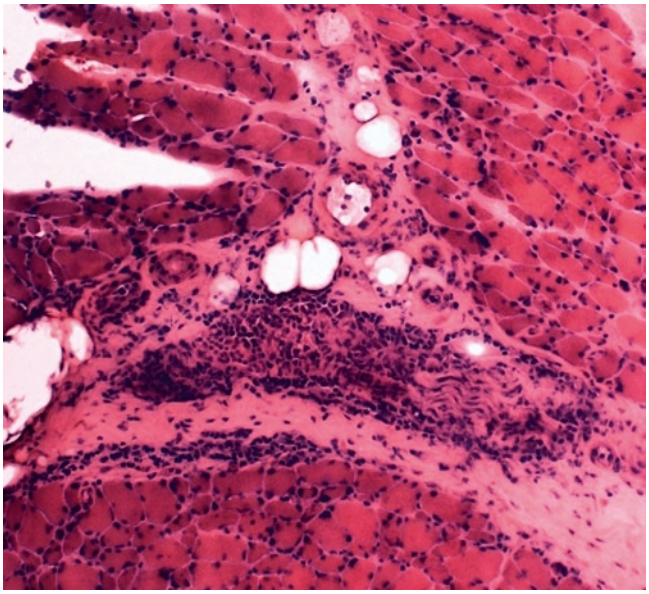

Fig. 79.1 Histopathological changes in skeletal muscle in a patient with EMS. Note the presence of perimysial inflammation (Hematoxylin and eosin stain, magnification ×250)

The exact etiologic agent responsible for EMS has yet to be identified. Impurities recognized within implicated LT have generated interest, although other uncharacterized impurities may likewise be responsible. Notably, EMS has been reported in individuals who have never consumed LT and in individuals consuming LT free of the previously implicated impurities [24, 64, 65]. These cases suggest that xenobiotics other than LT or perhaps LT itself may trigger a similar pathologic process. The potential role of eosinophils in fibroblast activation and connective tissue accumulation is further supported by the association of various forms of pathological fibroses with tissue eosinophilia shown in Table 79.2.

Clinical Presentation

EMS is a multisystem disorder with variable degrees of severity. Muscle, nerve, fascia, skin, and lung are most commonly affected. The clinical course consists of acute and chronic phases. In the acute phase, most patients develop severe myalgias, weakness, numbness, paresthesias, rash, and swelling [1, 4, 18, 66–71]. Complete blood count (CBC) classically reveals profound eosinophilia that resolves immediately when treated with glucocorticoids or otherwise spontaneously improves within 2–6 months [3, 27, 72–75]. Many patients evolve into a chronic phase, with persistent cutaneous, neuromuscular, and pulmonary involvement.

Neuromuscular

Objective evidence of myopathy and/or neuropathy is present during the first 18 months in many patients [67]. Prominent muscular manifestations of EMS include myalgia, cramps, and a predominantly proximal extremity weakness. Electrodiagnostic (EDX) studies may be indicative of a myopathy with abnormal spontaneous activity (fibrillation potentials and positive sharp waves) along with early recruitment of short-duration, low-amplitude, polyphasic motor unit action potentials [76]. Muscle biopsies often show extensive perimysial and epimysial inflammation (fasciitis) along with excessive perimysial connective tissue fibrosis surrounding the muscle [24, 32, 34, 77]. Endomysial inflammation is usually sparse and, when present, concentrated in perivascular areas. Muscle fiber atrophy and necrosis are less commonly observed.

Neuropathy has been reported in 14–40 % of individuals with EMS and in some patients may be the most prominent clinical feature [3, 35, 36, 56, 72, 78]. The neuropathy may be a painful sensory polyneuropathy, sensorimotor polyneuropathy, purely motor polyneuropathy involving distal muscles, or mononeuropathy multiplex [43, 79]. Cutaneous hypersensitivity with allodynia, burning, or extreme discomfort to light touch is common. A rapidly evolving proximal and distal sensorimotor polyneuropathy similar to Guillain-Barré syndrome occurs infrequently (<5 %) and may progress to respiratory failure and death [80]. EDX testing and nerve histopathology typically reveal evidence of axonal degeneration [36, 42]. Less commonly EDX studies show a demyelinating peripheral nerve process [35, 40]. Epineurial and perivascular inflammatory cell infiltration may be seen on biopsy of affected nerve.

Fig. 79.2 Elbow contractures with associated "groove sign" in a patient with EMS (Photograph courtesy of Dr. Joseph Duffy, Mayo Clinic)

Skin

Fasciitis or other cutaneous manifestations develop in most EMS patients. An acute, transient erythematous, maculopapular rash may be followed by mottled hyperpigmentation. Edema and induration often precede fasciitis. Cutaneous changes most commonly affect the distal forearms and legs and at times lead to joint contractures (Fig. 79.2). Some patients also develop alopecia, localized morphea, and intense pruritus. Thickened fascia, deep dermal fibrosis, and accumulation of mononuclear cells and eosinophils are typically apparent on skin biopsy [81].

Pulmonary

Pulmonary symptoms, including cough and dyspnea, are seen in as many as 60 % of patients. Rarely pulmonary hypertension develops, which gradually resolves except in a few catastrophic cases. Lung biopsies performed in a small number of patients have shown vasculitis and perivasculitis with chronic interstitial pneumonitis [37].

Other

Stroke and encephalopathy are occasionally seen [34, 82]. Although many EMS patients describe neurocognitive symptoms, evidence of organic CNS involvement is

lacking [83]. Palpitations, tachycardia, and chest pain have been reported. The prevalence of cardiac abnormalities is unknown, although life-threatening rhythm disturbances appear to be uncommon. Cardiac autopsy specimens have demonstrated neural lesions throughout the conduction system and inflammatory lesions of the small coronary arteries, similar to the neuropathology seen in skeletal muscle [84]. Gastrointestinal abnormalities, including pancreatitis, malabsorption, and cholangitis, have been observed. Eosinophil infiltration within the bowel mucosa has been appreciated in some patients [85].

Differential Diagnosis

Although the clinical and histopathological features of EMS are unusual, they are not unique. Eosinophilia is seen in a wide spectrum of disorders including atopic diseases, parasitic infections, drug ingestion, hematological diseases, and a variety of connective tissue diseases.

In atopic illness, eosinophilia is low grade and not accompanied by myalgia. Trichinosis may cause myalgia, periorbital edema, and eosinophilia. Most patients have a history of consuming pork or meat of wild mammals. Diagnosis relies on positive serology or demonstration of larvae in muscle. Churg-Strauss syndrome occurs in patients with asthma, nasal polyposis, or sinusitis and is associated with skin rashes, pulmonary infiltrates, and neuropathy. Necrotizing vasculitis of small blood vessels and necrotizing extravascular granulomas distinguish Churg-Strauss syndrome from EMS. Systemic sclerosis (SSc) and EMS are both multiorgan disorders that may have prominent skin thickening and induration. Unlike EMS, SSc is further characterized by Raynaud phenomenon, mat-like telangiectasias, and SSc-related autoantibodies. Muscle involvement is estimated to be at least 14 % but (unlike EMS) is typically accompanied by elevated CK levels. Furthermore, peripheral eosinophilia is rare. Nephrogenic systemic fibrosis (NFS) is a multiorgan fibrosing disorder that primarily affects the skin but may also involve the lungs, heart, and liver. Muscle involvement is unusual but may occur. Renal insufficiency and exposure to gadolinium-containing contrast distinguishes NFS from EMS. The idiopathic hypereosinophilic syndrome (HES) is a heterogeneous group of disorders associated with diffuse organ involvement and extreme eosinophilia that (unlike EMS) persists for more than 6 months [86]. Fibromyalgia has only a superficial resemblance to EMS, namely, myalgias. The hallmark clinical, laboratory, and histopathological features of EMS are not present in patients with fibromyalgia [87]. Diffuse fasciitis with eosinophilia (DFE – see below) shares many features with EMS. Symptoms in DFE are usually less severe and multisystem involvement less frequent (Table 79.3) [88–90]. Finally, EMS bears a striking resemblance to the toxic oil syndrome (TOS) which is discussed later.

Table 79.3 Clinical features of syndromes associated with fasciitis

Evaluation and Diagnosis

There is no diagnostic test for EMS. A detailed history (with particular attention to LT ingestion) and physical examination are essential to make the correct diagnosis. Laboratory data and histopathological analysis of skin, fascia, and/or muscle provide extremely valuable supportive information. Due diligence need be applied to exclude other similar conditions.

In addition to peripheral eosinophilia, laboratory studies may show modestly elevated levels of aldolase. Creatine kinase is usually normal [71]. The discrepancy between these two muscle-associated enzymes can be helpful in differentiating EMS from other myopathies. Erythrocyte sedimentation rate, rheumatoid factor, and levels of IgE, complement, and cryoglobulin (all markers of immune dysfunction) are usually normal. EDX studies may show myopathic with abnormal spontaneous activity (fibrillation potentials and positive sharp waves) and early recruitment of short-duration, low-amplitude, and polyphasic motor unit action potentials [76]. It also may reveal neuropathic abnormalities with evidence of axonal degeneration [36, 42] and less commonly a demyelinating polyneuropathy [35, 40]. Histopathologic analysis of involved tissues usually demonstrates typical features of EMS as previously discussed.

Shortly after the discovery of EMS in 1989, the *CDC case definition* was developed for epidemiological surveillance [68]. It required (1) peripheral eosinophil count greater than 1,000 cells per mm^3, (2) generalized debilitating myalgia, and (3) no evidence of infection or neoplasm that would explain eosinophilia or myalgias. An expert EMS panel subsequently proposed revised diagnostic criteria that were shown to be 97 % specific for EMS [91–93]. Revised criteria require (1) the presence of eosinophilia, myalgia, and either rash, edema, pulmonary involvement, or neuropathy within 6 months of illness onset or (2) either (a) fasciitis, neuropathy, and myalgia or muscle cramps or (b) any three or more of the following: fasciitis,

myopathy, neuropathy, or eosinophilia occurring within 24 months of illness onset. A diagnosis of EMS cannot be made in the presence of another infectious, inflammatory, or neoplastic condition that could account for these abnormalities.

Treatment

The response to therapy has generally been disappointing. In acute EMS, glucocorticoids typically correct the eosinophilia and may be helpful in improving myalgia, clearing pulmonary infiltrates, and resolving edema [78]. However, no evidence exists that glucocorticoids improve long-term outcome [94]. Prolonged treatment with glucocorticoids or other cytotoxic medications is not recommended [95]. A variety of immunomodulating medications have been used for EMS [96]. Although favorable responses have occasionally been reported, very small treatment numbers, the possibility of spontaneous improvement, and short follow-up limit the interpretation of these case reports. Therapy of chronic disability is targeted at amelioration of continuing symptoms and is focused on physical therapy, pain control, and psychological support [97].

Natural Course and Prognosis

Early in the outbreak, EMS caused serious illness resulting in the hospitalization of 30–70 % of patients with a mortality rate of 2 %. The majority of deaths occurred within 6 months of illness onset, most of which were related to neuropathy and myopathy complications (pneumonia, respiratory failure, and sepsis) [67, 84]. Poor prognostic indicators included severe disease at onset [74], increasing age, and multiorgan involvement [98].

Chronic disability largely results from cutaneous, neuromuscular, and pulmonary involvement mediated on the basis of persistent fibrosis. The most common features of chronic EMS are proximal weakness, paresthesias, numbness, muscle cramps, myalgia, joint pain, and scleroderma-like skin changes [78, 99, 100]. Although symptoms generally improve to some degree over 24 months, up to 88 % of patients manifest more than 3 of these symptoms after 3 years [78].

The Toxic Oil Syndrome (TOS)

Introduction

The toxic oil syndrome (TOS) was an epidemic illness with prominent diffuse fasciitis and neuromuscular involvement that occurred in Spain in the spring of 1981. The new disease was first recognized after an 8-year-old boy died with acute pulmonary insufficiency. Six of eight family members also became ill. Over 20,000 individuals were ultimately affected, and more than 11,000 hospital admissions related to TOS occurred within several months of the outbreak [101, 102].

