Although there are several classifications of peripheral nerve injury, the most useful classification of nerve injury is that of Sunderland [2], which categorizes nerve injury into five degrees (Fig. 39.1). *First-degree injury* represents disruption of the myelin sheath, the axons are intact with a completely intact stroma. *Second-degree injury* involves the transection of axons with the stroma remaining intact. *Third-degree injury* represents a transection of the axon as well as the endoneurial tubes. In this injury the surrounding perineurium remains intact. *Fourth-degree injury* involves loss of continuity of axons, endoneurial tubes, and perineurium. Individual nerve fascicles are transected, and the continuity of the nerve trunk is maintained only by the surrounding epineurium. Traction injuries commonly produce these types of lesions. *Fifth-degree injury* is a transection of the entire nerve trunk.

Seddon classified nerve injury into three categories [3]: (1) *neurapraxia* in which axons are intact but fail to conduct action potentials because of focal demyelination, (2) *axonotmesis* where axons themselves have been transected but the nerve trunk is still in continuity, and (3) *neurotmesis* where the nerve trunk has been divided. There is some overlap between these two classification systems (Table 39.1).

The determining factors for prognosis in peripheral nerve injury are the degree of injury, the extent of internal disorganization in the nerve, the site of injury, and the distance of the injury from the target organ. In the first-degree injury (neurapraxia), the prognosis for recovery is excellent since only remyelination of the injured axons is required. By contrast, in the fifth-degree injury (neurotmesis), the hope for recovery is not possible unless surgical repair of the lesion is performed. In the second- to fourth-degree injuries (axonotmesis), the prognosis ranges from intermediate to poor and depends not only on the degree of nerve injury but also on the number of transected axons and the site of nerve injury. Injuries grade 2 or higher result in wallerian degeneration of

Table 39.1 Comparison of classifications in peripheral nerve injury

Sunderland	Seddo	Injury
First degree	Neurapraxia	Disruption of myelin; intact axons and stroma
Second degree		Transection of axons with stroma intact
Third degree	Axonotmesis	Transection of axons and endoneurial tubes
Fourth degree		Transection of axons, endoneurium, and perineurium
Fifth degree	Neurotmesis	Transection of the entire nerve

the distal stump, making recovery less favorable. Also, when a nerve is injured far from its muscle, recovery is poor. This principle is maximally evident with nerve root avulsions, where no functionally useful axon regeneration occurs.

Reactions of Peripheral Nerve to Injury

Cellular

Peripheral nerve has a limited range of pathological responses to injury. The most common response to trauma is wallerian degeneration of axons. Segmental demyelination may contribute to the clinical deficit although it is rarely the predominant pathology in peripheral nerve injury. Wallerian degeneration is a sequence of cellular events that mainly involves the distal nerve stump. Soon after an axonal lesion has occurred, there are changes in both the proximal and distal axonal stump as well as the nerve cell body [4]. Myelin begins to retract from the axons at the nodes of Ranvier as early as 6–16 h after neural insult. In the distal nerve stump, a number of changes occur in the first 2 days. These include leakage of axoplasm from the severed nerve, retraction of the severed ends, swelling of the distal nerve segment, and subsequently the disappearance of neurofibrils in the distal segment. By day 3, there is a fragmentation of both axon and myelin with the start of digestion of myelin components. By day 8, the axon is digested, and Schwann cells are attempting to bridge the gap between the two nerve segments. Proximal nerve fibers also degenerate for a variable distance depending on the severity of the lesion. This retrograde degeneration may extend for several centimeters. If the lesion is sufficiently proximal, there are a number of changes that occur at the nerve cell body. Initially, within the first 48 h, the Nissl bodies (the cell's rough endoplasmic reticulum) break apart into fine particles. By 2–3 weeks after injury, the cell's nucleus becomes displaced eccentrically and the nucleolus is also eccentrically placed within the nucleus.

Molecular

Although the histological alterations that occur in wallerian degeneration have long been known, recent observations have provided insight into the molecular responses that occur after axotomy. The key to promoting successful axonal regeneration may lie in understanding these molecular changes. Breakdown of the axon initiates retrograde signaling to the nerve cell body that leads to a switch in gene expression and cell physiology from the normal operating state to the growth mode. Molecular changes in the distal stump include the enhanced expression of neurotrophins, cytokines, and other growth factors, as well as cell adhesion

molecules, lipid carriers, myelin proteins, extracellular matrix proteins, and integrins, thus, creating a microenvironment in the distal stump that supports regeneration of nerve fibers [5]. Schwann cells play a dominant role in creating the regeneration-supportive molecular microenvironment in the distal nerve stump. This switch from the normal "operating" mode of the myelin-forming differentiated Schwann cells into the "proliferation" mode is initiated by removal of axon-neuronal contact [6]. Schwann cells in acutely denervated nerve sections rapidly upregulate the expression of several factors including leukemia inhibitory factor [7], interleukin-6 [8], neuropeptides [9] and neuregulins [10]. These factors all appear to be involved in changing the microenvironment, upregulating the extracellular matrix constituents, and modifying the basal lamina of the distal stump for effective growth-promoting activity. In chronic nerve lesions, there are further and different changes in the Schwann cell expression of these and other chemicals, which may partly explain the markedly reduced long-term potential for axon regeneration [11]. Recent studies suggest that axon guidance depends on chemoattractant molecules, which entice axons, but also upon chemorepellents, which repel axons. Two families of proteins, the semaphorins and the netrins, have potent repellent effects [12]. Most studies have shown that these molecules selectively repel some types of axons but have no effect on others, providing selective steering of regenerating axonal tips.

The role of macrophages in peripheral nerve damage and repair is a central question in current neural regeneration investigations. The mechanism of recruitment of hematogenous macrophages into injured nerve is still unclear. Vougioukas et al. showed that intercellular adhesion molecule (ICAM-1) deficient mice have significantly reduced macrophage recruitment during wallerian degeneration, significantly delaying the process [13]. Similarly wallerian degeneration is retarded by the immunosuppressing drug, cyclosporin A [14]. Such observations suggest that immunosuppression may play an important role in promoting axonal regeneration.

Neuronal

Nerve trauma is tied inextricably to neuromas which histopathologically appear as tangled masses of regenerating axons embedded within the connective tissue of an injured nerve. Neuroma formation requires that the regenerating axons escape their confining endoneurial sheath. Thus, they occur when nerve injury is third degree or greater. The axons within a neuroma not only fail to reinnervate their original targets, but they may also develop abnormal electrical hyperexcitability [15]. The tips of injured sensory fibers often become generators of painful impulses and may also develop exquisite mechanosensitivity, which is demonstrable clinically by the Tinel sign. Recent studies suggest that there is an excessive accumulation of sodium channels within the axons of neuromas [16]. These sodium channels are usually restricted to the demyelinated segments of axons and occur at regenerating neurite tips devoid of myelin [17]. Such focal abnormal accumulations of axonal sodium channels may account, at least in part, for the ectopic axonal hyperexcitability of painful neuromas. The electrical hyperexcitability of neuromas may also be influenced by abnormal distributions of potassium channels [18]. More needs to be learned regarding neuromas. Major areas of inquiry include understanding further the basis of neuroma hyperexcitability and pain and understanding the reasons that neuroma axons fail to reach their target organs.

Electrophysiological Evaluation of Nerve Injury and Regeneration

The evaluation of peripheral nerve injuries is very complicated and should be performed in specialized centers. Referrals should be done in a timely fashion to ensure optimal recovery of function. The most important thing most physicians can do for peripheral nerve injury patients is to refer them quickly to centers with expertise in this area.

The electromyographer is frequently asked to participate in the clinical evaluation and therapeutic decision-making of patients with peripheral nerve injury. The electrodiagnostic (EDX) examination should try to address several key issues: (1) the injury site, (2) the pathophysiology of the injury, (3) the severity of the dysfunction, (4) the prognosis of the lesion, and (5) the progress of reinnervation. These issues can be addressed by assessing the compound motor action potential (CMAP) and the sensory nerve action potential (SNAP) and by performing a detailed needle electromyographic (EMG) examination of muscles.

The timing of the EDX evaluation is very important, as there is an orderly sequence of electrophysiological changes that follow nerve injury when wallerian degeneration occurs. Knowledge of these changes is necessary for proper interpretation of results. In humans, the distal CMAP can be recorded for 1–2 days after all voluntary muscle contraction is lost. The distal CMAP amplitude begins to decline by the third to fifth day after injury, and excitability is lost by the seventh to ninth day [19]. For sensory nerves, the loss of SNAP amplitude lags behind the motor nerves by 2–3 days, with the beginning of loss of amplitude occurring on the fifth to seventh day, and disappearance of the response by the ninth to eleventh day (see Fig. 7.68, in Chap. 7). The difference between the CMAP and SNAP responses is due to earlier physiological changes which occur at the neuromuscular junction [20]. In motor nerve fibers, the earlier deterioration

of neuromuscular transmission results in the earlier (≈2 days) failure of motor nerve conductions compared with sensory nerve conductions. The distal nerve segment continues to have an elicitable evoked response until the above changes have taken place.

Along a distal nerve segment undergoing wallerian degeneration, conduction velocity is unchanged as long as an electrical response can be elicited. This indicates that degenerating axons conduct normally until complete failure and that the largest, fastest conducting axons continue to conduct for the longest time [21]. Thus, before wallerian degeneration of axons is complete, EDX abnormalities resemble demyelinative conduction block: that is, whereas a distal electrical response is elicited, no response (or one of reduced amplitude with partial lesions) can be evoked proximally. It is important to recognize this axonal "noncontinuity conduction block" because it has a poor prognosis for recovery, while "demyelinative conduction block" usually recovers. In axonal-type injuries, the distal CMAP will decrease to approach the CMAP obtained proximally as wallerian degeneration takes place in the distal stump. *For these reasons, an electrophysiological evaluation performed within the first week post injury may result in underestimation of the severity of the injury. Sequential studies at least 2–3 weeks after the injury are necessary to quantify the severity of axonal degeneration.*

Changes in the electrical activity of muscles parallel the changes seen in motor nerves. Immediately following complete nerve transection, voluntary recruitment of motor unit action potentials (MUAPs) is abolished, and no abnormal spontaneous activity is seen yet on needle EMG. With partial resection, recruitment is reduced and is proportional to the loss of motor axons. Early on, the surviving MUAPs have a normal configuration. As wallerian degeneration proceeds, the trophic influence of nerve on muscle is lost, leading to denervational changes. Initially, there is an increase in insertional activity, followed by the appearance of abnormal spontaneous activity, i.e., fibrillation potentials and positive sharp waves, indicating active denervation. This spontaneous activity appears 2–5 days after the CMAP is lost and soon after the loss of the SNAP. It becomes profuse about 2–3 weeks after injury. The time to the appearance of spontaneous activity depends on the length of the distal stump, appearing sooner in more proximally denervated muscles than distal muscles [22].

When a complete nerve injury is clinically suspected, the EDX examination is oriented first toward confirming that there is a total nonfunction distal to the lesion and second to establishing that the pathophysiology is exclusively axonal in nature. Complete absence of volitional MUAP activity, lack of response to motor nerve stimulation distal to the site of injury, and active denervation in muscle suggest axonal injury to all motor nerve fibers. The amount of spontaneous activity observed is an unreliable indicator of axonal loss. *The best estimate of lesion severity is the diminution in size of the CMAP in response to distal stimulation* [23]. In partial lesions, the estimation of lesion severity is more complex. Localization of nerve injuries requires in-depth knowledge of the normal anatomy of myotomes, dermatomes, and peripheral nerve distributions as well as the numerous possible anatomical variations.

Partial peripheral nerve injuries that leave the nerve in continuity represent 60 to 70% of all peripheral nerve injuries [24]. They present a complex EDX challenge. A single EDX l assessment at 2–3 weeks after injury does not adequately discriminate between second-, third-, and fourth-degree injuries. All three of these grades of injury can show profound loss of motor axons. Serial EMGs should be performed over the course of 2–4 months to allow for grade 2 injuries to be distinguished from the more severe insults. Recovery of function occurs more frequently in grade 2 lesions. This recovery occurs both by distal collateral sprouting of remaining intact axons and regeneration of transected axons. During reinnervation by collateral sprouting, more muscle fibers are incorporated into the territory of each surviving motor unit. Electromyographically, this collateral sprouting is mirrored by an increase in duration, amplitude, and polyphasia of MUAPs. By contrast, the earliest definite evidence of muscle reinnervation by axonal regeneration following severe axonal loss is the appearance of one or a few small, complex, unstable MUAPs, sometimes referred to as "nascent" MUAPs. Immature sprouts conduct very slowly and their neuromuscular transmission is insecure. Like fibrillation potentials, these nascent or regenerating MUAPs develop in a centrifugal manner. Needle EMG may detect these MUAPs several weeks to months before there is any evidence of clinical improvement. The more severe nerve injuries, such as Sunderland grades 3 or 4, declare themselves by a lack of documentable recovery both clinically and electrophysiologically. *For most nerve lesions in continuity, surgical exploration is generally recommended, if there is no evidence of axonal regeneration by 3–6 months post injury.*

Therapeutic Interventions

Surgical

During the last quarter of a century, several significant development in the surgical tools available to treat nerve injuries have occurred: (1) the magnification by either an operating microscope or eye loupes, (2) the utilization of the bipolar coagulator, (3) the use of some microinstruments, and (4) the use of relatively fine suture [25]. Timing of the surgical repair depends on the type of injury as well as the degree

Table 39.2 Therapy of peripheral nerve injuries

Nerve lesion	EMG	Operative NAP	Therapy
Nerve transection	Not done acutely	Not done acutely	Early operation (72)h Sharp laceration = repair by end-to-end suture Blunt laceration = repair 2–4 weeks later Nerve intact = conservative
Nerve in continuity (focal lesion)	Serial EMG : 2–4 months Axonal integrity/regeneration = conservative Rx No axonal integrity = surgery with operative CNAP	Surgery: CNAP present→ CNAP absent→	 Simple neurolysis Resection and repair (graft)
Nerve in continuity (long lesion)	Serial EMG : 4–6 months Axonal integrity or regeneration = conservative Rx No axonal integrity = surgery with operative CNAP	Surgery: CNAP present→ CNAP absent→	 Simple neurolysis Resection and repair (graft)

EMG electromyography, *CNAP* compound nerve action potential

of injury. What follows is a brief summary of the current strategy for the surgical therapy of peripheral nerve injuries (Table 39.2).

Nerve Transection

Immediate repair is warranted in a nerve injury that has resulted in a relatively sharp transection, such as may be found with injuries due to glass, knives, or sharp metal edges. In this setting, the amount of tissue to be trimmed from each stump is minimal, the anatomy is not greatly distorted, and nerve repair can occur at the same time as other soft tissue repair. In contrast, the damage sustained by each stump in blunt transections is difficult to delineate acutely. These injuries are usually the result of propeller blades, power saws, or compound fractures. In blunt transection, immediate end-to-end repair of potentially damaged stumps leads to a poor result. Therefore, a formal repair is best accomplished after a delay of several weeks, when the amount of neuroma and scar tissue to be trimmed is very evident.

Lesions in Continuity

The majority of peripheral nerve injuries are of this variety. Most lesions in continuity are due to blunt trauma, stretch, and contusion, resulting in a mixture of grades 2, 3, and 4 nerve injuries. Gunshot wounds, which unfortunately account for a significant proportion of nerve injuries, also usually result in nerve lesions in continuity. Patients with total palsy of the brachial plexus following an accident have almost no chance for spontaneous recovery; this is different for partial injury which may have some spontaneous recovery. Patients with complete injury may benefit from earlier surgery. In a review of 335 adult patients with total palsies, operated between the third and sixth month after injury, they had good results with the return of elbow flexion. In partial injuries, some good results were observed even 10 months after the accident [26]. The type of surgical intervention performed on injured nerve depends on whether any axons extend across the lesion. Visual inspection of a surgically exposed nerve is necessary but is notoriously inadequate in determining the severity of the nerve injury. The best method for determining this is to use *intraoperative nerve action potential recordings*. Operative exploration not only allows for direct visualization of the injured site but provides the opportunity for direct recordings of evoked nerve activity of a lesion in continuity. The surgeon then has a solid physiological basis for deciding which sections of the nerve need to be resected or repaired. Intraoperative recordings are performed by placing stimulating and recording electrodes directly on the exposed nerve and attempting to elicit a nerve action potential. Muscle activity distal to the point of stimulation in the distribution of the nerve being stimulated is also monitored. The presence of a compound nerve action potential (CNAP) across and distal to the injury site is a direct evidence of viable axons. The amplitude of the action potential is indicative of the number of functioning axons within the nerve, as long as the stimulus used is sufficient to activate all axons. *The presence or absence of the CNAP is the single most important determinant of the type of surgical intervention to be used.* For a lesion in continuity, an absent CNAP usually indicates the need for resection and repair of the nerve, while the presence of a response usually indicates that a better result can be achieved with neurolysis or repair of only the damaged fascicles. Each component of the nerve can thus be tested and treated individually, as some fascicles or groups of fascicles may conduct while others may not.

Surgical techniques used in nerve repair are end-to-end suture, neurolysis, split repair, and graft repair. *End-to-end suturing* is still the procedure of choice for cleanly transected nerve or severe focal lesions in continuity where opposition of stumps can be done without excessive tension. With respect to *neurolysis*, there are two types, external and internal. External neurolysis consists of the dissection of nerve, freeing it from the surrounding tissues. Exposure of the entire circumference of the nerve is performed, allowing for intraoperative stimulation and recording studies. If a CNAP cannot be elicited across the nerve injury site, the nerve is resected beginning at the segment proximal to the lesion where a CNAP is first recordable. Internal neurolysis is then

done, and the nerve is repaired by end-to-end suture if mobilization of the stumps provides enough length for repair with minimal tension.

Occasionally a lesion conducting a CNAP will look and feel worse over a portion of its circumference than in other areas. Proximal and distal nerve is then split into its fascicular structure and traced as best as possible through and beyond the lesion. Recording at a fascicular level is then performed to identify those fascicles that are most severely involved. *Split repair* and internal neurolysis is then restricted to the most severely injured fascicles.

Many injuries produce lengthy lesions that if resected will lead to a gap not readily repaired by end-to-end suturing. Several techniques for repair are utilized, nerve grafts, nerve transfers, and tendon and muscle transfers. The gold standard in nerve gap management remains *autogenous nerve grafting* [27]. The most popular graft technique is an interfascicular grouped fascicular approach [28]. Groups of fascicles are isolated both proximally and distally, and a number of small caliber nerves are used to span the gap. Common donor nerves include the sural and antebrachial cutaneous nerves. Patients with injuries that are able to be reconstructed with both root grafting and nerve transfers have been shown to have better results [29]. More recently, nerve conduits, allografts, and nerve expansion have been investigated. Nerve conduits have been constructed of bone, silicone conduits, vein, artery [30], amnion [31], polyglactin 910 [32], and collagen [33]. Silicone conduits are rarely used since they have been implicated with serious problems, including chronic compression of the regenerating axons necessitating surgical removal. Clinical application of peripheral nerve allografting remains under experimental investigation and requires immunosuppression in the host. Typically, the nerves are harvested from a donor undergoing harvest of other organs. Tissue expansion has been fraught with difficulties, including compromised nerve perfusion and progressive demyelination. Muscle grafts have been used for peripheral nerve repair with good results over short distances [34].

Stimulation of Axonal growth

In all cases of nerve injury except neurapraxia, regeneration is slow and incomplete. In humans, nerves regenerate at an average rate of 1–2 mm/day [35]. Enhancing the rate and completeness of regeneration may significantly improve nerve repair results. There are two major determinants of successful nerve regeneration, intrinsic growth ability and an extrinsic permissive environment [36]. Axonal regeneration depends on Schwann cells and a substrate along which the axon can grow and presumably also on diffusible factors produced within the nerve and the peripheral target (neurotrophic and neurophilic factors). A major change in thinking regarding nerve regeneration is taking place. Recent research indicates that reinnervation of target organs depends not only upon the potency of axonal regeneration but also upon physical and chemical factors external to the axon. Schwann cells are now known to be very important in stimulating and guiding successful axonal regeneration. Along neural tubes and at the level of the neuromuscular junction, the Schwann cells elaborate processes that help guide the regenerating fibers to the muscle [37].

Several neurotrophic factors applied locally or systemically enhance nerve regeneration. The immunosuppressant drug FK506, a ligand of the immunophilin FK506 binding protein-12, increases the rate of axonal regeneration in lesioned rat peripheral nerve [38]. Nonimmunosuppressive analogues of FK506, rapamycin and cyclosporin, are potent drugs in promoting nerve fiber growth in vitro and in vivo [39]. The potential effectiveness of these compounds in promoting axonal regeneration is great, and they are being studied by many investigators.

Significant enhancement of nerve regeneration has also been reported by implanting prosaporin (a protein precursor of saporins), between proximal and distal stumps of transected peripheral nerve [40]. Studies with insulin-like growth factor (IGF) have identified that it has a neurotrophic effect upon motor axons [41]. Nerve growth factor (NGF) has yielded conflicting results [42], and epidermal growth factor (EGF) has been shown not to influence regeneration [43]. Gangliosides are abundant in axonal membranes, and topical GM1 ganglioside has resulted in a small improvement in regenerating axon diameter following nerve crush injury [44]. There have also been reports that use of direct current electric fields [45] and hyperbaric oxygen [46] may enhance axonal regeneration.

Another strategy that may promote axonal recovery is attenuation of neuronal cell death following axotomy. Recent attempts to rescue injured neurons with exogenous neurotrophins [47] (nerve growth factor {NGF}, brain-derived neurotrophic factor {BDNF}, neurotrophin-3 {NT-3}, and neurotrophin −4/5 {NT-4/5}) and neurokines (ciliary neurotrophic factor {CNTF}) have been very promising in some experimental studies.

A recent growth of knowledge has occurred in axonal guidance research. Certain proteins, netrins [47] and semaphorins [48], which are secreted by neuronal target cells into the surrounding tissue can act as either chemorepellents or as chemoattractants for axons. The presence of such proteins at critical locations along with a nerve helps to steer growing axons along the most appropriate pathways to their target organs. Ultimately, the signals are integrated into specific regulators of the nuclear transcription factors that induce the expression of large ensembles of distinct genes sequentially and under tight control. These include c-Jun, sox-11, CREB, Smad1, ATF3, AKRD1, NFILS, p53, STAT3, C/EBPβ, and several KLF family members. Although there is a theoretic

appeal of enhancing regeneration with the above-mentioned agents, the role that these agents may play in promoting axonal regeneration in humans must await further research.

Compressive and Entrapment Neuropathies of the Upper Extremity

40

David C. Preston

Median Neuropathy at the Wrist

Median neuropathy is the most common entrapment neuropathy affecting the upper extremity, with the usual site of compression occurring at the wrist. Entrapment of the median nerve at the wrist usually presents with *carpal tunnel syndrome* (*CTS*), a characteristic syndrome of wrist pain and digital paresthesias, often provoked during sleep or other activities that increase carpal tunnel pressure.

Anatomy (Fig. 40.1)

The median nerve is formed by a contribution of the lateral and medial cords of the brachial plexus [1]. The lateral cord fibers comprised of C6–C7 fibers and supply sensory fibers to the thenar eminence and thumb (C6), index (C6–C7), and middle (C7) fingers as well as motor fibers to the proximal median forearm muscles. The medial cord contribution comprised of C8–T1 fibers and supplies motor fibers to the distal median muscles of the forearm and hand, as well as sensory fibers to the lateral half of the ring finger.

In the upper arm, the median nerve descends giving off no branches. In the antecubital fossa, the nerve lies adjacent to the brachial artery. Passing into the forearm, the nerve runs between the two heads of the pronator teres before giving off muscular branches to the pronator teres, flexor carpi radialis, flexor digitorum sublimis, and, in some individuals, the palmaris longus muscles. The anterior interosseous nerve is given off next in the proximal forearm, innervating the flexor pollicis longus, medial head of the flexor digitorum profundus to index and middle fingers, and the pronator quadratus muscles.

Just proximal to the wrist and carpal tunnel, the palmar cutaneous sensory branch arises, running subcutaneously to supply sensation over the thenar eminence. The median nerve then enters the wrist through the carpal tunnel. Carpal bones make up the floor and sides of the carpal tunnel, with the transverse carpal ligament forming the roof. In the palm, the median nerve divides into motor and sensory divisions. The motor division travels distally into the palm supplying the first and second lumbricals. In addition, the recurrent thenar motor branch supplies muscular branches to most of the thenar eminence including the opponens pollicis, abductor pollicis brevis, and superficial head of the flexor pollicis brevis. The sensory fibers of the median nerve that course though the carpal tunnel supply the medial thumb, index and middle finger, and lateral half of the ring finger in most individuals.

Etiology and Pathogenesis

There are numerous etiologies of median neuropathy at the wrist, although most are idiopathic [1, 2]. Idiopathic cases were long considered to be tenosynovitis of the transverse carpal ligament. However, pathology typically shows little evidence of inflammation with the major findings being edema, vascular sclerosis, and fibrosis, most consistent with repeated stress to connective tissue. Median neuropathy at the wrist is more common in patients who have a narrow carpal canal [3, 4]. Imaging studies have demonstrated that the narrowest part of the canal is 2 to 2.5 cm distal from the entrance. Detailed nerve conduction studies with inching show the area of maximal slowing to be slightly distal to the wrist crease in the palm [1]. Demyelination follows compression and ischemia of the median nerve, and if severe enough, axonal loss ensues. Occupations or activities which

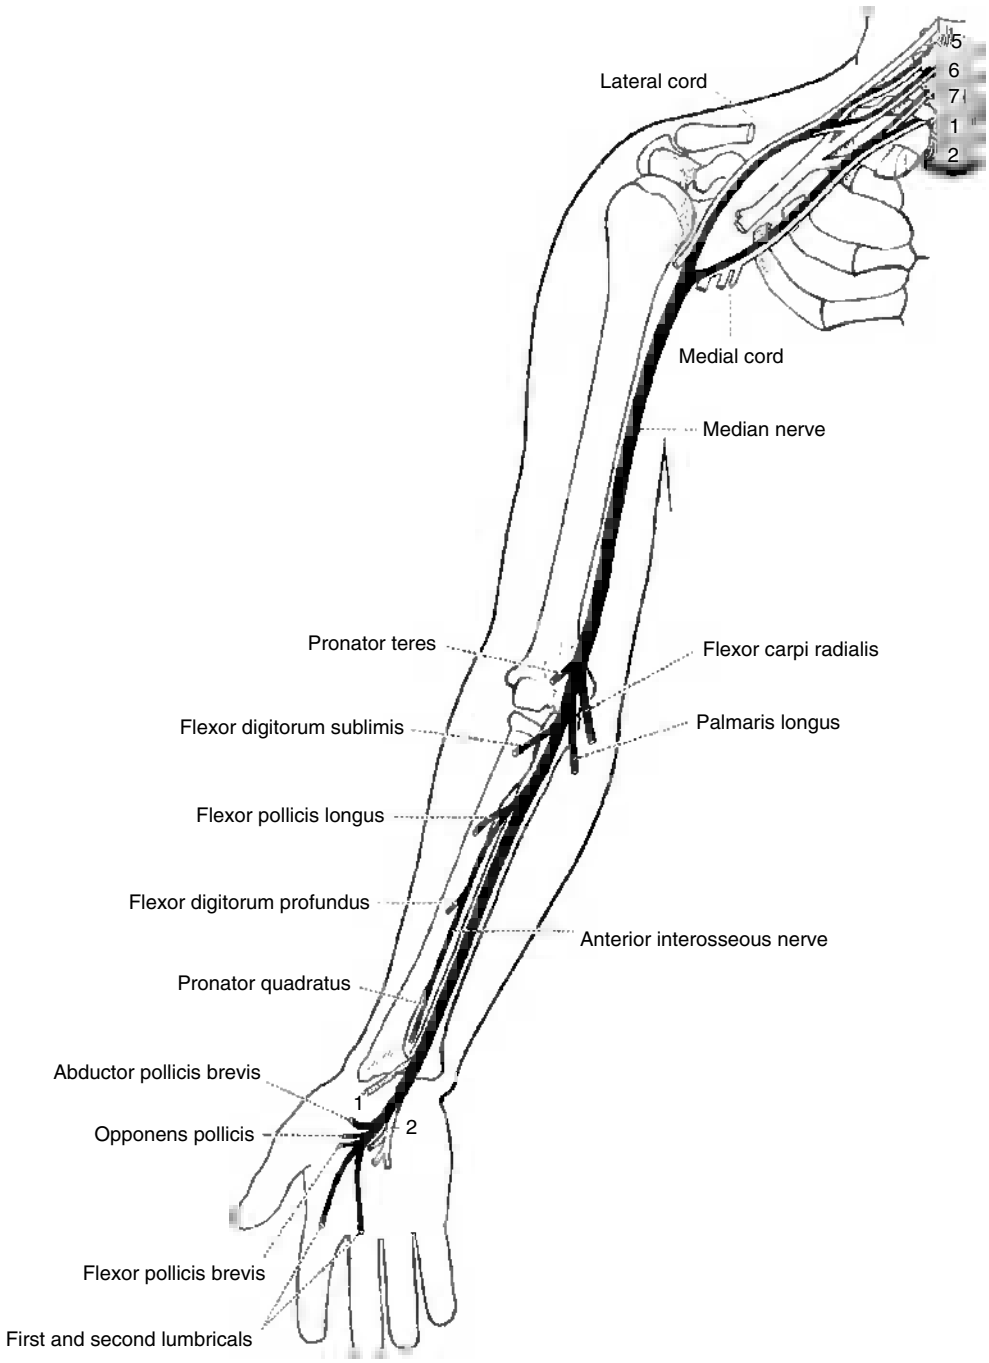

Fig. 40.1 Anatomy of the median nerve. The median nerve is derived from a combination of the lateral and medial cords of the brachial plexus. Motor innervation is supplied to forearm muscles and to muscles of the thenar eminence. Sensation is supplied to the thenar eminence by the palmar cutaneous sensory branch (*1*) and to the first three and one-half digits by several digital sensory branches (*2*) (Adapted from Haymaker and Woodhal [102]. With permission)

involve repetitive hand use increase the risk of CTS. Other predisposing etiologies include certain systemic disorders, most notably endocrine (e.g., hypothyroidism) or connective tissue diseases (e.g., rheumatoid arthritis); unusual mass or infiltrating lesions of the carpal tunnel; some congenital conditions; various infectious and inflammatory diseases such as Lyme disease and sarcoidosis; trauma, especially Colles fracture; and several other conditions including amyloidosis, hemodialysis, and pregnancy.

Clinical Presentation

CTS may present with a variety of symptoms and signs [1, 5, 6]. Women are more often affected than men. Although usually bilateral, the dominant hand is usually more severely affected, especially in idiopathic cases. Patients complain of wrist and arm pain associated with paresthesias in the hand. The pain may be localized to the wrist or may radiate to the forearm, arm, or rarely the shoulder. Some patients may describe a

Table 40.1 Clinical symptoms and signs

Highly suggestive of CTS	Possible CTS	Inconsistent with CTS
Nocturnal paresthesias awakening patient from sleep Shaking or ringing the hands	Hand, wrist, forearm, arm, and/or shoulder pain	Neck pain
Pain/paresthesias with driving and holding a phone, book, or newspaper	Perception of paresthesias involving all five digits	Radiating paresthesias from the neck down the arm
Sensory disturbance of the thumb and index, middle, and ring fingers; splitting the ring finger	No fixed sensory disturbance, or sensory disturbance of the thumb and index, middle, and ring fingers	Unequivocal numbness over the thenar eminence
Weakness/wasting of thenar eminence	Decreased hand dexterity	Weakness/wasting of hypothenar muscles, thumb flexion (IP joint), arm pronation, and/or elbow flexion/extension
Phalen's maneuver reproduces symptoms	Tinel's sign over the median nerve at the wrist	Reduced biceps or triceps reflexes

Source: Adapted from Preston and Shapiro [103]

diffuse, poorly localized ache involving the entire arm. Paresthesias are frequently present in a median nerve distribution (i.e., medial thumb, index, middle, and lateral ring fingers). While many patients report that the entire hand falls asleep, if asked directly about little finger involvement, most will subsequently note that the little finger is spared.

Symptoms are often provoked when either a flexed or extended wrist posture is assumed. Most commonly, this occurs during ordinary activities, such as driving or holding a phone, book, or newspaper. Nocturnal paresthesias are particularly common. During sleep, persistent wrist flexion or extension leads to increased carpal tunnel pressure, nerve ischemia, and subsequent paresthesias. Patients are frequently awakened from sleep and shake or ring out their hands or hold them under warm running water.

Sensory fibers are involved early in the majority of patients. Hence, pain and paresthesias are usually the presenting symptoms. Motor fibers may become involved in more advanced cases. Weakness of thumb abduction and opposition may develop, followed by atrophy of the thenar eminence. Some patients describe difficulty buttoning shirts, opening a jar, or turning a doorknob. However, it is unusual to develop significant functional impairment from loss of median motor function in the hand.

The sensory examination may disclose hypesthesia in the median distribution. Two-point discrimination is generally affected before pain and temperature. Sensation over the thenar area in spared, as this area is innervated by the palmar cutaneous sensory branch, arising proximal to the carpal tunnel. Often, paresthesias may be elicited by tapping over the median nerve (*Tinel's sign*) or by having the patient hold their wrists in a flexed position (*Phalen's maneuver*) [6, 7]. The Tinel's sign is present in over half of CTS cases; however, false-positive Tinel's signs are common in the general population. A Phalen's maneuver, which usually produces paresthesias within 1–2 min in CTS, is more sensitive than the Tinel's sign and has fewer false positives. Most commonly, the Phalen's maneuver will produce paresthesias in the middle or index fingers. The motor examination involves inspection of the hand looking for wasting of the thenar eminence in more severe cases and testing the strength of thumb abduction and opposition.

Differential Diagnosis

There are several peripheral as well as central nervous system lesions that may result in symptoms similar to CTS (Table 40.1). The peripheral lesions that may mimic CTS include median neuropathy in the region of the elbow, brachial plexopathy, and cervical radiculopathy. Cervical radiculopathy is the most common disorder confused with CTS, especially lesions of the C6 or C7 roots, which may cause both pain in the arm and paresthesias similar to CTS. The important clinical points that suggest radiculopathy rather than CTS are neck pain radiating to the shoulder and arm and exacerbation of symptoms by neck motion. Key points in the physical examination that suggest radiculopathy are abnormalities of the C6–C7 reflexes (biceps, brachioradialis, triceps), diminished power in proximal muscles (especially elbow flexion, elbow extension, arm pronation), and sensory abnormalities in the palm and/or forearm, which are beyond the distribution of sensory loss in CTS.

Median neuropathy in the elbow and brachial plexopathy are uncommon, especially when compared to the incidence of CTS. If present, however, they may easily lead to clinical confusion. Important points on physical examination that suggest a more proximal lesion of the median nerve are sensory disturbance over the thenar eminence and weakness of median muscles proximal to the carpal tunnel, especially distal thumb flexion, arm pronation, and wrist flexion. In brachial plexus lesions, the neurologic examination may reveal abnormalities similar to those noted in cervical radiculopathy, although the distribution of reflex abnormalities, weakness, and sensory loss may be more widespread, beyond the distribution of one spinal segment.

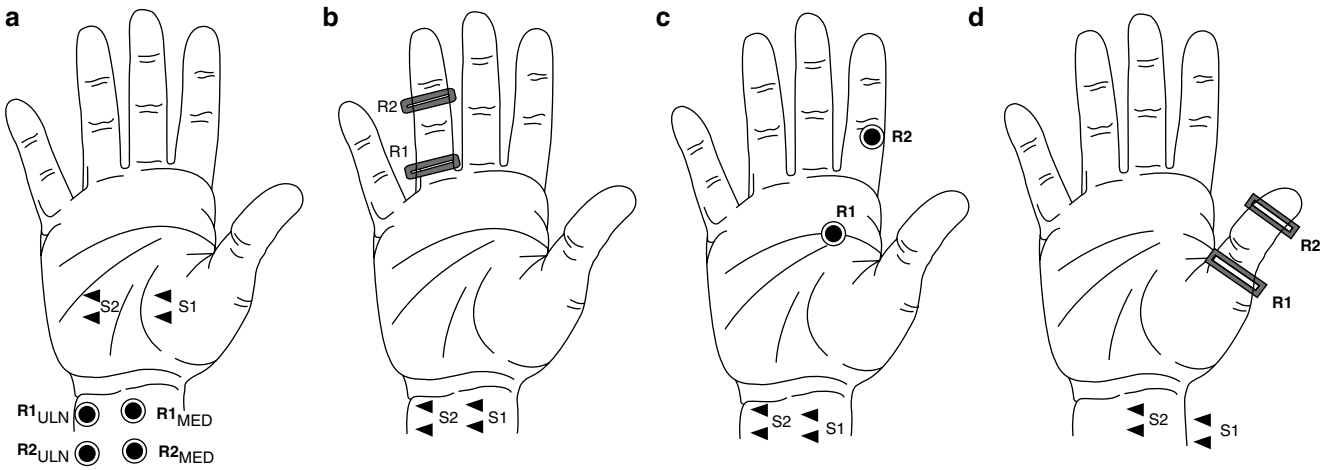

Fig. 40.2 Internal comparison studies. (**a**) Palmar-mixed studies, (**b**) ring finger sensory studies, (**c**) lumbrical-interosseous studies, and (**d**) thumb sensory studies. *S1*: median stimulation point, *S2*: ulnar/radial stimulation point, *R1*: active recording electrode, and *R2*: reference recording electrode. In each study, identical distances between stimulation and recording sites are used for the median and ulnar/radial nerves (Adapted from Preston and Shapiro [103])

As for central nervous system disorders, transient paresthesias in the hand may be seen in patients with seizures, migraine, and transient ischemic attacks and are occasionally misinterpreted as symptoms of CTS. Rarely, patients referred for CTS are found to have a small lacunar infarct involving the lateral thalamus and internal capsule, causing hand clumsiness and sensory disturbance predominantly affecting the median-innervated digits.

Evaluation and Diagnosis

The median nerve is easily studied in the EMG laboratory. A large number of nerve conduction studies are available to assess the median nerve across the carpal tunnel [1, 8]. Similar to the clinical examination, the goals of electrodiagnostic testing (EDX) are to demonstrate a distal lesion of the median nerve and exclude other peripheral conditions which can result in similar symptoms, especially high median neuropathy, C6–C7 radiculopathy, or lesions of the brachial plexus.

In most cases of compressive median neuropathy at the wrist, demyelination is present at the site of lesion with more severe cases demonstrating axonal loss. In moderate or severe cases, routine median motor and sensory nerve conduction studies easily demonstrate slowing of distal latency across the wrist. In cases with either conduction block at the wrist or secondary axonal loss, median motor and sensory amplitudes are reduced. Median motor conduction in the forearm may be slightly slowed if some of the largest and fastest median fibers are blocked or have undergone Wallerian degeneration [9]. Median minimum F wave latencies may be prolonged, especially in comparison to the ulnar nerve, reflecting the F wave response must also transverse the carpal tunnel [10]. It is essential that the electromyographer studies at least one additional motor and sensory nerve to ensure that the abnormalities seen in the median nerve do not simply represent a brachial plexopathy or more widespread polyneuropathy. Indeed, patients with an underlying polyneuropathy often are at risk for developing superimposed entrapment neuropathies, including distal median neuropathy.

Although patients with distal median neuropathy typically display prolonged median motor and sensory latencies, a substantial number of patients (approximately 10–25 %) will have normal routine studies. The diagnosis will be missed in these patients unless further testing is performed. Most often, a study to an adjacent nerve of similar length and size in the same hand is used (internal comparison study). These studies are most useful in patients with mild abnormalities or in those patients with an underlying polyneuropathy. The internal comparison studies most often employ the ulnar nerve and occasionally the radial nerve (Fig. 40.2). The common comparison studies include (1) the median vs. ulnar palm-to-wrist mixed nerve latencies [11], (2) the median vs. ulnar wrist-to-ring finger sensory latencies [12], (3) the median (second lumbrical) vs. ulnar (interossei) distal motor latencies [13, 14], and (4) the median vs. radial wrist-to-thumb sensory latencies [15–17].

In each comparison study, identical distances are employed between the stimulator and recording electrodes for the median and other adjacent nerve [18]. These techniques create an ideal internal control in which several variables that are known to affect conduction time are held constant, including distance, temperature, age, and nerve and/or muscle size. Thus, any mild slowing of the distal median nerve is much easier to appreciate. However, it is important to appreciate that these sensitive comparison studies rely on very small

differences in latencies as measures of distal median nerve dysfunction [1]. Therefore, meticulous attention must be paid to all technical factors, especially distance measurement, stimulus artifact, supramaximal stimulation, and electrode placement, in order to obtain reliable and reproducible data. In addition, avoiding overstimulation, which may cause unintentional stimulus spread to an adjacent nerve, is essential to avoid.

Each of the internal comparison studies has certain advantages. The median vs. ulnar palm-to-wrist mixed nerve studies take advantage of measuring the mixed nerve potential which contains both motor and sensory fibers, including the largest sensory fibers, the Ia afferents from the muscles spindles. Because these fibers are the largest and contain the most myelin, they are susceptible to demyelination, the primary pathology in distal median neuropathy. The mixed nerve study also has the advantage of conducting over a very short distance (typical distance 8 cm). By using such short distances, most of the conduction time is computed over the area of pathology, with the length of normal nerve that could potentially dilute the slowing being minimized. The median vs. ulnar wrist-to-ring finger sensory latency study makes use of the sensory innervation to the ring finger which is split by the median and ulnar nerves in most individuals. Using identical distances, the median sensory latency to the ring finger can be directly compared to the ulnar sensory latency to the ring finger. The studies can be performed either antidromically or orthodromically. The median vs. ulnar distal motor latencies, recording the second lumbrical and interossei, respectively, is an internal comparison technique using motor studies. This technique has the advantage that motor fibers are more easily recorded than sensory fibers and that in the case of polyneuropathy, the study can still be easily performed even if all the sensory responses are absent. Also, in severe CTS with absent routine median CMAPs and SNAPs, this study is able to localize the lesion to the wrist in over 90 % of cases. Identical distances are used and the distal latencies compared. Lastly, the median vs. radial sensory distal latencies recording the thumb are the only internal comparison study which utilizes the radial nerve. In most individuals, sensory innervation to the thumb is split between the median and radial sensory nerves. Thus, similar to the median ulnar to ring finger sensory studies, the median sensory latency can be directly compared to the radial sensory latency to the thumb, provided identical distances are used.

Using the above sensitive internal comparison studies, focal slowing of the distal median nerve can usually be demonstrated. However, none of the internal comparison studies or routine median motor and sensory studies are informative about the presence of conduction block. Indeed, low median motor or sensory amplitudes stimulating at the wrist may signify secondary axonal loss, conduction block, or a combination. The differentiation is important in regard to prognosis and possibly treatment. Secondary axonal loss signifies greater injury to the distal median nerve and a much longer or incomplete recovery even after appropriate therapy. Conduction block, which signifies demyelination, is readily reversible, provided that initial inciting event is no longer present. Conduction block across the distal median nerve can be recognized and quantitated in the EMG laboratory by comparing motor and sensory amplitudes with stimulation at the wrist and in the palm (Fig. 40.3) [19]. Although useful, technical factors sometimes limit these studies. Because of close distances between the stimulator and recording electrodes, stimulus artifact may obscure the baseline. In addition, one must be aware that there is always some drop in amplitude proximal to the wrist compared to distal due to normal temporal dispersion and phase cancelation with proximal stimulation. The effects of temporal dispersion and phase cancelation are greater for sensory fibers than motor fibers. In normal median nerves, the ratio of the distal/proximal motor amplitude does not exceed 1.2, whereas the distal/proximal sensory amplitude ratio does not exceed 1.6 [19]. Ratios larger than these suggest some element of conduction block. It is important that both stimulations are supramaximal, that there is no co-stimulation of adjacent nerves, and

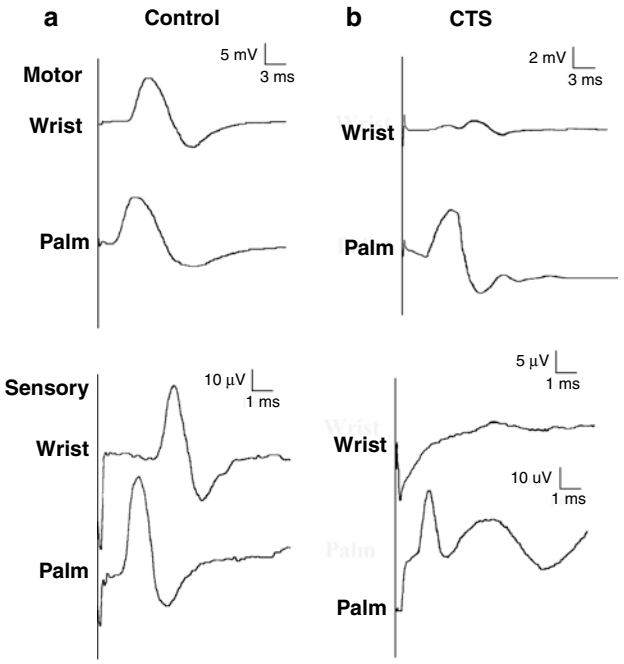

Fig. 40.3 Change in CMAP and SNAP amplitude across the carpal tunnel. To assess possible conduction block across the carpal tunnel, either the median CMAP or SNAP can be recorded, stimulating the wrist and palm. (**a**) Note in controls, there is only a slight increase in amplitude between palm and wrist stimulation sites. (**b**) A large difference between palm and wrist sites in CTS patients signifies conduction block. For motor studies, a normal palm/wrist amplitude ratio is 1.2; for sensory studies 1.6 (From Lesser et al. [19]. Reprinted by permission of John Wiley & Sons, Inc.)

that the baseline is not obscured by shock artifact or noise which precludes an accurate amplitude measurement.

Nerve conduction studies are often the principal test to confirm median neuropathy at the wrist. However, needle EMG should be employed in all cases to help assess the severity of the median neuropathy and help exclude other superimposed conditions, especially high median neuropathy, brachial plexopathy, or C6–C7 radiculopathy. The presence of fibrillation potentials or large reinnervated motor unit action potentials (MUAPs) in the abductor pollicis brevis or opponens pollicis signifies active or chronic denervation, respectively. These signs of axonal loss imply a more severe or advanced case and may have direct ramifications for recommendations for further therapy. It is important to note that in mild or early cases of distal median neuropathy, the thenar muscles are usually normal on needle EMG.

Other muscles which are useful to sample in selected cases are the proximal median muscles (e.g., flexor pollicis longus, flexor carpi radialis, pronator teres) and C6–C7-innervated muscles (e.g., pronator teres, triceps). If any abnormality is found, a more extensive needle EMG examination needs to be performed to localize the lesion. Of course, it is not uncommon that two peripheral nervous system conditions are present in the same patient (e.g., distal median neuropathy and polyneuropathy, distal median neuropathy and C6–C7 radiculopathy). In those cases, it is especially valuable for the electromyographer to assess the severity of each in relation to each other to help guide decisions regarding therapy.

EDX Studies After Carpal Tunnel Release

It is not uncommon to have a patient referred for EDX studies who has previously undergone carpal tunnel release surgery. Typically, the patient will have undergone surgery with no clinical improvement or will have developed recurrent symptoms months or years later after successful carpal tunnel decompression. In many cases, the patient will not have had a preoperative EDX study to confirm the diagnosis of CTS. Thus, one needs to be aware of what happens to nerve conduction study abnormalities after successful carpal tunnel release surgery [20]. In general, the distal median motor and sensory latencies and amplitudes improve. However, this may take many weeks to months, and in some studies, improvement continues up to a year after surgery. However, some slowing may persist indefinitely. In the authors' experience:

1. Median distal motor latencies improve and usually return to the "normal" range. Never do distal latencies remain in the demyelinating range (i.e., >130 % the upper limit of normal) after successful carpal tunnel release.
2. Median sensory latencies improve and usually return to the "normal" range. Never do conduction velocities remain in the demyelinating range (i.e., <75 % the lower limit of normal) after successful carpal tunnel release.
3. Median motor amplitudes improve and return to the normal range.
4. Median sensory amplitudes may or may not improve. Many remain in a slightly reduced or borderline normal range.
5. The sensitive internal comparison studies (i.e., palmar mixed studies, ring finger study, thumb study, lumbrical-interosseous study, and segmental sensory study) remain abnormal indefinitely, showing some slowing of median conduction across the carpal tunnel.

Although these findings are seen most often after carpal tunnel release surgery, similar findings are seen in other entrapment neuropathies. These persistent "abnormalities" occur as the result of remyelination. In entrapment neuropathies, such carpal tunnel syndrome, demyelination occurs at the site of compression, resulting in interruption of the internodes at the site of compression. When the compression is successfully released, remyelination can then occur. However, the new internodes are short. Therefore, more nodes are required to remyelinate the original site of compression. When remyelination is completed, nerve impulses can once again travel successfully up and down the nerve. However, the time of conduction (and hence conduction velocity) is completely dependent on the depolarization time at the nodes of Ranvier. The greater the number of nodes of Ranvier, the more depolarizations, and hence the longer total time of depolarization. Thus, conduction velocity across the remyelinated area of compression will be slower than normal, because of the increase in number of nodes. In any situation where there has been demyelination and then remyelination, sensitive techniques will always demonstrate a slightly slower conduction time across the remyelinated segment. Accordingly, one must always be cautious when interpreting any mild "slowing" on nerve conduction studies in patients who have undergone carpal tunnel release.

As noted above, median neuropathy at the wrist is more often idiopathic, the result of strain or repetitive use on the transverse carpal ligament. However, there are a large number of underlying medical conditions associated with entrapment of the distal median nerve. Some conditions (e.g., hypothyroidism, rheumatoid arthritis) are highly associated with distal median neuropathy. The decision to pursue an underlying diagnosis and additional testing must be made individually, based on each patient's medical background and other symptoms at the time. The routine use of screening tests (e.g., thyroid function test, rheumatoid factor, Lyme antibody) has a very low yield and is usually not indicated without the presence of other symptoms or other risk factors from the patient.

Rarely, imaging studies with CT or MRI are indicated in suspected distal median neuropathy. Nerve tumors (e.g., schwannoma, neurofibromas) and ganglion cysts can affect peripheral nerves including the distal median nerve. A fullness in the wrist or palm is an indication for imaging.

Likewise, the history of a slowing progressive deficit without intermittent fluctuations often calls for imaging studies to exclude a structural lesion.

Management and Prognosis

The practical management of distal median neuropathy is straightforward. In idiopathic cases, therapy involves (1) withdrawal of provoking factors, (2) neutral wrist splint, (3) local corticosteroid injections, and (4) surgical decompression [5].

In some patients, there are clear provoking factors, such as writing, typing, or playing a musical instrument. For instance, CTS can sometimes develop in college students who spend long hours on the computer or typing papers. If it is possible to curtail the activity, it is advisable to do so. At times, a change in posture or workstation may improve many of the symptoms. For example, a wrist pad on a computer keyboard can be used to keep the wrists in a neutral position while typing.

Other than curtailing provocative factors, the first course of treatment is usually the prescription of a neutral wrist splint worn on the symptomatic hand(s) during sleep. A neutral wrist splint at night prevents wrist flexion and extension which increases the pressure within the carpal tunnel. In addition to wrist splints, a 2–3-week course of a nonsteroidal anti-inflammatory drug is often useful to decrease pain and swelling in the carpal tunnel, provided there is no medical contraindication (e.g., gastritis, peptic ulcer disease).

If simple maneuvers are not helpful, local corticosteroids can often be helpful. Corticosteroids are injected adjacent to the carpal tunnel (typically 40–80 mg of Depo-Medrol) [5]. Care must be taken not to inject within the carpal tunnel itself due to the concern of increasing the intra-carpal pressure and inducing acute median nerve compression. Steroid injections begin to work within a few days and often last for several weeks or months. Their main disadvantage is that they are usually a temporary measure, and repeated use of more than two or three injections is not advised due to the possibility of local tendon damage. They are most useful as a temporizing measure before surgery, in mild cases, or in cases where the syndrome may be time limited, such as in pregnancy.

Definite treatment of distal median neuropathy usually involves surgical decompression. The transverse carpal ligament is sectioned, decompressing the underlying median nerve. The proper surgical technique involves a longitudinal incision which extends from the wrist into the palm. Endoscopic release has been used in some cases of median nerve compression, offering a much shorter recovery time. The main disadvantage of this technique over the commonly performed open technique is the incomplete direct visualization of the transverse carpal ligament and the possibility of either incomplete section or damage to the median nerve or other nearby structures.

Surgical decompression is indicated in patients who are symptomatic and have failed conservative measures and in those patients whose distal median neuropathy is severe and associated with axonal loss. Clinically, patients with thenar atrophy and persistent hypesthesia on physical examination require surgical compression. Likewise, patients with low median motor and sensory amplitudes from axonal loss on nerve conduction studies or evidence of ongoing axonal loss in distal median-innervated muscles on needle EMG typically require surgical decompression. Surgery is also indicated in the presence of a mass lesion (e.g., nerve tumor, ganglion) or urgently in cases of acute carpal tunnel syndrome, which may follow local trauma [5]. In these cases, the wrist and hand is swollen and numb shortly after trauma.

The prognosis of distal median neuropathy is usually very good. Pain and paresthesias bring most patients to medical attention before any significant axonal loss has occurred. In addition, the large number of sensitive EDX tests available to study the distal median nerve allows early recognition and diagnosis. Patients with intermittent pain and paresthesias without any fixed motor or sensory deficits whose course is short often respond well to conservative therapy. Surgery is usually highly effective (response rate of 85–90 %) [21, 22]. Pain, other than at the surgical incision, disappears or is greatly reduced within the first hours or days. Recovery of motor or sensory deficit depends on whether the underlying pathology is demyelination, axonal loss, or a combination. Remyelination is usually complete within several weeks. Axonal loss recovers slowly over several months. In severe cases with near complete thenar atrophy, recovery of motor and sensory function may occur incompletely or not at all, although often pain is significantly improved.

Proximal Median Neuropathy

Proximal median neuropathy is distinctly uncommon compared to median entrapment at the carpal tunnel [23]. Differentiating between median neuropathy at the wrist and more proximal entrapments can be difficult on clinical grounds alone, especially in mild cases. EDX plays a key role in localizing the lesion in these unusual cases, especially in traumatic or compressive lesions.

Anatomy

As the median nerve descends in the upper arm, it runs medial to the humerus and anterior to the medial epicondyle [1]. In a small minority of individuals, a bony spur originates from the shaft of the medial humerus just cephalad to the

medial epicondyle. A tendinous band may occur at this point (ligament of Struthers), stretching between the spur and the medial humeral epicondyle. In the antecubital fossa, the median nerve travels adjacent to the brachial artery. As it enters the forearm, it runs first beneath the lacertus fibrosus, a thick fibrous band that runs from the medial aspect of the biceps tendon to the proximal forearm flexor musculature. The median nerve then runs between the two heads of the pronator teres muscle to provide innervation to that muscle. In some individuals, there are fibrous bands within the two heads of the pronator teres muscle. The anterior interosseous nerve is given off posteriorly after the median nerve passes between the two heads of the pronator teres. As the median nerve runs distally, it passes deep to the flexor digitorum sublimis muscle and its proximal aponeurotic tendinous edge, known as the sublimis bridge.

Etiology and Pathogenesis

Proximal median neuropathy is described as a consequence of external compression from casting, trauma, venipuncture, and as the result of compressive mass lesions including tumor or hematoma. Rare cases of brachial artery puncture and subsequent hematoma formation have led to compartment syndromes and subsequent injury of the proximal median nerve. The proximal median nerve, especially the anterior interosseous nerve, may be involved in cases of neuralgic amyotrophy (see Chap. 46).

In addition, several sites of proximal median entrapment have been reported. All are uncommon and remain controversial [23–26]. These potential sites of entrapment include the ligament of Struthers, a hypertrophied lacertus fibrosus, the pronator teres muscle, and the sublimis bridge (see below).

Clinical Presentation

The clinical syndromes of proximal median neuropathy depend on the underlying etiology.

Traumatic Lesions

In traumatic lesions, there is usually an obvious, acute disturbance of median motor and sensory function. Importantly, sensory disturbance in proximal median neuropathy is noted in the entire median territory, including the thenar eminence, as well as the thumb, index, middle fingers, and lateral ring finger. This is distinctly different from CTS, where sensation over the thenar eminence is spared because the palmar cutaneous sensory branch, which innervates the thenar eminence, leaves the median nerve proximal to the carpal tunnel. Depending on the site of the lesion, weakness may include some or all of the proximal median forearm muscles, including the pronator teres, flexor carpi radialis, flexor digitorum sublimis, flexor digitorum profundus to index and middle fingers, flexor pollicis longus, and pronator quadratus, as well as the distal median-innervated muscles, including the abductor pollicis brevis, opponens pollicis, and first and second lumbricals. There is often local tenderness or pain at the site of compression or trauma.

Entrapment Syndromes

The symptoms and signs in the proximal median entrapment syndromes are much less specific. Typically, there is pain or discomfort in the region of the entrapment. Unlike CTS, there is no nocturnal exacerbation of symptoms. The two major syndromes include (1) proximal entrapment of the median nerve by the ligament of Struthers [26] and (2) median nerve entrapment more distally, either beneath the lacertus fibrosus, in the substance of the pronator teres, or beneath the sublimis bridge. These latter entrapments are usually referred to as "pronator syndrome" [24–27]. Although strictly speaking, the term is often reserved for nerve entrapment within the substance of the pronator teres muscle proper, entrapment at any of these last three locations usually produces a similar clinical syndrome. Lastly, the anterior interosseous neuropathy may occur as a separate entity.

Ligament of Struthers Entrapment

This is a very rare syndrome characterized by pain in the volar forearm and paresthesias in the median digits exacerbated by supination of the forearm and extension of the elbow. The radial pulse may also be attenuated with these maneuvers. A bony spur may be palpable at the distal humerus (Fig. 40.4). Weakness of the pronator teres and other median-innervated muscles may occur, and subtle sensory loss may be noted in the median distribution including the thenar eminence.

Pronator Syndrome

Though rare, this syndrome occurs more often than entrapment at the ligament of Struthers. The pronator teres muscle may be enlarged or firm, with a Tinel's sign over the site of entrapment. Maneuvers that may produce symptoms of pain in the forearm and paresthesias in the median digits depend on the site of entrapment: forced supination and elbow flexion (for the lacertus fibrosis), forced pronation and elbow extension (for the pronator teres), and flexion of the proximal interphalangeal joint of the middle finger (for the sublimis bridge). The sole finding of increased pain with these maneuvers is an unreliable sign, unless accompanied by paresthesias in the median nerve distribution. Significant weakness or wasting of median-innervated muscles is rare, but mild weakness of the flexor pollicis longus and abductor pollicis brevis is not uncommon, with occasional involvement of the

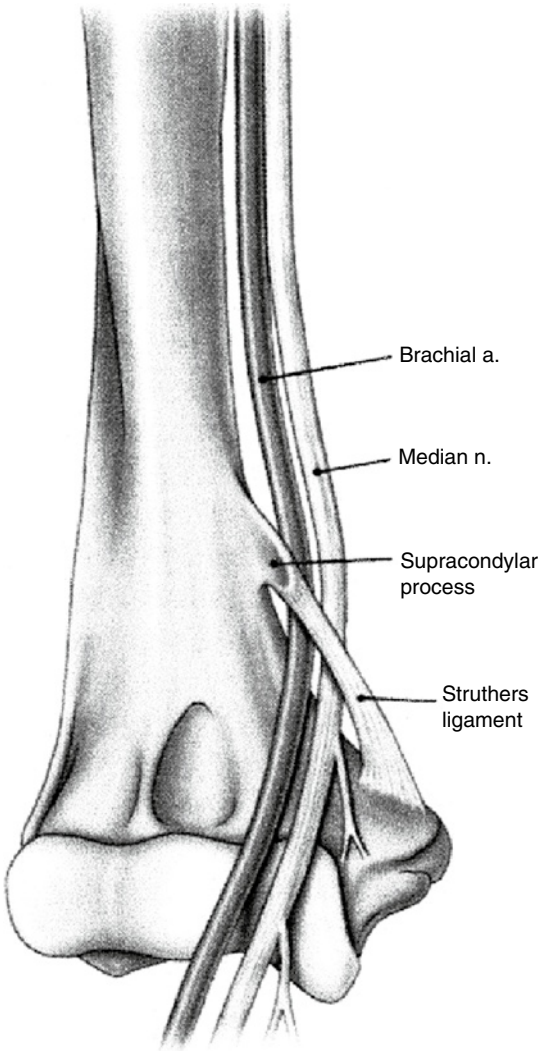

Fig. 40.4 Ligament of Struthers and high median neuropathy. The ligament of Struthers runs between the medial epicondyle and a supracondylar process of the distal humerus, creating a potential entrapment site of the high median nerve (From Gross and Tolomeo [104]. With permission from WMC. © 1998 Labey Clinic)

flexor digitorum profundus. There may be occasional paresthesias radiating into the median-innervated digits, with subtle impairment of sensation in the median nerve distribution including the thenar eminence.

Anterior Interosseous Nerve Syndrome

Clinically, patients present with inability to flex the distal phalanx of the thumb and index finger with weakness of pronation. Weakness of the pronator quadratus is best tested with the elbow flexed, to avoid the contribution from the pronator teres. There is no sensory loss. However, prominent pain may be present from involvement of deep sensory fibers to the wrist and interosseous membrane. A characteristic compensatory posture occurs when the patient attempts to make the "OK" sign and is unable to flex the distal thumb and index fingers: hyperextension of the distal interphalangeal joint of the index finger and interphalangeal joint of the thumb [1].

Differential Diagnosis

In cases of acute trauma or injury, the differential diagnosis is usually quite limited and straightforward. However, with the entrapment syndromes in the region of the elbow, the symptoms are often vague, and the differential diagnosis is extensive. For example, local orthopedic problems may present in a similar fashion. Median neuropathy at the carpal tunnel may also give rise to diagnostic confusion. Patients with CTS can present with vague pain or heaviness in the forearm associated with median paresthesias, similar to symptoms in the proximal median entrapment syndromes. Cervical radiculopathy may present with radiating pain and paresthesias into the hand. In cervical radiculopathy, however, there is usually a history of neck pain which radiates into the arm. Examination in cervical radiculopathy may reveal weakness and sensory disturbance outside the median territory, as well as depressed biceps, brachioradialis, or triceps reflexes.

The proximal median nerve and especially the anterior interosseous nerves can be involved in cases of neuralgic amyotrophy (aka, brachial neuritis) [29]. Indeed, in some cases, the syndrome is limited to the anterior interosseous nerve alone. It is important to question the patient about possible immunologic triggers (e.g., infection, vaccination) which can be identified in many but not all cases. Most cases of neuralgic amyotrophy have prominent pain which lasts a few days to weeks followed by weakness and wasting which slowly improves over months.

Evaluation and Diagnosis

EDX testing should be employed in all suspected cases of high median neuropathy, ideally to demonstrate median nerve abnormalities proximal to the wrist and exclude a more proximal lesion in the brachial plexus or cervical nerve roots [1]. Nerve conduction studies should include routine median motor studies stimulating the median nerve at the wrist and elbow, in addition to stimulation at the axilla. In all suspected median neuropathies, it is imperative to perform one of the median vs. ulnar internal comparison studies across the wrist to exclude the common median neuropathy at the wrist.

A lesion of the median nerve that results in Wallerian degeneration, regardless of the lesion site, results in decreased compound muscle action potential (CMAP) and sensory nerve action potential (SNAP) amplitudes. Often distal latencies are slightly prolonged and conduction velocity mildly slowed due to drop out of the fastest conducting axons.

However, while such findings are abnormal and indicate a median nerve lesion, they do not localize the lesion site. If there is focal demyelination at the ligament of Struthers, one might expect to see either focal slowing or a drop in CMAP amplitude (i.e., conduction block or temporal dispersion) between the elbow and the axilla sites. If there is a focal lesion in the region of the elbow, there may be focal slowing or conduction block between the wrist and elbow sites. However, while such findings are expected, in fact, they only rarely occur. In true cases of proximal median entrapment, EDX is often normal or nonspecific, despite what might be expected on theoretical grounds.

In addition, a plain X-ray of the distal arm and elbow may be helpful in suspected median neuropathy secondary to a ligament of Struthers in order to demonstrate a supracondylar bone spur on the median humerus.

Management and Prognosis

As high median neuropathies are rare, management is not as straightforward as in common median neuropathy across the wrist. In cases secondary to external compression (e.g., casts), observation is recommended. In patients with pronator syndrome secondary to repetitive pronation/supination, rest and splinting are indicated first. Otherwise, the treatment of high median neuropathy is usually surgical with exploration and decompression of the high median nerve. Obviously, in cases with vague symptoms and indeterminate EDX findings, such decisions should not be considered lightly. Surgery is best reserved for patients with continued or progressive symptoms who have not benefited from conservative therapy. Caution should always be given to any patient considering surgery for an anterior interosseous neuropathy. Many of these cases are likely inflammatory in nature (i.e., neuralgic amyotrophy) and will improve without surgery, although recovery may be delayed months or longer [28].

Ulnar Neuropathy at the Elbow

Ulnar neuropathy is second only to median nerve entrapment at the wrist as the most common entrapment neuropathy affecting the upper extremity, with the usual site of compression at the elbow. In contrast to CTS, however, exact localization of EDX is often much more demanding and treatment options more limited.

Anatomy (Fig. 40.5)

The ulnar nerve is derived from the C8 and T1 roots [1]. A small minority of patients receive a minor component

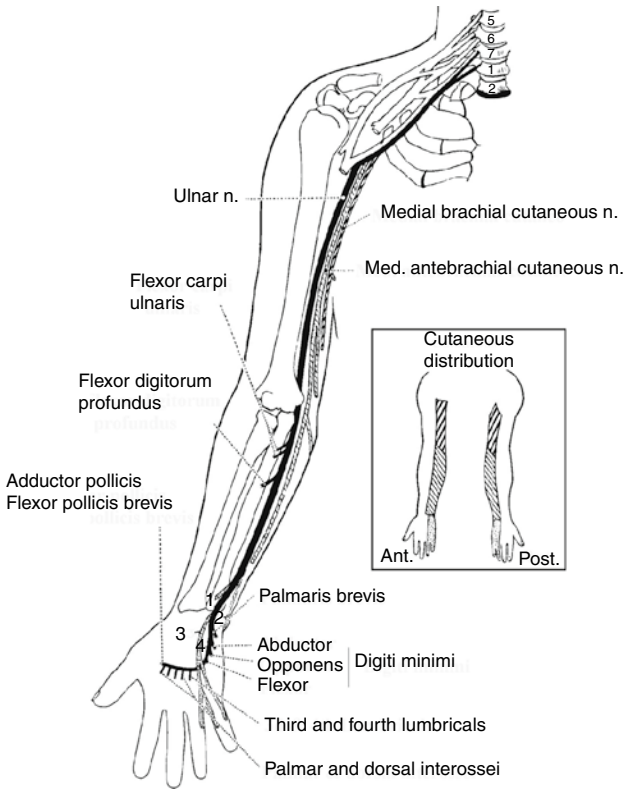

Fig. 40.5 Ulnar nerve anatomy. The ulnar nerve, along with the medial brachial and medial antebrachial cutaneous nerves, is derived from the medial cord of the brachial plexus. Insert: Cutaneous distributions of the ulnar, medial brachial cutaneous, and medial antebrachial nerves (Reprinted from Haymaker and Woodhal [102]. With permission)

from C7. Accordingly, nearly all ulnar fibers travel through the lower trunk and medial cord of the brachial plexus. The terminal extension of the medial cord becomes the ulnar nerve. The medial brachial and antebrachial cutaneous sensory nerves and a large part of the median nerve are derived from the medial cord as well. As the ulnar nerve descends through the medial arm, it gives off no muscular branches.

At the elbow, the nerve becomes superficial and enters the ulnar groove formed between the medial epicondyle and the olecranon process (Fig. 40.6). Normally, the ulnar nerve remains in the groove, although in some individuals, flexing the elbow results in subluxing of the nerve out of the groove and medially over the medial epicondyle. In a small number of individuals, a dense fibro-tendinous band and/or an accessory epitrochleoanconeus muscle may be present between the medial epicondyle and the olecranon process. Slightly distal to the groove in the proximal forearm, the ulnar nerve travels under the tendinous arch of the two heads of the flexor carpi ulnaris muscle, known as the humeral-ulnar aponeurosis (HUA) or "cubital tunnel" [29]. Muscular branches are then given off to the flexor carpi ulnaris and the medial division (fourth and fifth digits) of the flexor digitorum profundus. In the cubital tunnel, the ulnar nerve then continues under the flexor carpi ulnaris to exit 3–7 cm distal, between

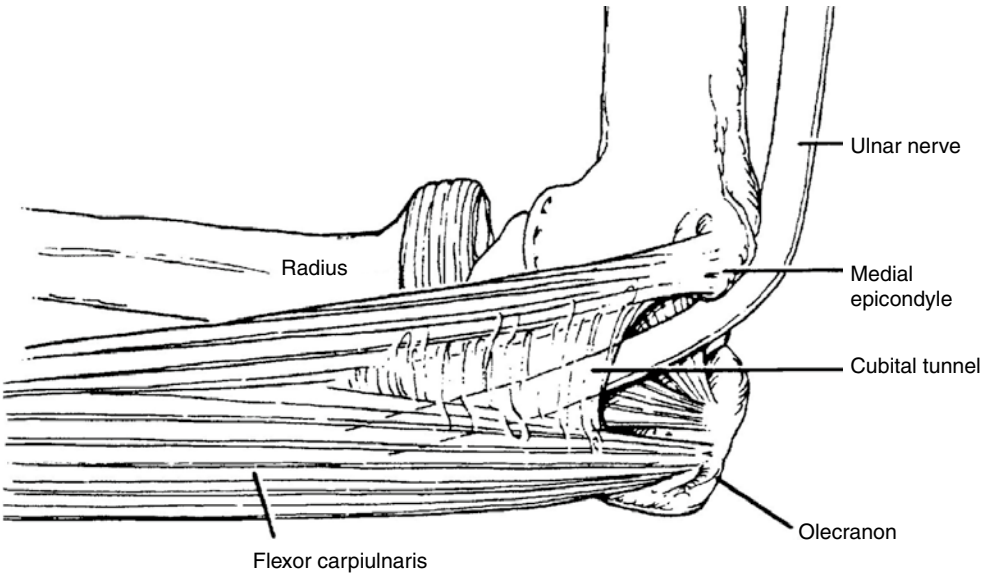

Fig. 40.6 Ulnar nerve anatomy at the elbow. Entrapment of the ulnar nerve can occur either at the ulnar groove between the medial epicondyle and the olecranon, or distally at the cubital tunnel (Adapted from Kincaid [35]. Reprinted by permission of John Wiley & Sons, Inc.)

the deep fascia separating the flexor carpi ulnaris and flexor digitorum profundus.