Etiology and Pathogenesis

Epidemiological studies showed a close relationship between TOS and consumption of industrial grade rapeseed oil. At the time, rapeseed oil could not be legally imported into Spain as a food substance, only as an industrial lubricant after denaturation with aniline. Once in Spain, the oil was illegally de-denatured by a refining process that removed almost all of the aniline and was subsequently mixed with other seed oils, animal fats, poor quality olive oil, or chlorophyll to produce the desired color. The resulting adulterated oil was sold as pure olive oil.

The number of TOS cases dropped sharply following removal of the oil from the market [103, 104]. Several impurities were proposed as the etiologic agent. Analyses of implicated oils demonstrated that free aniline and aniline derivatives were significantly associated with case-related samples. Another case-related contaminant, 3-phenylamino-1,2-propanediol (PAP) [18–20], generated particular interest when it was recognized that PAP shares chemical properties with the EMS tryptophan impurity PAA (see EMS; Etiology and Pathogenesis). Nonetheless, attempts to reproduce TOS-like biologic phenomena in vitro and in vivo have not been successful [105, 106], and the precise identity of the etiologic agent has not been determined [107–109].

The pathogenesis of TOS remains undefined. The most prominent pathological feature in TOS is a non-necrotizing vascular lesion principally affecting the intima of all types of blood vessels. Perivascular mononuclear inflammation was common, which typically progressed to intimal proliferation, with fibrosis and thrombosis. Inflammation was also noted in the fascia, the perineurium of peripheral nerves, the perimysium and epimysium, and occasionally muscle spindles and intramuscular nerves [110, 111].

Clinical Presentation

The latency between TOS and the ingestion of contaminated oil was between 4 and 10 days. After a prodromal period, three relatively well-defined phases [112] were recognized: the acute phase (0–2 months) with major lung involvement, the intermediate phase (2–4 months) with features of thrombotic phenomena and pulmonary hypertension, and the chronic phase (>4 months) with marked neuromuscular involvement. New symptoms cease to appear 8–10 months after onset.

Fig. 79.3 Severe muscle atrophy in a Spanish patient with advanced TOS

Neuromuscular

Myalgias and cramps, often severe and diffuse, were common in the acute and intermediate phases of the illness. About half of patients also developed a neuropathy, usually during the intermediate phase. EDX studies typically revealed an axonal process affecting sensory and motor nerve fibers. The neuropathy may be generalized affecting both proximal and distal areas and length-dependent or multifocal affecting multiple individual nerves. EDX may also reveal a superimposed myopathic process [113]. In some individuals, the neuropathic or myopathic process led to dysphagia and respiratory failure. Histopathologic analysis revealed inflammatory cell infiltration of the perimysium and around intramuscular nerves in muscle and into the epineurium and perineurium areas in peripheral nerve [114]. Non-necrotizing vasculitis was a prominent pathological feature in all affected organ systems, including muscle and nerve [115].

The chronic phase of TOS in some patients was characterized by progressive muscle wasting (Fig. 79.3) diffuse and symmetric polyneuropathy and fasciitis. Although inflammatory muscle involvement likely accounted for the early TOS neuromuscular symptoms, the chronic phase was driven by the progressive neuropathic process. The most distinctive pathological features during the chronic phase were neurogenic muscular atrophy, degeneration of myelinated axons, perineurial fibrosis, and endomysial fibrosis [114, 115]. In some individuals, muscle atrophy and weakness led to hand deformities and wrist contractures (Fig. 79.4). The most severe cases progressed to complete quadriplegia, respiratory failure requiring mechanical ventilation, or death.

Fig. 79.4 Contractures of the interphalangeal joints of the hand associated with peripheral neuropathy in a patient with late-stage TOS

Pulmonary

The onset of illness was classically associated with striking respiratory symptoms including shortness of breath and cough. Chest radiographs usually showed a diffuse interstitial and alveolar pattern described as non-cardiogenic pulmonary edema. Histopathological studies of lung tissue in the early phase revealed interstitial edema with little or no inflammation. Most patients recovered from this transient acute illness. Some, however, developed fulminant respiratory failure, which was the most common cause of early death [106]. In the intermediate phase of the illness, pulmonary hypertension secondary to pulmonary vessel thrombosis occurred in up to 20 % of TOS patients. Although many spontaneously resolved, in a small subset of patients, it had a malignant and fatal course [116–118]. Respiratory failure, sometimes requiring mechanical ventilation, during the chronic phase of the illness was typically due to progressive polyneuropathy.

Psychological

Many patients complained of psychological difficulties. A nonspecific syndrome that included nightmares, insomnia, anxiety, aggressiveness, difficulty concentrating, or memory difficulty was common. EEGs, brain imaging, and brain autopsy studies were generally normal. Although most patients slowly improved, some did not. Persistent psychological symptoms described as "reactive disaster syndrome" have been reported in approximately 10 % of affected individuals [119].

Other

Fever, pruritic rash, nausea and vomiting, diarrhea, headache, and malaise were common, especially during the acute phase of the illness. Skin rashes varying in appearance from macules or papules to eczema-like patches were frequent and in most patients cleared within 2 weeks. During the thrombotic intermediate phase, some patients developed ischemic cerebral infarction or intracerebral hemorrhage. Acute encephalopathy and seizures were rarely reported. Systemic thrombotic phenomena also included mesenteric and hepatic vein thrombosis.

Differential Diagnosis

Individual clinical findings of TOS are seen in other illnesses. Interstitial pulmonary infiltrates may be encountered in a variety of infectious or hypersensitivity pneumonias. The skin rashes described in early TOS are not specific and resemble those seen in other fasciitis syndromes. Generalized, multifocal axonal neuropathy or mononeuropathy multiplex may occur in any condition that affects the vasa nervorum and may be one component of several multiorgan diseases in which the pathologic process is driven by systemic vasculitis. Several diseases of unknown etiology, such as DFE, eosinophilic perimyositis, and EMS, share certain characteristics with TOS (Table 79.3) [120, 121]. Although TOS in the early stages with acute non-cardiogenic pulmonary edema and later with neuropathic involvement was more severe than EMS, the "average patient" with either disease has remarkably similar clinical manifestations and outcome [122].

Evaluation and Diagnosis

In 1981, the Spanish Clinical Commission proposed a TOS case definition [123]. However, like EMS, there is no diagnostic test for TOS. History and physical are essential to make the diagnosis. EDX studies typically revealed an axonal sensorimotor length-dependent neuropathy, or multifocal mononeuropathy multiplex, sometimes associated with a superimposed myopathic process [113]. Histopathological analysis of affected tissues can provide supportive information. Laboratory studies often showed high levels of peripheral blood eosinophils during the acute and intermediate phases. Increased aldolase with normal CK, hypothyroidism, elevated transaminases, Th2 cytokines (IL-4 and IL-5), IgE, antinuclear, anti-smooth muscle, and antimitochondrial and antiparietal autoantibodies have also sometimes been observed [124]. Compared to the general population, TOS patients have been shown to have a higher prevalence of cardiovascular risk factors, including diabetes, hypertension, and hyperlipidemia [125]. Immunogenetic studies have found that, as in EMS, the HLA-DR4 allele may influence disease susceptibility [126].

Treatment

Patients were initially treated with a variety of antibiotics without success. Although glucocorticoids reduced eosinophil count and led to improvement within hours in very severe pulmonary cases, they did not consistently control other symptoms nor prevent development of the chronic phase of TOS.

Prognosis

Although many TOS cases had severe initial symptoms, some patients improved without apparent sequela [127]. In most the illness evolved into the intermediate and chronic phases with chronic myalgia, muscle cramps, weakness, respiratory symptoms, edema, sicca syndrome, and weight loss [107]. No predictors were identified for development of the chronic phase that occurred in almost 60 % of patients [128]. More than 800 deaths were reported, most occurring within the first year of the disease [129].

Since the end of the 1980s, the main clinical deficits in most individuals have stabilized or improved. However, some degree of chronic disability is common. Approximately 15 % of patients experience total or partial disability [107, 130]. In 2 separate studies performed 18 years [131] and 12 years [132] after the epidemic, weakness, sensory complaints, fatigue, arthralgia, myalgias, sleep difficulty, and memory difficulty were commonly reported in TOS patient groups.

Eosinophilic Fasciitis (Diffuse Fasciitis with Eosinophilia)

Introduction

Eosinophilic fasciitis is clinically characterized by symmetrical skin induration, often accompanied by swelling of the extremities and joint contractures leading to impaired mobility. The syndrome, perhaps better called diffuse fasciitis with eosinophilia (DFE), was first described in 1974 by Shulman

[133]. In the original description, Shulman emphasized the distinctness of the syndrome from scleroderma/systemic sclerosis, with rapid onset of induration of the extremities and striking peripheral blood eosinophilia. The pathological hallmarks of DFE are fibrosis of the fascia and subcutaneous tissue, with or without eosinophilic infiltration of affected tissue.

Etiology and Pathogenesis

The cause of DFE is unknown. Several triggers have been proposed including an antecedent history of vigorous exercise or trauma [134], *B. burgdorferi* infection [135], and toxic exposures. DFE occasionally occurs with other autoimmune conditions, and in up to 15 % of patients, an underlying hematological disorder or malignancy may be uncovered [134]. Nonetheless, the casual relationship between any trigger, autoimmune disease, or malignancy remains unproven.

Like EMS and TOS, eosinophils appear to play a prominent early role in DFE. The association of degranulating eosinophils in tissues with pathological fibrosis is a recurrent finding in the broad group of eosinophilic illnesses (Table 79.2). Once activated, eosinophils are capable of expressing multiple growth factors and cytokines that have been implicated in tissue remodeling and fibrosis [63]. Elevated serum levels of the type two cytokine interleukin-5 and other pro-fibrotic molecules including TGF-β have been reported in patients with DFE [136]. Tissue infiltrating eosinophils may be able to generate a local fibrogenic response by increased expression of TGF-β and eosinophil-derived inducers of fibrogenesis. Fibroblasts derived from the fascia of patients with DFE produce increased amounts of collagen and display elevated levels of mRNAs for type I, type III, and type VI collagens in vitro compared to fibroblasts derived from the adjacent dermis [137].

The histopathological hallmark in established DFE is fascial fibrosis and collagen accumulation. The fibrosis may extend from the fascia into the lower dermis with entrapment of the dermal appendages, the subjacent muscle perimysium, and occasionally into the adipose tissue with panniculitis. The epidermis is usually spared. An inflammatory infiltrate, characterized predominantly by macrophages and CD8+ T cells, may be striking particularly in the early stages of the disease [138]. Eosinophils are usually observed within the affected tissues but may not be present when biopsies are obtained after institution of corticosteroid therapy. Even in the absence of eosinophils, eosinophil degranulation and tissue deposition of major basic protein may be demonstrated by immunohistochemistry, indicating the "footprint" of eosinophil inflammation and degranulation. Inflammation may extend into the adjacent muscle perimysium, but muscle fiber necrosis is not typically present. Inflammation is often perivascular, but true vasculitis is not seen.

Clinical Presentation

DFE affects men and women of all ages but is more common in males (2:1 ratio) and most often affects adults from ages 30 to 60 years [134]. The onset is generally rapid. Most patients experience symmetric spreading of skin changes over days to weeks.

Neuromuscular

Myalgias may be present early in the disease but gradually resolve. Variable degrees of muscle weakness may be present depending on the extent to which the fibrotic and inflammatory process affects the perimysial connective tissue and subjacent muscle fibers. Generalized or multifocal neuropathies are rare. A very small number of DFE associated multiple mononeuropathies have been reported, one of which demonstrated perivascular inflammatory cell collections around epineurial arterioles on sural nerve biopsy [139]. Conversely, carpal tunnel syndrome almost certainly due to median nerve compression at the wrist rather than inflammation has been frequently reported [134]. Extensive fibrosis involving the trunk or neck may be complicated by respiratory difficulty or dysphasia.

Skin and Fascia

The forearms and calves are the most severely affected, followed by the trunk. The hands, feet, and face are generally spared. DFE confined to a single limb, the arms, or legs is rare but has been described. Edema is usually the first visible abnormality to appear, resulting in a dimpling orange peel ("peau d'orange") skin appearance, followed by induration of subcutaneous tissues. If the dermis becomes fixed to the fascial and muscular layers, the uplifted arm may reveal the so-called groove sign with skin puckering and indentation along the course of veins. The skin is often warm, sometimes erythematous, and typically becomes hyperpigmented. The most superficial skin epidermal layer should maintain normal elasticity. With chronic disease, joint contractures and limited mobility can develop.