Next the ulnar nerve descends through the medial forearm, giving off no further muscular branches until after the wrist. Five to eight centimeters proximal to the wrist, the dorsal ulnar cutaneous sensory branch exits to supply sensation to the dorsal medial hand and the dorsal fifth and medial fourth digits. The palmar cutaneous sensory branch originates at the level of the ulnar styloid to supply sensation to the proximal medial palm. The ulnar nerve then enters the medial wrist through Guyon's canal to supply sensation to the volar fifth and medial fourth digits. It also supplies muscular innervation to the hypothenar muscles, the palmar and dorsal interossei, the third and fourth lumbricals, and two muscles in the thenar eminence, the adductor pollicis and the deep head of the flexor pollicis brevis.

Etiology and Pathogenesis

Ulnar neuropathy usually occurs as a result of chronic mechanical compression or stretch of the ulnar nerve [30]. In the elbow region, ulnar neuropathy can occur either at the groove or at the cubital tunnel. Although rare cases of ulnar neuropathy at the groove are caused by ganglia, tumors, fibrous bands, or accessory muscles, most are caused by external compression and repeated trauma. Trauma and subsequent arthritic changes at the elbow joint, often years before clinical presentation, may result in so called *tardy ulnar palsy*. Chronic minor trauma and compression, including leaning on the elbow, can either exacerbate or cause ulnar neuropathy at the groove. Ulnar neuropathy at the groove is also common in patients who have been immobilized because of surgery or who sustain compression during anesthesia or coma. Whether repeated subluxation of the ulnar nerve out of the groove also leads to ulnar neuropathy is controversial.

The other major site of compression of the ulnar nerve in the region of the elbow is distal to the groove in the cubital tunnel. Although some use the term *cubital tunnel syndrome* to mean all lesions of the ulnar nerve around the elbow, it is more properly used to denote compression of the ulnar nerve under the humeral-ulnar aponeurosis. Some individuals have congenitally tight cubital tunnels that predispose them to compression. Repeated and persistent flexion stretches the ulnar nerve, which along with increasing the pressure in the cubital tunnel, leads to subsequent ulnar neuropathy.

Clinical Presentation

Ulnar neuropathy at the groove or the cubital tunnel presents in a similar manner [1]. In contrast to CTS in which sensory symptoms predominate, motor symptoms are common in ulnar neuropathy, especially in chronic cases. In some patients, motor loss may develop insidiously without any sensory symptoms, particularly in those with slowly worsening mechanical compression. Since most of the intrinsic hand muscles are ulnar innervated, weakness of these muscles leads to loss of dexterity, with decreased grip and pinch strength. However, thumb abduction is spared in ulnar neuropathy, innervated via the median and radial nerves. Weakness of ulnar-innervated flexor digitorum profundus may result in inability to flex the distal interphalangeal joints of the ring and little fingers. There may be atrophy of both the hypothenar and thenar eminences.

Examination may reveal one of the classic hand postures that occurs with ulnar muscle weakness. The most widely recognized is the *benediction posture* (ulnar clawing). In this posture, the ring and little fingers are clawed with the

X, may be abnormal; UNW, ulnar neuropathy at the wrist; UNE, ulnar neuropathy across the elbow; –, assumes both motor and sensory branches are involved; some cases of UNW may spare the hypothenar muscles and/or the sensory branch (see text for details)

metacarpophalangeal joints hyperextended and the proximal and distal interphalangeal joints flexed, due to weakness of the third and fourth lumbricals. The fingers and thumb are held slightly abducted due to weakness of the interossei and adductor pollicis. The *Wartenberg's* sign is recognized as abduction of the little finger due to weakness of the third palmar interosseous muscle. Patients may report that their little finger gets caught when trying to put their hand in their pocket. The *Froment's* sign is seen when attempting to pinch an object or piece of paper. In order to compensate for intrinsic ulnar hand weakness, the long flexors to the thumb and index finger (median innervated) are used to pinch, creating a flexed thumb and index finger posture.

Sensory disturbance may involve the medial hand and the volar and dorsal fifth and medial fourth digits. Sensory disturbance does not extend much beyond the wrist crease. Sensory involvement extending into the medial forearm or arm implies a more proximal lesion in the plexus or cervical nerve roots. The medial brachial and antebrachial cutaneous sensory nerves which supplies sensation to the medial forearm and arm, respectively, arise from the medial cord of the brachial plexus. Pain, when present, may localize to the elbow or radiate down to the medial forearm and wrist. Paresthesias may be reproduced by placing the elbow in a flexed position or applying pressure to the groove behind the medial epicondyle. The ulnar nerve may be palpably enlarged and tender in the groove. Especially in patients with ulnar neuropathy at the cubital tunnel, the nerve may be palpably taut with decreased mobility.

Differential Diagnosis

The differential diagnosis in a patient suspected of having ulnar neuropathy at the elbow includes C8–T1 radiculopathy, lower trunk or medial cord brachial plexopathy, or rare cases of ulnar nerve entrapment distally in the arm or forearm (Table 40.2). Ulnar nerve entrapment at the wrist, discussed later in this chapter, presents in a somewhat different fashion.

A cervical radiculopathy at the C8–T1 level from cervical disk disease or spondylosis, although less common than C6 or C7 radiculopathy, may be difficult to differentiate clinically from ulnar neuropathy. The major differentiating features that point toward cervical radiculopathy include neck pain and radiation into the arm, sensory disturbance extending into the forearm, and weakness involving ulnar-, median-, and radial-innervated C8–T1 muscles. Of course, weakness is often minimal and sensory loss often vague in radiculopathy, making the differentiation between a mild C8–T1 radiculopathy and ulnar neuropathy at the elbow demanding, if based on clinical exam alone.

Lower trunk/medial cord brachial plexopathies are uncommon. Entrapment of the lower trunk by a fibrous band or hypertrophied muscle may rarely result in neurogenic thoracic outlet syndrome (see Chap. 46). Lower trunk plexopathies may also result from infiltration by neoplasm, prior radiation, or self-limited inflammatory processes. As in C8–T1 radiculopathy, lower trunk plexopathies present with weakness that usually includes ulnar as well as non-ulnar C8–T1 muscles and sensory disturbance that extends into the medial forearm.

Entrapment of the ulnar nerve in the arm or forearm is uncommon. Rarely, the ulnar nerve may become entrapped at the exit of the cubital tunnel by the deep fascia between the flexor carpi ulnaris and flexor digitorum profundus [31]. Unusual cases of ulnar neuropathy in the distal forearm have also been reported due to a fibrovascular band supplying blood to a hypertrophied flexor carpi ulnaris muscle [32]. Differentiating these unusual cases clinically from typical ulnar neuropathy at the elbow is quite difficult. They are

usually discovered either by careful EDX testing, or at the time of surgery, or occasionally when a failed ulnar surgery at the elbow requires a second surgical exploration.

Evaluation and Diagnosis

EDX testing plays the principle role in assessing suspected ulnar nerve disorders [30–34]. The EDX evaluation of ulnar neuropathy at the elbow, however, is more demanding than many other entrapment neuropathies. Many cases show a nonlocalizing axonal loss pattern. Localizing ulnar neuropathy at the elbow relies upon the demonstration of focal demyelination across the elbow. Motor conduction studies should be performed recording the hypothenar muscles and stimulating at the wrist, below and above the elbow. A flexed elbow is the preferable position when performing ulnar motor studies, as the surface measured nerve length is more accurate than when performing the study in the straight elbow position [35–39]. A drop in amplitude of greater than 20 % across the elbow, or focal slowing greater than 11 m/s across elbow compared to forearm conduction velocity, is consistent with focal demyelination. In addition to recording the abductor digiti minimi (ADM), recording the first dorsal interosseous (FDI) muscle increases the yield of finding focal slowing or conduction block [33].

The other issue that must be considered when performing EDX studies for suspected UNE is the proper interpretation of a Martin-Gruber anastomosis (MGA). MGA is a normal anatomic variant resulting in a crossover of median to ulnar fibers in the forearm. It is typically recognized as a drop in amplitude between wrist and below-elbow stimulations on routine ulnar motor studies and mimics a "conduction block" in the forearm. The site of the MGA is typically between 3 and 10 cm distal to the medial epicondyle, a location that is not thought to interfere with electrodiagnostic evaluation of UNE. However, there are rare reports of very proximal MGAs wherein the drop in amplitude and area occurs between the below-elbow and above-elbow stimulation sites – that is, across the elbow. Thus, in all cases of ulnar conduction block across the elbow, it is prudent to also check for a MGA (by stimulating the median nerve at the wrist and antecubital fossa, and recording the ulnar muscle). When a MGA is present, a potential (or higher potential) will be seen when stimulating the median nerve at the antecubital fossa as compared to the median nerve at the wrist, while recording an ulnar-innervated muscle [40].

To exactly localize the site of demyelination, short segment incremental studies ("inching") can also be performed, stimulating the ulnar nerve in successive one centimeter increments across the elbow, looking for either an abrupt drop in amplitude or increase in latency (>0.5 ms) [1, 39, 40]. This technique is potentially useful in planning subsequent surgery. Ulnar neuropathy at the cubital tunnel (typically 1–2 cm distal to the medial epicondyle) may be treated by simple decompression, whereas ulnar neuropathy at the retrocondylar groove requires ulnar transposition surgery [41].

Ulnar sensory nerve conduction studies are helpful in identifying an ulnar neuropathy and differentiating it from a cervical radiculopathy. Ulnar sensory studies recording the little finger are more sensitive than motor studies in detecting ulnar neuropathy, but cannot localize the lesion other than to the peripheral nerve. Performing the dorsal ulnar cutaneous sensory study can be useful; abnormalities of this nerve imply the lesion is higher than the wrist [42, 43].

The strategy in the needle EMG exam of suspected ulnar neuropathy at the elbow is to identify denervation and/or reinnervation limited to the ulnar-innervated hand and forearm muscles [1]. Median- and radial-innervated C8–T1 muscles are screened to rule out evidence of a C8 radiculopathy or lower trunk/medial cord brachial plexopathy. Interestingly, the flexor carpi ulnaris is often normal or only minimally affected in many surgically proven cases of ulnar neuropathy at the elbow [44]. Overall, involvement of the flexor carpi ulnaris correlates with the severity of the ulnar neuropathy, both clinically and electrically.

It is important to emphasize if nerve conduction studies do not identify focal slowing or conduction block around the elbow, needle EMG can only be used to identify the lesion at or above to the most proximal abnormal muscle. Although most ulnar neuropathies are due to a lesion at the elbow, if there is no focal slowing or conduction block, EDX testing cannot exclude an unusual ulnar neuropathy in the proximal arm or a lower trunk/medial cord brachial plexopathy which selectively involves ulnar fibers. If a lower trunk or medial cord brachial plexus lesion is a diagnostic consideration in this situation, then examination of the medial antebrachial cutaneous sensory nerve, which comes directly off the medial cord of the plexus, may help clarify the situation.

Management and Prognosis

Management of ulnar neuropathy at the elbow is predominantly surgical [5]. Conservative therapy is often first employed with advice to avoid leaning on the elbows and curtail any activity which results in repetitive or sustained elbow flexion [45]. Often, using a simple elbow pad is helpful. In some cases, a physical therapist can fashion an elbow splint to prevent elbow flexion.

In patients who do not improve with conservative therapy, and especially those who have progressive weakness and wasting, surgery in indicated. A variety of surgical procedures are available including simple decompression of the cubital tunnel, medial epicondlectomy, and sub-

muscular transposition of the ulnar nerve. There is no clear consensus of which procedure is optimal. In general, submuscular transposition has a higher success rate but is a more complex surgery with greater morbidity, including the risk of nerve devascularization. Some have advocated that surgery be tailed to the underlying etiology. In cases where the lesion is at the cubital tunnel, simple decompression may be optimal [41]. In cases where the lesion is at the ulnar groove, transposition would be indicated. Most surgical series demonstrated a high rate of success with operative management. Advanced age and symptoms present for over a year correlate with a poorer prognosis [46].

Ulnar Neuropathy at the Wrist

Ulnar neuropathy at the wrist is a rare condition, sometimes confused with ulnar neuropathy at the elbow or more often with cervical radiculopathy or early motor neuron disease. Because of local complex anatomy, several possible clinical and electrophysiologic patterns are caused by a lesion here.

Anatomy (Fig. 40.7)

At the wrist, the ulnar nerve enters Guyon's canal at the level of the distal wrist crease [1]. The canal is formed proximally by the pisiform bone and distally by the hook of the hamate. The floor is formed by a combination of the thick transverse carpal ligament and adjacent hamate and triquetrum bones. The roof is loosely formed. However, there is a thick band at the outlet that runs from the hook of the hamate to the pisiform bone, known as the pisohamate hiatus. Before exiting through the pisohamate hiatus, motor fibers are given off to the hypothenar muscles (abductor digiti minimi, flexor digiti minimi, opponens digiti minimi, palmaris brevis). In the canal, the nerve divides into the superficial branch and the deep palmar branch. After the hiatus, the superficial branch supplies sensation to the volar little and medial ring fingers, while the deep palmar branch innervates the third and fourth lumbricals, the four dorsal and three palmar interossei, the adductor pollicis, and the deep head of the flexor pollicis brevis muscles.

Etiology and Pathogenesis

Entrapment of the ulnar nerve at the wrist is uncommon. It may occur in association with trauma and wrist fracture or as a result of mass lesions, often a ganglion, within Guyon's canal (Fig. 40.8) [47–50]. In addition, certain occupations or activities that involve repetitive movement or pressure against the ulnar wrist predispose to lesions here. This is especially

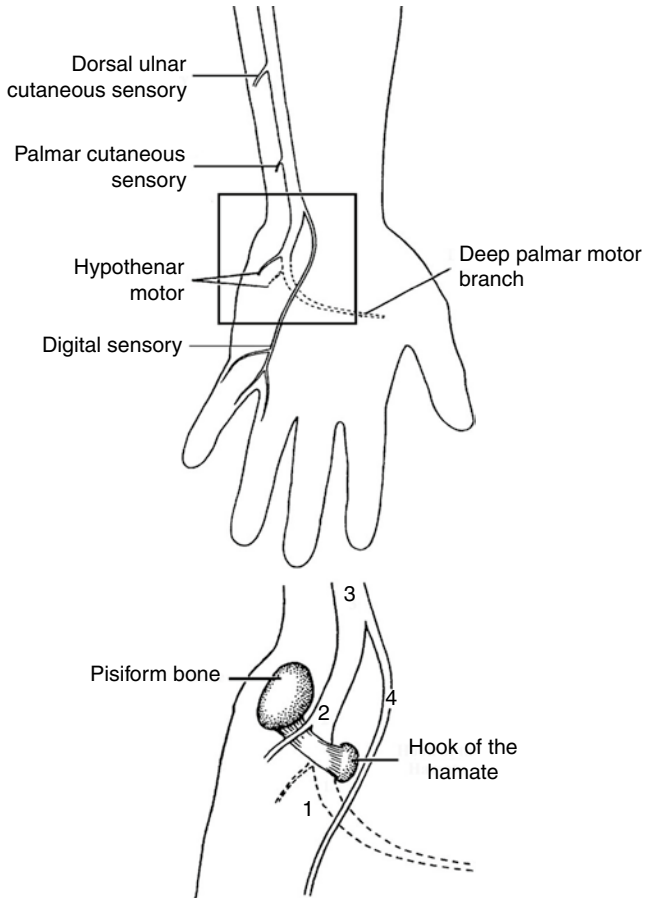

Fig. 40.7 Detailed anatomy of the ulnar nerve at the wrist. Entrapment of the ulnar nerve at the wrist can take on several patterns: (*1*) pure motor lesion affecting only the deep palmar motor branch, (*2*) pure motor lesion affecting the deep palmar and hypothenar motor branches, (*3*) motor and sensory lesion (proximal canal lesion) affecting the hypothenar and deep palmar motor and digital sensory branches, and rarely (*4*) pure sensory involving only the digital sensory fibers to the volar 4th and medial 5th fingers (Adapted from Olney and Hanson [49]. Reprinted by permission of John Wiley & Sons, Inc.)

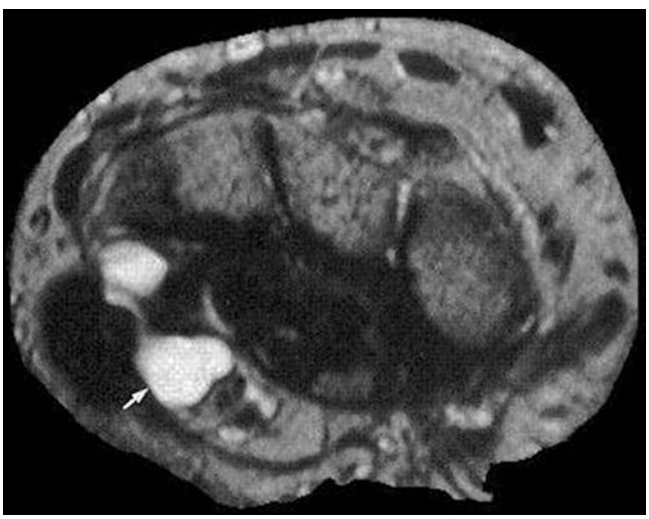

Fig. 40.8 Ulnar neuropathy at the wrist from a ganglion cyst. Axial T1-weighted MRI of wrist. Note the dumbbell-shaped high T1 signal abnormality displacing the ulnar nerve in Guyon's canal (*arrow*) (From Kothari et al. [57]. Reprinted by permission of John Wiley & Sons, Inc.)

Table 40.3 Various types of distal ulnar mononeuropathies

Lesion site	Nerve affected	Clinical presentation
Proximal Guyon's canal	Main trunk of ulnar nerve or ulnar cutaneous branch	Sensory loss of the medial palm, little finger, and medial half of ring finger, along with weakness of all ulnar intrinsic hand muscles or sensory loss of the medial palm, little finger, and the medial half of ring finger only
Distal Guyon's canal	Deep palmar branch (proximal to the branches to the hypothenar muscles)	Weakness of all ulnar intrinsic hand muscles (interossei, ulnar lumbricals, and hypothenar muscles) without sensory loss
Pisohamate hiatus	Deep palmar branch (distal to the branches to the hypothenar muscles)	Weakness of all ulnar intrinsic hand muscles with sparing of the hypothenar muscles and without sensory loss
Mid-palm (rare)	Deep palmar branch (distal in the palm)	Weakness of adductor pollicis; first, 2nd, and possibly the third interossei only, sparing fourth interossei and without sensory loss

true for bicyclists, or laborers who use the same hand tools repetitively causing pressure on the hypothenar eminence [51–53]. In such patients, the hypothenar area may be calloused at the compression site.

Clinical Presentation

There are several subtypes of ulnar neuropathy at the wrist, depending on the localization of the lesion in the wrist and which fibers are affected (Table 40.3) [48]. Lesions of the deep palmar branch result in weakness and wasting of the interossei and ulnar-innervated thenar muscles, with sparing of the hypothenar muscles and sensory branch. Lesions proximal to the hypothenar branches result in a similar motor syndrome but also affect the hypothenar muscles. Proximal lesions of the canal affect hypothenar and deep palmar motor fibers as well as involving volar sensory fibers to the medial hand and ring and little fingers. Lastly, rare lesion affects only the sensory fibers at the wrist resulting in sensory loss of the medial hand and ring and little fingers with sparing of all motor fibers.

The first two patterns are the most common and are easily confused with early motor neuron disease. Patients present with painless weakness and atrophy of ulnar intrinsic hand muscles, sparing sensation. As the ulnar-innervated adductor pollicis and deep head of the flexor pollicis brevis are in the thenar eminence, both the hypothenar and thenar eminences may be wasted in these lesions. Motor neuron disease is often suspected because of the complete absence of sensory loss or symptoms.

In more proximal lesions, the sensory branch is also affected, leading to sensory disturbance of the volar little and medial ring fingers. In contrast, the dorsal aspect of the medial hand and fingers are spared, being innervated by the dorsal ulnar cutaneous sensory branch which arises several centimeters proximal to the wrist. In addition, the proximal volar medial hand is also spared as the palmar cutaneous branch arises just proximal to the wrist as well.

Differential Diagnosis

In cases of ulnar neuropathy at the wrist which involve both motor and sensory fibers, the differential diagnosis includes more proximal entrapment of the ulnar nerve at the elbow, lower trunk/medial cord brachial plexopathies, and C8–T1 radiculopathies. In the more common presentation involving the deep palmar branch alone, early motor neuron disease is the main concern as the patient usually has no pain or sensory symptoms. Preservation of strength and bulk of the abductor pollicis brevis muscle (median innervated) is the key finding on physical exam in helping to exclude early motor neuron disease clinically.

Evaluation and Diagnosis

EDX testing is essential to differentiate ulnar neuropathy at the wrist from the more common ulnar neuropathy at the elbow and from early motor neuron disease. EDX findings depend on which branches are affected – sensory branch, hypothenar muscle branches, deep palmar motor branch, or all three [1]. If there is a distal lesion affecting only the deep palmar motor branch, then ulnar sensory and motor conductions recording the little finger and ADM, respectively, are normal. In all cases of suspected ulnar neuropathy at the wrist, it is imperative to perform motor studies recording the FDI. In lesions of the deep palmar motor branch, the latency to the FDI may be prolonged with a decreased CMAP amplitude, while the ADM latency and amplitude remain normal [1, 48]. Comparison with the contralateral asymptomatic side is often helpful. If the lesion is more proximal, affecting the hypothenar branches, the distal motor latency to the ADM may also be prolonged. However, even in such proximal lesions, the deep palmar motor branch is often affected out of proportion to the hypothenar branch, and the amplitude and latency to the FDI are still relatively worse than to the ADM.

If the lesion involves the distal sensory branch, the routine ulnar SNAP recording the little finger is abnormal.

In contrast, the dorsal ulnar cutaneous SNAP is normal in lesions at the wrist. This combination of an abnormal ulnar SNAP and a normal dorsal ulnar cutaneous SNAP is highly suggestive of a lesion at the wrist. However, this finding alone is not sufficient to diagnose ulnar neuropathy at the wrist, due to fascicular sparing of the dorsal ulnar cutaneous SNAP in some proximal ulnar nerve lesions including those at the elbow [54, 55].

There are two other potentially very helpful EDX tests in suspected ulnar neuropathy at the wrist: the distal latency comparison of the median and ulnar nerves recording the lumbrical and interossei muscles, respectively, and inching across the wrist. The lumbrical-interosseous distal latency comparison test is usually done for suspected CTS to identify relative slowing of the median nerve across the wrist. Since the ulnar interossei are innervated by the deep palmar motor branch, this test can be very useful in identifying differential ulnar slowing at the wrist as well in lesions that involve the deep palmar motor branch [56]. A distal motor latency difference > 0.5 ms comparing the ulnar interossei to second lumbrical suggests focal slowing across the wrist [57]. Similar to inching across the elbow, inching can also be performed across the ulnar nerve at the wrist while recording the FDI (Fig. 40.9). This technique can be very useful in demonstrating a conduction block or focal latency shift signifying focal demyelination. Care must be taken to avoid high stimulation currents distal to the wrist which might inadvertently co-stimulate the median nerve.

The needle EMG examination of suspected ulnar neuropathy at the wrist is straightforward. The FDI and ADM must be sampled looking for involvement of the deep palmar motor and hypothenar branches, respectively. Needle EMG of the 4th or 3rd dorsal interosseous is also helpful in lesions of the deep palmar branch at the pisohamate hiatus. An abrupt change from a normal ADM to denervated 4th and 3rd interosseous may occur [58]. The flexor digitorum profundus (ulnar slip) and flexor carpi ulnaris must be sampled to exclude an ulnar neuropathy proximal to the wrist. Finally, median and radial C8–T1 muscles (i.e., abductor pollicis brevis, flexor pollicis longus, extensor indicis proprius) and the lower cervical paraspinal muscles must be sampled to exclude a cervical root or motor neuron lesion.

Lastly, MRI of the wrist is frequently helpful in identifying structural lesions with Guyon's canal, including ganglion cysts and nerve sheath tumors [58]. Imaging should be considered in patients with ulnar neuropathy at the wrist who have a history of progressive worsening and in especially those who do not have clearly identified occupational wrist factors.

Management and Prognosis

Similar to the management of other entrapment neuropathies, ulnar neuropathy at the wrist can be managed both conservatively and surgically. Surgery is indicated for any mass lesion in the canal and in cases in progressive symptoms. In patients who have obvious occupational risks (e.g., bicyclists), many can be managed with simply curtailing the offending activity and observing.

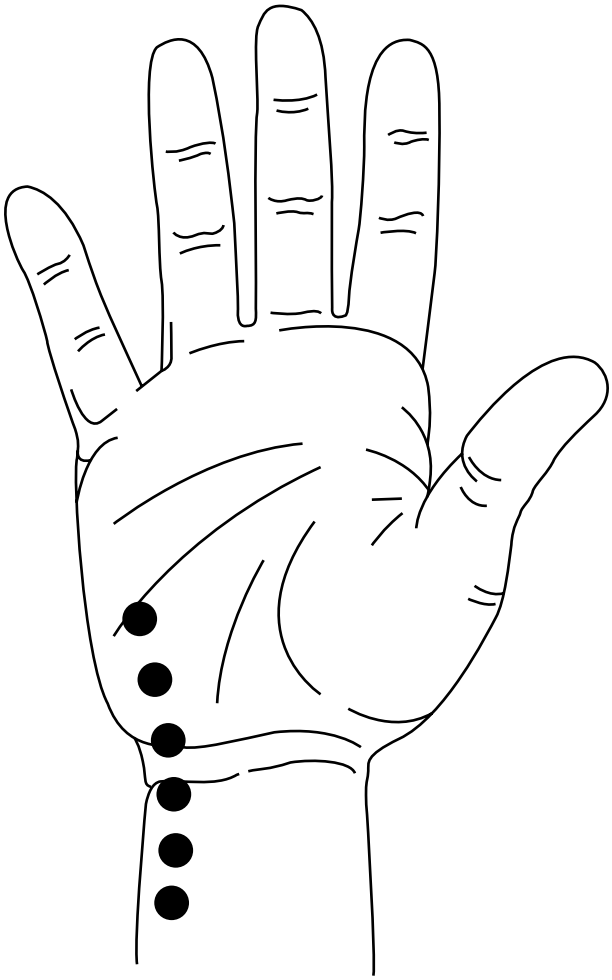

Fig. 40.9 Ulnar inching across the wrist. Recording the first dorsal interosseous, the ulnar nerve can be stimulated in successive 1 cm increments across the wrist

Radial Neuropathy

Entrapment of the radial nerve occurs less frequently than the more common lesions of the median and ulnar nerves. However, because of its long circuitous course, the radial nerve can be potentially entrapped in several sites along its course, most often in the upper arm and axilla. In addition, isolated lesions of its terminal divisions in the forearm, the posterior interosseous and superficial radial sensory nerves, also occur.

Anatomy (Fig. 40.10)

The radial nerve receives innervation from the C5–T1 nerve roots and, correspondingly, a contribution from all three

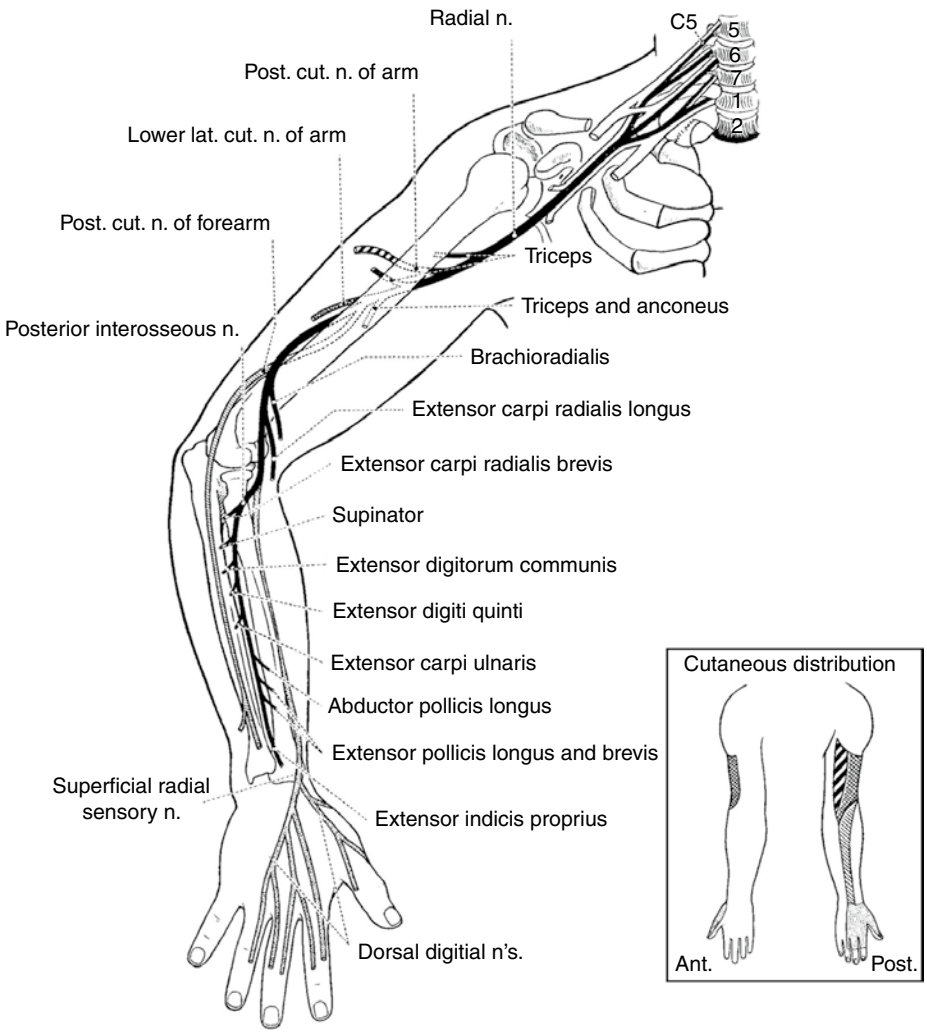

Fig. 40.10 Anatomy of the radial nerve. The radial nerve is derived from the posterior cord of the brachial plexus. In the proximal arm, the radial nerve first gives off the posterior cutaneous nerve of the arm, lower lateral cutaneous nerve of the arm, and the posterior cutaneous nerve of the forearm, followed by muscular branches to the triceps brachii and anconeus. The nerve then wraps around the humerus, descending into the region of the elbow, where muscular branches are given off to the brachioradialis, extensor carpi radialis-long head, and supinator. More distally, the nerve bifurcates into the superficial radial sensory and posterior interosseous nerves. The posterior interosseous nerve supplies the remainder of the wrist and finger extensors, as well as the supinator and abductor pollicis longus. Insert: Sensory territories supplied by the radial nerve (Adapted from Haymaker and Woodhal [102]. With permission)

trunks of the brachial plexus [1]. After each trunk divides into an anterior and posterior division, the posterior divisions from all three trunks unite to form the posterior cord. From the posterior cord, the axillary, thoracodorsal, and subscapular nerves are given off before it becomes the radial nerve. In the proximal arm, the radial nerve first gives off the posterior cutaneous nerve of the arm, lower lateral cutaneous nerve of the arm, and the posterior cutaneous nerve of the forearm, followed by muscular branches to the three heads of the triceps brachii (medial, long, and lateral) and the anconeus. The anconeus is a small muscle in the proximal forearm that is effectively an extension of the medial head of the triceps brachii. After giving off these muscular branches, the radial nerve wraps around the humerus in the spiral groove. As the nerve descends into the region of the elbow, muscular branches are given off to the brachioradialis, extensor carpi radialis-long head, and supinator. Three to four centimeters distal to the lateral epicondyle, the radial nerve bifurcates into two separate nerves, one superficial and one deep.

The superficial branch continues as the superficial radial sensory nerve and descends distally into the forearm over the radius to supply sensation to the lateral dorsum of the hand as well as part of the thumb and dorsal proximal phalanges of the index, middle, and ring fingers. Distally, the nerve is quite superficial, running over the extensor tendons to the thumb, where it is easily palpated. The deep motor branch usually supplies the extensor carpi radialis brevis and the supinator before it enters the supinator muscle under the arcade of Frohse at the elbow (Fig. 40.11). At that point, the deep motor nerve is known as the posterior interosseous nerve which supplies the remaining extensors of the wrist, thumb, and fingers (extensor digitorum communis, extensor carpi ulnaris, abductor pollicis longus, extensor indicis proprius, extensor pollicis longus, and extensor pollicis brevis). Although the posterior interosseous nerve is usually considered a pure motor nerve (supplying no cutaneous sensation), it does in fact carry sensory fibers to supply deep sensation to the interosseous membrane and the joints between the bones of the radius and ulnar.

Etiology and Pathogenesis

Radial neuropathy most often occurs following external compression [1, 5, 59, 60]. The main radial nerve can be affected in both the axilla and mid-arm. It is most vulnerable in the

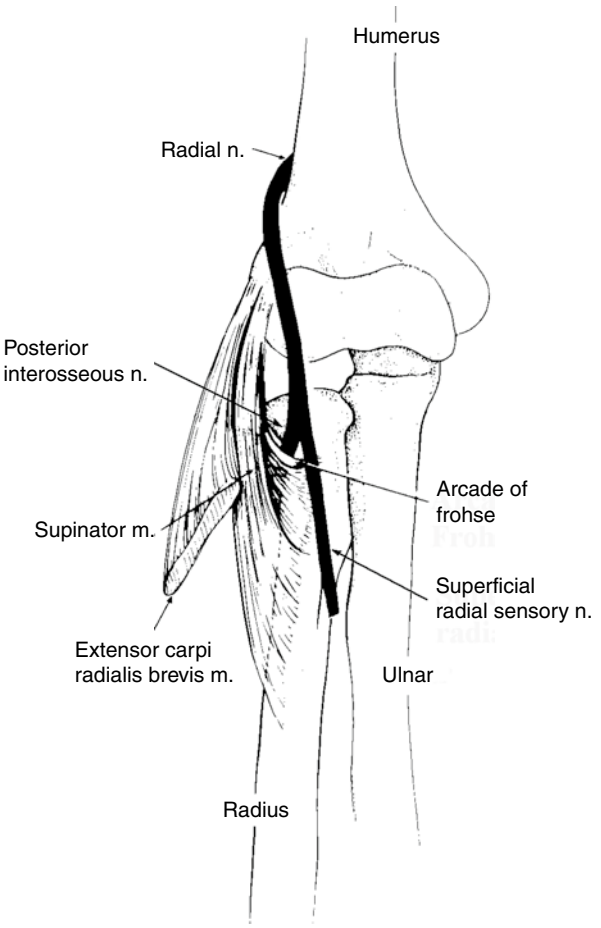

Fig. 40.11 Anatomy of the radial nerve at the elbow. Distal to the elbow, the radial nerve bifurcates into the superficial radial (sensory) and deep radial (motor) nerves. When the deep radial motor nerve enters the *arcade of Frohse*, it is known as the posterior interosseous nerve. The posterior interosseous nerve supplies most of the extensors of the wrist, and the thumb and finger extensors. (The main radial nerve only supplies on extensor: the extensor carpi radialis-long head) (From Wilbourn [105]. Adapted with permission from American Association of Electrodiagnostic Medicine)

mid-arm as it wraps along the spiral groove of the humerus where it lies adjacent to bone. The superficial radial sensory branch also lies adjacent to bone, in this case the radius, where it too can be affected from external compression in the distal forearm. Rarely is the radial nerve or its branches compressed by internal structures. The posterior interosseous nerve may potentially become entrapped at the arcade of Frohse [61]. Exceptional cases of radial neuropathy are reported secondary to muscular contraction of the triceps muscle around the radial nerve [62]. Similar to other upper extremity nerves, radial neuropathy may occur secondary to trauma and fracture, hematoma formation, nerve sheath tumors, or as a part of the presentation of neuralgic amyotrophy.

Clinical Presentation

Radial neuropathies can be divided into those caused by lesions at the spiral groove, in the axilla, and isolated lesions of the posterior interosseous and superficial radial sensory nerves. They can usually be differentiated by findings on the clinical examination (Table 40.4) [1].

Radial Neuropathy at the Spiral Groove

The most common radial neuropathy occurs at the spiral groove, also known as *Saturday night palsy* or *honeymoon palsy.* At the spiral groove, the nerve lies juxtaposed to the humerus, making it quite susceptible to compression, especially following prolonged immobilization. This characteristically occurs when a person has fallen asleep with their arm draped over a chair or bench, especially during a deep sleep or following intoxication. The resultant prolonged immobilization leads to compression and demyelination of the radial nerve. Other lesions at this location may occur following fracture of the humerus, infarction

Table 40.4 Clinical differentiating factors in radial neuropathy

	PIN	Radial-spiral groove	Radial-axilla	Posterior cord	C7
Wrist/finger drop	X	X	X	X	X
Radial deviation on wrist extension	X				
Weakness of supination (mild)		X	X	X	
Weakness of elbow flexion (mild)		X	X	X	
Decreased brachioradialis tendon reflex		X	X	X	
Weakness of elbow extension			X	X	X
Decreased triceps tendon reflex			X	X	X
Weakness of shoulder abduction				X	
Sensory loss – lateral dorsal hand		X	X	X	X
Sensory loss – posterior arm/forearm			X	X	X
Weakness of wrist flexion					X

X, may be abnormal

from vasculitis, or after strenuous muscular effort. Clinically, patients present with a marked wrist and finger drop, along with mild weakness of supination (due to weakness of the supinator muscle) and elbow flexion (due to weakness of the brachioradialis). Notably, elbow extension (triceps brachii) is spared. Sensation is disturbed over the lateral dorsal hand and dorsal aspects of the thumb and index, middle, and ring fingers, in the distribution of the superficial radial sensory nerve.

In isolated radial neuropathy at the spiral groove, median- and ulnar-innervated muscles are normal. However, if tested in a dropped posture, finger abduction may appear weak and give the mistaken impression of ulnar nerve dysfunction [63]. To avoid this error, finger abduction (ulnar-innervated function) should be tested with the fingers and wrist held passively extended to a neutral wrist position. This can often be accomplished by placing the hand on a flat surface.

Although demyelinating lesions of the radial nerve most often result from external compression, they also occur rarely in acquired demyelinating polyneuropathies, especially multifocal motor neuropathy with conduction block (MMNCB) (see Chap. 29). MMNCB is a rare condition that results in conduction block along motor nerves, with a predilection for certain sites, especially the radial nerve. Patients often come to neurologic attention with a wrist drop. However, in contrast to most radial neuropathies which present acutely from a compressive lesion, this condition evolves slowly, and a careful neurologic exam usually reveals more widespread weakness involving distal more than proximal muscles. In patients with a wrist drop from MMNCB, nerve conduction studies may reveal conduction blocks anywhere along the course of the radial nerve.

Radial Neuropathy in the Axilla

Radial neuropathy from prolonged compression may also occur in the axilla. This can occur in patients on crutches, who use them incorrectly, applying prolonged pressure to the axilla. The clinical deficit is similar to that seen in radial neuropathy at the spiral groove, with the key exception of weakness of arm extension (triceps brachii) and sensory disturbance extending from the lateral dorsal hand into the posterior forearm and arm (lateral cutaneous nerve of the arm, posterior cutaneous nerves of the forearm and arm). Radial neuropathy in the axilla is differentiated from a more proximal lesion in the posterior cord of the brachial plexus by findings of normal strength in the deltoid (axillary nerve) and latissimus dorsi (thoracodorsal nerve).

Posterior Interosseous Neuropathy

Posterior interosseous neuropathy (PIN) may superficially resemble entrapment of the radial nerve at the spiral groove. In both, patients present with wrist and finger drop, with sparing of elbow extension. However, several important features easily separate the two. In PIN, there is sparing of radial-innervated muscles above the takeoff to the posterior interosseous nerve (i.e., brachioradialis, extensor carpi radialis-long head, triceps). When patients with PIN attempt to extend their wrist, they may do so weakly, with a radial deviation. The wrist deviates radially in extension due to the relative preservation of the extensor carpi radialis, in comparison to the weak extensor carpi ulnaris, which comes off distally to the lesion. The second major difference involves the sensory findings. In PIN, there is no cutaneous sensory loss. There may be pain in the forearm from dysfunction of the deep sensory fibers supplying the interosseous membrane and joint capsules. In contrast, radial neuropathy at the spiral groove results in cutaneous sensory loss in the dorsal hand.

Rarely, mass lesions (e.g., ganglion cysts, tumors) result in PIN. PIN usually results from entrapment under the tendinous arcade of Frohse of the supinator muscle (aka radial tunnel). True neurogenic radial tunnel syndrome is identifiable by motor weakness in the distribution of the posterior interosseous nerve [64]. Others have used the term radial tunnel syndrome in patients with forearm pain and tenderness in the region of the supinator muscle who do not have any weakness. This latter syndrome remains controversial [64]. As opposed to patients with a true posterior interosseous neuropathy (see above), these patients typically have no objective neurologic signs on examination and accordingly have normal EDX studies. They are said to have increased pain with maneuvers that contract the extensor carpi radialis or the supinator (e.g., resisted extension of the middle finger or resisted supination, respectively). However, there is has been no compelling evidence that this chronic pain syndrome is caused by any nerve entrapment. Whether entrapment of the posterior interosseous nerve results in such a syndrome, and likewise if surgical decompression is indicated, continues to be debated.

Superficial Radial Sensory Neuropathy

The superficial radial sensory nerve is derived from the main radial nerve in the region of the elbow. It runs subcutaneously next to the radius in the distal third of the forearm. This superficial location next to the bone makes it extremely susceptible to compression [65, 66]. Tight fitting bands, such as watches or bracelets, may result in compression. Handcuffs, especially when excessively tight, characteristically result in a superficial radial sensory neuropathy [66]. Injury during intravenous cannulation by a needle or following hematoma may occur. As the superficial radial sensory nerve is purely sensory, there is no associated weakness. A characteristic patch of altered sensation develops over

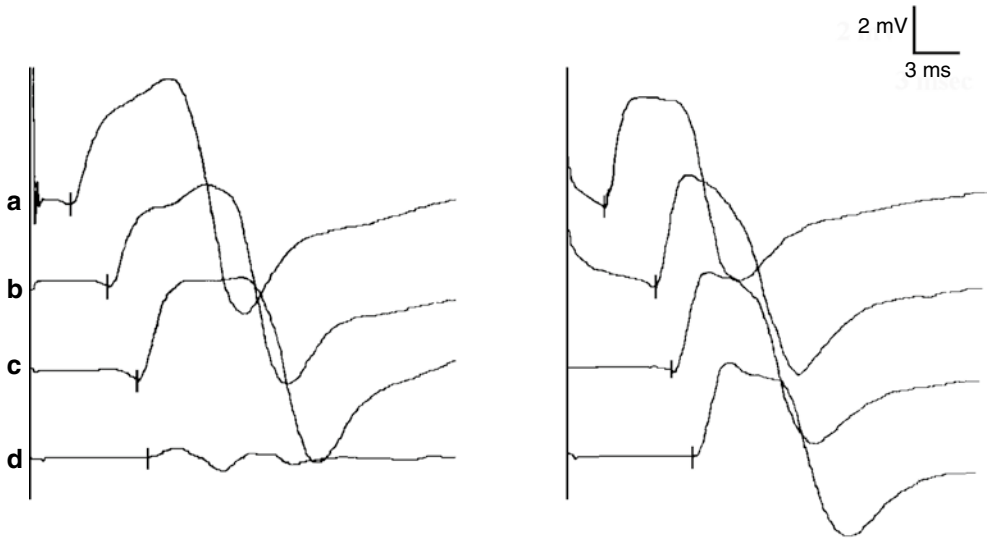

Fig. 40.12 Radial motor studies: radial neuropathy at the spiral groove. Left traces, symptomatic arm; right traces, contralateral asymptomatic arm. Recording extensor indicis proprius; stimulating (top to bottom traces): forearm, elbow, below spiral groove, above spiral groove. Note marked drop in amplitude and area across spiral groove on the left (conduction block) and symmetric distal CMAP amplitudes. Both imply a predominantly demyelinating lesion at the spiral groove (From Preston and Shapiro [103])

the lateral dorsum of the hand, part of the dorsal thumb, and the dorsal proximal phalanges of the index, middle, and ring fingers.

Differential Diagnosis

Radial neuropathies, including lesions of the PIN, most often present with a wrist drop. A similar clinical presentation also includes unusual C7–C8 radiculopathies, brachial plexus lesions, and central causes [1]. Since most muscles that extend the wrist and fingers are innervated by the C7 nerve root, radiculopathy may rarely present solely with a wrist and finger drop, with relative sparing of nonradial C7–innervated muscles. Radial neuropathy at the spiral groove or axilla should result in weakness of the brachioradialis, a C5–C6 muscle, which is not affected by a lesion of the C7 nerve root. In contrast, radial neuropathy at the spiral groove spares the triceps, which would be weak in a C7 radiculopathy. If a C7 radiculopathy is severe enough to cause muscle weakness, other nonradially innervated C7 muscles should also be weak (e.g., pronator teres, flexor carpi radialis), leading to weakness of arm pronation and wrist flexion. However, in rare situations, nonradial C7 muscles may be relatively spared, and the clinical differentiation is quite difficult to make.

While lesions of the posterior cord of the brachial plexus result in weakness of radial-innervated muscles, the deltoid (axillary nerve) and latissimus dorsi (thoracodorsal nerve) should also be weak. Central lesions may also result in a wrist and finger drop. The typical upper motor neuron posture results in flexion of the wrist and fingers, which in the acute phase, or when the lesion is mild, may superficially resemble a radial neuropathy. Central lesions are identified by increased muscle tone and deep tendon reflexes (unless acute), slowness of movement, associated findings in the lower face and leg, and the absence of altered sensation in the superficial radial distribution.

Evaluation and Diagnosis

Similar to other entrapment neuropathies, EDX plays a critical role in the evaluation and management of radial neuropathy in helping localize the site of the lesion [1, 59]. The most important nerve conduction study to perform is the radial motor study. The radial nerve can be stimulated in the forearm, at the elbow, and below and above the spiral groove while recording a distal radial muscle (e.g., extensor indicis proprius or extensor digitorum communis). Often, comparison to the contralateral asymptomatic side may be useful. The value of performing radial motor studies usually lies in looking for a focal conduction block between the proximal and distal sites and in determining the relative CMAP amplitude to assess axonal loss (Fig. 40.12).

In radial neuropathy at the spiral groove, CMAPs recorded with stimulation at the forearm, elbow, and below the spiral groove may be completely normal, if the lesion is purely demyelinative. However, stimulation proximal to the spiral groove will result in either marked temporal dispersion and/or conduction block.

Rarely, there may be conduction block between the forearm and elbow sites in PIN. However, most cases of PIN are pure axonal lesions and no conduction block is demonstrable. In these cases, the distal and proximal radial CMAP amplitudes are equally low in proportion to the amount of axonal loss.

In contrast to radial motor studies, the superficial radial sensory nerve is easy to record. If there has been secondary

axonal loss, the response is diminished in amplitude or absent. If the pathology is one of pure or predominant demyelination, the radial SNAP is normal. Similar to motor studies, it is often useful to compare the response with the contralateral asymptomatic side. A normal superficial radial SNAP is also seen in PIN, as expected, as the nerve carries no cutaneous sensory fibers.

In patients with suspected radial neuropathy, an extensive needle EMG study is usually indicated. The role of needle EMG is to differentiate between PIN, radial neuropathy at the spiral groove, radial neuropathy in the axilla, a lesion of the posterior cord of the brachial plexus, a C7 radiculopathy, and a central lesion. In PIN, denervating potentials, decreased MUAP recruitment, and large MUAPs are limited to those muscles innervated by the posterior interosseous nerve. As one moves more proximally to radial neuropathy at the spiral groove, the brachioradialis, extensor carpi radialis-long head, and supinator will also be affected, but the triceps is spared. If the lesion is even more proximal at the axilla, the triceps and anconeus will be involved. Moving more proximally to a lesion of the posterior cord of the plexus, additional abnormalities are seen in the deltoid and latissimus dorsi. A C7 radiculopathy will include abnormalities in the cervical paraspinal muscles and nonradial-innervated C7 muscles (e.g., pronator teres, flexor carpi radialis). Lastly, in central lesions, MUAPs are normal in weak muscles, though one expects to see decreased activation of MUAP firing.

Management and Prognosis

Management of radial neuropathies from external compression is conservative in nearly all cases. Simple avoidance of the offending compression is first recommended (e.g., proper use of crutches, not wearing constrictive wrist bands). Most cases of radial neuropathy at the spiral groove occur from prolonged compression from one specific incident. Splinting the wrist and fingers is indicated in patients with any significant finger or wrist drop. Whether the compression resulted in demyelination or axonal loss has direct consequences on length of recovery. This determination is usually easily made on EDX studies. Most patients with demyelinative lesions recover well after several weeks; axonal loss cases may require many months to over a year to effect recovery.

Decisions regarding surgical treatment, especially entrapment of the PIN, are more controversial [67]. In patients with progressive symptoms and in those who have not responded to conservative treatment (i.e., rest, splinting, anti-inflammatory agents), surgical exploration and release may be advisable and to exclude a structural lesion (e.g., nerve sheath tumor, lipoma, fibrous band).

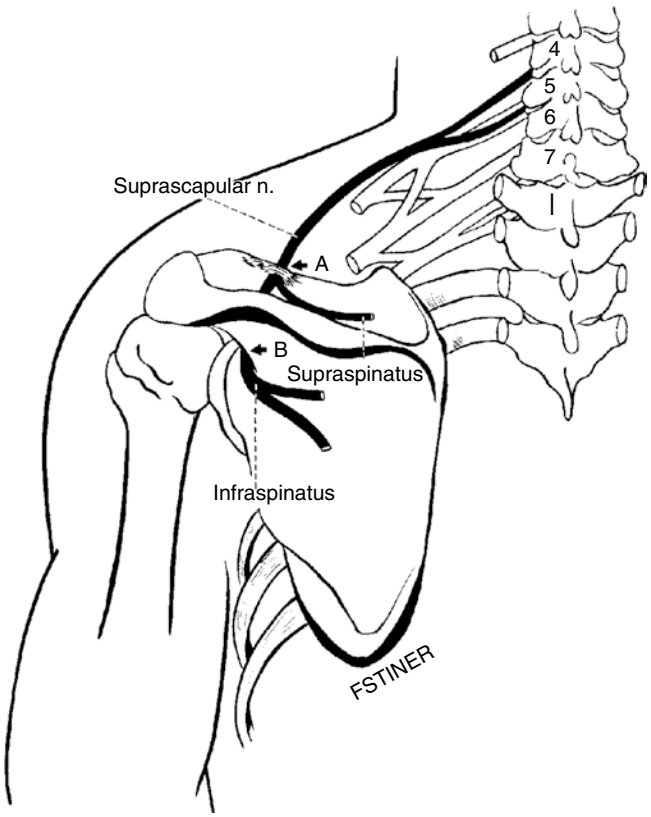

Fig. 40.13 Anatomy of the suprascapular nerve. The suprascapular nerve originates from the upper trunk of the brachial plexus. The nerve first runs under the suprascapular notch (*A*) to innervate the supraspinatus muscle. Sensory fibers are then given to the shoulder joint before the nerve wraps around the spinoglenoid notch (*B*) to supply the infraspinatus muscle (Adapted from Haymaker and Woodhal [102]. With permission)

Suprascapular Neuropathy

Anatomy (Fig. 40.13)

The suprascapular nerve arises off the upper trunk of the brachial plexus, receiving innervation from the C5 and C6 roots. The nerve runs posteriorly under the trapezius, passing through the suprascapular notch of the scapula to enter the supraspinous fossa. The suprascapular notch is U-shaped, located along the superior border of the scapula, and covered by the transverse scapular ligament. The suprascapular nerve supplies motor fibers to the supraspinatus muscle before proceeding laterally to supply deep sensory fibers to the glenoacromial and acromioclavicular joints. It then wraps around the spinoglenoid notch of the scapular spine to enter the infraspinous fossa where it supplies motor fibers to the infraspinatus muscle. The suprascapular nerve usually carries no cutaneous sensory fibers, although rare anomalous innervations have been reported whereby the suprascapular nerve carries cutaneous sensation to the proximal lateral arm, the area usually supplied by the axillary nerve.

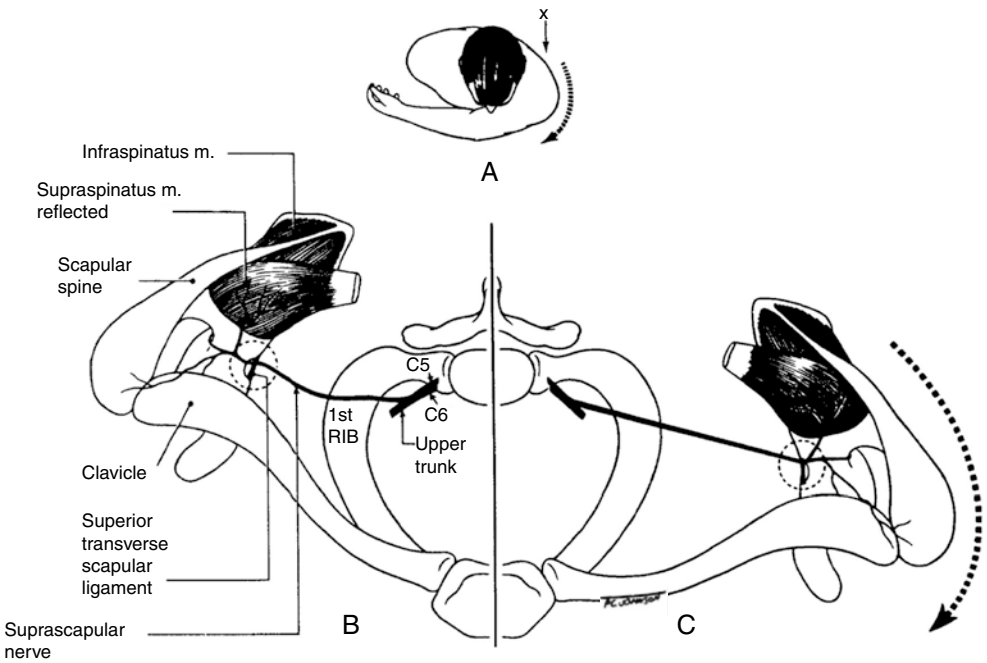

Fig. 40.14 Suprascapular neuropathy. Suprascapular neuropathy may occur from repetitive protraction of the scapular and tethering of the nerve between the suprascapular notch and the upper trunk of the brachial plexus. Coronal view of the suprascapular nerve from above: (*B*) normal position, (*C*) nerve stretch produced by arm posture in (*A*) (From Kopell and Thompson [106]. By permission of Surgery, Gynecology & Obstetrics, now known as the Journal of the American College of Surgeons)

Etiology and Pathogenesis

Suprascapular entrapment most commonly occurs at the suprascapular notch, under the transverse scapular ligament [1, 5, 68–71]. Less frequently, the nerve can also be entrapped distally at the spinoglenoid notch [72, 73]. The suprascapular nerve is relatively immobile both at its origin at the upper trunk and at the suprascapular notch. As both the shoulder and scapula are quite mobile, movement, especially repetitive movement, results in stretch and nerve injury (Fig. 40.14) [71].

Rare cases of suprascapular nerve entrapment have also been reported secondary to a variety of mass lesions, including ganglion cysts, sarcomas, and metastatic carcinomas. In addition, certain activities, professions, and positions are associated with suprascapular entrapment. For example, suprascapular neuropathy has been reported as a consequence of positioning during surgical procedures, whereby patients are placed in a knee-chest position with the scapula protracted. Weight lifting has been implicated in several reports as a provocative factor in suprascapular entrapment, likely as a consequence of repetitive movement of the scapular, especially during lifts that involve shoulder abduction and protraction [5, 68]. Several other professions are at risk for suprascapular entrapment. These include professional volleyball players, baseball pitchers, and dancers where the clinical and EDX findings most often suggest a distal lesion at the spinoglenoid notch [72].

In addition, suprascapular neuropathy, which is sometimes confused clinically with a rotator cuff injury, may also accompany a rotator cuff injury. First, one might initially assume that both would have a common traumatic etiology. However, it is also possible that suprascapular neuropathy may actually occur as a result of a rotator cuff tear, usually a large and full thickness tear. Following a rotator cuff tear, there may be medial retraction of the tendon to the supraspinatus and infraspinatus muscles. This then may result in increased tension of the suprascapular nerve both at the suprascapular notch and the spinoglenoid notch [74]. Finally, the suprascapular nerve may be involved selectively or with other proximal upper limb nerves during an attack of neuralgic amyotrophy.

Clinical Presentation

Symptoms and signs depend on the site of nerve entrapment [1]. At the most common site of compression, the suprascapular notch, shoulder pain may be prominent. The pain is typically described as deep and boring, occurring along the superior aspect of the scapula and radiating to the shoulder, but usually no more distally. The pain may be exacerbated by shoulder movements, especially adduction of the extended arm. This movement results in protraction of the scapula, which increases the nerve tethering between the upper trunk and the suprascapular notch. Occasionally, the suprascapular notch may be tender to palpation. Weakness involves shoulder abduction and external rotation. Atrophy may be recognized, especially over the infraspinatus muscle, which is not covered by the trapezius muscle.

If the entrapment occurs distally at the spinoglenoid notch, the syndrome is isolated to atrophy and weakness of the infraspinatus muscle. Pain is usually absent, since the deep sensory fibers to the shoulder joint have exited more proximally.

Differential Diagnosis

Several conditions may be confused with suprascapular neuropathy, including cervical radiculopathy, rotator cuff injury and other orthopedic conditions, and neuralgic amyotrophy [1]. In contrast to suprascapular neuropathy, a C5–C6 radiculopathy may have radiating pain from the neck into the arm and is associated with sensory abnormalities in the lateral arm, forearm, and thumb. Often, the biceps and brachioradialis tendon reflexes will be depressed or absent.

Orthopedic conditions, especially rotator cuff injuries, may be difficult to differentiate clinically from suprascapular neuropathy. Although weakness should not be present, pain often prevents full muscle activation. Exacerbation of pain by palpation (other than at the suprascapular notch) or by passive shoulder movement (other than abduction and protraction of the shoulder) is unusual for suprascapular entrapment.

Lastly, neuralgic amyotrophy often presents with severe proximal arm and shoulder pain and later weakness and, in some cases, primarily involves the suprascapular nerve.

Evaluation and Diagnosis

Patients with suspected suprascapular neuropathies should undergo EDX and imaging studies. EDX studies can demonstrate abnormalities of the suprascapular-innervated muscles and exclude cervical radiculopathy or brachial plexopathy [1]. Since the suprascapular nerve has no cutaneous distribution, there is no corresponding sensory nerve to be recorded. However, sensory nerve studies (i.e., lateral antebrachial, median, and radial sensory nerves) are helpful in excluding an upper trunk brachial plexopathy. Motor conductions can be performed with technical difficulties, stimulating Erb's point and recording with either a surface or monopolar needle electrode over either the supraspinatus or infraspinatus muscles [1, 70]. Comparing amplitude side to side can give an estimate of the amount of axonal loss present. However, these studies generally do not increase the yield over conventional electromyography in terms of localizing the lesion. Typically, the pathophysiology of suprascapular neuropathies is axonal loss.

During needle EMG, both the supraspinatus and infraspinatus muscles should be studied. In lesions at the suprascapular notch, both are abnormal. However, with spinoglenoid lesions, only the infraspinatus is involved. If either of these muscles is abnormal, it is essential to sample other C5–C6-innervated muscles (e.g., deltoid, biceps, brachioradialis), as well as the cervical paraspinal muscles, to exclude a cervical radiculopathy or more widespread brachial plexus lesion.

In addition, patients with suspected suprascapular neuropathy should undergo MRI of the shoulder. Ganglion cysts are easily demonstrable as well as other mass lesions which can affect the suprascapular nerve [73]. In patients which suprascapular neuropathy at the suprascapular notch, imaging will be normal, although atrophy of the supra- and infraspinatus muscles may be present.

Management and Prognosis

Therapy of suprascapular neuropathy is usually surgical, with the exception of those cases resulting from neuralgic amyotrophy [5, 68]. In cases of repetitive trauma (e.g., weight lifting), avoidance of the activity, physical therapy, and observation are indicated before consideration of surgical release. Unless a cyst or other mass lesion is present in the spinoglenoid notch on imaging, the site of entrapment is usually at the suprascapular notch. Surgical release of the suprascapular ligament usually results in excellent recovery.

Axillary Neuropathy

Anatomy (Fig. 40.15)

Along with the radial nerve, the axillary nerve originates from the termination of the posterior cord of the brachial plexus [1]. The axillary nerve is composed primarily of

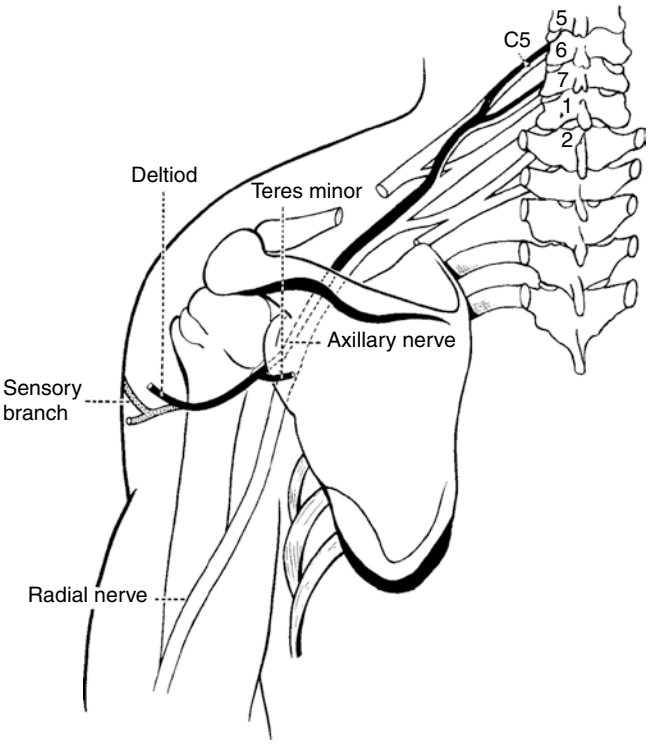

Fig. 40.15 Anatomy of the axillary nerve. The axillary nerve originates from the posterior cord of the brachial plexus. The nerve innervates the teres minor and deltoid muscles as well supplies sensation to the lateral shoulder (Adapted from Haymaker and Woodhal [102]. With permission)

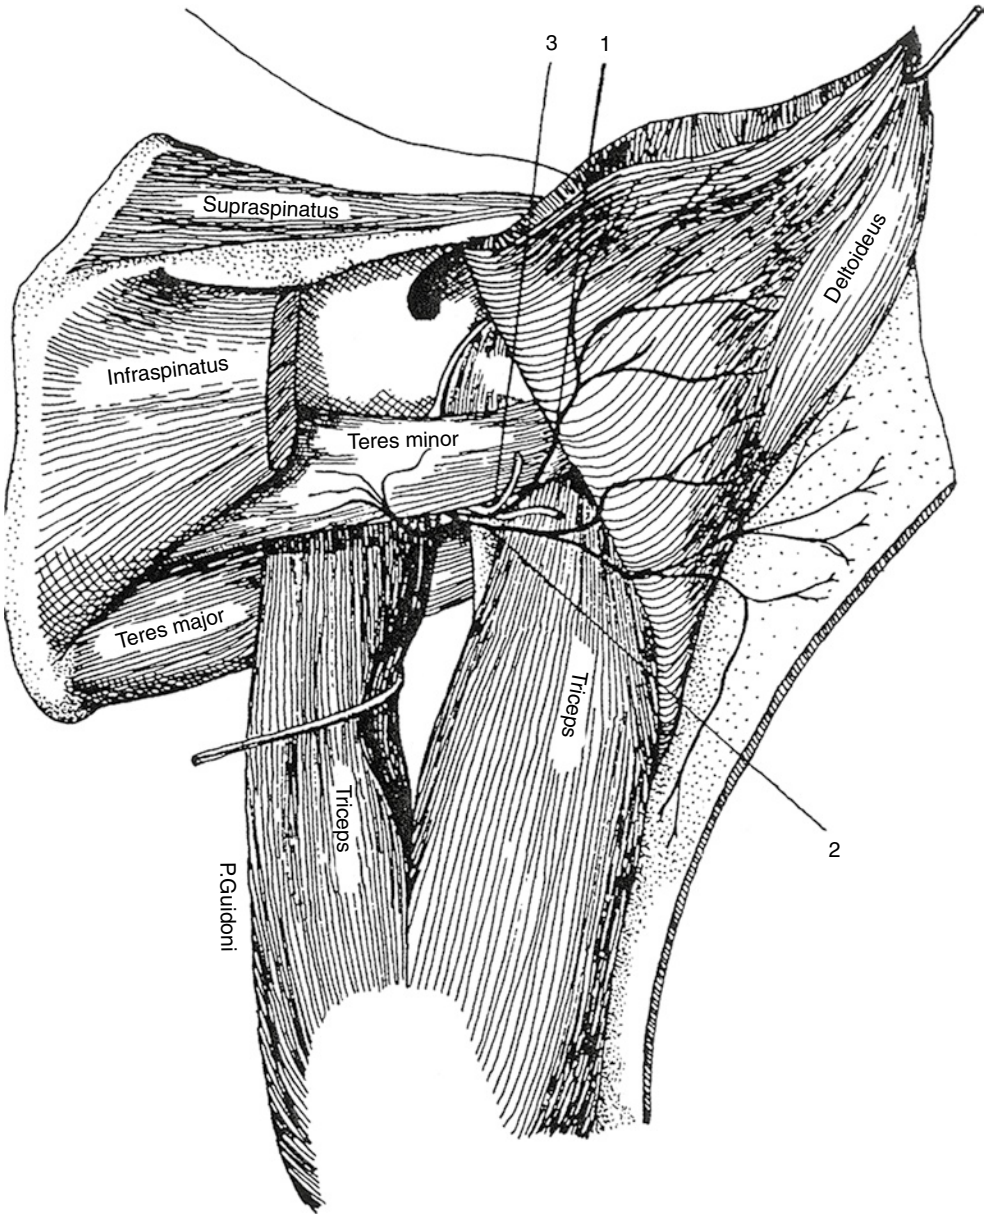

Fig. 40.16 Posterior view of the quadrilateral space: anterior (*1*) and posterior (*2*) branches of the circumflex nerve and circumflex artery (*3*) (From Paladini et al. [107]. With permission)

C5–C6 fibers, running through the upper trunk and posterior cord of the plexus. The nerve leaves the axilla through the quadrangular space, formed by the humerus, teres minor, teres major, and long head of the triceps muscles (Fig. 40.16). Muscular innervation is supplied to the teres minor and deltoid muscles, which aid in shoulder external rotation and abduction, respectively. A small cutaneous sensory branch supplies an oval-shaped area over the lateral shoulder.

Etiology and Pathogenesis

Axillary neuropathies typically result from trauma, especially dislocation of the shoulder and fracture of the humerus [5, 76, 77], and surgical positioning [78, 79]. Rare cases of entrapment in the quadrangular space have been reported, but are exceptional [80–84].

Clinical Presentation

Patients with axillary neuropathies have a well-defined circular area of numbness over the lateral shoulder, along with partial weakness of shoulder abduction and external rotation. The degree of weakness varies from patient to patient. The weakness is only partial, since other muscles also contribute to shoulder external rotation (i.e., the infraspinatus) and abduction (i.e., the supraspinatus).

Differential Diagnosis

Axillary neuropathy may be confused with suprascapular neuropathy, C5–C6 radiculopathy, neuralgic amyotrophy, and local orthopedic conditions. Key physical exam findings include sensory loss over the lateral shoulder (not present in suprascapular neuropathy) and intact biceps and brachioradialis reflexes (may be depressed in C5–C6 radiculopathy). Orthopedic conditions, especially rotator cuff injuries, may be difficult to differentiate clinically from axillary neuropathy. Although weakness should not be present, pain often prevents full muscle activation. Similar to its involvement of the suprascapular neuropathy, neuralgic amyotrophy may present with severe proximal arm and shoulder pain and later weakness and, in some cases, primarily involves the axillary nerve.