Other

Typically there is no visceral organ involvement. Fatigue, weight loss, fever, and other constitutional symptoms may be reported in some patients. Raynaud's phenomenon is usually absent.

Differential Diagnosis

The clinical, serological, and histopathological features as well as the pattern and distribution of skin involvement help to distinguish DFE from other fibrosing disorders. Although DFE may be confused with scleroderma/systemic sclerosis,

the absence of characteristic scleroderma associated autoantibodies, sparing of the fingers, and lack of Raynaud phenomenon in DFE are helpful diagnostic clues to differentiate this disease from scleroderma. Additionally, telangiectasia, gastric vascular ectasia, and pulmonary vascular injury are hallmark features common to systemic sclerosis but absent in DFE.

Evaluation and Diagnosis

DFE diagnostic criteria has been proposed but not validated. The most recent proposed criteria require both the typical clinical and histopathological DFE features for diagnosis (major criteria). One major criterion can be replaced by any two of the following minor criteria: eosinophilia, hypergammaglobulinemia, muscle weakness and/or elevated aldolase, groove sign and/or peau d'orange, or hyperintense fascia on T2-weighted MRI imaging [140]. Appropriate exclusionary data must be applied.

The diagnosis of DFE should be established by a full thickness excisional skin biopsy. Especially if weakness is present, extension of the biopsy into the muscle is encouraged. The leading edge of the affected skin, usually the forearm, is the optimal biopsy site. As outlined above, the histopathological findings include fascial fibrosis with infiltration by macrophages, CD8+ T cells, and often eosinophils.

Peripheral blood eosinophilia $>0.5\times10^9$/l is universal early in the disease. Inflammatory markers (erythrocyte sedimentation rate and C-reactive protein) are frequently elevated. Protein electrophoresis usually shows polyclonal hypergammaglobulinemia. Although aldolase is often elevated, CK is usually normal or only mildly elevated. Tests for serum antinuclear and other antibodies are usually negative. Other hematological abnormalities including aplastic anemia, thrombocytopenia, and lymphoproliferative disorders are occasionally observed [141]. MRI can provide supportive data and perhaps is a useful tool to monitor the disease course. Fluid-sensitive MRI images may reveal fascial thickening and edema [142].

Treatment and Prognosis

There are no controlled trials of therapeutic interventions for the treatment of DFE. The optimal immunosuppressant drug, dose, and treatment duration are uncertain. Reports of uncontrolled trials claiming therapeutic efficacy are numerous in the literature but are difficult to interpret. In clinical practice, most consider prednisone 0.5–1 mg/kg daily (or equivalent corticosteroid) first-line DFE treatment. Most patients experience complete or partial improvement with normalization of peripheral eosinophilia over weeks to months [134, 143]. High-dose corticosteroids are generally continued until the beneficial response is maximized (often weeks to months), followed by very slow tapering over several months to a year or more.

Although DFE is generally considered a benign disease with occasional spontaneous remissions, some patients may be refractory to corticosteroid treatment and some patients may relapse when tapered from corticosteroids [134]. Younger age and involvement of the trunk have been associated with residual cutaneous fibrosis and may be considered unfavorable prognostic indicators [144]. Multiple other agents used alone or in combination with corticosteroids have been reported. Histamine receptor blockers (e.g., cimetidine), hydroxychloroquine, methotrexate, mycophenolate mofetil, azathioprine, infliximab, UVA photochemotherapy, cyclophosphamide, and cyclosporine have been used with variable degrees of success. In all patients, physical therapy is important to prevent and improve joint contractures.

Neuropathic Pain and Other Chronic Musculoskeletal Pain Conditions

80

Steven N. Sykes and Said R. Beydoun

Introduction

Neuropathic pain and certain other types of chronic pain occur as a result of maladaptive changes in the peripheral and central nervous system. The same peripheral and central nervous system pathways involved in normal, protective mechanisms of pain are involved in disease states of chronic pain. Chronic pain occurs as a result of neural plasticity, with changes in the structure and function of neurons and glia. These changes occur at the level of the receptors and gene regulatory proteins, leading to phenotype switch of certain neurons and altered function. Understanding the pathophysiology of chronic pain affords the opportunity to more optimally manage symptoms, using a scientific rational mechanistic treatment approach.

Neuropathic Pain

The International Association for the Study of Pain in 1979 defined pain as "an unpleasant sensory and emotional experience." Neuropathic pain is a form of chronic maladaptive pain, which was recently redefined as pain due to "a lesion or disease affecting the somatosensory system" [1, 2]. That definition encompasses all causes of neuropathic pain, irrespective of etiology or symptom description. Symptom descriptors commonly used to describe neuropathic pain include electric shock-like, shooting, stabbing, burning, lancinating, lightening-like, or radiating. This is in contrast to "somatic" or non-neuropathic pain, commonly described using terms such as throbbing, dull, or aching; it should be noted that the latter descriptors of pain can overlap in both neuropathic and non-neuropathic pain conditions. The presence of neuropathic pain can further be characterized as "definitive," "probable," or "possible," based on features including the presence of a localizing neuroanatomical distribution of pain, a history of some illness or injury expected to affect the somatosensory system, and demonstration of that illness or injury by objective examination findings, diagnostic testing, and/or other diagnostic criteria [2].

In addition to neuropathic pain, there are other types of chronic pain, such as pain due to inflammatory and musculoskeletal conditions as well as non-neuropathic/noninflammatory musculoskeletal pain, which can result in pathophysiological changes in the nervous system. Despite their seemingly different etiology and underlying mechanisms, distinguishing neuropathic from non-neuropathic pain can be difficult clinically, particularly as both processes may exist concurrently. Understanding its pathogenesis may however allow the clinician to better manage neuropathic pain, as well as other forms of chronic pain.

In contrast to neuropathic pain, nociceptive pain, also known as "physiologic pain," refers to acute pain generated as a result of tissue injury activating an intact nervous system; nociceptive pain usually results in "adaptive neural responses." Nociceptive pain is self-limited in nature, subsiding and resolving with subsidence of the tissue injury. While nociceptive pain is distinguished from neuropathic pain by the absence of an abnormality within the nervous system, the patient's subjective symptoms may be indistinguishable.

Pathophysiology

Nociceptive pain processing occurs in different regions or "stations" of the nervous system, including the peripheral nervous system, spinal cord, and brain. The structures and pathways that transmit the normal pain signal to the brain are the same as those pathologically involved in transmitting the abnormal pain signal in chronic pain conditions. The normal

DOI 10.1007/978-1-4614-6567-6_80, © Springer Science+Business Media New York 2014

response to acute pain is protective or adaptive; however, in chronic pain conditions, pain itself becomes a disease state due to plasticity changes within the nervous system.

Perception of pain is an important protective, physiologic warning signal of potential tissue damage [3]. Transduction refers to the phenomenon whereby certain signals (mechanical, chemical, or thermal) acting on specialized nociceptors become converted into an electrical signal occurring as a result of depolarization of cell membranes. Conduction occurs when that electrical signal travels along primary afferent fibers to the dorsal horn of the spinal cord. Inside the spinal cord, transmission occurs via ascending pathways, including the spinothalamic and spinoparabrachial (spinoreticular and spinomesencephalic) tracts. These signals are then relayed to the thalamus and then to the somatosensory cortex. Once these impulses reach the somatosensory cortex, pain perception occurs.

In addition to the ascending pathways, pain perception is also affected by an important descending pathway, which modulates pain transmission. Thus, pain is a dynamic bidirectional process. The descending pathway normally has an inhibitory function; inhibitory interneurons project from the brainstem to the dorsal horn of the spinal cord and thus can modulate pain signaling from the dorsal horn into the higher structures (thalamic and cortical). Whereas the spinothalamic tract projects to the thalamus and somatosensory cortex, allowing the cognitive perception of pain and localization of pain, an affective response also occurs as a result of the relay of signals from the spinoparabrachial tract into the parabrachial nuclei of the brainstem which project to the hippocampus and amygdala [3].

Pain sensation can be spontaneous or stimulus-induced. In the latter, and in normal pain (adaptive or nociceptive) situations, as the intensity of a given stimulus is increased, pain will not be perceived below a certain threshold. Above that threshold, the sensation may then be perceived as pain, with the pain perception increasing proportional to the increase in stimulation. However, in chronic pain conditions, plasticity ensues, neurons become sensitized, and, as a result, stimuli of subthreshold intensity can elicit pain; this phenomenon is referred to as allodynia, defined as pain in response to touch or mechanical stimulation. There are various types of allodynia: dynamic, static, and thermal. Static allodynia is usually elicited by applying a single light pressure stimulus and is thought to be due to sensitized C-nociceptors, whereas mechanical allodynia is tested by moving a brush or soft cloth and is due to activation of A-beta afferent fiber activation. Hyperalgesia refers to a heightened perception of pain for a given pain stimulus, due to a shift in the sensitivity curve. Hyperpathia is a complex abnormal sensation. It refers to a slightly delayed but then an abnormally painful and exaggerated pain response, especially in reaction to repeated stimuli, reflecting summation and aftersensation (Fig. 80.1).

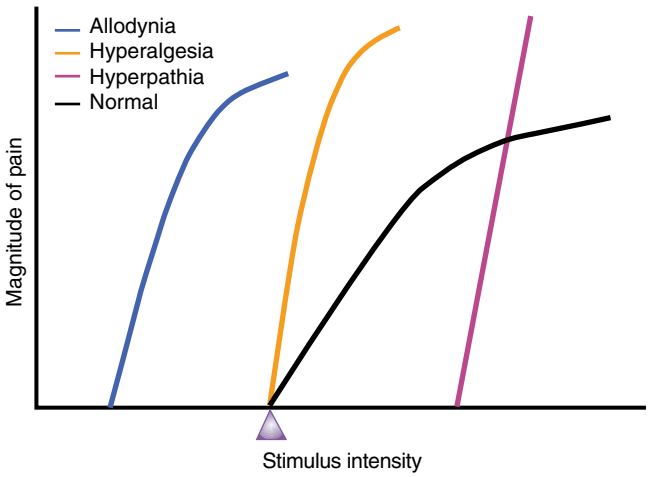

Fig. 80.1 Changes in pain sensation in stimulus-induced chronic pain conditions

As mentioned above, physiologic pain occurs as a consequence of acute nociceptor activation and is a protective and adaptive phenomenon. While the focus of this discussion is on neuropathic pain, other types of pain, including chronic inflammatory joint pain and noninflammatory, non-neuropathic pain, deserve mention. Inflammatory joint pain occurs as a consequence of tissue damage or inflammation; pain pathways and structures are normal but are functioning abnormally. Noninflammatory, non-neuropathic pain occurs as a result of an abnormal central processing of normal input. For example, patients with fibromyalgia (see "Fibromyalgia" section below) experience an augmentation of the pain signal transmission [4, 5]. Fibromyalgia is an example of maladaptive pain, where structures are normal and pathways are intact but the function of those pathways is abnormal. Diagnoses of maladaptive pain conditions such as fibromyalgia may be difficult to establish, as the structures involved are expected to be normal, limiting the utility of diagnostic testing.

Neuropathic and other chronic maladaptive pain may occur as a result of injury and/or pathological changes at various levels or "stations" of the nervous system, including the peripheral nervous system, the spinal cord, and the brain.