Evaluation and Diagnosis

X-ray of the shoulder and humerus should be performed in traumatic cases to help exclude fracture and shoulder dislocation. EDX studies should be delayed for several weeks when they can better define the lesion anatomy and assess the amount of axonal loss. From a localization point of view, the major goals of EDX testing are to demonstrate abnormalities of axillary-innervated muscles and rule out cervical radiculopathy or brachial plexopathy [1]. There is no routine sensory conduction study available for the axillary nerve. However, as the axillary nerve originates from the posterior cord and upper trunk, sensory nerves that run through the posterior cord and upper trunk should be studied. These include the radial and lateral antebrachial cutaneous sensory nerves and the median sensory nerve, especially when recording the thumb. Abnormalities of any of these sensory studies suggest a more widespread brachial plexopathy.

Axillary motor nerve conduction studies can be performed stimulating the axilla and Erb's point and recording with a monopolar needle or preferably a surface electrode over the deltoid [74]. CMAP amplitude can be compared both from side to side to assess the amount of axonal loss and between the axilla and Erb's point on the symptomatic side to look for conduction block. However, these studies can be technically difficult to perform, especially obtaining supramaximal stimulation in obese patients. Since these are usually axonal loss lesions, motor studies are best used to assess axonal loss by comparing the symptomatic to asymptomatic side and thus generally do not increase the yield of localizing the lesion beyond what is obtained from routine needle EMG.

In axillary neuropathies, needle EMG is used to demonstrate denervation and/or reinnervation in the two axillary-innervated muscles, the deltoid and teres minor. All three heads of the deltoid are easily accessible to needle EMG; the teres minor is considerably more difficult to sample. If abnormalities are found in any of these muscles, other muscles innervated by the upper trunk and posterior cord should be studied to ensure that the abnormalities found in the axillary-innervated muscles are not part of a more widespread brachial plexus or cervical root lesion.

Management and Prognosis

In traumatic cases of axillary neuropathy, observation and physical therapy are the first in order while awaiting signs of reinnervation and recovery. Much of the action of axillary-innervated muscles can be subserved by suprascapular-innervated muscles. In cases where a complete laceration of the nerve is likely clinically and in those who had not had any recovery over 6 months, surgical exploration and nerve grafting should be considered.

Musculocutaneous Neuropathy

Anatomy (Fig. 40.17)

The musculocutaneous nerve arises directly from the lateral cord of the brachial plexus [1]. In the upper arm, it pierces the coracobrachialis muscle to run in the fascia between the biceps and brachialis muscles. It innervates all three of these elbow flexor muscles, including the biceps, brachialis, and coracobrachialis. The terminal extension of the nerve past the elbow is the musculocutaneous sensory or lateral antebrachial cutaneous branch. In the region of the elbow, it runs deep to the brachial fascia and over the brachialis muscle with the biceps tendon medial and the brachioradialis lateral. In the forearm, the nerve becomes subcutaneous and separates into two terminal divisions (anterior and posterior) to supply sensation to the lateral half of the forearm. The posterior branch may form anastomoses with either the radial sensory nerve or posterior cutaneous nerve of the forearm. The anterior branch may rarely anastomose with the median sensory fibers.

Etiology and Pathogenesis

Isolated musculocutaneous neuropathies are rare. More commonly, they occur as part of more widespread traumatic lesions of the shoulder and upper arm, especially fractures of the proximal humerus [5, 77]. Musculocutaneous neuropathy has been associated with positioning during general

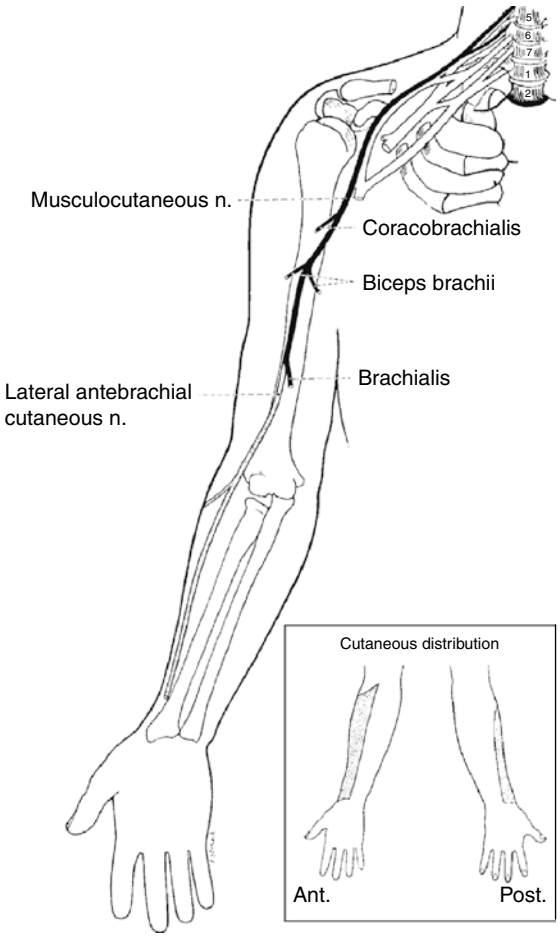

Fig. 40.17 Anatomy of the musculocutaneous nerve. The musculocutaneous nerve originates from the lateral cord trunk of the brachial plexus. The nerve innervates the biceps, brachialis, and coracobrachialis muscles. It then continues past the elbow as a pure sensory nerve, the lateral antebrachial cutaneous nerve, to supply sensation to the lateral forearm (From Haymaker and Woodhal [102]. With permission)

anesthesia and peripheral nerve tumors [85]. Some cases have occurred after strenuous upper extremity exercise without apparent cause, included weight lifting, football throwing, rowing, and carrying heavy textile rolls on the shoulder with the arm curled over the roll [86–88]. Various mechanisms have been proposed for these exercise-related cases. Bony tumors, including benign humeral exostoses, have resulted to mononeuropathies through direct impingement [89]. Often, in these later cases, symptoms were preceded by upper extremity exercise.

In addition, the musculocutaneous sensory (lateral antebrachial) nerve can be entrapped in isolation [90]. It occurs at the elbow where the nerve becomes entrapped between the biceps tendon/fascia and brachialis muscles. This neuropathy may also occur from a hyperextension injury of the elbow, including during sports-related activities such as tennis or following intravenous cannulation in the antecubital fossa.

Clinical Presentation

Clinically, musculocutaneous neuropathies result in weakness of elbow flexion, an absent biceps reflex, and sensory loss in the lateral forearm. In isolated involvement of the musculocutaneous (lateral antebrachial) sensory nerve, patients report worsening pain and/or paresthesias when the arm is pronated and extended. This position increases the pressure on the nerve at the elbow site. Examination in these cases shows isolated altered sensation in the lateral forearm, with normal muscle strength and reflexes. There may be tenderness to palpation over the nerve at the elbow.

Differential Diagnosis

The differential diagnosis of musculocutaneous neuropathies includes lesions of the lateral cord and upper trunk of the brachial plexus and the more common C5–C6 radiculopathies. Although less common than suprascapular and axillary neuropathies, neuralgic amyotrophy can present with prominent involvement of the musculocutaneous nerve as well. In addition, rupture of the biceps tendon may present with apparent weakness of arm flexion and mimic a musculocutaneous neuropathy. However, in tendon rupture, there is no sensory loss, and typically the biceps muscle is retracted, and there is bulging in the upper arm.

Evaluation and Diagnosis

Imaging is necessary in traumatic cases. X-ray of the shoulder and humerus should be performed in traumatic cases to help exclude fracture and shoulder dislocation. EDX studies can also be helpful but are best delayed for several weeks when they can better define the lesion anatomy and assess the amount of axonal loss. From a localization point of view, the major goals of EDX testing are to demonstrate abnormalities of musculocutaneous-innervated muscles and rule out cervical radiculopathy or brachial plexopathy [1]. The most important nerve conduction study to perform is the lateral antebrachial cutaneous sensory study. Musculocutaneous neuropathies, both distal and proximal, result in abnormal lateral antebrachial SNAPs.

Similar to axillary motor studies, musculocutaneous motor nerve conduction studies can be performed stimulating the axilla and Erb's point and recording with either a monopolar needle or preferably a surface electrode over the biceps [75]. The CMAP amplitude can be compared both from side to side to assess the amount of axonal loss and between the axilla and Erb's point to look for a conduction block. In contrast to the sensory studies, these motor studies are more technically difficult, especially obtaining supramaximal stimulation in obese patients. They are best used to assess the degree of axonal loss by comparing the

symptomatic to asymptomatic side. Similar to axillary and suprascapular neuropathies, musculocutaneous neuropathies are usually axonal loss lesions. Accordingly, motor studies generally do not increase the yield of localization over performing the needle EMG alone.

In distal musculocutaneous sensory neuropathies at the elbow, the needle EMG is normal. In proximal lesions, EMG demonstrates denervation and/or reinnervation with decreased recruitment of MUAPs in the biceps. The brachialis and coracobrachialis can also be sampled, but are more difficult than the biceps and offer little additional information. If abnormalities are found in the biceps, it is essential that other upper trunk- and lateral cord-innervated muscles are studied to ensure that the abnormalities found are not part of a more widespread brachial plexus lesion or C5–C6 radiculopathy.

Management and Prognosis

In traumatic cases of musculocutaneous neuropathy, observation is first in order looking for reinnervation. In cases where a complete laceration of the nerve is likely clinically and in those who had not had any recovery over 6 months, surgical exploration and nerve grafting should be considered.

In cases of isolated distal musculocutaneous sensory neuropathy, treatment usually involves time, splinting, and analgesics in the hope that if the lesion is neurapraxic, it will recover [75]. If unsuccessful, steroid injection adjacent to the nerve is often attempted. Ultimately, surgery decompression and partial resection of the biceps fascia are required.

Long Thoracic Neuropathy

Anatomy (Fig. 40.18)

The long thoracic nerve arises directly from the C5–C6–C7 roots, before the brachial plexus proper. The nerve runs inferiorly to innervate only one muscle, the serratus anterior. Anatomically, the serratus anterior muscle is considered as having an upper portion of the muscle, supplied by C5–C6 fibers, and a lower portion, supplied by C7 fibers. The upper portion is responsible principally for scapular protraction (i.e., pulling the scapula forward over the rib cage) and the lower portion for scapular stabilization. Protraction is the movement of the scapula forward along the chest wall. The serratus anterior arises from the first eight to ten thoracic ribs and inserts on the costal margin of the scapula.

Etiology and Pathogenesis

Long thoracic nerve palsies may occur as part of a more widespread traumatic lesion affecting the cervical roots [5].

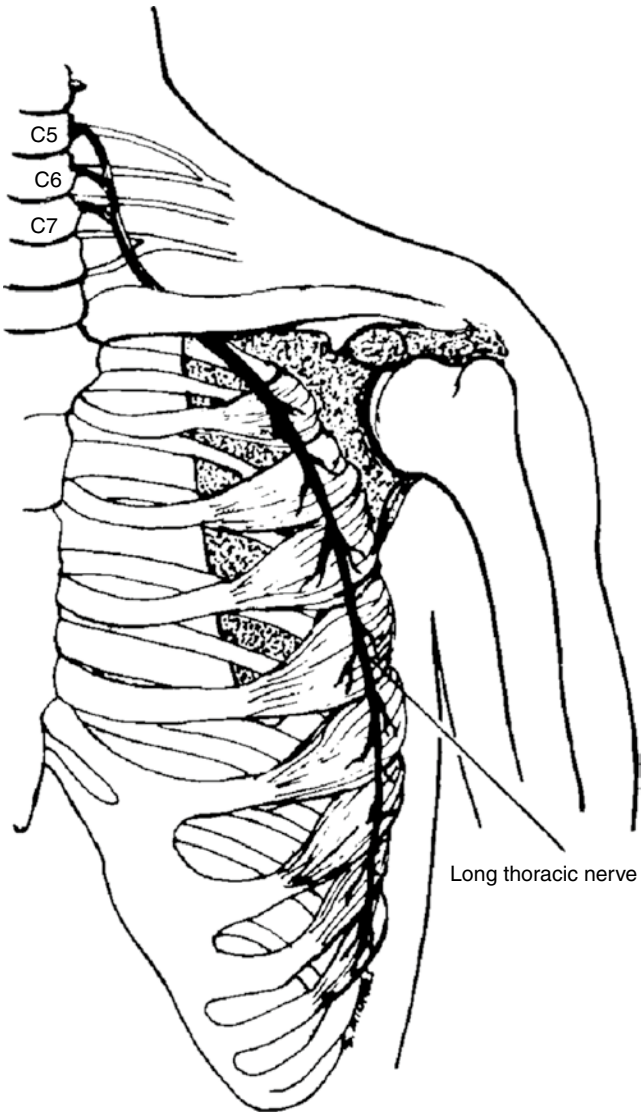

Fig. 40.18 Anatomy of the long thoracic nerve. The long thoracic nerve originates directly from the C5, C6, and C7 roots, proximal to the brachial plexus proper. It runs inferiorly to supply the serratus anterior muscle. There is no cutaneous sensory innervation (From Fisher [78]. With permission)

Although isolated long thoracic palsies have also been reported as a consequence of external compression and stretch, many result from neuralgic amyotrophy (see Chap. 46). Indeed, in some attacks of neuralgic amyotrophy, the long thoracic nerve is affected in isolation. Patients describe severe pain in the shoulder region that last several days to weeks. As the pain abates, patients note difficulty with shoulder movement.

Clinical Presentation

Weakness or paralysis of the serratus anterior characteristically results in winging of the scapula. Winging from serratus anterior dysfunction becomes most pronounced when

the arm is extended in front of the body. As the serratus anterior is a shoulder stabilizer, other shoulder muscles may also appear weak, including the deltoid, supraspinatus, and infraspinatus. However, if these muscles are tested with the examiner's hand pressed against the scapula or in the recumbent position, much of the "weakness" disappears. As the long thoracic nerve has no cutaneous distribution, there is no area of altered sensation or numbness.

Differential Diagnosis

Apparent winging of the scapula can occur with weakness of the serratus anterior, rhomboids, and/or trapezius muscles [77]. Winging from serratus anterior weakness results as the scapula is displaced medially and superiorly with the inferior angle rotated toward the midline, and the vertebral border of the scapula becomes prominent as it no longer is opposed to the thoracic cage. The winging becomes more prominent as the patient attempts to push forward against resistance. In winging from weakness of the rhomboids, the scapula moves the opposite direction, farther from the midline of the back as the rhomboids normally draw the scapula toward the back. In weakness of the trapezius, winging is not as pronounced as that of the serratus anterior. A decreased shoulder shrug is easily apparent when looking at the patient from the back.

In addition, scapular winging can be a prominent part of some inherited myopathies, especially facioscapulohumeral (FSH) muscular dystrophy where weakness usually involves other muscle groups including the facial muscles, biceps and triceps, wrist extensors, and ankle dorsiflexors.

Evaluation and Diagnosis

EDX studies can be helpful in both the diagnosis and prognosis of long thoracic neuropathies [1]. Unfortunately, there is no reliable way to study the long thoracic nerve with nerve conductions. In order to look for evidence of a more widespread brachial plexus lesion, sensory conductions should be performed, studying especially those nerves that travel through the upper and middle trunks, which have the same root innervation as the long thoracic nerve. These studies include the lateral antebrachial cutaneous, median, and radial sensory nerves.

The EDX evaluation relies on the needle EMG. In long thoracic nerve palsy, abnormalities are limited to the serratus anterior muscle. Other C5–C6–C7-innervated limb muscles should be sampled to exclude a radiculopathy or brachial plexopathy. In addition, the cervical paraspinal muscles should be checked as well, to help exclude a more proximal lesion at the roots.

Management and Prognosis

As most long thoracic neuropathies occur as part of neuralgic amyotrophy, management and prognosis of isolated long thoracic palsies is similar to that of neuralgic amyotrophy [91]. As the underlying etiology is unknown, there is no proven therapy that alters prognosis. Some patients are prescribed a short course of steroids, similar to their use in Bell's palsy, if recognized during the acute painful part of the presentation. Results with steroids are mixed; some patients report decreased pain. Otherwise, treatment is largely supportive. Analgesics, including narcotics, are often needed early on to treat pain. Physical therapy, especially range of motion and light exercise, is essential. Although most patients with neuralgic amyotrophy make a good recovery, the time to recovery is usually months to years. During that time, prevention of contractures, especially around the shoulder, is important in ensuring a good functional outcome. Overall, the long-term prognosis in neuralgic amyotrophy is excellent with 36 %, 75–80 %, and 90 % recovering by 1, 2, and 3 years, respectively. Rare patients have reported continued improvement up to 6–8 years after the event.

In patients with an obvious penetrating trauma or iatrogenic injury, early exploration with neurolysis, direct repair, or nerve grafting should be considered. Otherwise patients should be observed for clinical and EDX signs of recovery. In patients who fail to recover and have disabling symptoms, surgical therapy, including muscle transposition or scapula fixation, can be considered. Surgical options for patients with serratus anterior palsy include scapulothoracic fusions and dynamic muscle transfers [92]. Scapulothoracic fusions are generally regarded as salvage procedures after failure of other surgical techniques. Fusion of the scapula to the thorax eliminates scapular winging but also eliminates scapular motion. Dynamic muscle transfers consistently have shown the best results for correction of scapular winging and restoration of function in patients with serratus anterior palsy because of long thoracic nerve injury with the current preferred treatment being transfer of the sternal head of pectoralis major to the inferior angle of the scapula extended [92].

Spinal Accessory Neuropathy

Anatomy (Fig. 40.19)

The spinal accessory nerve is a pure motor nerve, with no cutaneous sensory fibers. The spinal accessory nerve is derived from C1 to C4 cervical levels. The nerve ascends through the foramen magnum, to return through the jugular foramen. It first supplies motor innervation to the sternocleidomastoid muscle and then runs superficially in the posterior cervical triangle to innervate the trapezius muscle.

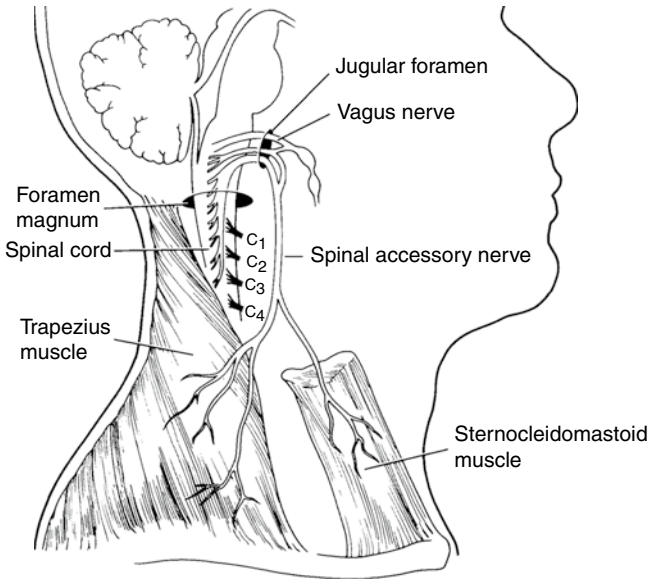

Fig. 40.19 Anatomy of the spinal accessory nerve. The spinal accessory nerve originates from C1 to C4 roots, ascending through the foramen magnum then to return via the jugular foramen. The nerve first innervates the sternocleidomastoid muscle before running over the posterior cervical triangle to innervate the trapezius muscle. There is no cutaneous sensory innervation (From Spence [108]. Reprinted by permission)

The trapezius is the major suspensory muscle of the shoulder. The upper fibers of the trapezius elevate the scapula and rotate its lateral angle upward, the intermediate fibers adduct and retract the scapula, and the lower fibers depress and rotate the scapula downward.

Etiology and Pathogenesis

Often, spinal accessory palsies occur in the region of the posterior cervical triangle, resulting in isolated weakness of the trapezius. This may occur from stretch, external compression (e.g., golf bag), but most commonly following local surgical procedures [93–95]. Carotid endarterectomy and cervical lymph node biopsy are the most common procedures that injure the spinal accessory nerve [96–99].

Clinical Presentation

In distal spinal accessory palsies, atrophy and weakness of the trapezius occur, resulting in a shoulder drop [1]. The destabilized scapula moves downward from the weight of the limb. It also moves laterally away from the spine as a result of the unopposed action of the serratus anterior. In this posture, the head of the humerus cannot articulate properly with the glenoid, resulting in impaired shoulder abduction. Mild scapular winging may also be seen, especially during attempted arm abduction. Indeed, an intact trapezius is needed for proper shoulder fixation and essentially all movements around the shoulder. A destabilized shoulder from trapezius weakness often results in apparent weakness of other shoulder movements as well. Thus, it is not uncommon for patients with a spinal accessory neuropathy to be misdiagnosed clinically as a brachial plexopathy or other proximal neuropathy, in addition to primary orthopedic problems of the shoulder. Indeed, patients with a spinal accessory neuropathy commonly go many months before the correct diagnosis is reached. Adding to the confusion is that pain and paresthesias may occur, presumably from traction on the brachial plexus as a result of the dropped shoulder. The dropped shoulder can also cause similar symptoms on a vascular basis, from compression of the axillary artery, resulting in pain and paresthesias [100].

In the less common proximal lesions of the spinal accessory nerve, weakness of the sternocleidomastoid muscle also occurs, in addition to trapezius weakness. This manifests as weakness of neck flexion as well as contralateral turning of the head and neck.

Differential Diagnosis

The diagnosis is straightforward when there is a history of local compression or if the patient has had a recent local surgical procedure. Otherwise, one must consider skull-based pathology and involvement of the lower cranial nerves. The scapular winging should be differentiated from those due to rhomboid and serratus anterior weakness (see above).

Evaluation and Diagnosis

EDX studies can confirm the presence of an isolated spinal accessory neuropathy and help assess prognosis in the traumatic cases [1]. Motor studies can be performed with surface recording electrodes over the upper trapezius. The CMAP from the upper trapezius can be compared to the contralateral side. Since the posterior sternocleidomastoid is the only easily accessible stimulation site, the major use of this study is to measure the distal CMAP amplitude and compare it to the contralateral side, to estimate the amount of axonal loss.

As the spinal accessory nerve carries no sensory fibers, there is no corresponding sensory nerve study to perform. However, in those patients who appear to have shoulder weakness from poor fixation, it is advisable to assess the sensory nerves that travel through the upper trunk of the brachial plexus. These studies, including the lateral antebrachial cutaneous, radial, and median SNAPS, should be sampled bilaterally to help exclude a more widespread lesion affecting the upper plexus.

Needle EMG can be used to assess the trapezius (upper, middle, and lower fibers) as well as the sternocleidomastoid muscles. If the trapezius is severely atrophied, it is easy to inadvertently pass through this muscle with the needle and actually be sampling underlying muscles (e.g., supraspinatus, infraspinatus, rhomboids). Along with checking the spinal accessory-innervated muscles, needle EMG should be used to sample other proximal muscles, especially those that control the shoulder. Since spinal accessory neuropathies may result in apparent weakness of the shoulder, it is essential to confirm that other shoulder girdle muscles are normal on needle EMG.

Management and Prognosis

In cases caused by external compression, avoidance of the activity is first indicated. Physical therapy can be of benefit to build up adjacent shoulder stabilizing muscles. In cases caused by stretch or those following lymph node biopsy where laceration is likely, management is more problematic [99]. Similar to other traumatic neuropathies, if no recovery has been noted either clinically or by needle EMG at 6 months, surgical exploration and possible nerve grafting can be considered. In addition, muscle transfer procedures may be considered to substitute for the loss function of the trapezius [101].

The Fibular (Peroneal) Nerve

Anatomy

The peroneal nerve was recently renamed as the fibular nerve by the Federative Committee on Anatomic Terminology to eliminate confusion between the terms peroneal and perineal nerves. The common fibular nerve (formerly known as the common peroneal nerve and lateral popliteal nerve) and the tibial nerve (formerly known as the posterior tibial nerve and medial popliteal nerve) form the sciatic nerve. Both nerves share a common sheath within the sciatic nerve but never exchange fascicles [1]. The first branch of the common fibular nerve is a motor branch that usually exits near to the gluteal fold and innervates the short head of biceps femoris. The tibial nerve innervates the rest of the hamstring muscles. The common fibular and tibial nerves separate completely in the upper popliteal fossa or slightly above that, with significant individual variability.

In the popliteal fossa, the common fibular nerve gives off two branches, the lateral cutaneous nerve of the calf, which innervates the skin over the upper third of the lateral aspect of the leg (Fig. 41.1), and the fibular communicating nerve which joins the sural nerve. The common fibular nerve then descends and curves around the anterolateral aspects of the fibular head and neck. After the fibular nerve gives off a small articular branch to the proximal tibiofibular joint, the common fibular nerve winds around the fibular neck and passes through the "fibular tunnel"; this is formed between the tendinous edge of the peroneus longus muscle and the fibula [1, 2]. Near that point, the common fibular nerve divides into its terminal branches, the deep and superficial fibular nerves.

The deep fibular nerve (formerly named deep peroneal nerve or anterior tibial nerve) is primarily motor. It passes through the proximal lateral compartment of the leg to enter the anterior compartment, where it innervates the tibialis anterior, extensor hallucis longus, peroneus tertius, and extensor digitorum longus. Slightly proximal to the ankle joint, the deep fibular nerve passes under the extensor retinaculum and then divides into a lateral motor branch which innervates the extensor digitorum brevis, and a medial sensory branch which becomes subcutaneous in midfoot and supplies the skin of the web space between the first and second toes (Fig. 41.2).

The superficial fibular nerve is predominantly sensory. It traverses usually the lateral compartment, where its gives motor branches to the peroneus longus and brevis. Less commonly, it passes through the lateral compartment or both the anterior and lateral compartments [3]. In the distal leg, the nerve, now a purely sensory nerve called the superficial fibular sensory nerve, pierces the crural fascia approximately 10 cm proximal to the lateral malleolus, to become subcutaneous [4, 5]. Soon after, it divides into a small medial cutaneous and a larger intermediate cutaneous nerve and innervates the skin of the lower two thirds of the lateral aspect of the leg and the dorsum of the foot (except for the first web space) (see Fig. 41.1).

The accessory deep peroneal nerve is a common anomaly occurring in 19–28 % of the general population, based on electrophysiological studies, and in up to 67 %, based on anatomical studies, with a likely autosomal dominant mode of inheritance [6–8]. When present, it arises as a motor branch of superficial fibular nerve, usually a continuation of the muscular branch that innervates the peroneus brevis muscle. The accessory deep fibular nerve traverses along the posterior aspect of the peroneus brevis muscle and then, accompanied by peroneus brevis tendon, passes behind the lateral malleolus near the sural nerve to reach the foot (Fig. 41.3). There, it sends branches to the lateral part of

extensor digitorum brevis, ankle joint, and ligaments. Rarely, the extensor digitorum brevis receives complete innervation through the accessory deep fibular nerve [9–11].

Common Fibular (Peroneal) Mononeuropathy at the Fibular Neck

Etiology and Pathogenesis

Common fibular mononeuropathies around the fibular neck are usually caused by external nerve compression or by knee trauma (Table 41.1) [12–14]. In compressive lesions, the common fibular nerve is often trapped between an external object or internal structure and the fibular neck. Typically, the deep fibular branch is more severely affected than the superficial branch. This phenomenon is related to the topographical arrangement of the common fibular nerve around the fibular neck, where the exiting fascicles, forming the superficial branch, are placed laterally while the deep fibular nerve is located medially in direct contact with the fibular bone [15]. Occasionally, the lesion at the fibular neck is restricted to the deep fibular nerve (see below) [14, 15].

Intraoperative compression is the most common cause of acute fibular mononeuropathies at the fibular neck [12, 14]. This occurs during anesthesia for surgical procedures in which the fibular nerve is distant from the surgical field, such as during coronary bypass artery grafting or craniotomy. The fibular nerve becomes compressed due to malpositioning of legs and failure to properly pad the knees. Weight loss, due to a concurrent illness or with dieting, is another common precipitating factor of fibular nerve compression at the fibular neck [14, 16–19]. Loss of subcutaneous fat padding around

[a]Usually with weight loss

the common fibular nerve, rendering it exposed to the fibular bone, is the likely cause of compression in these patients. A reduction in the peroneal nerve transverse cross-sectional area has been reported on ultrasonography in these patients. The nerve appeared thinner and its ultrasonic reflectivity was lower [20]. Weight loss is often overlooked by treating physicians who may be unaware of this precipitating factor. Habitual leg crossing is also an important risk factor [21], but this is invariably associated with another risk factor, particularly weight loss [14]. Prolonged hospitalization, bed rest, or coma, particularly when associated with weight loss, is not uncommon causes of fibular nerve compression at the fibular

neck. This is likely precipitated by poor patient positioning resulting in leg compression against firm mattresses and bed rails or, merely, prolonged external rotation in a "frog-leg position." Diabetes mellitus, with or without a peripheral polyneuropathy, is a likely independent risk factor for developing common fibular nerve lesions around the fibular neck [14, 22]. Although it was reported in only one patient of 380 diabetics studied in a cross-sectional population study [23], a series of 103 patients with peroneal neuropathy at the fibular head found that 8 % were diabetics [14]. Patients with underlying peripheral polyneuropathy in general have also a higher incidence of such a lesion. Iatrogenic compression by external devices applying pressure on the fibular nerve against the fibular neck may cause fibular mononeuropathy. These include above and below knee casts, ankle-foot orthoses, pneumatic compression devices, and antithrombotic stockings, bandages, and straps [24–28].

Prolonged squatting, such as during crop harvesting ("strawberry pickers fibular palsy"), Yoga meditation, or childbirth, is associated with common fibular nerve lesions at the fibular neck [29–35]. The exact site of fibular nerve compression during squatting is not well understood. Aided by weight of the body, the common fibular nerve may be stretched around the fibular neck or compressed between the biceps femoris tendon and the lateral head of the gastrocnemius muscle. Lithotomy positioning, particularly with the use of stirrups, for hysterectomy, prostatectomy, or vaginal delivery, is another cause of fibular nerve compression at the fibular neck.

Intrapartum fibular neuropathy in the setting of normal childbirth is rare. It is usually compressive across the fibular neck. This may occur bilaterally. It may be caused by the stirrups during lithotomy positioning which is used less commonly during childbirth. Squatting during labor, which is common in certain countries but rarely in the United States, may result in compressive fibular neuropathy at the knee, particularly when labor is prolonged [33, 35]. Finally, direct pressure on the nerve across the fibular neck may occur while the knees are grasped by the patient or assistants to keep her hips and knees forcibly flexed [36, 37]. This has been referred to as "pushing palsy" [36]. Nurses and obstetricians must be aware of potential fibular nerve injury during labor, and women should be instructed to avoid maintaining positions that result in prolonged, uninterrupted pressure on the fibular nerves by frequently varying their position during childbirth. It is also not clear whether reported patients with postpartum foot drop following vaginal delivery may actually represent cases of intrapartum lumbosacral plexopathy due to compression of the lumbosacral trunk by the fetal head in the pelvis [38, 39].

Direct nerve trauma is the second most common cause of common fibular mononeuropathies at the fibular neck. This includes blunt or open trauma, as well as surgical nerve injury. Blunt trauma is often associated with vehicular accidents or sport injuries leading to soft tissue injuries such as ligamental ruptures of the knee joint, tibiofibular fracture with or without a coexisting fibular head fracture, knee dislocation, or dislocation of the superior tibiofibular joint [40, 41]. Open injuries are usually due to lacerations (by knives, chainsaws, broken glass, etc.), gunshot wounds, or animal bites. Iatrogenic fibular nerve lesions around the fibular neck are common following surgical procedures in which the fibular nerve is in or near the operative field, such as with conventional knee surgery as well as knee arthroscopy [42–44]. Finally, stretch injuries of the common fibular nerve or to one of its terminal branches may occur following inversion ankle sprains [45–47]. This is likely caused by traction and compression of the common peroneal nerve as it winds around the neck of the fibula and possible compression by hematoma. This may be more common than suspected and may account for the persistent weakness of ankle and the increased risk of recurrent ankle sprains in patients with prior ankle inversion injuries [48].

Intraneural ganglia of the fibular nerve causing fibular neuropathy and foot drop are increasingly diagnosed but remain under-recognized despite that fibular intraneural ganglion is the most common type of intraneural ganglia. These are mucinous cysts which originate from the superior tibiofibular joint after disruption of its capsule, allowing dissection of the synovial fluid along the articular branch of the fibular nerve reaching the epineurium of the nerve [49]. In 40 % of cases, there is a residual pedicle connecting to the joint which may explain the high (10–20 %) recurrence rate. Patients with fibular nerve lesions who have no precipitating factors (such as weight loss or immobility) and who exhibit knee pain, neuropathic leg pain, and fluctuating foot weakness should be suspected as harboring intraneural fibular ganglia. Pain and fluctuating foot weakness are good predictors for the presence of intraneural fibular ganglion [50]. A palpable mass at the fibular neck is only detected in only about ½ of the patients. On neurological examination, there is a preferential involvement of the deep fibular nerve and with predominant tibialis anterior weakness, since the tibialis anterior branch is consistently involved while other muscular branches are less affected [51]. Imaging of the knee by MRI with fat suppression images or ultrasound is necessary to visualize the lesion.

Rare causes of fibular nerve lesions around the fibular neck include extrinsic masses such as osteochondromas which are more common in children and adolescents and usually arise from the proximal fibula and often compress the deep more than the superficial fibular nerve [52]. Baker's cysts, hematomas, and pseudoaneurysms are other mass lesions associated with such lesions [53]. Intrinsic nerve sheath tumors, including schwannomas, neurofibromas, and neurogenic sarcomas, are relatively rare [52, 53]. Leprous

neuritis is accompanied by significant thickening of the epineurium which results in fibular nerve injury [54].

In contrast to the carpal tunnel and cubital tunnel syndromes, chronic fibular nerve entrapment at the fibular tunnel is extremely rare [2]. This seems to occur mainly in athletes, particularly runners, and overlap with the exertional form of the anterior compartment of the leg (see below) [55, 56].

Common fibular mononeuropathies in children are similar to those of adults with compression and trauma as the leading causes [57]. Weight loss, sometimes associated with anorexia nervosa, iatrogenic lesions, such as with casts or following tibial osteotomies, and bone tumors, such as osteochondromas, are more common etiologies of common fibular nerve lesions than in adults [52, 57, 58]. Neonatal fibular nerve injuries are uncommon, usually associated with breech presentations and malpositioning but may have a prenatal onset likely from intrauterine stretching of the infant's fibular nerve [59, 60]. The prognosis is usually good, since most cases are due to neurapraxia despite that significant axonal loss may dominate in few cases [59, 60].

Idiopathic cases of fibular nerve lesions at the fibular neck constitute about 10–15 % of case series [61]. These cases do not have any of the known precipitating risk factors and do not have any identifiable mass lesion such as intraneural ganglion.

Clinical Presentation

Fibular mononeuropathy is the most common compressive mononeuropathy in the lower extremity [12, 14, 15, 29]. All age groups are equally affected but the disorder is almost three times more common in men [61]. Most fibular nerve lesions are unilateral and affect the right and the left side equally. Bilateral lesions are seen in less than 10 % of all the cases [13, 14, 61]. By far, lesions of the common fibular nerve at the fibular neck are the commonest, while selective proximal deep and high common fibular nerve lesions occur in a small percentage.

Common fibular mononeuropathy at the fibular neck is a frequent cause of acute foot drop, which may be complete or partial. In some instances, the foot drop develops gradually over days or even weeks. Though the foot drop is often acute in compressive lesions, the onset of foot drop may be subacute, or cannot be determined [12, 14, 57]. In general, postoperative compression and direct trauma to the fibular nerve have a well-defined history of an acute foot drop, while cases associated with weight loss or prolonged hospitalization often present in a gradual fashion or their onset may not be ascertained (Fig. 41.4).

Foot drop may cause the toes to get trapped or causes the patient to fall. Also, patients may inadvertently sprain or fracture their foot or ankle. Subjective numbness, mostly on the dorsum of foot, but occasionally extending into the lower

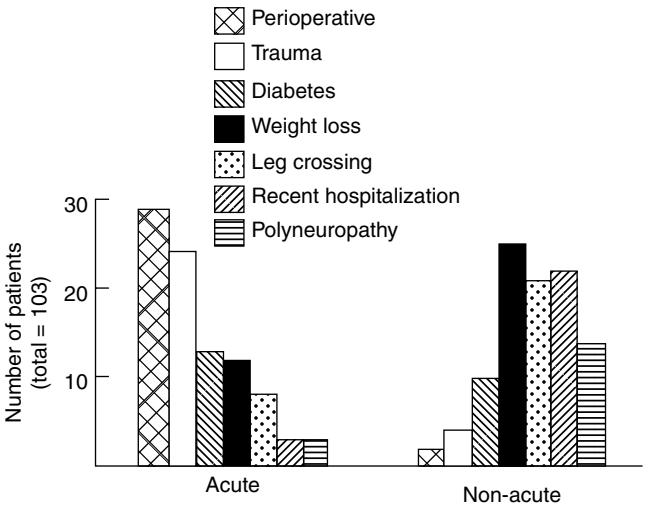

Fig. 41.4 Predisposing factors in 103 patients with fibular mononeuropathies. Note the difference between lesions of acute versus non-acute onset (From Katirji and Wilbourn [14]. With permission)

lateral leg, is common. In high (proximal) fibular lesions, the sensory loss in the lateral leg may extend into the knee (see section "Differential Diagnosis"). Most patients with lesions at the fibular neck have a mild deep, boring pain around the knee or in the leg, except for patients with intraneural ganglia who may have more pronounced pain [50]. A steppage gait with significant foot drop is evident in 2/3 of the patients with significant disability [61], since the patient has to raise the leg in order to avoid striking the foot and toes on the ground.

The neurological findings are restricted to weakness and sensory loss in the distribution of the common fibular nerve. In most cases, weakness of ankle and toe dorsiflexion dominates, while ankle eversion is relatively stronger, since the superficial fibular nerve is often less damaged than the deep fibular nerve. In contrast, ankle inversion, toe flexion, and plantar flexion are spared. Also, knee flexion and extension and hip abduction, adduction, and extension are normal. Deep tendon reflexes are normal. Hypoesthesia or hyperesthesia to touch and pain is common and limited to the lower two thirds of the lateral leg and dorsum of foot. In some patients, Tinel's sign may be elicited by percussion of the common fibular nerve around the fibular neck.

Ankle inversion may be difficult to assess in patients with complete or severe foot drop. An apparent weakness of ankle inversion often results in incorrect diagnoses, such as sciatic mononeuropathy or L5 radiculopathy, which may lead to unnecessary investigations and therapies [14]. Ankle inversion strength is best evaluated with the foot slightly dorsiflexed. In patient with significant foot drop, the ankle should be dorsiflexed passively to around 90°, before asking the patient to invert the foot.

Athletes, particularly runners, may have transient sensory symptoms or foot weakness after exercise, which may be attributed to the fibular tunnel syndrome [55, 56]. Often, the neurological examination in these patients is normal except for possible Tinel's sign at the fibular head.

Differential Diagnosis

The differential diagnosis of common fibular mononeuropathy at the fibular neck is similar to that of foot drop. Foot drop is defined as severe weakness of ankle dorsiflexion with intact plantar flexion and is a common presentation in neurological practice. It should be distinguished from a flail foot in which there is no or minimal ankle or foot movement in all directions, including severe weakness of ankle dorsiflexion, plantar flexion, and intrinsic foot muscles. In contrast to a flail foot, voluntary movement at or distal to the ankle occurs in foot drop due to intact plantar flexion and intrinsic foot muscles. Many patients with peripheral polyneuropathy, such as Charcot-Marie-Tooth disease, are often mislabeled as having bilateral foot drop, while careful examination reveals foot and ankle weakness in all direction, compatible with bilateral flail foot.

Unilateral foot drop may be due to an upper or lower motor neuron lesion (Table 41.2). Lower motor neuron lesions, causing unilateral foot drop and often confused with common or deep fibular mononeuropathy, include sciatic mononeuropathy (especially when affecting the common fibular nerve predominantly), lumbosacral plexopathy (particularly when involving the lumbosacral trunk lesion), or lumbar radiculopathy (particularly L5 radiculopathy and, less commonly, L4 radiculopathy). Table 41.3 reveals the useful diagnostic features of these disorders [62]. In general, radicular pain and positive straight leg test (Lasègue test) are common in L5 radiculopathy, may be present in sciatic nerve lesions, and are not seen in or plantar flexion, or absent/depressed ankle jerks are findings which are inconsistent with fibular nerve lesion. Establishing the diagnosis of fibular mononeuropathy may be based on clinical grounds in many cases, but often requires electrodiagnostic (EDX) studies for diagnostic as well as prognostic reasons (Table 41.4).

Bilateral fibular nerve palsies resulting in bilateral foot drop are more challenging to diagnose and much less common than unilateral cases [13, 14, 29, 61]. They often mimic generalized neuromuscular disorders such as peripheral polyneuropathies, myopathies, or motor neuron diseases (Table 41.5).

Evaluation and Diagnosis

Electrodiagnostic Studies

The EDX studies in patients with foot drop and suspected fibular mononeuropathy are extremely useful. The evaluation is aided by the anatomy of the common fibular nerve and its branches which are accessible to multiple nerve conduction studies (NCSs) and to needle electromyography (EMG). The objectives of the EDX studies in evaluating such patients are the following:

1. To confirm that the foot drop is due to a common or deep fibular mononeuropathy and exclude other causes of foot drop such as L5 radiculopathy and sciatic mononeuropathy
2. To localize the site of the fibular nerve lesion (fibular neck, upper thigh, or selective deep branch)
3. To define the primary pathophysiological mechanism of injury (demyelinating versus axonal versus mixed)

Table 41.3 The differential diagnosis of common causes of foot drop: Clinical

	Fibular neuropathy at the fibular head	L5 radiculopathy	Lumbar plexopathy (lumbosacral trunk)	Sciatic neuropathy (mainly fibular)
Common causes	Compression (weight loss, perioperative), trauma, intraneural ganglion	Disc herniation, spinal stenosis	Pelvic surgery, hematoma, prolonged labor	Hip surgery, injection injury, coma
Ankle inversion	Normal	Weak	Weak	Normal or mildly weak
Toe flexion	Normal	Weak	Weak	Normal or mildly weak
Plantar flexion	Normal	Normal	Normal	Normal or mildly weak
Ankle Jerk	Normal	Normal (unless with S1)	Normal (unless with S1)	Normal or depressed
Sensory loss distribution	Fibular nerve distribution only	Poorly demarcated, predominantly big toe	Well demarcated to L5 dermatome	Fibular nerve distribution plus lateral cutaneous of calf and sole (tibial)
Pain	Rare, deep	Common, radicular	Common, can be radicular	Can be severe

5. To assess the presence and extent of reinnervation (in axonal loss lesions)

Nerve Conduction Studies

Sensory and motor fibular NCS are essential in the EDX evaluation of patients with foot drop or suspected fibular mononeuropathy. These studies should include the following:

1. *Superficial fibular sensory NCS* is extremely important in assessing patients with foot drop or with suspected fibular mononeuropathy. The superficial fibular SNAP is easy to obtain and is not more technically demanding than the sural SNAP [63, 64]. The superficial fibular SNAP is evaluated in the leg, distal to the frequent site of common fibular nerve compression at the fibular neck. It is low in amplitude or absent when there is significant axonal loss, but remains normal in purely demyelinating common fibular nerve lesions at the fibular neck, in deep fibular mononeuropathies, and in L5 radiculopathies. Occasional patients with definite L5 radiculopathy may have low-amplitude or absent superficial fibular SNAP [65].
2. *Fibular motor NCS, recording the extensor digitorum brevis (EDB)*, is a commonly utilized motor NCS. It is routinely applied for the study of the integrity of the fibular nerve and its motor fibers during assessment of all patients subjected to an EDX evaluation of the lower extremity. In patients with suspected fibular mononeuropathies, particular attention should be made to the compound muscle action potential (CMAP) after stimulating the deep fibular nerve at the ankle and the common fibular nerve below the fibular neck and at the popliteal fossa.

   Fibular motor NCS, recording EDB, is easy to perform, familiar to all electromyographers, and has well-established normal values. Its major disadvantage is that the EDB muscle may be asymptomatically atrophic and chronically denervated in isolation, possibly due to local trauma or the use of tight shoes. This results in low-amplitude fibular CMAP recording EDB, which may erroneously suggest the presence of an axon-loss fibular nerve or an L5 root lesion. In these instances, the denervation is restricted to the EDB, and all other fibular nerve and L5-root-innervated muscles are normal.

   Partial innervation of the EDB by the accessory deep fibular nerve is a common anomaly, occurring in 19–28 % of the population (Figs. 41.3 and 41.5) [4, 7]. When present, the fibular motor CMAP is higher while stimulating the

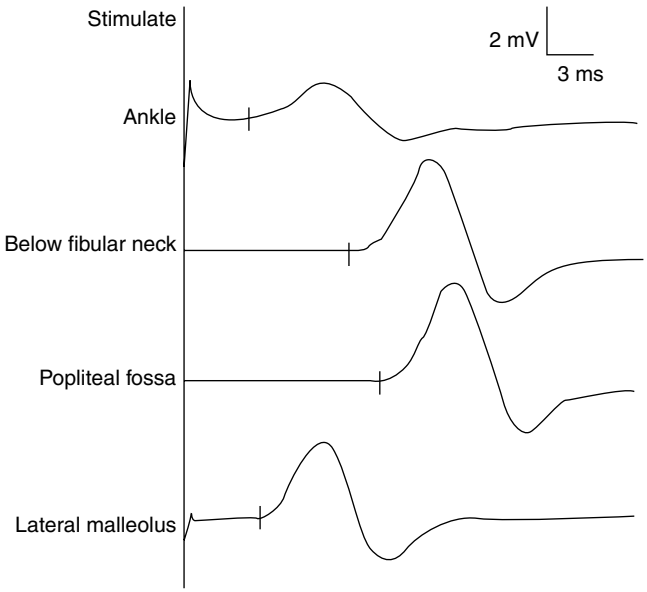

Fig. 41.5 Nerve conduction studies in the presence of an accessory deep fibular nerve (From Preston and Shapiro [394]. With permission)

knee compared to ankle stimulation. Stimulation of the accessory deep fibular nerve behind the lateral malleolus results in a CMAP, which accounts for most of the difference in fibular CMAP amplitudes with distal and proximal stimulation. Rarely, the EDB is totally innervated by the accessory deep fibular nerve, resulting in absent fibular CMAP, recording the EDB, following ankle stimulation [9–11]. To avoid a misdiagnosis of fibular mononeuropathy, a proximal stimulation of the fibular nerve at the knee should always be done, and if a motor response is recorded, then stimulation of the accessory deep fibular nerve behind the lateral malleolus should follow.

3. *Fibular motor NCS recording tibialis anterior* is extremely important in patients with foot drop and fibular mononeuropathy [13, 14, 66]. The tibialis anterior is the principal dorsiflexor of the ankle and is the most clinically relevant muscle in patients with foot drop. Evaluating the motor fibers destined to the tibialis anterior is far more pertinent than the EDB in predicting the outcome of foot drop in patients with fibular nerve lesions. Also, since the EDB is not uncommonly atrophic and denervated in isolation, low-amplitude CMAP, recording EDB, may erroneously suggest that the fibular lesion is axonal and severe. In fact, fascicular involvement of the common fibular nerve at the fibular neck is not uncommon [15]. This is sometimes manifested by low-amplitude or absent fibular CMAPs, recording EDB, and normal distal fibular CMAP, recording tibialis anterior, with a conduction block across the fibular neck. In these situations, the fibular motor NCS, recording tibialis anterior, helps establishing the extent of demyelination and axonal loss of motor fiber destined to this muscle. This assessment is extremely helpful prognostically, since conduction block due to segmental demyelination carries an excellent prognosis for recovery, while axonal lesions have a protracted course.

At least two deep fibular-innervated muscles (tibialis anterior, extensor hallucis, extensor digitorum brevis, and longus)
At least one superficial fibular-innervated muscle (peroneus longus and brevis)
The short head of biceps femoris[b]
At least two L5-innervated muscles (e.g., tibialis posterior, flexor digitorum profundus, gluteus medius, or tensor fascia lata) and one L4-innervated muscle (e.g., vastus lateralis), preferably with the corresponding lumbar paraspinal muscles
At least one tibial-innervated muscle (e.g., medial head of gastrocnemius)

Source: Adapted from Katirji [13]. With permission
[a]These should be done bilaterally, if there is any suspicion of a proximal (high) fibular nerve lesion (sciatic neuropathy affecting the fibular nerve predominantly or exclusively)
[b]Mandatory in axon-loss fibular mononeuropathies

The fibular motor and sensory NCS should be performed bilaterally, for comparison and accurate estimation of distal fibular CMAPs and SNAPs (Table 41.6). The sural sensory and tibial motor NCS should be studied on the symptomatic side and bilaterally when there is a suspicion of a sciatic nerve lesion or a proximal (high) common fibular mononeuropathy. The tibial H-reflexes, done bilaterally, assess the integrity of the tibial component of the sciatic nerve.

Needle EMG

At least two deep fibular-innervated muscles (such as tibialis anterior and extensor hallucis longus) and one superficial fibular-innervated muscle (such as peroneus longus) should be sampled. In axon-loss common fibular mononeuropathies, which are unlocalizable by NCS, sampling the short head of biceps femoris is required to exclude a proximal common fibular lesion, i.e., a sciatic neuropathy affecting the fibular nerve predominantly or exclusively [44].

Sampling non-fibular muscles is also essential. This includes muscles innervated by the L5 root such as the tibialis

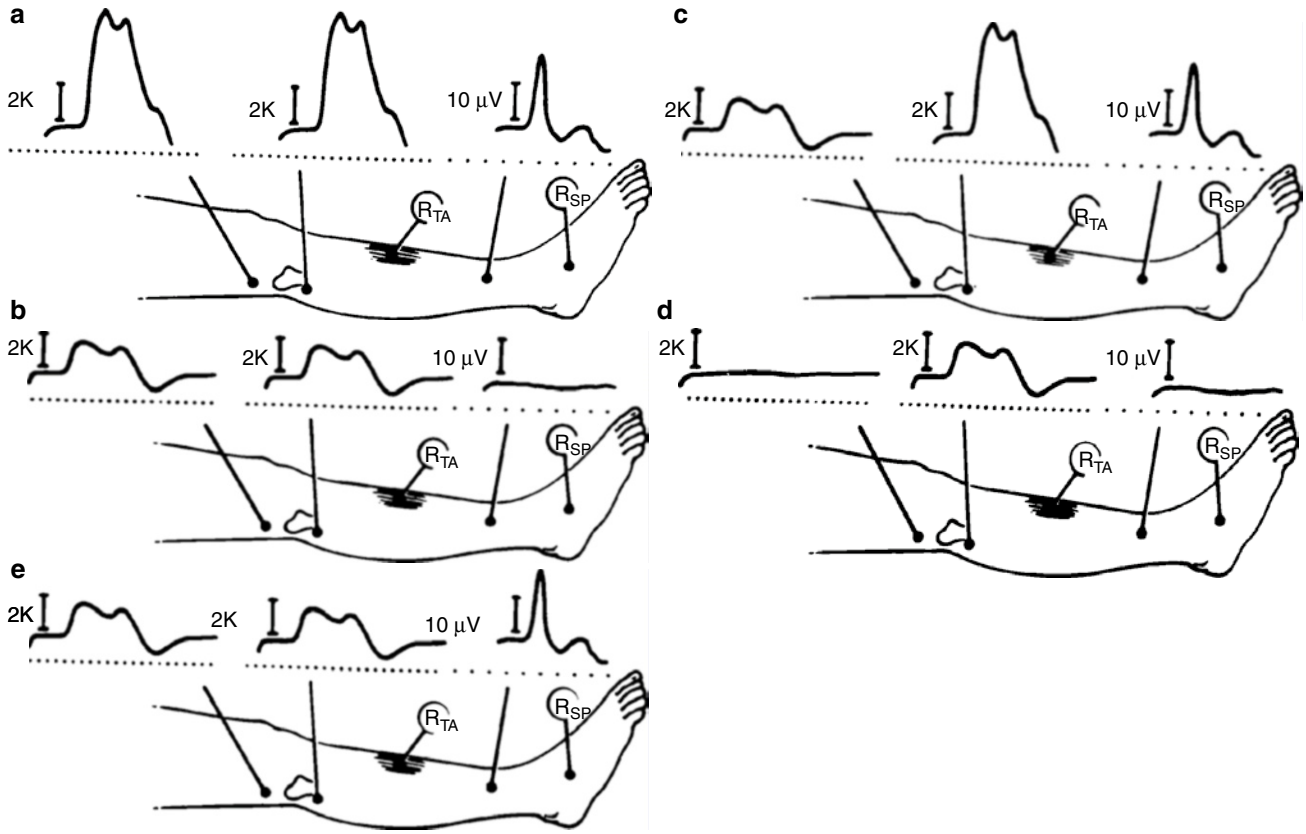

Fig. 41.6 Diagrams of the nerve conduction studies in fibular mononeuropathies (RTA, recording tibialis anterior CMAP; RSP, recording superficial fibular SNAP; proximal latencies are not shown to scale). (**a**) Normal, (**b**) partial "pure" axonal loss, (**c**) partial "pure" demyelinative conduction block, (**d**) mixed axonal loss and demyelinative conduction block, and (**e**) deep fibular axonal loss (From Katirji and Wilbourn [14]. With permission)

posterior, flexor digitorum longus, tensor fascia lata, or gluteus medius and the tibial nerve such as the medial gastrocnemius, flexor digitorum longus, tibialis posterior, and long head biceps femoris. These muscles are normal in common fibular nerve lesions, but abnormal in L5 radiculopathy or lumbosacral plexopathy.

Electrodiagnostic Findings in Fibular Mononeuropathies

The EDX findings in fibular mononeuropathies often conform to one of the following patterns (Fig. 41.6 and Table 41.7) [12–15, 61]:

1. *Demyelinative common fibular nerve lesions across the fibular neck* constitute about 20–30 % of all fibular mononeuropathies. In patients with weight loss or prolonged abnormal posture (such as squatting), 50–70 % have purely demyelinative conduction blocks. These lesions present, solely, with partial or complete conduction block across the fibular neck. On NCS, the distal fibular CMAPs (recording EDB and tibialis anterior) and superficial fibular SNAP are normal. However, there is a significant (>20–50 %) drop in CMAP amplitude and/or area, consistent with conduction block across the fibular neck (Fig. 41.6c). The primary pathology of these common fibular nerve lesions is segmental demyelination, which carries excellent prognosis with expected recovery in 2 to 3 months provided the cause of compression is eliminated. Care should be taken into account for the time required for Wallerian degeneration, since "axonal conduction block" may occur when NCSs are performed less than 10 days following the onset of acute axonal lesions (see below).

   In contrast to the carpal tunnel syndrome and ulnar mononeuropathy across the elbow, isolated focal slowing across the fibular neck is not a common feature of fibular mononeuropathy, seen in less than 5 % of the cases [13, 14, 61]. When present it is almost always associated with a localized conduction block. It is also occasionally encountered in patients recovering from fibular nerve lesions across the fibular neck.
2. *Axon-loss fibular nerve lesions* are characterized by low-amplitude or absent distal and proximal fibular CMAPs, recording EDB and tibialis anterior. The fibular motor conduction velocities are normal in mild and moderate lesions, but may be slightly reduced diffusely, without focal slowing, in severe lesion. In general, complete axon-loss fibular nerve injuries are slow to improve since they

Table 41.7 Electrophysiological patterns of fibular mononeuropathies

Pattern	Site of lesion	Frequency	Superficial fibular SNAP	Distal fibular CMAPs[c]	Conduction block at fibular head	Focal slowing across the fibular head	Needle EMG of peroneus longus	Needle EMG of biceps femoris (short head)	Prognosis for recovery
Conduction block	Fibular head	20–30 %	Normal	Normal	Present	Rare	Abnormal	Normal	Excellent
Axonal loss	Mid-thigh and fibular head[a]	15–20 %	Usually absent	Low amplitude or absent	Absent	Absent	Abnormal	Normal	Protracted
	Deep fibular	5–8 %	Normal	Low amplitude or absent	Absent	Absent	Normal	Normal	Fair
	Proximal[b]	<5 %	Usually absent	Low amplitude or absent	Absent	Absent	Abnormal	Abnormal	Very poor
Mixed	Fibular head	30–40 %	Low amplitude or absent	Low amplitude	Present	Rare	Abnormal	Normal	Biphasic

[a]Usually around the fibular head
[b]High, proximal to the gluteal fold
[c]Recoding tibialis anterior and EDB

are dependent on proximal to distal reinnervation, while partial lesions recover faster due to sprouting.

Axon-loss fibular lesions are poorly localized by NCS and often require a detailed needle EMG for better characterization. Based on location, they may be subdivided into three types:

a. *Axon-loss common fibular nerve lesions* constitute about 15–20 % of all fibular mononeuropathies. In contrast, axon-loss lesions constitute about 60 % of patients with fibular nerve lesions due to local trauma [61]. Pure axon-loss lesions are not easily localized by EDX studies due to the absence of focal slowing or conduction block. Though they are often labeled by EDX studies as located between mid-thigh and fibular neck or at/proximal to fibular neck, most of these lesions are actually at the fibular neck, as often supported by the clinical history (such as following knee surgery, fracture, laceration). These lesions are characterized by axon-loss pattern on motor NCS (i.e., low-amplitude or absent fibular CMAPs recording EDB and tibialis anterior) with low-amplitude or absent superficial fibular SNAP (Fig. 41.6b). On needle EMG, there are often fibrillation potentials and decreased number of rapidly firing MUAPS in all common fibular-innervated muscles below the knee with normal short head of biceps femoris. Sensory NCS of the lateral cutaneous nerve of the calf is a promising, yet not proven, study which may help better in localizing these lesions distal to the popliteal fossa [67].

b. *Axon-loss common fibular nerve lesions located proximal to the gluteal fold* share the same NCS abnormalities as distal axon-loss common fibular mononeuropathies (Fig. 41.6b). However, these lesions are associated with denervation of the short head of biceps femoris. They have very poor prognosis, but are, fortunately, extremely rare accounting for less than 5 % of all fibular mononeuropathies [14, 68].

Selective proximal common fibular mononeuropathies in the upper thigh are essentially sciatic nerve lesions affecting the common fibular nerve exclusively. More typically, sciatic nerve lesions are associated with tibial nerve injury. This usually results in low-amplitude or absent sural SNAP, delayed or absent H-reflex, or mild denervation in the tibial-innervated muscles (such as the medial gastrocnemius, flexor digitorum longus, tibialis posterior, or abductor hallucis).

c. *Axon-loss proximal deep fibular nerve lesions* are less frequent than common fibular mononeuropathies and constitute about 5–8 % of all fibular nerve lesions [13, 14, 61]. However, these isolated deep fibular nerve lesions constitute about 1/3 of all the traumatic cases [61] and are the typical lesions seen with intraneural fibular ganglia [50, 51]. The distal fibular CMAPs, recording EDB and tibialis anterior, are low in amplitude and/or area with normal superficial fibular SNAP (Fig. 41.6e). The fibular motor conduction velocities are often normal but may be minimally and diffusely reduced without focal slowing. The superficial fibular SNAP and needle EMG of peroneus longus and brevis are normal. Since this NCS pattern is identical to that of moderate or severe L5 radiculopathy, needle EMG of other L5-innervated muscles helps to distinguish a deep fibular nerve lesion from an L5 radiculopathy. Tested muscles should include muscles innervated by the L5 root via the tibial nerve (flexor digitorum longus or tibialis posterior) and the gluteal nerves (tensor fascia lata, gluteus medius, or gluteus maximus), as well as the lumbar paraspinal muscles.

3. *Mixed common fibular nerve lesions (demyelinative across the fibular neck with axon loss)* are common and constitute 30–40 % of all fibular nerve lesions at the fibular neck. They are characterized by a low amplitude and/or area of the distal fibular CMAPs, recording EDB and/or tibialis anterior, with partial or complete conduction block across the fibular neck (Fig. 41.6d). The superficial fibular SNAP is low in amplitude or absent. The findings often reflect a fascicular nerve injury with different pathophysiological processes involving fibers directed to the EDB versus tibialis anterior [14, 15, 67]. For example, it is not uncommon to find conduction block across the fibular neck (consistent with segmental demyelination) while recording the tibialis anterior and low-amplitude distal and proximal fibular CMAPs (consistent with axonal loss) while recording the EDB. Fibular motor conduction velocities are usually normal, and, rarely, there is an accompanying focal slowing. Recovery of the neurological deficit in these cases is usually biphasic; the first phase is due to remyelination and is relatively rapid occurring over 6–8 weeks, while the second phase is due to reinnervation and sprouting and is more protracted extending into months or years.

Clinico-Electrodiagnostic Correlations in Fibular Mononeuropathies

When assessing mononeuropathies in general, the distal CMAP amplitude is the best quantitative parameter in the evaluation of the presence and extent of axonal loss. This applies also to fibular mononeuropathy, where low-amplitude distal CMAPs are the best evidence for the presence of motor axonal loss. Though a low or absent superficial fibular SNAP indicates sensory axonal loss, this rarely results in disability. Hence, axon-loss and mixed fibular mononeuropathies should be restricted to lesions with low-amplitude distal fibular CMAPs. These nerve injuries are often associated with protracted improvement.

In contrast to the distal CMAP amplitudes, fibrillation potentials, which are sensitive evidence of recent motor axonal loss, are poor quantitative measures of the extent of

motor axonal loss. In fibular nerve lesions, fibrillation potentials are detected in all cases regardless of the primary pathophysiological process, provided the needle EMG is done at least three weeks after the onset of foot drop [14]. In fact, fibrillation potentials are seen in "purely" demyelinating fibular nerve lesions, manifesting with conduction block and normal distal fibular CMAPs. This finding is best explained by the loss of few "clinically irrelevant" motor axons in the midst of significant demyelination. Patients with fibular nerve lesions, normal distal fibular CMAPs, and "purely" demyelinating conduction blocks recover quickly, despite the presence or absence of fibrillation potentials.

Based on a strict criterion of low-amplitude distal fibular CMAP, a clinically significant axonal loss is present in about 70–80 % of all cases of fibular mononeuropathies [13, 14, 57, 61]. This includes cases of pure axon-loss as well as mixed lesions and occurs independent of its mode of onset (i.e., in acute, subacute, or undetermined onset lesions). In fibular nerve lesions due to trauma, about 60 % of cases have exclusive axonal damage [61]. In patients with weight loss or prolonged hospitalization/bedridden, conduction block is present in 50–70 % of the cases [61]. In perioperative cases or fibular nerve lesions caused by iatrogenic compression (such as casting), the fibular nerve lesions are equally divided between pure demyelination (conduction block) and mixed damage [14, 61]. This finding is in contrast to the common belief that acute perioperative compressive fibular lesions are due to neurapraxia (i.e., segmental demyelination) and should recover rapidly.

Timing of Electrodiagnostic Studies in Fibular Mononeuropathies

Sequential EDX studies are often indicated in patients with acute fibular mononeuropathies. In acute fibular nerve lesions at the fibular neck, examined within few days of the onset of foot drop, it is often possible to localize the lesion by demonstrating a conduction block pattern. However, this is not always consistent with segmental demyelination, since the distal axons are excitable after an axon-loss fibular nerve lesion until Wallerian degeneration is completed 7–11 days later. Serial NCS of axon-loss fibular mononeuropathy reveals that the distal CMAP decreases steadily to reach their nadir in 5–6 days and the SNAP in 10–11 days following the injury (Fig. 41.7) [62, 69]. Thus, a repeat NCS, after 10–11 days from the onset of an acute fibular nerve lesion, is often necessary to establish the primary pathology and prognosis. If conduction block persists, then the fibular lesion is demyelinating and has a relatively good prognosis. However, in axonal loss lesions, the distal fibular CMAPs decrease, to reach values very similar to the proximal CMAPs, and the superficial fibular SNAP, studied distal to the lesion, is often low in amplitude or absent. In mixed lesions, a combination of the above findings occurs (see Fig. 41.6).

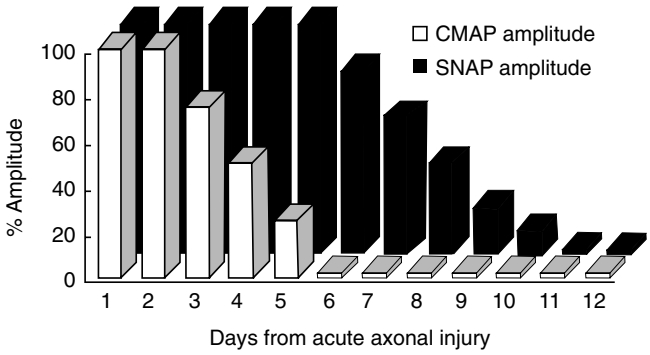

Fig. 41.7 Distal sensory nerve action potentials (SNAP) and compound muscle action potential (CMAP) after acute axonal nerve injury (From Katirji [62]. With permission)

Conduction block across the fibular neck detected in the early days of foot drop is extremely helpful in localization, particularly in closed nerve injury or compression, where the exact site of lesion is not clear based on clinical grounds. This explains the importance of obtaining NCS in the first few days of symptoms though these findings are not useful prognostically. If the lesion is due to axonal loss and the NCSs are performed after the completion of Wallerian degeneration (i.e., after 7–11 days), finding low or absent distal and proximal fibular CMAPs does not allow a precise localization of the injury site. In these cases, needle EMG often assists in localizing the lesion to a nerve segment rather than to a well-defined point along the nerve. In acute fibular nerve lesions, fibrillation potentials appear in affected muscles at about the second week first in proximally situated muscles, such as tibialis anterior and peroneus longus, and then more distally, such as extensor hallucis longus and extensor digitorum brevis. Fibrillation potentials become widespread in all denervated muscles after three weeks, and they are most profuse at about 4–6 weeks after axonal injury. They will ultimately decrease due to either reinnervation or fatty degeneration of muscle fibers.

In complete axon-loss fibular lesion, follow-up EDX studies are often necessary in attempt to detect evidence of early reinnervation, even before it becomes evident clinically. In these cases, the early signs of reinnervation often manifest by recording nascent MUAPs, which are rapid firing, low amplitude, short duration, and polyphasic in morphology. Also, sequential EDX studies are often necessary following surgical interventions such as neurolysis or nerve repair [69, 70].

Imaging Studies

Imaging studies are increasing utilized in the diagnosis of the causes of fibular nerve lesions around the fibular neck. Plain X-rays may be useful in revealing bony abnormalities, bony tumors, and dislocations. Ultrasonography of the popliteal fossa or fibular neck region may help identifying cystic lesions such as Baker's cysts, intraneural ganglion cysts, or

aneurysms [50, 71, 72]. MRI is effective in visualizing soft tissue masses, cysts, intraneural ganglia, or intrinsic nerve tumors [50, 73–75]. Intraneural ganglia were detected by ultrasound in 5 of 28 (18 %) consecutive fibular nerve lesions and by MRI in 6 of 10 (60 %) consecutive patients with non-traumatic fibular nerve lesions [72, 74].

Treatment, Management, and Prognosis

Fibular nerve injury may result in significant disability mostly due to foot drop, which may not recover completely or in a timely manner, particularly when axonal loss is severe. Ankle-foot orthosis (AFO), to improve gait and prevent ankle contractures and sprains, is indicated when the foot drop is profound, axonal, or expected to have a protracted course [76]. Active foot exercises and passive range of movements are useful. Patients with significant weight loss should be warned about leg crossing and should wear protective knee pads, properly placed over the fibular head and neck to prevent recurrent external compression.

Patients with axon-loss fibular nerve lesions around the fibular neck should be observed for 4 to 6 months to allow for improvement by spontaneous reinnervation [70]. Restoration of ankle dorsiflexion is a realistic goal for those with severe axon-loss fibular nerve injuries. In contrast to proximal axon-loss peripheral nerve lesions (such as brachial plexopathies and sciatic mononeuropathies), fibular nerve lesions around the fibular neck reinnervate relatively quick since the lesion site (fibular neck) is not far removed from the main target muscle (i.e., tibialis anterior). In general, partial lesions recover faster due to sprouting, while complete lesions reinnervate only by proximal to distal axonal growth only, which usually proceeds at a rate of 1 mm/day. Severe lesions often require sequential EDX examination to look for early evidence of reinnervation and follow its progression. Needle EMG of the tibialis anterior and/or peroneus longus may reveal fast-firing, low-amplitude, short-duration, and polyphasic MUAPs ("nascent" MUAPs) as the first sign of reinnervation.

Surgical intervention on the fibular nerve is appropriate in certain situations with relatively good outcome [53, 70, 77, 78]:

1. When the nerve is lacerated and visibly discontinuous. This repair could be done, usually by end-to-end anastomosis, at the time of laceration suturing (primary repair) or at a later date if local infection is feared (secondary repair).
2. In severe axonal lesions, particularly those associated with closed or open trauma, when there is no clinical or EMG evidence for reinnervation in the tibialis anterior or peroneus longus despite four to six months from injury. Intraoperative EDX evaluation is useful for optimal results [53, 70, 77]. Neurolysis, nerve cable grafting, or end-to-end repair, done in a timely fashion, often results in satisfactory outcome [53, 70, 77].
3. In slowly progressive fibular neuropathies, when a mass lesion, nerve tumor, synovial cyst, or intraneural ganglion is suspected. In these patients, preoperative EDX studies combined with MRI may delineate the nature of the lesion and guide the surgical procedure.
4. Rarely, in patients with chronic persistent conduction block, or in athletes with possible "fibular tunnel syndrome" who do not respond to conservative therapy, fibular nerve exploration, and neurolysis, might be of help.
5. Patients with leprous fibular neuritis may respond to neurolysis of the thickened epineurium in the popliteal fossa and near the fibular neck [79]. Pain is often relieved while the foot drop may not respond.