Station 1: Peripheral Nervous System, Peripheral Sensitization (PNS)

The peripheral nervous system consists of specialized nerve fibers that transmit distinct signals. *A-beta fibers* are large myelinated afferent fibers that conduct information about touch and pressure sensation. These fibers have a low threshold for activation and transmit signals at a fast velocity (50–60 m/s). A-beta fibers may be measured with nerve conduction studies. Although the physiologic role of A-beta fibers is to transmit touch and pressure sensation, these fibers may also

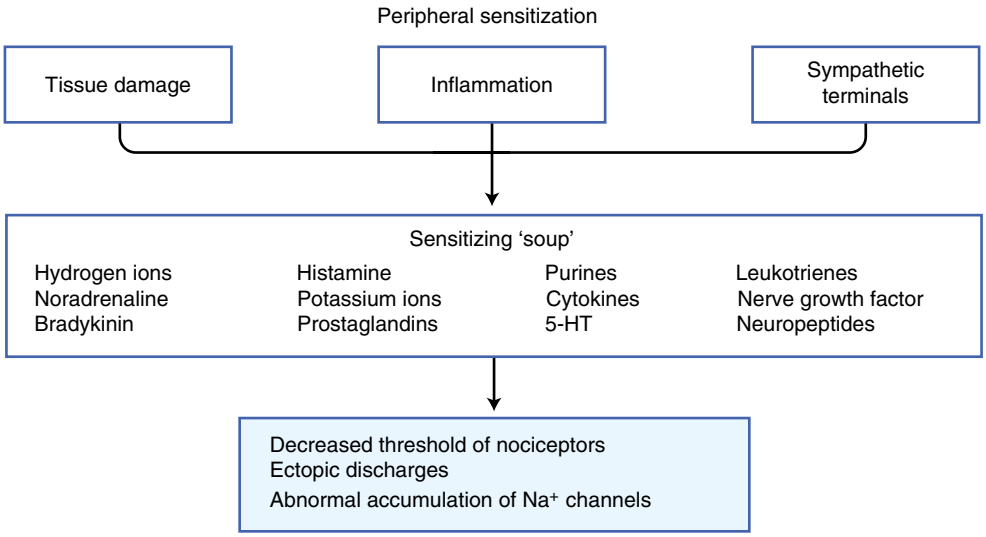

Fig. 80.2 Peripheral sensitization and the sensitizing "soup" (Adapted from Siddall and Cousins [19])

conduct pain signals as a result of plasticity in the dorsal horn of the spinal cord in certain pathologic conditions.

A-delta fibers are smaller, thinly myelinated fibers, which are activated by heat, cold, and pressure sensation. These fibers have a high threshold for activation and transmit signals at a slower velocity (5–30 m/s). *C fibers* are unmyelinated and respond to heat, mechanical, and chemical stimulation. C fibers have a high threshold and transmit signals slowly (1 m/s or less). Certain neuropathies may preferentially affect certain nerve fibers; for example, selective small fiber neuropathies involve A-delta and C fibers and result in normal nerve conduction study parameters. Conversely, large fiber neuropathies affect A-beta fibers, result in abnormal nerve conduction study parameters, and may not be associated with pain.

While nerve conduction study parameters are expected to be normal in small fiber neuropathies, the diagnosis may be established with skin biopsy and assessment of epidermal nerve fiber density using special immunostaining to quantify the number and density of the epidermal nerve fibers;[6] if normal, this can effectively rule out the presence of a small fiber neuropathy. Other diagnostic tests that may be utilized in small fiber neuropathies include quantitative sensory testing and autonomic testing (such as quantitative sudomotor axon reflex testing (QSART) and thermoregulatory sweat testing).

Ion channels play an essential role in transduction of the pain response in both physiologic and neuropathic pain. Additionally, the targeting of specific ion channels underlies the mechanism of many medications used to treat neuropathic pain. Electrogenesis refers to the change in membrane voltage that occurs at the distal aspect of the axon as a result of mechanical, thermal, or chemical stimuli [7], and sodium channels play a crucial role in membrane excitability. The "pacemaker" zone of the axon determines the neuron's excitability. The presence of a stimulus results in the opening of some sodium channels; if the stimulus reaches threshold, an action potential is generated as a result of the opening of voltage-gated sodium channels. Sustained firing of action potentials occurs in neuropathic pain and occurs as a result of the activation of voltage-gated sodium channels and changes in the peaks of intrinsic oscillations that occur in the membrane potentials of some sensory neurons [7]. Changes within the pacemaker zone as well as the development of ectopic pacemaker zones occur in neuropathic pain and contribute to the phenomenon of peripheral sensitization [7]. Membrane-stabilizing medications (see below) are of benefit in neuropathic pain in part because of the suppression of ectopic pacemakers.

The excitability of neurons is likely the consequence of three cellular processes that impact sodium (and other ion) channels: trafficking, up- and downregulation of gene expression, and altered kinetics [7]. Focal injury to the axon may affect transport of sodium channels along the axon, resulting in accumulation of sodium channels, thereby generating an ectopic pacemaker.

Interactions between the peripheral nervous system and the immune system may impact the pain response. With the occurrence of initial injury, nociceptors become activated in the periphery by "a sensitizing soup," the products of tissue inflammation including histamine, prostaglandin E, serotonin, bradykinin, adenosine triphosphate, free radicals, and ions such as potassium and hydrogen (Fig. 80.2). These activate afferent fibers, lowering their threshold to thermal and mechanical stimuli. Receptors involved include the tyrosine kinase A (TrkA) receptor, a nerve growth factor receptor, and TRPV1 (transient receptor potential vanilloid type 1) [8]. Capsaicin is an agonist of the TRPV1 receptor; when activated, substance P is released, which can activate neighboring endothelial cells and mast cells, causing more

release of histamine and bradykinin, which can further sensitize those nociceptors [9]. Additional immune system-mediated molecules such as tumor necrosis factor, interleukin 1, and interleukin 6 may also contribute to peripheral sensitization of nociceptors. Chronic inflammatory conditions resulting in activation of these receptors may then result in activation of intracellular kinases (such as protein kinase C and protein kinase A). Sensitization is mediated through activation of these intracellular kinases, which can result in phosphorylation of sensory neuron-specific (SNS) sodium channels and the TRPV1 receptor [10].

Proliferation and abnormal accumulation of sodium channels are known to occur at the sites of injured nerves and along neuromas [11]. This results in foci of hyperexcitability and ectopic discharges in the axon and cell body of the injured neuron [7]. Upregulation of SNS sodium channels and TRPV1 receptors is one component of the neuronal plasticity in neuropathic pain. The role of the sodium channels in peripheral nociception has been well established [12–14].

Intracellular kinases phosphorylate the voltage-gated sodium channels (e.g., 1.8 and 1.9, located on the periphery of the nociceptor), and once activated, these receptors may then be depolarized at low-intensity subthreshold stimulation or may fire independently, resulting in ectopic discharges [15].

Axon injury also alters gene expression of various other ion channel subunits and subtypes. For example, some sodium channels ($Na_v1.6$) tend to open a second time following activation, which may result in repetitive firing. A gain-of-function mutation in the $Na_v1.7$ channel results an increase in the firing capacity of some dorsal root ganglion (DRG neurons), resulting in familial erythromelalgia [7] manifesting as severe burning pain with bright red discoloration of the feet and hands, in association with ambient temperature changes. Alteration in the gene expression of specific ion channels (either inherited or by injury-induced changes) may therefore affect membrane excitability.

Unlike sodium channels, there are also voltage-gated potassium channels; activation of those results in inhibition of DRG neurons. Their function is to repolarize neurons, restoring their baseline membrane potential. Thus, development of potassium channel opener agents will likely have role in lessening peripheral sensitization. Other inflammatory mediators include prostaglandins which bind prostanoid receptors and activate adenylate cyclase, increasing the amount of cyclic AMP, further sensitizing nerve terminals. Nerve growth factor can stimulate tyrosine kinase A receptors, which can phosphorylate and sensitize TRPV1 receptors. Additionally, activation of the TrkA receptor can result in alteration of gene expression, whereby the TrkA-NGF complex is internalized and retrogradely transported to the DRG. There, it initiates gene transcription with resultant upregulation of receptors, ion channels, and release of neuropeptides, contributing to the maladaptive issues in neuropathic pain [8, 16].

Station 2: Spinal Cord, Central Sensitization (CNS)

Following activation of peripheral nociceptors, action potentials are generated and conducted to the central nervous system. The C fibers' nociceptors use glutamate as one of their neurotransmitters, and glutamate activates α-amino-3 hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and N-methyl-D-aspartate (NMDA) receptors. Fast excitatory synaptic transmission is mediated by the former receptors [17]. With sustained and intense noxious stimuli, the prolonged activation of nociceptive unmyelinated C fibers results in hyperexcitability of the dorsal horn neurons and plasticity-related changes in the receptive field, a phenomenon referred to as "wind-up."[18] At the molecular level, peripheral nociceptors' activation also results in the release of substance P and neurokinin 1(NK1). Sustained activation of the neurokinin receptors located postsynaptically in the dorsal horn primes the NMDA receptors and triggers the release of intracellular calcium, resulting in upregulation of the NMDA receptors.

The NMDA receptor's ion channel is normally blocked by magnesium ions via a voltage-dependent mechanism (Fig. 80.3) [19]. The depolarization induced by calcium results in the removal of the magnesium ion and opens up the ion channel receptor. Binding of glutamate causes further influx of calcium and sodium ions intracellularly. Voltage-gated calcium channels do play a crucial role in neuropathic pain by regulating neuronal excitability and neurotransmitter release. As with sodium channels, various subtypes of voltage-gated calcium channels play different roles in pain transduction and are potential targets for neuromodulatory pain medications. N- and P/Q-type channels regulate neurotransmitter release; N-type channels trigger release from dorsal root ganglia neurons, and P/Q-type channels trigger release at central excitatory synapses [15]. The surface expression of N- and P/Q-type channels are reduced by binding of the alpha 2 delta subunit by gabapentin or pregabalin (see *treatment*, below).

Intracellular calcium leads to neuroplasticity changes, including the activation of protein kinase C. The latter can result in phosphorylation of proteins including NMDA receptors, lowering the threshold of activation; this phenomenon is referred to as short-term sensitization. Kinase activation may also phosphorylate gene regulatory proteins, which can alter gene expression, referred to as long-term sensitization. Activation of nitric oxide synthase, altered gene transcription, and the induction of early gene expression occur, which results in more chronic alteration of the responsiveness of neurons to additional stimuli [20]. The latter is an extreme example of a maladaptive state of chronic pain, in which pain may become severe and intractable [21, 22]. Furthermore, reorganization changes in the dorsal horn occur secondary to sprouting of A-beta fibers into one of the more superficial

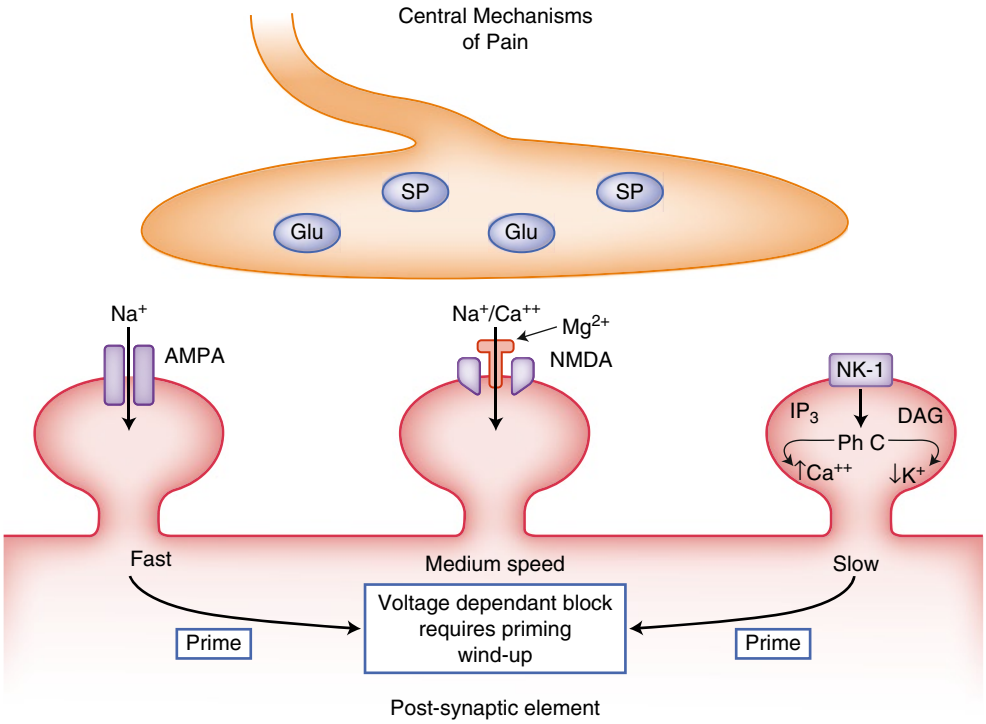

Fig. 80.3 Central mechanisms of pain at the level of dorsal horn. *SP* substance P, *Glu* glutamate, *AMPA* α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid, *NMDA* N-methyl-D-aspartate, *NK1* neurokinin 1, second messengers: (IP3, DAG), *IP3* inositol triphosphate, *DAG* diacylglycerol (From Siddall and Cousins [19])