Apart from nerve lacerations or gunshot injuries, which usually results in axonal injury, clinical assessment often cannot predict the prognosis in common fibular mononeuropathy. For example, patients with acute perioperative compressive nerve lesions at the fibular neck, which were traditionally considered benign, have a high likelihood of harboring axon loss which carries relatively poor prognosis [13, 14]. The EDX evaluation is essential in the planning of management and prognostication of fibular nerve lesions. It distinguishes lesions with a predominant segmental demyelination from those with extensive axonal loss. Compressive fibular neuropathies at the fibular neck due to demyelinative conduction block often have good prognosis with spontaneous recovery in 2 to 3 months as long as further compression is prevented. However, the prognosis of axon-loss fibular lesions is less promising and variable since it is dependent on its extent (partial or complete) and the degree of disruption of supporting nerve elements (i.e., endoneurium, perineurium, and epineurium) [1]. In general, gunshot and stretch injuries, and proximal (high) fibular nerve lesions carry a grave prognosis. In a longitudinal prospective study of fibular nerve lesions, greater muscle strength of tibialis anterior and higher fibular nerve conduction velocity at baseline were seen to be good prognostic factors in patients who were treated conservatively with no surgical intervention [12, 61, 73].

Deep Peroneal Mononeuropathy at the Fibular Neck

Etiology and Pathogenesis

Although fibular nerve lesions at the fibular neck often affect the deep fibular nerve predominantly, occasionally the deep fibular nerve is selectively injured [10]. In general, causes of deep fibular mononeuropathies at the fibular neck are the same as those leading to common fibular nerve lesions at the fibular neck (see above). However, certain causes have a predilection to the deep fibular nerve. These include intraneural

ganglion cysts [50, 51, 72], inversion ankle sprains of the foot [46, 80], osteochondromas [52], and following arthroscopic knee surgery [42].

Clinical Manifestations

Selective deep fibular mononeuropathies near the fibular neck are much less frequent than common fibular mononeuropathies, constituting about 5–8 % of all fibular nerve lesions [13, 14, 61]. However, these isolated deep fibular nerve lesions constitute about 1/3 of the traumatic cases [61]. They result in foot drop, but the weakness is restricted to foot dorsiflexion and toe extension, while ankle eversion remains normal. Also, the sensory manifestations are absent or minimal and limited to the first web space on the dorsum of the foot. Occasionally, the deep fibular lesion is more distal in the leg (such as with traction injury associated with ankle sprain), resulting in selective weakness of toe extension with normal foot dorsiflexion.

Differential Diagnosis

An L5 radiculopathy may mimic a deep fibular nerve lesion at the fibular head, since both entities may cause foot dorsiflexion weakness. However, as with a common fibular lesion, ankle inversion, toe flexion and hip abduction are normal in deep fibular mononeuropathy while often weak in L5 radiculopathy.

The anterior compartmental syndrome of the leg may be confused with a selective deep fibular mononeuropathy. By definition, compartmental syndrome is a state of emergency in which increase pressure within a limited space (compartment) in a limb compromises the perfusion, circulation, and function of the contents of that space [81]. Anterior compartmental syndrome of the leg occurs mainly following limb trauma (crush, contusion, fractures) or spontaneous bleeding into the compartment, but it may follow strenuous exercise such as running. The anterior compartment of the leg contains the deep fibular nerve and all its innervated muscles (tibialis anterior, extensor hallucis longus, and extensor digitorum longus) except the extensor digitorum brevis (EDB) which lies outside (distal) to the compartment.

Anterior compartmental syndrome of the leg is the most common compartmental syndrome in the lower extremity (see Chap. 37). Ischemia or necrosis of compartmental muscles results in weakness of foot and toe dorsiflexion. If there is concomitant deep fibular nerve ischemia, the EDB becomes weak and denervated, sometimes with hypesthesia in the distribution of the deep fibular nerve (the dorsal first web space). In these situations, anterior compartmental syndrome of the leg may be difficult to distinguish from a primary deep fibular nerve lesion, particularly when associated with trauma (such fibular fracture). However, characteristic findings of anterior compartmental syndrome of the leg, not present in primary deep fibular mononeuropathy, include the following [81]:

- Limb pain, often severe and out of proportion to what is anticipated from the clinical situation (such a tibial fracture). This may peak after a time interval from the primary etiological event (usually 1 to 3 days).
- Pain on flexion of toes and plantar flexion of ankle, which lead to stretch of the anterior compartmental muscles of the leg.
- Tenseness of the anterior compartmental fascia and, occasionally, focal herniation of muscle into the subcutaneous tissue.

The diagnosis of anterior compartmental syndrome of the leg requires a high degree of suspicion in patients at risk (i.e., trauma, fracture, crush, etc.). When suspected, tissue pressure measurement is of a great value in confirming the diagnosis. A tissue pressure above 60 mm Hg is diagnostic, although muscle and nerve tolerance to ischemia may be reduced by additional factors such as arterial occlusion, limb elevation, or hypotension.

Evaluation and Diagnosis

The EDX studies recommended in patients with suspected deep fibular mononeuropathy are similar to those required for patients with foot drop or common fibular mononeuropathy (see Table 41.6). The findings are generally compatible with an axon-loss or mixed proximal deep fibular lesion near the fibular neck. In pure axon-loss lesions, not associated with conduction block across the fibular neck, the NCS imitates a moderate or severe L5 radiculopathy: the fibular CMAPs, recording EDB and tibialis anterior, are low in amplitude with normal superficial fibular SNAP (Fig. 41.6e). In severe and complete axon-loss lesions, the fibular CMAP recording EDB is absent; however, the fibular CMAP recording tibialis anterior is low in amplitude but always recordable due to volume conduction from the normal neighboring peroneus muscles which remain intact. In partial axon-loss lesions, the fibular motor conduction velocities are often normal but may be minimally decreased without focal slowing. Needle EMG of peroneus longus and brevis is normal, while all deep fibular-innervated muscles reveal neurogenic changes. Also, needle EMG of other L5-innervated muscles (flexor digitorum longus, tibialis posterior, tensor fascia lata, gluteus medius, or gluteus maximus) is normal and helps to distinguish a deep fibular nerve lesion from an L5 radiculopathy.

The EDX studies are of little diagnostic value in the acute evaluation of the anterior compartmental syndrome of the leg. Often, they are performed after the acute phase to confirm or estimate the extent of injury. The superficial fibular SNAP and needle EMG of the peroneus longus and brevis are usually normal. On motor NCS, the fibular CMAP recording tibialis anterior is often absent or low in amplitude early in the illness due to muscle ischemia and necrosis. In contrast, stimulation of the fibular nerve at the ankle,

below the fibular neck, and behind the knee, recording EDB, results in normal CMAP when ischemia is restricted to muscles of the anterior compartment of the leg. This combination (normal CMAP recording EDB with absent or very low-amplitude CMAP recording tibialis anterior) is characteristic for the anterior compartment syndrome of the leg and uncommon in patients with common or deep fibular mononeuropathies [13–15]. However, when the compartmental syndrome is accompanied by deep fibular nerve ischemia (and equally in primary axon-loss deep fibular nerve lesions), the fibular CMAPs, recording EDB and tibialis anterior, are equally low in amplitude or absent following distal and proximal nerve stimulations.

Needle EMG of the anterior compartment muscles (all deep fibular-innervated muscles) reveals decreased insertional activity and no or very few MUAPs due to muscle fiber degeneration. In contrast, the EDB either is normal or shows fibrillations with no or few MUAPs, depending on whether the deep fibular nerve is intact or affected.

Treatment, Management, and Prognosis

The treatment of deep fibular nerve lesions at the fibular neck is similar to that of common fibular mononeuropathy (see above). In the anterior compartmental syndrome, a high index of suspicion, rapid diagnosis, and surgical intervention (fasciotomy) is warranted [81]. When treatment is delayed, severe muscle necrosis and permanent limb contractures occur resulting in severe disability.

Common Fibular Mononeuropathy at the Hip (Sciatic Mononeuropathy Affecting the Fibular Division Selectively)

Etiology and Pathogenesis

Partial lesions of the sciatic nerve at the hip usually affect the lateral division (fibular division) more than the adjacent medial division (tibial division) [1]. On rare occasions, the common fibular nerve is the only nerve injured leaving the tibial nerve completely intact [68]. As outlined earlier, though these two nerves form the sciatic nerve and share a common sheath, they are separate from the outset and do not exchange fascicles.

The greater vulnerability of the fibular division of the sciatic nerve to physical injury occurs with a variety of causes of sciatic nerve lesions including hip trauma, hip joint replacement, and gluteal injection. This is related to two reasons [1]:

1. The difference in the fascicular pattern of the perineurium among these two nerves in the upper thigh: the fibular nerve has fewer and larger fascicles with limited supportive tissue, while the tibial nerve is composed of many cushioning fascicles, well placed between the elastic epineurial tissues. This renders the fibular division of the sciatic nerve more susceptible to external pressure.
2. The anatomical course of the common fibular and tibial nerves: the fibular nerve is taut and secured at the sciatic notch and fibular neck, while the tibial nerve is loosely fixed posteriorly. Hence, traction of the sciatic nerve in the upper thigh (such as during total hip replacement) results in more extensive stretch injury to the fibular nerve than the tibial nerve.

Causes of high common fibular mononeuropathies are similar to sciatic nerve lesions in general (see below, the sciatic nerve) [68, 82–84]. This includes total hip replacement, hip fracture or dislocation, femoral fracture, gluteal injection, gluteal compartment syndrome, gunshot or knife wound, and acute compression during coma, drug overdose, prolonged sitting, or intensive care unit hospitalization (see below).

Clinical Presentation

High common fibular lesions manifest with findings similar to common fibular mononeuropathies at the fibular neck. However, these lesions are sometimes accompanied by subtle manifestations of tibial nerve involvement such as severe foot pain, absent/depressed ankle jerk, weak ankle inversion, or sensory loss in the sole.

Differential Diagnosis

A proximal (high) common fibular mononeuropathy often presents a diagnostic challenge since it imitates a common fibular nerve compression at the fibular neck. Although the clinical history is useful (such as following a gluteal injection or gunshot wound), it may be also misleading. For example, following a total hip replacement, a foot drop may be due to an iatrogenic sciatic nerve lesion (affecting mainly the fibular nerve) or a fibular nerve compression at the fibular neck due to leg malpositioning during anesthesia.

Perhaps, the best clinical way to establish that a common fibular lesion is proximal is by looking for subtle signs of tibial nerve involvement, such as weak ankle inversion, sensory loss in the sole, or absent/depressed ankle jerk. These findings are inconsistent with a common fibular mononeuropathy at the fibular neck. Despite this, distinguishing patients with axon-loss sciatic nerve lesions affecting exclusively the fibular component (i.e., proximal or high common fibular mononeuropathy) from a distal axon-loss common fibular mononeuropathy at the fibular neck remains clinically difficult (see Tables 41.3 and 41.4) [68]. The only useful clinical sign is detecting sensory loss in the upper lateral third of the leg, corresponding to the territory of the lateral cutaneous nerve of the calf, which originates from the common fibular nerve proximal to the fibular head (see Fig. 41.1). In practical terms, these lesions are only diagnosed accurately after a detailed EDX testing.

Evaluation and Diagnosis

When the tibial component of the sciatic nerve is slightly involved, the EDX study reveals additional findings, such as asymmetrically low (or sometimes absent) sural SNAP amplitude, borderline or low tibial CMAP amplitude, asymmetrically abnormal H-reflex, or minimal neurogenic changes in tibial-innervated muscles (such as gastrocnemius, tibialis posterior, or flexor digitorum longus).

The NCSs in proximal (high) common fibular nerve lesion are identical to an axon-loss common fibular mononeuropathy and do not distinguish it from a distal lesion at the fibular neck. However, needle EMG of the short head of biceps femoris, the only hamstring muscle innervated by the common fibular nerve, reveals signs of denervation. This muscle cannot be evaluated satisfactorily in isolation on manual muscle testing nor palpated during such testing because of its location deep to the long head. Its function is often concealed by the other more powerful tibial-innervated hamstring muscles (semitendinosus, semimembranosus, and long head of biceps femoris). However, the short head of biceps femoris is easily accessible to needle EMG. As a rule, this muscle should be sampled in all patients presenting with a foot drop, but in particular in patients with axon-loss common fibular mononeuropathies, where accurate localization is often dependent on this muscle.

Treatment, Management, and Prognosis

The treatment of a patient with high proximal fibular mononeuropathy is similar to patients with sciatic nerve lesions. Most lesions are managed conservatively with ankle-foot orthosis, pain management, and physical therapy. Rarely, severe lesions may be treated surgically, but the outcome of these patients is often poor.

Deep Fibular Mononeuropathy at the Ankle (Anterior Tarsal Tunnel Syndrome)

Etiology

Lesion of the distal segment of the deep fibular nerve on the dorsum of the ankle is sometimes referred to as the anterior tarsal tunnel syndrome, a term coined by Marinacci in 1968 [85]. However, the anterior tarsal tunnel is not a true anatomic tunnel, in contrast to the carpal tunnel or medial tarsal tunnel. Its floor is the fascia overlying the talus and navicular, and its roof is the inferior extensor retinaculum (Fig. 41.8).

Causes of the anterior tunnel syndrome include direct contusion to the dorsum of the ankle, chronic pressure from shoe rims or straps, ganglion cyst, pes cavus, talonavicular osteophyte, or fractures, dislocations, or sprains of the ankle [86–90]. Unusual positioning of the foot, such as with marked foot plantar flexion accompanied by dorsiflexion of the toes (e.g., with wearing high-heeled shoes) or extreme inversion of the foot (e.g., with spasticity or dystonia), is also associated with this syndrome [88].

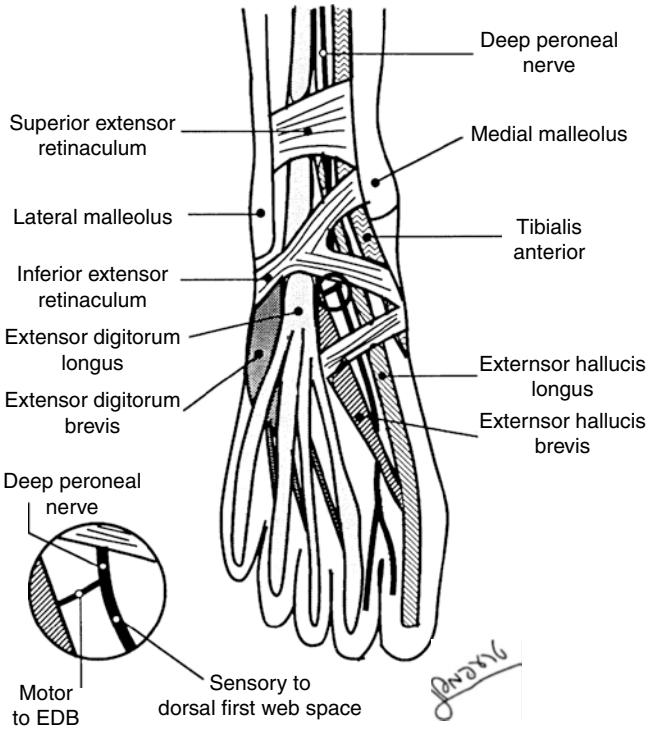

Fig. 41.8 Anatomy of the deep fibular nerve at the ankle and foot (dorsal view of ankle and foot) (From Dawson et al. [395]. With permission)

Clinical Presentation

The anterior tarsal tunnel syndrome is often asymptomatic, detected incidentally during EDX testing of the lower limbs for other symptoms such as lumbosacral radiculopathies. This has raised many questions as to the true existence of this entity.

In the symptomatic patients, the syndrome is slightly more common in women, probably related to the use of high-heeled shoes. It may be unilateral or bilateral. There is often numbness and paresthesias limited to the web space between the first and second toes. Ankle and foot pain, worse at night, are common, while foot weakness is not part of the syndrome. On examination, there is diminished sensation in the web space between the first and second toes (i.e., in the region innervated by the terminal portion of the deep fibular nerve) as well as wasting of the EDB muscle. In almost all the patients, the findings are sensory and motor since the bifurcation of the deep peroneal nerve into its medial terminal sensory branch (to the first web) and lateral terminal motor branch (to the EDB muscle) occurs underneath the extensor retinaculum in the majority of patients [91]. In contrast to EDB atrophy, weakness of the EDB is difficult to

assess due to the more powerful other toe dorsiflexors, i.e., the extensor hallucis longus and extensor digitorum longus. At times, a Tinel's sign over the deep fibular nerve at the ankle may be elicited.

Evaluation and Diagnosis

The EDX findings in the anterior tarsal tunnel syndrome are limited to prolongation of fibular motor distal latency recording EDB, with a normal proximal conduction velocity, and long-duration, high-amplitude, and polyphasic MUAP changes, usually with fibrillation potentials, in the EDB muscle [86, 87]. The fibular CMAP recording EDB is often low in amplitude, while the CMAP recording tibialis anterior and the superficial fibular SNAP are always normal. Similarly, needle EMG of common fibular- and L5- or S1-innervated muscles is normal. The findings may be unilateral or bilateral.

In asymptomatic patients, it may be difficult to separate the above findings from the common occurrence of denervation of the EDB, with or without slowing of fibular motor distal latency [87]. It is advised that the diagnosis of anterior tarsal tunnel syndrome be reserved to patient with typical clinical manifestations and EDX findings.

Treatment

Shoe modifications, avoiding high-heel or tight shoes, and correcting ankle malposition (e.g., by bracing) are often helpful. Corticosteroid injections are also useful [89]. Occasionally, surgical exploration may be necessary to remove a ganglion cyst or an osteophyte, or to simply divide the extensor retinaculum [88–90].

Superficial Fibular Mononeuropathy

Etiology

It is extremely rare for fibular nerve lesions at the fibular neck to affect the superficial fibular nerve only, without greater damage to the deep fibular nerve [13–15]. Superficial fibular mononeuropathies are usually due to nerve entrapment in the distal leg or ankle. The sites of these lesions are located distal to the motor branches to the peroneus longus and brevis; the symptoms are purely sensory including pain. A common site of entrapment is at the facial defect, 10 cm above the lateral malleolus, where the nerve becomes superficial. Most reported cases have been in athletes, and common precipitating events include long marches, tight boots, or direct blunt trauma [92–94]. Rarely, tumors such as lipomas or neuromas, or herniation of muscle through the facial defect may entrap the superficial fibular nerve. Near the ankle, superficial fibular nerve injuries may be due to tight shoes or ski boots, neuromas, acute contusions of the nerve, or iatrogenic (such as during ankle arthroscopy or needle insertion) [4, 92, 95–97].

Clinical Presentation

Lesions to the superficial fibular nerve in the distal leg are uncommon. They manifest with sensory loss in the lower lateral third of the leg and dorsum of foot, excluding the first web space. Pain in the distal anterolateral leg is common. Both numbness and pain may be worse with walking or running. Tenderness of the leg or swelling or both may be evident. Occasionally, Tinel's sign may be induced there.

Ankle pain with or without numbness over the dorsum of the foot is the only manifestation of superficial fibular lesions at the ankle. The pain is variable and may be present at rest or with exercise. Symptoms may worsen with ankle plantar flexion or inversion. Tinel's sign may be present.

Evaluation and Diagnosis

The EDX studies in patients with superficial fibular mononeuropathy in the distal leg often reveal an absent or low-amplitude superficial fibular SNAP, with or without a delay in its distal latency [93]. In contrast, fibular motor NCS and needle EMG of all fibular-innervated muscles, including the peroneus longus and brevis, are normal.

With ankle lesions, the SNAP abnormalities are less consistent, partially since most superficial fibular sensory nerve techniques are performed proximal to these lesions, with stimulation in the distal leg and recording at the ankle [63, 64].

Plain foot X-rays or MRI may reveal the potential causes such as mass lesion, osteophyte formation, or bony deformity. A diagnostic nerve block is also useful in confirming the source of symptoms.

Treatment, Management, and Prognosis

Distal leg and ankle lesions of the superficial fibular nerve may respond to change of foot wear, use of a removable cast boot, or night splinting in neutral position. Nonsteroidal anti-inflammatory agents or local corticosteroid injection may be helpful. Nonresponders may require surgical exploration with fasciotomy, neurolysis, or both.

Many patients with superficial fibular sensory mononeuropathy have persistent chronic foot pain and causalgia [93, 94]. Ankle lesions are particularly notorious in resisting treatment and resulting in chronic pain and disability.

The Sciatic Nerve

Anatomy

Originating from the L4, L5, S1, and S2 roots, the sciatic nerve is formed from the lumbosacral plexus after the exit of the superior and inferior gluteal nerves. It is composed of a lateral division, named the common fibular nerve (formerly the common peroneal nerve or the lateral popliteal nerve), and a medial division named the tibial nerve (formerly the medial popliteal nerve).

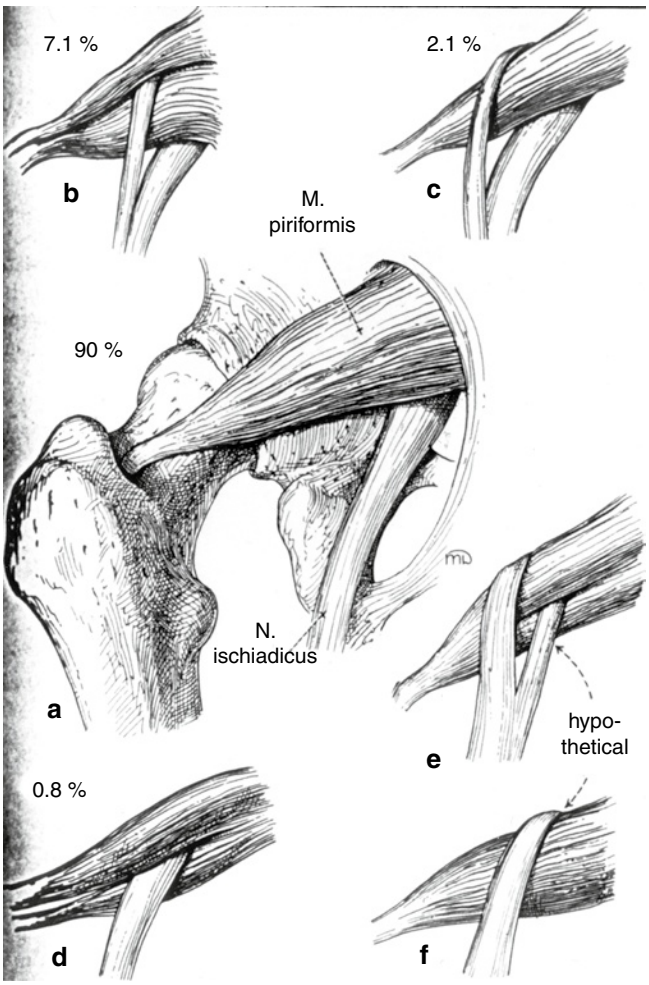

Fig. 41.9 Anatomic relationships of the sciatic nerve to the piriformis muscle. (**a**) the entire sciatic nerve passes underneath the piriformis muscle, (**b**) the fibular division pierces the piriformis muscle while the tibial exits underneath it, (**c**) the fibular division only exits above the muscle, (**d**) the entire sciatic nerve pierces the muscle, (**e**) and (**f**) hypothetical variations (Adapted from Beaton [99])

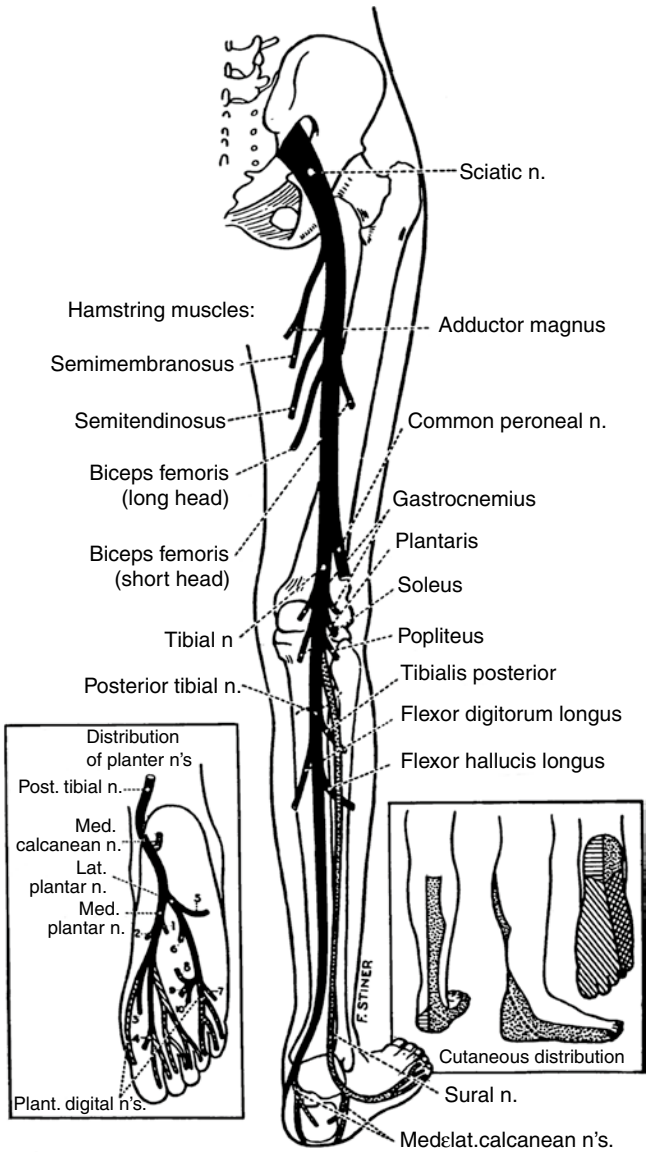

Fig. 41.10 The sciatic nerve and tibial nerves with motor and sensory branches (From Haymaker and Woodhall [393]. With permission)

Though enclosed in a common sheath, these two nerves are separate from the outset and do not exchange any fascicles [1].

The sciatic nerve leaves the pelvis via the sciatic notch, where the nerve has a close relation with the piriformis muscle, a flat pyramidal muscle, which originates from the front of the sacrum, the gluteal surface of the ilium, and the anterior capsule of the sacroiliac joint. The piriformis muscle leaves the pelvis via the greater sciatic foramen and inserts into the upper border of the greater trochanter, along with the obturator internus, gemelli, and quadratus femoris. All four muscles are external rotators of the hip. With the hip in the flexed position (such as while sitting), the piriformis is an abductor of the hip.

The interrelation between the piriformis and sciatic nerve anomalies is variable with a reported prevalence of "anomalies" ranging from 10 % to 30 % of individuals, but more realistically at about 16 % [98, 99]. Usually, the sciatic nerve passes underneath the piriformis muscle (Fig. 41.9). However, sometimes the fibular division only passes through or above the piriformis muscle, and, less frequently, the entire sciatic nerve pierces the piriformis muscle, or the nerve passes through the muscles or above it.

In the thigh, the tibial component of the sciatic nerve innervates most hamstring muscles (semitendinosus, semimembranosus, and long head of biceps femoris) and supplies a branch to the adductor magnus, while the common fibular component innervates the short head of biceps femoris only (Fig. 41.10). Usually, the common fibular and tibial nerves physically separate near mid-thigh or the upper popliteal fossa, but there is significant individual variability [1]. The common fibular nerve travels laterally and sweeps around the fibular head to travel in the anterior leg, while the tibial nerve continues posteriorly in the midline to enter the calf.

Sciatic Mononeuropathy at the Hip or Thigh

Etiology and Pathogenesis

Among the lower extremity mononeuropathies, sciatic nerve lesions at the hip are second in frequency only to fibular mononeuropathies. The sciatic nerve is predisposed to injury due to its close proximity to the hip joint and its relatively long course from the sciatic notch to the upper popliteal fossa. Since at least World War I, it has been known that partial sciatic nerve injuries usually affect the lateral division (common fibular nerve) more severely than the medial division (tibial nerve) [1]. This occurs independent of the causation of the sciatic nerve lesion. The greater vulnerability of the fibular division is due to the difference in the fascicular pattern and cushioning effect of the epineurium and the difference in the anatomical course between these two nerves (see above, the fibular nerve).

Hip replacement, dislocation, and fracture are the most common causes of sciatic nerve lesions at the hip (Table 41.8) [82–84, 100, 101]. Total hip joint replacement is a leading cause of such lesions, and sciatic mononeuropathy is the most common neurologic complication of total hip arthroplasty [100–102]. The estimated incidence of sciatic nerve lesion following total hip replacement is about 1–3 % [100, 101], although EDX studies may detect electrophysiological signs of sciatic nerve damage in as many as 70 % of patients [102]. The risk of sciatic nerve injury is higher in women, with procedures requiring limb lengthening, in patients with congenital hip dislocation or developmental dysplasia or undergoing total hip revisions [100, 101]. The sciatic nerve injury is often noted in the immediate postoperative period and is due to direct intraoperative stretch injury. Rarely, it is due to hemorrhage, prosthetic dislocation, migrating trochanteric wire, or leaking cement (methyl methacrylate) used in the arthroplasty [103, 104]. Occasionally, the onset is delayed for several years, usually due to prosthetic dislocation, osseous formation, or migrating trochanteric wire [104, 105]. Hip fracture or dislocation, or femur fracture, may also result in sciatic nerve injury, which may also occur during closed reduction or internal fixation [68, 82–84].

External compression of the sciatic nerve is the second common cause of sciatic nerve lesions at the hip. This occurs usually in the setting of unattended coma (such as with drug overdose) or coma associated with poor positioning (such as in the intensive care unit) [82, 106]. In many of these patients, the sciatic nerve injury is part of a gluteal or posterior thigh compartmental syndrome [106, 107]. Prolonged sitting, such as in "toilet seat" and "lotus" sciatic neuropathies or operative positioning in the sitting position, such as with craniotomy, may by itself cause sciatic compression [108–110]. Mass lesions in the buttock or thigh, such as malignant or benign tumors, persistent sciatic artery, vascular malformations (angioma, venous or arteriovenous malformation), or enlargement of the lesser trochanter (possibly from frequent sitting on hard benches), may compress the sciatic nerve [68, 84, 111–116].

Open sciatic nerve injuries are usually caused by gunshot wounds, knifes, or other sharp objects. Hemorrhage with the gluteal compartment is sometimes associated with sciatic nerve lesions. This may occur during anticoagulant therapy, in patients with hemophilia or Ehlers-Danlos syndrome, following hip surgery or due to rupture of an iliac artery aneurysm [100, 101, 106, 107]. Intramuscular gluteal injections, not administered properly in the upper outer quadrant of the buttock particularly in thin patients or children, may damage the sciatic nerve or its fibular component exclusively [68, 117–120]. This often occurs soon after the injection of a large quantity of a neurotoxic drug but may be delayed following repeated injections or due to fibrosis [120].

Sciatic mononeuropathies as a manifestation of endometriosis are an uncommon condition typically caused by pelvic endometriosis affecting the lumbosacral plexus or proximal sciatic nerve [121–123]. Menstruating women may have cyclic radicular pain ("catamenial sciatica") which waxes and wanes with the menstrual cycle. The majority of patients have cyclical radicular pain, but occasionally the patient develops fluctuating foot drop and signs of overt

Table 41.9 Differential diagnosis between fibular neuropathy at fibular head and sciatic neuropathy affecting predominantly the common fibular nerve

Symptom/sign	Sciatic nerve lesion affecting predominantly the common fibular nerve	Common fibular nerve lesion at the fibular head
Foot pain	Common	Rare
Radicular pain "Sciatica"	Common	Absent
Straight leg raise "Lasègue test"	Positive	Negative
Ankle jerk	Often depressed or absent	Normal
Ankle inversion	Often weak	Normal
Toes flexion	Often weak	Normal
Plantar flexion	May be weak	Normal
Tinel's sign at fibular neck	Negative	Common
Sensory loss	May extend into upper third of lateral leg[a] or sole[b]	Distal two thirds of lateral leg and dorsum of foot

[b]Tibial nerve distribution

sciatic mononeuropathy [123]. Typically, the symptoms start few days before menstruation and stop after menses end. With progression of disease, the manifestations of endometriosis become more constant, though often worse during menses.

Ischemic injuries to sciatic nerve may be due to small vessel disease, as with vasculitis involving the vasa nervorum, or large vessel disease, as with iliac or femoral artery occlusion [82, 84, 124, 125]. Similar injuries were described in patients with cardiac surgery, usually with intra-aortic balloon pump therapy with a catheter placed through the ipsilateral femoral artery [126, 127]. It is not clear whether the injury in the latter patients is due to selective sciatic nerve ischemia or to a distal axonopathy due to watershed ischemia of the lower limb (i.e., monomelic ischemic neuropathy) [128, 129].

Sciatic nerve lesions in children are rare and traumatic and iatrogenic causes constitute about 50 % of the cases [84, 124]. Less frequent causes include tumors, extrinsic compression and immobilization, and vascular causes [125]. In about 15–20 % of patients with sciatic nerve lesions, particularly children and young adults may develop a slowly progressive idiopathic sciatic mononeuropathy. These cases have evidence of axonal loss on EDX testing. No cause is identified despite imaging studies and surgical exploration [84, 130, 131].

Clinical Presentation

Sciatic mononeuropathy presents with weakness, pain, and sensory loss [82, 84, 105]. The foot weakness commonly manifests as a foot drop, since the fibular component is usually more affected than the tibial. Though weakness of tibialis anterior dominates the picture, careful examination often detects weakness of hamstrings (knee flexion), gastrocnemius (plantar flexion), or tibialis posterior (ankle inversion). Occasionally, sciatic nerve lesions in the hip are essentially pure high common fibular lesions, manifesting similar to common fibular lesions at the fibular neck (see above, the fibular nerve) [68]. In contrast, severe sciatic nerve lesions are associated with a flail foot (i.e., weak foot and ankle in all directions) and hamstring weakness.

Foot pain and dysesthesia are common symptoms of sciatic nerve injuries. This may give rise to diagnostic confusion since the site of pain is distant from the site of the lesion in the hip or thigh. Not infrequently, signs of complex regional pain syndrome (allodynia with skin, nail, and bone dystrophic changes) become dominant and disabling.

The ankle jerk is usually asymmetrically depressed or absent, a useful clinical clue in patients with mild sciatic lesions. Sensory loss and dysesthesia of the sole and dorsum of the foot and lateral leg are common.

Differential Diagnosis

Severe or complete sciatic nerve lesions pose little difficulty in diagnosis since the weakness involves all muscles along the knee, often with the hamstrings. Also, the sensory loss below the knee spans both the fibular and tibial distributions while sparing the medial leg (saphenous nerve distribution). In contrast, partial sciatic nerve lesions, which usually present with foot drop, may be difficult to differentiate from fibular mononeuropathy, lumbosacral radiculopathy, and lumbosacral plexopathy (see Table 41.3). There are clinical hints which are useful in distinguishing a sciatic mononeuropathy from fibular nerve lesion at the fibular neck (Table 41.9). Lumbosacral radiculopathies, particularly when the L5 and S1 roots are involved, may mimic partial sciatic nerve lesions. The lack of back pain and well-demarcated sensory loss favors a sciatic lesion. Lumbosacral plexopathies, particularly those involving the lumbosacral trunk mainly, are often mislabeled as a sciatic mononeuropathy. These lesions are often due to pelvic fracture, hematoma, or fetal head compression during a labor in women with short stature or delivering large babies [38, 39].