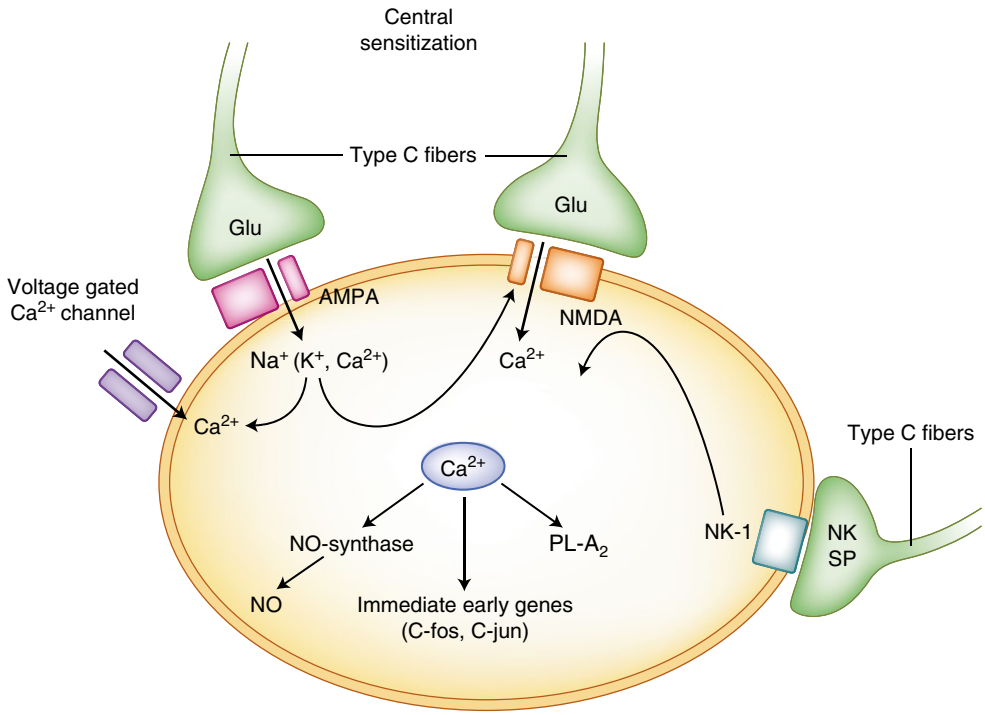

Fig. 80.4 Central sensitization in the dorsal horn. *SP* substance P, *Glu* glutamate, *AMPA* α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid, *NMDA* N-methyl-D-aspartate, *NK1* neurokinin 1, *PL-A2* phospholipase, *NO* nitric oxide (Adapted from Ollat et al. [20])

layers of the dorsal horn of the spinal cord [23–26]. All of these mechanisms do underlie the pathophysiological state of central sensitization in neuropathic pain (Fig. 80.4) [19, 20, 23, 27]. In addition to playing a role in the development of chronic pain [28], excitatory neurotransmission through the NMDA receptors has a role in the development of opioid tolerance [29, 30]. Besides the wide dynamic range neurons (WDR) in the dorsal horn which receive input from A-delta and A-beta fibers, glial cells also play an important role. An interaction between dorsal horn neurons and microglial cells is suggested by the overexpression of microglial receptors following nerve injuries. These receptors include chemokine

receptors such as CX3CR1 and adenosine triphosphate receptor (P2X4) [31]. Blocking those receptors in animals has been associated with a reduction in neuropathic pain [31]. Furthermore, the release of cytokines by microglial cells may result in further excitation and depolarization of the dorsal horn neurons, contributing to the maladaptive pain response.

Within this specialized environment of the dorsal horn of the spinal cord, inhibitory interneurons inhibit the excitatory input with GABA, glycine, endorphins, and monoamines. Perhaps more importantly, the descending spinal cord pathways originating in the rostral ventral medulla and dorsolateral pontine tegmentum terminate in the dorsal horn, synapse with the WDR neurons, and modulate the pain signal with inhibitory actions. When functioning normally, these descending pathways release both serotonin and norepinephrine, which combined can have an inhibitory effect on the dorsal horn neurons. Dysfunction of the inhibitory pathway can therefore contribute to chronic neuropathic pain. Restoring the balance or function of the descending pathways is an important aspect in the treatment of neuropathic pain.

Station 3: Brain, Central Sensitization

The "pain matrix" or network of brain pathways involved in pain perception has been identified largely by studying both normal healthy subjects subjected to painful stimuli and individuals suffering from chronic pain using functional imaging techniques, such as positron emission tomography (PET), single-photon emission computed tomography (SPECT), and functional magnetic resonance imaging (fMRI), identifying activated areas in the brain [32]. The pain matrix includes the somatosensory cortex (primary and secondary), prefrontal cortex, insular cortex, anterior cingulate cortex, thalamus, hippocampus, and amygdala. These structures and their connecting circuits are particularly important in pain processing by regulating attention, emotion, anticipation, memory, and expectation states. The amygdala has an important role in attaching an emotional experience to pain. The anterior cingulate cortex is often associated with the affective component of pain, anticipation of pain, and the cognitive-attention and motor responses to pain [33]. Changes in thalamocortical rhythmic activity, possibly as a result in an imbalance between T- and P/Q-type calcium channel activation, have also been implicated in neuropathic pain [15]. Certain pharmacologic and behavioral medicine approaches may be of particular benefit in targeting the unique pathological processes occurring within the brain's pain matrix.

Treatment: A Mechanistic Approach

The appropriate treatment of neuropathic pain depends upon the establishment of a proper diagnosis, treating (when possible) the underlying cause, and targeting the various pathologic processes affecting the stations or pathways noted above, often by pharmacologic means. Neuropathic pain can result as a consequence of damage to a variety of components of the nervous system, and therefore neuropathic pain as a disease state is heterogeneous. Specific examples include diabetic peripheral neuropathy (DPN), various peripheral neuropathies, postherpetic neuralgia (PHN), trigeminal neuralgia, thalamic and spinal cord pain syndromes, and complex regional pain syndrome (CRPS). The majority of clinical trials in neuropathic pain have targeted the far more commonly occurring peripheral, rather than central, causes of pain. A detailed discussion of each of these conditions is beyond the scope of this chapter. While treatments have been studied for a variety of peripheral neuropathic pain conditions, postherpetic neuralgia and painful diabetic peripheral neuropathy (DPN) represent the prototypic neuropathic pain conditions for many clinical trials. The discussion below will focus on postherpetic neuralgia, which provides an excellent model of a neuropathic pain syndrome in which pathophysiology and treatment principles can be expanded and applied to other neuropathic pain conditions.

Postherpetic Neuralgia

The largest series to date of postmortem examination of patients who had herpes zoster infection was reported more than 110 years ago by Head and Campbell [34]. The neuropathological changes and evolution in terms of initial hemorrhagic inflammation in the sensory ganglia and nerves followed by fibrotic changes in the ganglia and degenerative changes in the sensory roots and tracts were eloquently described in their series of 20 patients. Their findings provided the basis for one of the earliest knowledge of the neurosegmental anatomy and description of the dermatomal map.

Pathology and Clinical Manifestations

Following primary varicella infection, the varicella zoster virus (VZV), a human DNA alphaherpesvirus, establishes latency in the dorsal root ganglia. It has a genome consisting of 125 kilobase pairs, encoding approximately 70 different gene products [35]. The VZV is a ubiquitous agent, and its reactivation is determined primarily by host factors perturbation.

Among various neurological disorders, herpes zoster has one of the highest incidences, occurring annually at a rate of 400/100,000 [36]. The incidence increases dramatically with age, reaching up to 12/1,000 in people older than 80 years. The lifetime risk of developing herpes zoster has been quoted to be as high as 20 % of the population [36, 37]. In the majority of patients, a prodrome of dermatomal pain (preherpetic

neuralgia) precedes the appearance of the rash by several days [38]. Rare cases of prodromal pain lasting more than 100 days have been described [39]. The rash of herpes zoster is characterized by a unilateral vesicular eruption in a dermatomal distribution, preceded by erythematous maculopapular lesions. Crusting of the lesions follows and occurs in 7–15 days in the majority of the patients. There is predilection for involvement of the thoracic dermatomes accounting for 50 % of the cases [40], followed by the ophthalmic division of the trigeminal nerve.

Herpes zoster may present as a subclinical disease, consisting of viral replication without evidence of pain, as described in some patients who undergo bone marrow transplantation [41]. This can be demonstrated by an appropriate rise in the VZV antibody titer and/or by polymerase chain reaction. Along the presentation spectrum is the entity known as zoster sine herpete, defined as a neuralgic pain condition or other neurologic syndrome but without the skin rash [42, 43]. Among some of the other neurological complications of herpes zoster include leptomeningeal spread of the infection causing inflammation of the gray matter of the ventral and dorsal horn [44]. Other described neurologic disorders include motor involvement [45], cranial polyneuritis such as the Ramsay-Hunt syndrome [46], transverse myelitis [47], meningitis [48], and cerebral angiitis [49].

There have been various definitions of postherpetic neuralgia, in terms of the temporal relationship between pain occurrence and the rash of zoster [38, 50, 51]. PHN is most commonly defined as pain arising or persisting in areas affected by herpes zoster lasting more than 3 months following healing of the skin lesions [52]. The annual incidence of PHN has been estimated to be 11/100,000, its lifetime prevalence being 70/100,000 [53]. The probability of PHN following zoster infection increases with age [54]. About 10–20 % of patients with herpes zoster will develop PHN, with an approximate incidence of 50 % in patients over the age of 60 years. The proportion of patients whose PHN persists for more than 1 year increases significantly in patients older than 60 years of age [55]. PHN risk factors include trigeminal distribution of zoster [56], severe acute pain, sensory loss, and extensive rash [51, 56]. Thermal threshold abnormalities at 3 months correlate with greater chance of PHN occurrence [57].

Immunolabeling of punch skin biopsies with PGP 9.5, an axonal marker in patients with herpes zoster [58], showed that patients with postherpetic neuralgia had lower mean number of epidermal neurites versus patients without PHN. Evidence of the reduction of the epidermal neurites was also seen on the contralateral side, unaffected by the herpes zoster rash. The latter may support the theory of spinal cord injury in this patient population.

The pain in PHN can be either spontaneous or stimulus-evoked; it can be associated with either intact sensory function or sensory loss [59] in a dermatomal distribution pattern [34]. Various pain descriptors include burning, deep pain, stabbing, sharp, throbbing, paroxysmal with lancinating component, or more commonly allodynic in nature [24, 60]. In addition to thermal sensory misperception [57, 61, 62], a spectrum of positive and negative sensory symptoms and signs occur in PHN. These range respectively from allodynia, hyperesthesia, and hyperalgesia to hypesthesia, anesthesia, and analgesia to light touch and pinprick [63, 64]. Although patients may have distinct sensory symptoms and findings, these can coexist in all combinations [65]. The area of positive sensory findings is greater than the area affected by skin scarring. In a detailed study of the clinical features of PHN, allodynia was observed in 58 % of patients [66].

Pathophysiology of PHN

Peripheral and central sensitization processes underlie the mechanism of PHN. One of the characteristic features in patients with PHN is the presence of dynamic mechanical allodynia [57]. It is thought that this phenomenon is due to activation of low-threshold A-beta mechanoreceptors into a sensitized dorsal horn [64], and reorganization changes in the dorsal horn occur secondary to sprouting of A-beta fibers into one of the more superficial layers of the dorsal horn of the spinal cord, described above [23, 25, 26, 61].

Fields and Rowbatham introduced the concept of irritable nociceptors [65]. They also described a spectrum of pathophysiological states in patients with PHN [61, 62, 65], which have implications in terms of selecting the appropriate treatment modality for a given patient. The subtypes include the following: (1) irritable nociceptors where patients manifest significant allodynia, pain intensified by capsaicin and relieved by local anesthetics; (2) deafferentation without allodynia, in which there is marked sensory loss without pain; and (3) deafferentation in conjunction with allodynia, the latter reflecting central reorganization, with the implication that the patient will respond better to antineuralgic therapy directed against central sensitization maladaptive changes rather than to agents which have peripheral mechanism of analgesia.

Pharmacologic Management

Treatment of Herpes Zoster

Oral agents approved in the United States are acyclovir, valaciclovir, and famciclovir. The latter two agents are prodrugs; valaciclovir is a prodrug of acyclovir, and famciclovir is a prodrug of penciclovir. The goals of antiviral therapy are to shorten the duration of the cutaneous lesions and reduce the incidence of acute pain, which these agents will accomplish, if initiated within 72 h of the rash onset [66–68]. Valaciclovir and famciclovir are currently considered the drugs of choice because of their pharmacokinetic profile. Antiviral therapy should be more aggressive in patients older than 60 years. In general, these patients who present with

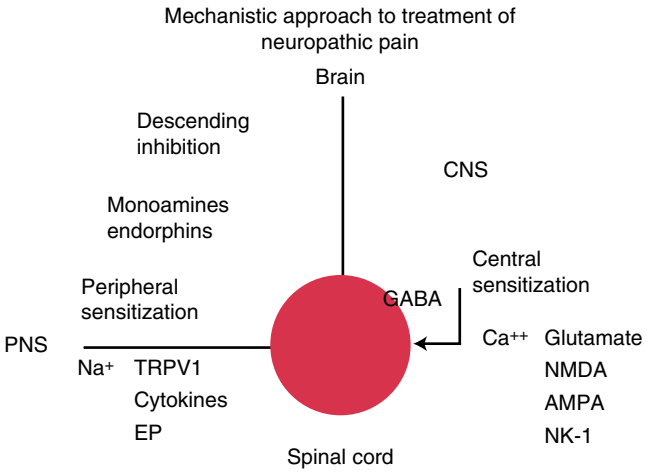

Fig. 80.5 A mechanistic approach to the treatment of neuropathic pain; *EP* prostaglandin E receptor, *TRPV1* transient receptor potential vanilloid type 1, *GABA* gamma aminobutyric acid, *AMPA* α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid, *NMDA* N-methyl-D-aspartate, *NK1* neurokinin 1, *PNS* peripheral sensitization, *CNS* central sensitization

significant pain at onset and who have a large number or active lesions are likely to benefit more from antiviral therapy. Unlike acyclovir, which was found not to alter the incidence of postherpetic neuralgia [69], famciclovir was found to reduce the median duration of postherpetic neuralgia in subjects over 50 years old, from 163 to 63 days, when compared to placebo [67].

Although adding corticosteroids to antiviral therapy would accelerate healing of the skin lesions and reduce the requirements of analgesic therapy, they do not affect the incidence of postherpetic neuralgia [70, 71].

Prevention of Postherpetic Neuralgia

Vaccination: A large, randomized, placebo-controlled trial assessing the benefit of a live attenuated varicella vaccine administered to individuals 60 years of age or older revealed a marked reduction in morbidity associated with herpes zoster and postherpetic neuralgia [72]. Use of the vaccine was associated with a 51.3 % reduction in the incidence of herpes zoster and a 66.5 % reduction in the incidence of postherpetic neuralgia [72].

Antidepressants: The effects of preemptive treatment using antidepressants have been studied in a randomized, double-blind, placebo-controlled study [73]. Patients older than 60 years, when treated with amitriptyline 25 mg at the time of herpes zoster diagnosis, showed a reduction in the prevalence of pain by 50 %, when compared to placebo at 6 months after the diagnosis of zoster. This finding would lend credence to the role of aggressive and/or preemptive treatment of pain to lessen the chance of neuronal sensitization and maladaptive changes in the peripheral and central nervous system.

Treatment of Postherpetic Neuralgia

Being a model of neuropathic pain, it would make sense to treat postherpetic neuralgia using a mechanistic approach (Fig. 80.5) [74]. What will be reviewed next is a discussion of some of the drugs that have demonstrated efficacy in certain clinical trials.

Descending Inhibition, Modulation of the Opiates Receptors

Opioids: Although opioids were considered in the past as being non-useful for the treatment of neuropathic pain, there has been a change in this belief, with the current consensus being that for patients refractory to various non-opioid antineuralgic agents or in need of acute pain relief, treatment with opioids should be considered. Opioids have peripheral, spinal, and supraspinal targets. The antineuralgic mechanism of their action is through direct inhibitory effects on primary nociceptive afferents and the neurons in the dorsal horn of the spinal cord. Various opioids receptor subtypes have been identified including mu, delta, and kappa [75, 76]. Opioids have a presynaptic mechanism of action by closing voltage-gated calcium channels, in the primary nociceptive afferents [77]. Activation of the presynaptic opioid receptors would result in a reduction in the release of neurotransmitters from nociceptive primary afferent fibers. Opioids also have a postsynaptic mechanism of action, resulting in hyperpolarization/inhibition of the postsynaptic dorsal horn neurons by opening of potassium channels [78]. The combined effect results in a decrease in nociceptive transmission. In the midbrain, opioids activate "off" cells and inhibit "on" cells, leading to activation of the descending inhibitory pathway on the dorsal horn neurons. Mu opioid receptor activation is also believed to interact with TRPV1 receptors, resulting in glutamate release [9]. Adverse effects including sedation, nausea, and constipation can be, however, limiting factors.

Sustained-release oxycodone has been evaluated in a randomized, double-blind, 8-week crossover trial of 50 patients [79]. In this study, oxycodone was titrated up to 30 mg twice daily. Efficacy was evaluated on a 100 mm visual analog scale (VAS). It was shown that 58 % of patients experienced moderate improvement in pain versus 18 % on placebo. The controversial issue of opioids in the treatment of neuropathic pain was addressed in a randomized, double-blind crossover trial comparing tricyclic antidepressants and opioids with placebo in PHN [80]. Each study participant was scheduled to undergo three treatment periods: one with opioid, one with tricyclic antidepressant, and one with placebo. Each treatment period lasted 2 months, with a 1-week washout period. In this study, opioids were found to have a significant effect on pain reduction with minimal cognitive effects.

Tramadol is a centrally acting opioid analgesic with weak inhibition of reuptake of norepinephrine and serotonin. A potential benefit of tramadol in PHN was exhibited in a pilot study comparing its impact on pain relief to clomipramine, a

tricyclic antidepressant (TCA) [81]. A randomized, placebo-controlled trial of tramadol also showed an improvement in the pain associated with diabetic peripheral neuropathy in patients treated with a four times per day regimen of tramadol [82]. Tapentadol is a centrally acting analgesic with both μ-opioid receptor agonist and norepinephrine reuptake inhibition activity, with minimal serotonin reuptake inhibition; trials supporting its benefit in PHN are lacking, though a benefit was seen using the extended-release formulation of tapentadol in patients with painful DPN [83]. The additional noradrenergic mechanism of action shared by tramadol and tapentadol may provide an advantage over other opioid analgesics in the management of neuropathic pain. The potential for serotonin syndrome must be considered when using these agents in combination with serotonergic medications, such as TCAs and serotonin-norepinephrine reuptake inhibitors (SNRIs).

Descending Inhibition, Modulation of the Monoaminergic Systems

Independent of their antidepressant effects, antidepressants including selective *serotonin-norepinephrine reuptake inhibitors* (*SNRIs*) have been shown to reduce the pain of PHN. These agents potentiate serotonin (5HT) and norepinephrine (NE), likely inhibitory transmitters in the descending pathway from the brainstem to the dorsal horn of the spinal cord. Multiple double-blind controlled studies have established the role of antidepressants in the treatment of postherpetic neuralgia [50, 84–88].

Agents that are mixed (NE/5HT) reuptake blockers such as nortriptyline and amitriptyline have been found to be slightly more effective than selective noradrenergic blockers such as maprotiline (a tetracyclic antidepressant) [87]. Selective serotonergic agents such as zimelidine have been found not to be effective [89]. Sedation, anticholinergic effects, hypotension, cardiac effects, and weight gain however may limit the use of the tricyclic antidepressants, which have mixed (5HT/NE) mechanism of action. This is of special importance in the elderly, the predominant population affected with intractable postherpetic neuralgia. While large randomized trials for their use in PHN are lacking, SNRIs such as duloxetine, venlafaxine, desvenlafaxine, and milnacipran have shown efficacy in other neuropathic (DPN) and/or chronic pain (fibromyalgia) trials and together with TCAs are now considered among first-line agents for the treatment of such neuropathic pain conditions.

Modulation of Peripheral Sensitization

Tricyclic Antidepressants: Unlike selective serotoninergic reuptake inhibitors (SSRIs), tricyclic antidepressants have some peripheral sodium modulation effect, which is likely a contributing mechanism in the treatment of neuropathic pain, and may also explain the greater antineuralgic effectiveness of these agents, when compared to SSRIs.

Anticonvulsants: Until the gabapentin and pregabalin trials, carbamazepine was the only agent evaluated in PHN. Carbamazepine has peripheral sodium modulation effect and was evaluated in a very small randomized clinical trial [90]. Its pain relief effect was found not too different compared to placebo, although it did help in lessening the lancinating pain component. Oxcarbazepine, a keto-analogue of carbamazepine, has modulating effect on the sodium channels and N- and P-type calcium channels [91, 92]. Activation of the latter plays a role in the development of central sensitization. Oxcarbazepine is safer and has a more favorable tolerability and pharmacokinetic profile than carbamazepine. This was found in a meta-analysis of three studies comparing it to carbamazepine in trigeminal neuralgia [93]. Oxcarbazepine has been evaluated in DPN trials; its safety was also evaluated in multicenter phase 3 studies with 12 months open-label extension [94, 95].

Lamotrigine inhibits voltage-gated sodium channels and inhibits N- and P/Q-type calcium channels and has been demonstrated to reduce pain in a variety of neuropathic pain conditions, including diabetic neuropathy [96], though data supporting its use in PHN is lacking. Additionally, the need for slow titration to reduce risk of rash with lamotrigine delays the time to therapeutic effect.

Lidocaine is a prototype sodium channel blocker. Infusion of lidocaine has been found to relieve neuropathic pain in diabetic neuropathy and in PHN [97–99]. Its systemic side effects and potential proarrhythmic effects limit its use. Topical lidocaine gel 5 % has been shown to be effective in postherpetic neuralgia [100]. Use of a lidocaine patch is a convenient means of administration, with minimal systemic absorption. Lidocaine patch 5 % has been evaluated in multiple randomized controlled trials [101–104]. In an enriched enrollment design, double-blind, crossover study of 32 patients who used lidocaine patch for at least 1 month prior to enrollment, the time to exit until the patient reported a decrease of 2 or more on categorical pain relief for 2 consecutive days was significantly longer with lidocaine patch than the vehicle patch (14 days vs. 3.8 days) [103]. In a randomized, double-blind, placebo-controlled trial of lidocaine 5 % patches for focal neuropathic pain (which included patients with PHN), treatment was clearly effective in decreasing pain and allodynia during the first 8 h following application of the patch, with a sustained benefit at 7 days [104]. A study using fMRI to assess changes in brain activity with use of lidocaine 5 % patches for PHN revealed that in addition to a reduction in spontaneous pain, short-term treatment with lidocaine (6 h) was associated with fMRI changes in affective and sensory-discriminative areas (thalamus, somatosensory cortex, insula, and anterior cingulate) and that longer-term treatment (2 weeks) was associated with changes in the reward-related regions (ventral striatum and amygdala) [105].

Capsaicin: Capsaicin, a natural product extracted from red chili peppers, stimulates unmyelinated primary afferent C fibers but depending on its concentration can also inactivate and destroy them [106, 107]. Capsaicin alters nociceptor sensitization by acting on the vanilloid receptor TRPV1, as noted above [108]. The latter is activated by noxious heat and low pH. Capsaicin seems to reduce substance P (mostly secondary to C fiber degeneration) as well as calcitonin gene-related peptide (CGRP) and vasoactive intestinal polypeptide (VIP). Substance P is an important mediator of neurogenic inflammation and primary hyperalgesia, where activation and sensitization of C mechanoheat polymodal nociceptors (CMH) occur [109–111]. Various trials using different concentration of topical capsaicin have been carried with dissimilar and nonconsistent results [112–114]. One main difficulty in using capsaicin in a double-blind, controlled study is the lack of true blinding secondary to the burning sensation induced by capsaicin [115]. This side effect as well as the need for multiple daily applications limits the use of capsaicin cream. However, multiple double-blind, placebo-controlled trials of NGX-4010, a high-concentration (8 %) capsaicin patch, have revealed a sustained improvement in pain after a single 60 min treatment [116–118]. Although a transient increase in pain was experienced by some patients, pretreatment with a topical anesthetic allows the treatment to be quite well tolerated.

Modulation of Central Sensitization

Calcium Channel Alpha 2 Delta Ligands: Gabapentin and pregabalin bind to the alpha 2 delta subunit of voltage-gated calcium channels [1, 15], decreasing the release of glutamate, norepinephrine, and substance P [119]. The alpha 2 delta site is part of the physiologic calcium channel [120], which is an important component of the phenomenon of central sensitization that occurs in neuropathic pain. The analgesic efficacy of gabapentin and pregabalin was identified in various animal models of neuropathic pain, showing a decrease in allodynia and hyperalgesia behavior.

The benefits of gabapentin in PHN were illustrated in two pivotal double-blind, placebo-controlled trials carried out in the USA [121] and UK [122]. In the US study, gabapentin was increased up to 3,600 mg, and in the UK study, the dose was titrated either 1,800 or 2,400 mg. A statistically significant difference was noted by week 1 in the UK study and by week 2 in the US study, maintained to the end of the treatment period. Given its relatively poor bioavailability, gabapentin is ideally administered three times per day and is associated with a high incidence of dizziness (28 %) and somnolence (21 %). Absorption of gabapentin occurs via a saturable transport mechanism in the proximal small intestine, resulting in decrease in the bioavailability as the dosage is increased [123]. A once-daily dosage of gabapentin was approved recently by the FDA for the treatment of PHN. This formulation utilizes an advanced polymer gastric retentive technology, allowing the gradual release of gabapentin in the small intestine. An 11-week, randomized, placebo-controlled trial in PHN revealed significant pain relief in treated patients when compared to placebo [124].

Pregabalin is a gabapentinoid with greater bioavailability than gabapentin. It is FDA-approved for the treatment of pain associated with PHN, in addition to DPN and fibromyalgia. A multicenter, double-blind, randomized, placebo-controlled trial of pregabalin for treatment of PHN at doses of either 600 mg/day (or 300 mg/day for patients with impaired renal function) showed significant reductions in pain scores and improvement in sleep in the pregabalin treatment groups [125]. Another double-blind, placebo-controlled trial of pregabalin for PHN at doses of 150 or 300 mg/day revealed significantly more responders (defined as ≥50 % decrease in mean pain score from baseline to endpoint) in both pregabalin groups (150 mg, 26 %; 300 mg, 28 %) compared to the placebo group (10 %) [126]. Sleep improved in the treatment groups as well [126]. Unlike their effect in neuropathic pain, gabapentin and pregabalin have no effect in conditions of nociceptive pain.

Additional *voltage-gated calcium channel blockers* such as topiramate, levetiracetam, and zoconotide have been investigated for management of neuropathic pain. Zoconotide, administered intrathecally, is the only of these FDA-approved for the management of severe chronic pain [96]. Levetiracetam was shown in an open-label trial to have analgesic effects and to be well tolerated in patients with PHN [96, 127], though large, randomized controlled trials are lacking. In addition to blocking of voltage-gated calcium channels, topiramate modulates voltage-gated sodium channels and potentiates GABA inhibition [96]. Despite its broad-spectrum mechanisms of action, the benefits of topiramate in neuropathic pain conditions (such as peripheral neuropathy and trigeminal neuralgia) have been variable [96]. Additionally, side effect such as cognitive slowing, sedation, and paresthesias may limit tolerability of topiramate.

NMDA Blockers: Dextromethorphan, an NMDA antagonist, was evaluated in PHN with little evidence of benefit [128, 129]. Ketamine, which is not fully selective for NMDA receptors, has been used in various neuropathic pain conditions including PHN, showing improvement of certain pain components [130–133]. Systemic effects of ketamine limit its chronic use. Memantine is a noncompetitive NMDA antagonist and unlike other NMDA receptor antagonists, it tends to be well tolerated. It has been evaluated in experimental animal models of neuropathic pain and has shown good prophylactic and antinociceptive effects [134], although clinical trials in various neuropathic pain conditions have not established efficacy.

Other Mechanisms

Nerve Blocks: Nerve blocks have been used for the treatment of herpes zoster since the 1930s. Sympathetic block in the treatment of herpes zoster was described by Rosenak in

1938 [135]. Tenicela, in a double-blind, randomized study, confirmed the efficacy of sympathetic blocks in the treatment of herpes zoster [136]. Colding noted that the earlier the block is performed after the zoster eruption, the more likely its beneficial effect. The role of nerve blocks either as a preemptive approach or as a symptomatic treatment of PHN was evaluated with controversial results [136–141]. Various trials have included the use of somatic, epidural, and sympathetic blocks. Most of these trials were however not uniform in design; they were not truly randomized or controlled studies, and some were either anecdotal reports or included a small number of patients. Thus, whereas nerve blocks can be a beneficial treatment option for acute herpes zoster pain [142], there is no conclusive scientific evidence to date or consensus establishing their role as a treatment modality in PHN.

Other Agents: Topical formulations of lidocaine with prilocaine or eutectic mixture of local anesthetics (EMLA) have been reported to be useful in uncontrolled trials [143]. EMLA cream failed to show significant benefit over placebo in a controlled trial [144].

Comparison of Different Treatment Regimens

Given the small size in individual clinical trials, it is difficult to determine outcome accuracy [145], specifically when projections of the results of clinical trials are applied to individual patients. An alternative approach would be to pool results from many neuropathic pain placebo-controlled trials using a meta-analysis approach [146, 147].

The number needed to treat (NNT) approach is considered as a benchmark analgesic efficacy index [146, 147]. NNT is defined as the number of patients needed to be treated with a given agent to obtain one patient with at least 50 % pain relief that would not have happened with a placebo. Thus, the lower the NNT number, the more efficacious is the drug. Also, the numbers needed to harm (NNH) can also be calculated for minor and major adverse effects with study withdrawal being considered a major adverse event.

In PHN, NNT with tricyclic antidepressants ranged from 1.8 to 4.1 [146], with gabapentin it was 3.2 (2.4–5) [121, 148], and with pregabalin it was 3.9 (3.3–4.7) [125, 126, 149]. NNT for oxycodone was 2.5 (1.6–5.1), although in 30 % of patients, oxycodone was an add-on therapy to tricyclic antidepressants [150]. In neuropathic pain conditions, gabapentin and pregabalin can be considered as effective as SNRIs and tricyclic antidepressants; however, unlike TCAs, gabapentin and pregabalin have fewer contraindications in terms of anticholinergic and cardiac side effects. NNT for lidocaine 5 % patch was 4.4, comparing relatively well with other treatment approaches [104]. Collins also found that there was little difference in the incidence of NNH for minor adverse effects, being around 3 for both antidepressants and gabapentin. For major adverse effects (drug-related study withdrawal), antidepressants had an NNH of 17 when compared to placebo, versus no significant difference between gabapentin and placebo [150]. These represent major considerations in terms of side effects and management issues in the elderly PHN population.

Other Approaches to the Management of Neuropathic Pain

While large randomized trials showing a benefit are lacking, acupuncture has gained broader "mainstream" acceptance as a viable approach to pain management in recent years. The precise mechanisms underlying the potential benefits of acupuncture in managing pain are not well understood, though a possible interruption in the imbalance between competing excitatory and inhibitory pain pathways has been suggested. Benefits have been reported in various neuropathic pain conditions including acute herpetic pain [151, 152]. Transcranial magnetic stimulation (TMS) is a noninvasive method that alters brain activity by causing local depolarization or hyperpolarization and may be of benefit in management of chronic pain [153, 154]. While its use has not been reported in PHN, monochromatic infrared photo energy (MIRE) treatments have been studied in patients with DPN and did not improve pain [155]. Other non-pharmacologic techniques, including relaxation training, biofeedback, hypnosis, guided imagery, and stress management, are all useful techniques that can help patients manage their pain, likely by acting at the level of the "pain matrix" and altering the affective component of pain perception.

Proposed Algorithm for Management of Neuropathic Pain

Successful treatment of neuropathic pain relies upon the establishment of a correct diagnosis, assessment of the pain, and, quite often, a multi-faceted approach to therapy. Establishment of the diagnosis is particularly important; for example, certain neuropathic pain conditions, such as trigeminal neuralgia, respond to different first-line medications, with carbamazepine or oxcarbazepine considered as first agents of choice. If treatable or preventable, the underlying condition should be treated appropriately (e.g., antiviral medications for acute herpetic neuralgia, glycemic control for diabetic polyneuropathy). Non-pharmacologic approaches, such as physical therapy, biofeedback, and stress management, are also important co-treatment approaches.

As described above, a variety of pharmacologic agents are available for the management of neuropathic pain. Many factors should be considered when selecting a medication, including mechanism of action, comorbid medical conditions (which may be either favorably or adversely impacted by the choice of medication), available evidence supporting the medication's use in neuropathic pain, potential side effects, possible drug-drug interactions, urgency of medication efficacy, medication abuse potential, and the risks of overdose (intentional or unintentional) [119, 156].

Guidelines have been developed for the treatment of various neuropathic pain conditions, particularly DPN, PHN, and other chronic neuropathic and non-neuropathic pain conditions [119, 156–160]. These guidelines are based on systematic literature reviews, randomized clinical trials, and consensus expert opinion. Consensus treatment guidelines indicate a stepwise approach in the management of neuropathic pain. Recommended *first-line treatments* include certain antidepressants, such as tricyclic antidepressants and SNRIs (such as duloxetine or venlafaxine), calcium channel alpha 2 delta ligands (gabapentin or pregabalin), and topical lidocaine.

Opioids and tramadol tend to be considered *second-line agents* for the management of neuropathic pain. However, these agents may be incorporated as first-line agents (usually in combination with medications discussed above) under special circumstances, such as the need for rapid pain relief during the titration period of a first-line medication, episodic exacerbations of severe pain, acute neuropathic pain, and neuropathic cancer pain [119]. In addition to common side effects of constipation and sedation, abuse potential must be considered when introducing opioids.

When first- and second-line medications are ineffective, poorly tolerated, or not indicated, other medications may be considered as a *third-line approach*. These include various anticonvulsants (such as carbamazepine, oxcarbazepine, lamotrigine, topiramate, valproic acid, lacosamide), other antidepressants (SSRIs, bupropion), NMDA receptor antagonists (dextromethorphan, memantine), mexiletine (a sodium channel blocker), and topical capsaicin. These medications are considered third line based on the existence of less evidence supporting efficacy, inconsistent results of randomized trials, and expert opinion.

With most medications used to treat neuropathic pain (with exceptions including opioids), pain relief tends to occur in a gradual manner, and patients should be counseled accordingly, and expectations in terms of the degree of pain relief (which typically is partial or incomplete) should be discussed with patients in detail. Counseling needs to include education about the underlying disease state and its treatment, the concept of treating chronic pain as a separate coexisting disease state, the rationale for using various medications (at times in combination), the importance of functional outcomes and improvement in quality of life, issues surrounding medication adherence, and the potential for adverse side effects. Combination pharmacotherapy using a mechanistic treatment approach is typically used in severe pain or when pain relief is partial or inadequate.

Other Chronic Musculoskeletal Pain Conditions

Fibromyalgia

As mentioned above, noninflammatory, non-neuropathic pain occurs as a consequence of dysfunction of otherwise normal structures and pathways, with fibromyalgia representing the prototypical model of this process. While considered a non-neuropathic pain syndrome, fibromyalgia may manifest with a variety of neurological symptoms including hyperalgesia, dysesthesias, weakness, or fatigue; additionally, similar pathologic neuroplasticity processes implicated in neuropathic pain may underlie the maladaptive pain response seen in fibromyalgia. Further discussion of fibromyalgia is therefore warranted.

Fibromyalgia is a chronic pain condition characterized by the presence of widespread musculoskeletal pain, without an associated "lesion" or evidence of tissue injury. Fibromyalgia is common, with a prevalence of 2.5 % in the general population; women are more commonly affected than men, and incidence peaks between 40 and 60 years of age. The pain of fibromyalgia is commonly described as aching, cramping, and dull; nonetheless, pain descriptors typically considered "neuropathic" such as burning, stinging, or electricity-like sensations may also occur. As with neuropathic pain, spontaneous pain and evoked pain are both common features of fibromyalgia. Spontaneous pain (commonly aching or soreness) occurs as a consequence of spontaneous firing of axons or dorsal horn neurons, while evoked pain (manifesting as allodynia or hyperalgesia) occurs as a result of alteration in peripheral and central neurons. While widespread musculoskeletal pain is the hallmark feature of fibromyalgia, many accompanying symptoms are common, including fatigue, sleep disturbances, forgetfulness, dysesthesias, headaches, temporomandibular disorders, weakness, fatigue, gastrointestinal symptoms (particularly irritable bowel syndrome), interstitial cystitis, and psychiatric symptoms (such as depression, anxiety, and posttraumatic stress disorder). The common coexistence of psychiatric comorbidities and absence of associated tissue injury may lead to delays in diagnosis or, worse, dismissal of symptoms as psychiatric in origin.

Functional imaging studies have revealed abnormal activation of regions within the "pain matrix" of the brain, including the somatosensory cortex, amygdala, cingulate, caudate, and thalamus [161]. As described above, these pathways are particularly important in the affective and emotional component of pain perception. Despite the abundant evidence of centrally mediated processes underlying the maladaptive pain response in fibromyalgia revealed with functional imaging, the diagnosis of fibromyalgia remains clinical. Criteria defined in 1990 by the American College of Rheumatology (ACR) include widespread pain of ≥3 months' duration in all four quadrants of the body, with pain present with palpation at ≥11 of 18 defined tender points [162]. These criteria result in a sensitivity of 88.4 % and specificity of 81.1 % [162]. "Control points" have also been proposed as regions of the body which should not be tender in fibromyalgia, though tenderness in fibromyalgia extends throughout the body, and tenderness that also involves these control points does not argue

against the diagnosis [161]. The ACR criteria do not take into account the other common associated symptoms (fatigue, sleep disturbances, etc.). More recent diagnostic criteria for fibromyalgia were developed based on a widespread pain index and symptom severity scales of various somatic symptoms, fatigue, waking unrefreshed, and cognitive symptoms [163]. These new criteria provide a method for quantifying fibromyalgia severity and an alternative method to diagnosis, without using the tender points criteria.

Sleep disturbances are common in fibromyalgia; approximately 76 % of patients with fibromyalgia awaken feeling tired or not refreshed [162]. Abnormal sleep architecture has been described in fibromyalgia patients, with a high prevalence of paradoxical alpha wave activity in deeper stages of sleep [164].

The underlying etiology of fibromyalgia remains uncertain, though a variety of factors appear to contribute. A familial component is suggested by the eight-fold increase in risk of fibromyalgia occurring in first-degree relatives of affected individuals [161]. Additionally, polymorphisms in monoamine transport or metabolism have been associated with an increase in risk of developing fibromyalgia [161]. Environmental and biological factors have also been implicated as triggers of fibromyalgia, including physical trauma (especially to the neck and trunk), infections (such as Lyme disease and Epstein-Barr virus), and psychosocial stressors. Disturbances in the autonomic system and hypothalamic-pituitary-adrenal axis (HPA) have been described in patients with fibromyalgia, though the precise nature of the disturbances and their role in pathogenesis of the condition is unclear [161]. The diffuse noxious inhibitory control (DNIC) response, which is characterized by whole-body analgesia occurring after a sustained painful stimulus, is reduced in patients with fibromyalgia. This may occur as a result of dysfunction of the descending opioidergic and serotonergic-noradrenergic pathways, from binding of opioid receptors by endogenous ligands [161]. Central sensitization and "wind-up" have also been implicated in fibromyalgia [161]. This has been validated by some functional imaging studies, supporting the concept of amplification of the normal pain response in patients with fibromyalgia [165], as well as cerebrospinal fluid measurement of certain neurotransmitters involved in nociception, such as substance P and glutamate [166, 167].

While the underlying factors resulting in fibromyalgia remain elusive, a mechanistic approach to management of pain due to fibromyalgia is useful. Treatment of non-pain fibromyalgia manifestations, including fatigue, sleep disturbances, psychiatric comorbidities, and gastrointestinal manifestations, is important. Pharmacologic options for treatment of pain include various agents, proven effective in controlled clinical trials. First-line therapeutic agents include gabapentinoids, tricyclic antidepressants (TCAs), and selective serotonin-norepinephrine reuptake inhibitors (SNRIs). The impact of TCAs and SNRIs on descending inhibitory pain pathways described in neuropathic pain likely accounts for their benefits in fibromyalgia. Several randomized controlled trials have supported the benefits of TCAs in fibromyalgia, improving pain, sleep, and fatigue [161]. Two of the only three medications approved by the US Food and Drug Administration (FDA) for the treatment of fibromyalgia, duloxetine and milnacipran, are SNRIs. Large multicenter trials have shown each to be beneficial for multiple outcome measures, independent of their impact on mood [168]. Pooled analyses of multiple randomized controlled trials of duloxetine for treatment of fibromyalgia revealed that 69 % of improvement in pain was a direct consequence of medication treatment, whereas 31 % of the pain improvement occurred as a result of improvement in mood [169]. The benefits of milnacipran in fibromyalgia were demonstrated in two randomized, double-blind, placebo-controlled trials [170]. Evidence supporting the use of selective serotonin reuptake inhibitors (SSRIs) has been less consistent [168]. Pregabalin is also FDA-approved for fibromyalgia and (as described above) shares a similar mechanism of action with gabapentin by binding the alpha 2 delta subunit of voltage-gated calcium channels. A large multicenter trial of pregabalin at a dose of 450 mg/d showed benefits in pain, fatigue, sleep, and quality of life [171].

Non-pharmacologic therapy, including patient education, graded exercise, and cognitive behavioral treatments, are extremely important and should be incorporated in the care of patients with fibromyalgia [168].

Polymyalgia Rheumatica

Many of the environmental and biological factors implicated as potential triggers of fibromyalgia listed above (infections, HPA axis dysfunction) are also common considerations in the differential diagnosis of fibromyalgia. Other conditions to consider as causes for widespread muscle pain include polymyalgia rheumatica (PMR), rheumatoid arthritis, osteoarthritis, systemic lupus erythematosus, and myopathy. Whereas fibromyalgia represents a model of noninflammatory, non-neuropathic pain, PMR, in contrast, represents a model of inflammatory pain. Like fibromyalgia, PMR results in proximal muscle pain, though features distinguishing PMR include the presence of constitutional symptoms (fever, sweats, weight loss), abnormal acute phase reactants (elevated erythrocyte sedimentation rate and C-reactive protein), a tendency to occur after age 60, and the favorable response to corticosteroids. PMR may also be associated with temporal arteritis, manifesting with headaches, temporal tenderness, jaw claudication, and the possible dreaded complication of anterior ischemic optic neuropathy with vision loss.

The underlying cause of polymyalgia rheumatica is unknown, though a combination of infectious triggers (parvovirus B19, *Mycoplasma pneumoniae* and *Chlamydia*

pneumonia) and genetic factors (including an association with the HLA DR4 allele) is suspected to play a role in the pathogenesis [172]. PMR is exceedingly rare in individuals younger than 50. Subacute onset of bilateral shoulder pain and tenderness of the upper arms are hallmark features of PMR. Additional symptoms include morning stiffness and constitutional symptoms. Weakness is not expected in PMR, though patients may report weakness as a consequence of limitations from pain. The erythrocyte sedimentation rate and/or C-reactive protein is typically elevated, though either can rarely be normal [172]. Diagnostic guidelines proposed in 2010 include an age of onset of >50, the presence of bilateral shoulder and/or pelvic girdle pain, morning stiffness, and abnormal acute phase reactants [173]. Inflammatory, infectious, endocrine, and neoplastic causes of pain and elevated acute phase reactants should be excluded as part of the evaluation of the patient with suspected PMR. Temporal arteritis occurs in up to 30 % of patients with PMR, typically manifesting with headache, jaw claudication, or visual disturbances (classically amaurosis fugax). Temporal artery biopsy may reveal characteristic inflammatory changes, though the presence of "skip lesions" may result in a falsely normal biopsy, placing additional importance upon the clinical nature of the diagnosis.

Corticosteroids are the mainstay of therapy for PMR. Management guidelines, also proposed in 2010, suggest low-dose steroid therapy (i.e., prednisolone 15 mg daily for 3 weeks) with gradual tapering in treatment-responsive patients [173]. A steroid treatment duration of 1–2 years is anticipated in most patients. Response to therapy is determined by assessment of clinical symptoms and measurement of acute phase reactants. Higher dose and/or parenteral corticosteroids may be considered in treatment-resistant patients or for relapses. Other immunomodulatory medications are also considered in refractory patients or those intolerant to corticosteroids. Long-term corticosteroid use necessitates monitoring (and when feasible, measures to avoid) side effects including osteoporosis, hypertension, diabetes mellitus, and cataracts.

Chronic Fatigue Syndrome

While not considered a pain syndrome per se, joint pains and myalgias are common accompanying features of chronic fatigue syndrome (CFS). Additionally, some of the central mechanisms implicated in neuropathic pain may be involved in the pathophysiology of chronic fatigue syndrome. Like fibromyalgia, chronic fatigue syndrome occurs in the absence of identifiable tissue injury or lesion within the nervous system and has been the topic of great debate, often mislabeled as a psychiatric illness. Diagnostic criteria were defined by the US Centers for Disease Control and Prevention in 1994 and include the development of persisting or relapsing fatigue resulting in substantial limitations present for at least 6 months, which is not relieved by rest and is not the result of a medical condition, psychiatric condition, or alcohol or substance abuse [174]. Additional symptoms including impairments in memory or concentration, sore throat, tender lymph nodes, myalgias, arthralgias, headaches, unrefreshing sleep, and malaise after exertion are also among the features included in the diagnostic criteria [174, 175]. Subsequent revisions to these diagnostic criteria have been proposed, though the 1994 criteria remain the standard [175].

The prevalence of chronic fatigue syndrome (also referred to as myalgic encephalomyelitis) ranges between 0.23 and 0.50 %, with a female to male ratio of approximately 3:1 [175]. The etiology of CFS remains uncertain, though a variety of predisposing and precipitating factors have been suggested. Inactivity in childhood and inactivity after infectious mononucleosis have been identified as risk factors, and while no genetic abnormality has yet been identified, a familial predisposition is suggested by twin studies [175]. Physical stressors, psychological stressors, and infections (including flu-like illnesses, infectious mononucleosis, Q fever, and Lyme disease) have been implicated as potential precipitants of CFS [175]. Psychological processes (such as avoidance behaviors) and social factors (such as a lack of social support) are believed to contribute to the perpetuation of CFS [175].

A study utilizing FDG PET revealed hypometabolism in the right mediofrontal cortex and brainstem [176]. A widespread reduction in 5-HT1A receptor binding potential was shown in CFS patients using a specific radioligand and PET imaging; patients with concurrent psychiatric illness or taking any medications were excluded [177]. These findings suggest a role of serotonergic pathways in CFS, either in the underlying pathophysiology or as a biological consequence of the condition. A potential role of increased oxidative stress has been proposed by recent studies revealing an increase in ventricular lactate using MR spectroscopy in patients with CFS, though similar findings were seen in patients with major depressive disorder [178].

The mainstay of CFS treatment is non-pharmacologic. Cognitive behavioral therapy (CBT) and graded exercise therapy (GET) are the only interventions consistently found to be effective [175, 179]. Adaptive pacing therapy had previously been proposed as an effective treatment but was found to add no benefit when added to routine specialist medical care in a randomized, parallel group trial [179].