Sciatic nerve lesions may be difficult to separate from acute ischemic monomelic mononeuropathy, since all muscles below the knee are innervated by the sciatic nerve (see Chap. 37) [128, 129]. A history of large vessel compromise in the involved limb is common in ischemic monomelic neuropathy. In sciatic nerve lesions, there is usually preservation of saphenous sensory territory, while the sensory loss in ischemic monomelic neuropathy is diffuse in the involved leg with a stocking glove distribution.

In sciatic nerve lesions, particularly when partial or presenting with foot drop, EDX studies are often necessary for final confirmation and exclusion of all the above lesions (see Table 41.4).

Evaluation and Diagnosis

Electrodiagnostic Studies

The EDX findings in sciatic mononeuropathy parallel the clinical manifestations. Often, the EDX study unveils involvement of the tibial nerve which could not be detected clinically despite careful neurological examination. The EDX examination often confirms the presence of axon-loss sciatic mononeuropathy and helps to exclude a common fibular nerve lesion around the fibular neck, a lumbosacral radiculopathy or plexopathy. It is not uncommon for the NCS to suggest that the lesion is an axon-loss common fibular mononeuropathy, since the fibular nerve is often affected more severely than the tibial nerve. Helpful clues for the presence of a sciatic nerve lesion on nerve conduction studies include an asymmetrically low or absent sural SNAP or H-reflex, or an asymmetrically low-amplitude M-response recording soleus/gastrocnemius (recorded during H-reflex testing), or tibial CMAP recording abductor hallucis. Therefore, it is highly recommended that the contralateral H-reflex, M-response, sural sensory and tibial motor nerve conduction studies be done in all patients with foot drop, especially when a sciatic nerve lesion is considered.

It is important to recall that the sural nerve is formed by the medial sural cutaneous nerve, which originates from the tibial nerve in the popliteal fossa, and fibular (peroneal) communicating nerve (also called the lateral sural nerve), which originates from the common fibular nerve in the popliteal fossa. These two branches join in the calf to form the sural nerve. This fibular communicating nerve is present in 40–84 % of dissected cadavers and contributes to about 30–40 % of the antidromic sural SNAP (stimulating at the calf and recording at the ankle) with minimal side-to-side difference [132]. Thus, an abnormally low-amplitude sural SNAP does not automatically indicate involvement of the tibial nerve.

The needle EMG is frequently necessary to confirm that the foot drop is a sciatic nerve lesion. The common fibular-innervated muscles are usually significantly denervated. Among tibial-innervated muscles, those located below the knee, such as the abductor hallucis, flexor digitorum longus, and gastrocnemius (medial and lateral heads), are most useful by revealing fibrillation potentials and neurogenic changes. This is especially important when the lesion is relatively chronic and the hamstrings were allowed to reinnervate. The hamstring muscles innervated by the tibial nerve (semitendinosus, semimembranosus, and long head of biceps femoris) may also reveal fibrillation potentials, decreased recruitment, and large MUAPs. The short head of biceps femoris, innervated by the common fibular nerve, is frequently much more affected than the other hamstrings. Finally, one may occasionally find neurogenic changes in the thigh adductors, particularly in severe sciatic nerve injuries, since the adductor magnus receives dual innervation from the sciatic as well as the obturator nerves. The needle EMG in these cases is not complete unless the glutei, tensor fascia lata, and lumbar paraspinal muscles are sampled to exclude a lumbosacral plexopathy or radiculopathy.

On rare occasions, the common fibular component of the sciatic nerve is selectively injured in the hip or thigh (see above, the fibular nerve) [68]. In these occasions, the H-reflex, and sural sensory and tibial motor conduction studies, as well as all tibial-innervated muscles above and below the knee are normal. These lesions are purely axonal and mimic a common fibular mononeuropathy at the fibular neck. Thus, sampling the short head of biceps femoris is mandatory in all patients with fibular mononeuropathy, especially those axonal ones which could not be localized by NCS due to the lack of conduction block or focal slowing.

Ancillary Testing

Plain X-rays of the hip is useful in the diagnosis of hip dislocation or fracture. CT of the pelvis and gluteal compartment, urgently in patient with possible compartmental syndromes, may reveal a hematoma or significant compartmental swelling. MRI is also useful in the diagnosis of endometriosis or nerve tumor as a cause of sciatic mononeuropathy [133].

Treatment, Management, and Prognosis

Patients with gluteal compartmental syndrome should undergo emergency surgical decompression. Surgical intervention is required for patients with hip fracture, dislocation, or prosthetic hip dislocation. Surgical exploration and neurolysis or surgical repair with sutures or grafts is also indicated for patients with sciatic nerve lesions due to lacerations, gunshot wounds, and hip replacement [134, 135]. Surgical management should be guided by intraoperative nerve action potential recordings. Partial or complete surgical excision should be attempted in sciatic neurogenic tumors [113]. Patients with mild manifestations of sciatic mononeuropathy due to endometriosis may respond to pharmacologic suppression of the ovarian cycle [122, 123]. Those with severe symptoms require surgical resection of endometrial foci and adhesions. When the above fails, particularly when reproduction is not an issue, a permanent

cure may be accomplished by surgical menopause through bilateral oophorectomy.

Most symptomatic sciatic nerve lesions require pain management. Anticonvulsants, such as gabapentin or pregabalin, and antidepressants, such as duloxetine or tricyclics, are the drugs of choice. This, coupled with physical therapy and ankle-foot orthosis for foot drop, often assists patients in ambulation.

The prognosis of sciatic nerve lesions is generally guarded. At least 1/2 of patients with sciatic nerve lesions following total hip arthroplasty recover completely, while 15 % have a poor outcome with significant weakness, pain, and sensory loss [100, 101]. In general, patients with severe lesions have significant residual weakness, while partial lesions may improve significantly due to reinnervation. Many patients are left with chronic foot pain and signs of complex regional pain syndrome.

The Piriformis Syndrome

Etiology and Pathogenesis

The piriformis syndrome is an ill-defined and controversial entity. It is proposed that leg pain ("sciatica") may be caused by compression of the sciatic nerve at the pelvic outlet by the piriformis muscle. In 1928, Yeoman was the first to refer to the piriformis muscle as a possible cause of sciatic nerve entrapment [136]. He suggested that periarthritis of the anterior sacroiliac ligament may extend into the piriformis muscle and the adjacent sciatic nerve. Later in 1947, Robinson coined the term "piriformis syndrome" and set six criteria for diagnosis: history of trauma to the buttock, pain in the buttock extending to the leg, worsening of pain by stooping or lifting, palpable and tender sausage-shaped mass over the piriformis muscle, positive Lasègue sign, and possible gluteal atrophy [137]. The piriformis syndrome was popularized in the thirties and forties based on the close relation between the sciatic nerve and the piriformis muscle, but has become less known since the advances of radiological techniques (myelography, CT, and MRI) that have demonstrated that many patients with sciatica harbor a lumbosacral radiculopathy due to nerve root compression within the spinal canal. The lack of objective clinical findings and confirming investigations has increased the controversies and severely compromised the credibility of this syndrome [138, 139]. Also, despite the high incidence of anomalous relationship between the sciatic nerve and the piriformis muscle, the prevalence of these anomalies in patients is not significantly different treated with surgical intervention for in piriformis syndrome are compared to the general population. This suggests that the anatomical variation may not be as important in the pathogenesis of this syndrome [98, 99].

There is a recent resurgence of interest in the piriformis muscle in an attempt to explain the cause of sciatica and buttock pain in patients with no demonstrable nerve root compression on imaging studies [140]. Currently, there is a great controversy among physicians as to the frequency and, even, existence of this syndrome [138, 139]. The piriformis syndrome is likely a very rare cause of leg pain and sciatica, and only a small number of such patients have "true" piriformis syndrome. Typically, these are women with a history of trivial trauma to the buttock, who have exquisite buttock tenderness near the sciatic notch, and EDX findings of a mild axon-loss sciatic mononeuropathy, with or without an inferior gluteal mononeuropathy. At operation most of these patients have an anomalous band (or vessel), in the region of the piriformis muscle, compressing the sciatic nerve [141, 142]. This suggests that in these selected cases of sciatic neuropathy at the sciatic notch, the piriformis muscle plays no role in pathogenesis and is likely a mere innocent bystander.

Clinical Presentation

The piriformis syndrome is up to six times more common in women than men. Often patients complain of buttock pain and tenderness that may (or may not) radiate down the thigh and lower leg. Most patients are aware of point tenderness in the buttock which is usually near the sciatic notch. The pain is worse with prolonged sitting (such as while driving or biking), during bending at the waist, or during an activity that requires hip adduction and internal rotation (such as cross-country skiing). It is often much relieved with standing or walking. Dyspareunia in women or pain with bowel movements are not uncommon symptoms. Back pain is usually absent or minimal. Paresthesias of the buttock and/or in a patchy sciatic nerve distribution are not uncommon. There is usually no objective weakness. A history of buttock trauma is common in most patients with the piriformis syndrome. Prolonged sitting on hard surfaces may also trigger this syndrome (hence the terms "wallet neuritis" and "hip pocket neuropathy").

The absence of physical signs is considered an essential criterion for the diagnosis, which is also a major criticism for the existence of the piriformis syndrome. In contrast to other causes of sciatic neuropathy, the piriformis syndrome is not associated with weakness, reflex changes, or definitive sensory loss.

Reproduction of sciatica upon deep palpation in the sciatic notch or upon rectal or pelvic examination is common and considered by some as diagnostic [140, 143]. Patients with piriformis syndrome tend to walk with their leg externally rotated. This is sometimes seen when the patient is in a supine position (positive piriformis sign). A positive Trendelenburg test in which the patient stands on the asymptomatic foot and the buttock of the unsupported foot falls (rather than rise) may be present. This suggests weak gluteal

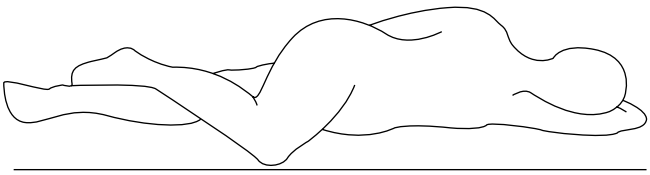

Fig. 41.11 The FAIR test (*f*lexion, *a*dduction, and *i*nternal *r*otation) in the diagnosis of the piriformis syndrome

muscles, as seen in few patients with the piriformis syndrome. More rarely, there may be mild wasting of the buttock (gluteus maximus) due to concomitant entrapment of the inferior gluteal nerve.

Many proponents of the piriformis syndrome rely on the presence of positive test maneuvers in the bedside diagnosis of the piriformis syndrome [140]. These may be divided into two categories: one in which passive stretching of the piriformis muscle and the other in which active contraction (with resistance) of the piriformis muscle occur. Pain in the affected buttock (and sometimes thigh) during the maneuver is considered a positive test.

- *Freiberg test.* Passive forceful internal rotation of the extended thigh at the hip while the patient is lying reproduces the pain. Unfortunately, this test may be positive in other disorders around the hip joint and buttock.
- *Pace test.* Resisted abduction of the thigh induces buttock pain. This is usually done while the patient is in the sitting position, but may be difficult to do because of pain induced by sitting.
- *Beatty test.* An alternative method to the Pace test. It is done with the patient lying with the painful side up, and the painful leg semi-flexed, and the knee resting on the table [143]. Deep buttock pain is produced when the patient lifts (abducts the thigh) and holds the knee several inches off the table. In herniated lumbar discs, the maneuver often produces lumbar and leg pain but not deep buttock pain, while in primary hip abnormalities, pain was often produced in the trochanteric area but not in the buttock.
- *Flexion, adduction, and internal rotation (FAIR) test.* The patient lies on the unaffected side, bends the knee of the affected leg to a 90° angle and catching the foot behind the calf of the affected leg, and swings the affected leg over the healthy one until the knee touches the examining table (Fig. 41.11). The FAIR maneuver often reproduces the buttock pain and sciatica. The FAIR test correlates well with patients with true piriformis syndrome and is a better predictor of successful physical therapy and surgery [144].

More recently, criteria for the diagnosis have been proposed. Fishman proposed the following criteria: (1) positive Lasègue sign at 45°, (2) tenderness at the sciatic notch, (3) increased pain in the sciatic distribution with the thigh in the FAIR position, and (4) EDX studies that exclude myopathy or neuropathy [138, 144].

Differential Diagnosis

Buttock pain and tenderness with or without back pain are common symptoms and may be caused by a variety of disorders including lumbosacral radiculopathy, bursitis, and hip joint disease. In all of these entities, referred pain down the thigh and tenderness in the buttock is possible. Also, many of the maneuvers used in the diagnosis of the piriformis syndrome are nonspecific, subjective, and often positive in a variety of disorders of the hip and buttock.

The major differential diagnosis of patients with suspected piriformis syndrome is a lumbosacral radiculopathy, particularly an L5 or S1 radiculopathy. Sciatica is a common symptom of radiculopathies and is often associated with low back pain. In contrast to the piriformis syndrome, the pain in lumbosacral radiculopathy is often worse with standing or walking. Finally, pain with sitting and exquisite tenderness in the sciatic notch is rare in lumbosacral radiculopathies.

Evaluation and Diagnosis

The piriformis syndrome is a clinical diagnosis often supported by the patient's history and few of the findings on the clinical examination. EDX and imaging studies are useful, mostly in excluding other entities such as lumbar spine disease or mass lesions compressing the sciatic nerve.

Electrodiagnostic Studies

In the majority of cases of piriformis syndrome, the EDX studies (NCS and needle EMG) are normal, which has kept the controversy around this syndrome active. The sural sensory and fibular and tibial motor nerve conduction studies, as well as the F waves and H-reflexes, are normal and symmetrical [145]. Chang et al. found significant slowing of the sciatic motor nerve conduction velocity in the gluteal segment of the sciatic nerve with magnetic stimulation of the L5, but not S1, nerve root [145]. Fishman and colleagues found also that the H-reflex, done at rest and during the FAIR maneuver, displays an asymmetrical delay in latency during the FAIR test in patients with the piriformis syndrome [144, 146]. On needle EMG, reports of rare cases have revealed denervation changes on needle EMG of the hamstring muscles and gastrocnemius. These patients often have fibrous band or aberrant artery compressing the sciatic nerve in the region of the piriformis muscle [141, 142, 145].

Imaging

Imaging of the spine is essential in excluding lumbar radiculopathy as the causation of leg pain. Imaging of the sciatic notch is helpful in excluding a tumor or hematoma. MRI of the sciatic notch may show hypertrophy of the piriformis in patients with suspected piriformis syndrome [147, 148]. MRI also often shows the relation between the sciatic nerve and piriformis muscle and its anomalies [147]. Occasionally, MRI have helped in identifying abnormal vessels or bands in

the region of the piriformis muscle, though these MRI findings (bands, vessels, hypertrophy of piriformis) are equally common in asymptomatic subjects or on the asymptomatic sides of patients.

Diagnostic Nerve Block

Relief of symptoms by a nerve block with corticosteroids or lidocaine in the region of the sciatic notch is considered a diagnostic confirmation of the piriformis syndrome. However, opponents of this syndrome argue that pain relief from corticosteroid injection is not a proof that the sciatic nerve is compressed by the piriformis muscle. Patients with distal nerve or proximal root lesions (such as lumbosacral radiculopathies) often get pain relief by sciatic nerve blocks.

Management, Treatment, and Prognosis

Therapy of the pain syndrome in patients with the piriformis syndrome includes one of the following methods:

Conservative therapy. This should be the initial treatment and is aimed at relaxing the tight piriformis muscle. As a home program, the patient is instructed to perform prolonged stretching of the piriformis muscle by flexion, adduction, and internal rotation of the symptomatic hip. This could be done in the supine and standing positions. The patient should hold the leg in the stretched position for 5 s and gradually increase to 60 s [149, 150]. Moist heat or ultrasound prior to stretching is often useful.

Corticosteroid and lidocaine injection. Injection into the piriformis muscle with corticosteroids with or without lidocaine preferably done under imaging (CT or MRI) guidance has been advocated. This has been reported to be effective in almost 2/3 of the patients, particularly those with a positive FAIR test. The muscle may be injected through the sciatic notch, from the perineum, or through the vagina.

Botulinum toxin. Botulinum toxin type A (Botox or Dysport) or type B (Myobloc) is injected usually with CT guidance into the piriformis muscle. Several trials demonstrated better efficacy with botulinum toxin-A over both placebo and corticosteroid with lidocaine [140, 151–154]. The effects persist for up to 3 months. If done with piriformis stretching therapy, there is usually a reduction in the need for repeated injections.

Surgery. Surgical exploration of the sciatic nerve in the region of the piriformis muscle should be reserved to patients who have failed conservative or injection therapies [140–142]. Section of the piriformis muscle is the most popular advocated procedure, but its value is uncertain. Abnormal bands or vessels constricting the sciatic nerve in the buttock, if encountered, should also be removed (Fig. 41.12). The success rate of surgery is unknown but failures have been reported [155]. Fishman et al. reported that 68 % of carefully selected patients with the piriformis syndrome showed a 50 % or greater improvement in pain at a mean follow-up of 16 months [144]. Surgical release should be considered a treatment of last resort, since it could be hazardous since it may lead to debilitating sciatic nerve injury [156].

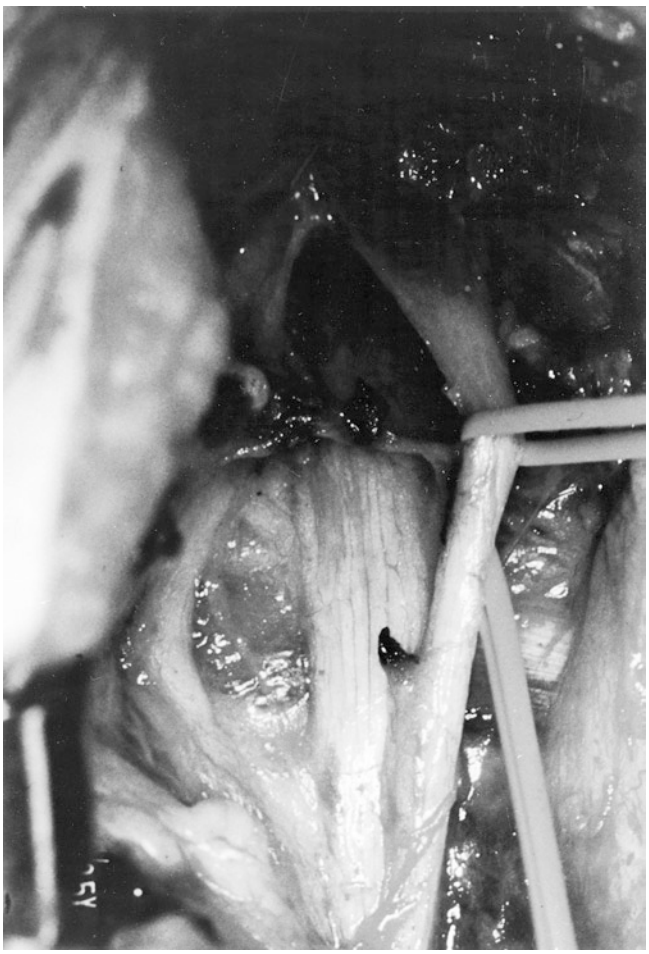

Fig. 41.12 Intraoperative findings in a patient with the piriformis syndrome, revealing a compressive band over the tibial component of the sciatic nerve. The fibular component is pulled away and the piriformis muscle has been divided (Courtesy of Drs. Henry H. Bohlman and Cheryl A. Petersilge)

The prognosis of patients with the piriformis syndrome is unknown because of its controversial nature. Good outcome has been reported in patients treated with botulinum toxin injection with piriformis stretching [152]. Surgical intervention is useful in about 50 % of the patients [144], particularly those with abnormal EMG findings or with compressive bands or vessels [142, 157].

The Tibial Nerve

Anatomy

The tibial component of the sciatic nerve innervates all of the hamstring muscles except the short head of the biceps femoris which is supplied by the common fibular nerve. The tibial nerve

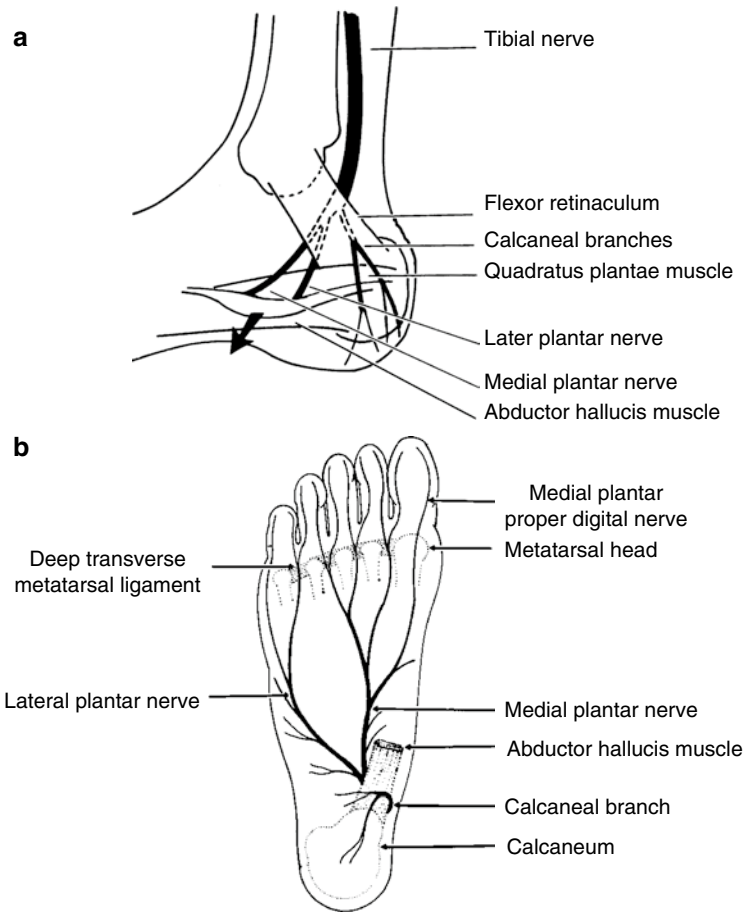

Fig. 41.13 The course of the distal tibial nerve and its terminal branches. (**a**) Medial view and (**b**) plantar view (From Dyck and Thomas [396] and Stewart [397]. With permission)

(sometimes referred to as the posterior tibial nerve [158]) separates completely from the common fibular nerve in the upper popliteal fossa (see sciatic nerve). Soon, it gives off its first branch, the sural nerve, a purely sensory nerve which innervates the skin over lateral aspect of the lower leg and foot including the little toe. In 80 % of individuals, the sural sensory nerve is joined by a sensory branch, referred to as the sural communicating nerve, fibular communicating nerve, or the lateral sural nerve (with the main sural nerve as the medial sural nerve), which originates from the common fibular nerve in the popliteal fossa. Then, the sural nerve runs between the Achilles tendon and lateral malleolus and innervates the lateral side of the ankle and lateral border of the sole up to the base of the fifth toe.

In the upper calf, the tibial nerve dips underneath a tendinous arch of soleus muscle, the fibromuscular soleal sling, and innervates the gastrocnemius, soleus, tibialis posterior, flexor digitorum profundus, and flexor hallucis longus (see Fig. 41.10). Beyond the soleus arcade, the tibial nerve is sometimes referred to as the posterior tibial nerve.

At the ankle, the tibial nerve passes posterior to the medial malleolus and through the tarsal tunnel (also called medial tarsal tunnel) to enter the foot. The tarsal tunnel is roofed by the laciniate ligament (flexor retinaculum) which extends between the medial malleolus and the calcaneus. It contains,

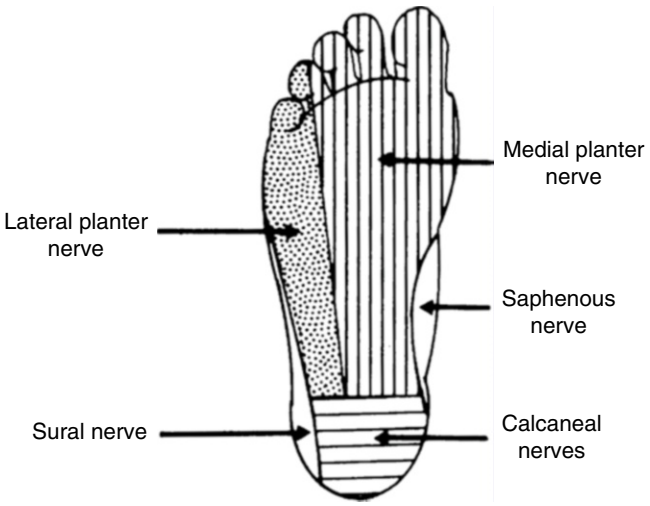

Fig. 41.14 Cutaneous innervation of the sole of the foot (From Dyck and Thomas [396]. With permission)

in addition to the tibial nerve, the posterior tibial artery and the tibialis posterior, flexor digitorum longus, and flexor hallucis longus tendons. There or slightly distal to that point, the tibial nerve divides into its three terminal branches (Figs. 41.13 and 41.14) [159]: (1) the calcaneal branch, a

purely sensory nerve, that innervates the skin of the sole of the heel; (2) the medial plantar nerve which innervates the abductor hallucis, flexor digitorum brevis, and flexor hallucis brevis in addition to the skin of the medial sole and, at least, the medial three toes; and (3) the lateral plantar nerve which innervates the abductor digiti quinti pedis, flexor digiti quinti pedis, adductor hallucis, and the interossei in addition to the skin of the lateral sole and two lateral toes.

The interdigital nerves are sensory branches which arise from the medial and lateral plantar nerves. Similar to the digital branches in the hand, each interdigital nerve in the foot innervates the skin on the sole of two opposing toes. Exceptions are the medial plantar proper digital nerve and lateral plantar proper digital nerve which innervates the medial side of the great toe and the lateral side of the little toe, respectively. Before entering the toes, the interdigital nerves cross over the metatarsal heads and the deep transverse metatarsal ligaments which connect the metatarsal heads (Fig. 41.13).

Proximal Tibial Mononeuropathy

Tibial nerve lesions proximal to the ankle are rare and most are located near the popliteal fossa. The nerve may be compressed by a Baker's cyst [160, 161], intraneural ganglion (likely originating from the superior tibiofibular ganglion cyst) [162, 163], a hematoma [164], or a fibrous band or the aponeurotic arch of the soleus muscle ("soleal sling syndrome") [165–168]. The proximal tibial nerve may also be injured during surgical procedures involving the knee [169, 170]. Nerve sheath tumors, including schwannomas and neurofibromas, may arise in the tibial nerve near the popliteal fossa [171, 172].

Clinically, these lesions often present with foot pain and numbness and pose a diagnostic challenge since they may mimic a tarsal tunnel syndrome [172]. This may be aggravated, particularly in patients with nerve compression by the tendinous arch of the soleus, by passive ankle dorsiflexion, and, sometimes, by active dorsiflexion or plantar flexion. Tenderness in the popliteal fossa and upper calf and a positive Tinel's sign on percussion of the tibial nerve in the lower popliteal fossa are common and useful localizing signs [165]. Weakness of plantar flexion, toe flexion, and ankle inversion with absent ankle jerk is not common, but, when present, helps to guide the clinician away from the tarsal tunnel. Also, sometimes the sensory loss not only involves the foot but extends into the lateral border of the foot (sural nerve distribution).

The EDX studies of tibial nerve lesions in the popliteal fossa may be normal or reveal evidence of an axon-loss proximal tibial mononeuropathy. The tibial CMAPs, recording abductor hallucis and abductor digiti minimi pedis, are low or absent. There is no accompanying focal slowing across the ankle as seen in some patients with the tarsal tunnel syndrome. Tibial distal latencies and proximal conduction velocities are normal or diffusely borderline or slow. The sural SNAP may be normal, low, or absent depending on whether the lesion is distal or proximal to the takeoff of the nerve in the popliteal fossa. Needle EMG may reveal denervation usually in the intrinsic muscles of the foot, but, at times, in both heads of gastrocnemius, soleus, tibialis posterior, or flexor digitorum longus. In contrast, the fibular NCSs and needle EMG of the hamstrings and all common fibular-innervated muscles are normal unless there is a concomitant fibular nerve palsy [164]. The EDX examination may have difficulty distinguishing these lesions from S1/S2 radiculopathies when the sural SNAP is normal or from tarsal tunnel syndrome when the proximal tibial nerve lesion is fascicular resulting in sparing of the gastrocnemius and soleus muscles. Detecting denervation in the gluteus maximus, gluteus medius, and lumbar paraspinal muscles confirms an S1/S2 radiculopathy. Focal slowing of the tibial motor distal latencies or mixed plantar latencies is a useful distinguishing EDX feature, but unfortunately not a common, localizing finding in the tarsal tunnel syndrome (see below).

The treatment of tibial nerve lesions in the popliteal fossa is often surgical. Removing the cystic lesion, nerve sheath tumor, or hematoma is often indicated. Division of the tendinous arch of the soleus muscle with neurolysis of the tibial nerve often leads to relief of pain and improvement of muscle strength in more than half of the patients [165, 168].

Tarsal Tunnel Syndrome

Etiology and Pathogenesis

Tarsal tunnel syndrome (TTS) was first described by Keck in 1962 [173]. Its true incidence is unknown, though it is an uncommon entrapment mononeuropathy. TTS is not as well understood as its counterpart in the hand, the carpal tunnel syndrome [174]. TTS is sometimes referred to as the medial tarsal tunnel syndrome, to distinguish it from the anterior tarsal tunnel syndrome which is an entrapment of the terminal segment of the deep fibular nerve under the extensor retinaculum in the dorsum of the foot (see fibular nerve above).

TTS is caused by compression of the tibial nerve or any of its three terminal branches under the flexor retinaculum [85, 174, 175]. The disorder is insidious in onset, more common in women and is usually unilateral. Bilateral TTS is rare accounting for less 10–20 % of cases. Most cases of TTS are idiopathic with no clear precipitating cause (Table 41.10). Ankle trauma, particularly sprains and fractures, is the second most common cause of TTS [175]. The trauma is usually remote and often sports related, and the entrapment is due to fibrosis or bony changes within the tarsal tunnel space. Athletes, including runners, joggers, and dancers, are

Table 41.10 Causes of tarsal tunnel syndrome

Systemic lupus erythematosus
Hypothyroidism
Hyperlipidemia

particularly at high risk for developing TTS [176, 177]. Arthritis and tenosynovitis of the ankle may be associated with TTS [178, 179]. Rheumatoid arthritis is the most common systemic disorders associated with TTS. The prevalence of TTS in patients with rheumatoid arthritis is about 5 % [178, 179], while, based on electrophysiological criteria, TTS may be present in up to 15 % of patients with rheumatoid arthritis [179]. Other systemic disorders, including diabetes mellitus, acromegaly, hypothyroidism, systemic lupus erythematosus, and hyperlipidemia, may be associated with TTS [180, 181]. Finally, biomechanical causes, such as ill-fitting foot wear or heel varus and valgus deformity, may precipitate TTS [85, 173, 175]. Hypertrophic or anomalous abductor hallucis mass lesion within the tarsal tunnel (ganglion, lipoma, schwannoma) or varicose veins occupying the tarsal tunnel space are not uncommon findings on MRI or on surgical exploration for TTS [182–185]. Tibial nerve lesions at the ankle may be iatrogenic, such as after ankle arthroscopy [186, 187].

Clinical Presentation

The most common symptoms of TTS are burning pain and numbness in the sole of the foot and heel. The pain may worsen, or occur only, after prolonged standing, walking, jogging, or running. Occasionally, the pain radiates proximally to the calf. Subjective weakness or imbalance is extremely rare. The neurological examination reveals sensory impairment in the sole in the distribution of one or all of the terminal tibial branches (medial plantar, lateral plantar, or calcaneal). In 40 % of patients, the heel is spared when the calcaneal branch takes off before the flexor retinaculum, while in 25 % of patients, the sensory loss involves all three terminal branches territory. In 25 % of TTS patients, the sensory loss is only in the medial plantar nerve distribution, while in 10 % it follows the lateral plantar nerve selectively. The sensory manifestations may be triggered or exaggerated by foot eversion. Tinel's sign, induced by percussion of the tibial nerve at the flexor retinaculum (behind the medial malleolus), is present in most patients [175, 188]. Muscle wasting in the sole is rare. Weakness is usually not detected since the long toe flexors are intact. The ankle jerk and sensation of the dorsum and lateral foot are normal.

Differential Diagnosis

TTS may be difficult to distinguish from other common orthopedic, rheumatological, and neurological conditions particularly in patients with a prior history of foot or ankle trauma. Plantar fasciitis, stress fracture, arthritis, or bursitis causes foot pain. However, the pain in these latter conditions is usually worse in the morning, improves with walking, and is not associated with paresthesia or Tinel's phenomenon. Complex regional pain syndrome, with or without ankle trauma, leads to severe foot burning pain, but is often associated with swelling, skin trophic changes, and poorly localized dysesthesia.

Proximal tibial mononeuropathy particularly when caused by nerve compression by the tendinous arch of the soleus muscle (the soleal sling syndrome) [165, 168], or a sciatic mononeuropathy affecting the tibial component particularly when due to nerve sheath tumors [172], often presents with indolent symptoms that may mimic TTS. These lesions may present with foot pain and numbness, but they are often associated with calf weakness or atrophy and absent or depressed ankle jerk, findings not consistent with TTS. An S1 or S2 radiculopathy, in isolation or as a component of lumbar spinal canal stenosis, may result in foot numbness or pain which is often worse with walking or standing. However, there is usually low back and posterior thigh pain ("sciatica"), depressed or absent ankle jerk, or weakness of gastrocnemius or glutei muscles.

A particularly troublesome task is distinguishing patients with TTS from those with early sensory peripheral polyneuropathy, particularly in the elderly. A useful feature is that TTS is rarely bilateral while peripheral polyneuropathy often affects both feet. Also, the sensory loss in polyneuropathy usually involves both the sole and dorsum of foot and is rarely associated with Tinel's sign at the flexor retinaculum.

Lesions of the medial or lateral plantar nerves at the tarsal tunnel may mimic selective lesions of these nerves within the sole of the foot. Causes of *medial plantar mononeuropathy* distal to the tarsal tunnel include trauma, jogging, bunion surgery, foot deformities (such as pes cavus), arthritis or synovial cyst of the first metatarsophalangeal joint, schwannoma, or entrapment at the abductor tunnel [189–192]. The

clinical manifestations and the EDX findings are indistinguishable from TTS affecting the medial plantar nerve selectively. A careful history and a Tinel's sign distal to the tarsal tunnel are useful features. *Lateral plantar mononeuropathy* distal to the ankle is extremely rare and is also indistinguishable from TTS affecting the lateral plantar nerve selectively. These lesions are usually due to fracture, trauma, or a schwannoma [193, 194].

TTS affecting the medial plantar nerve selectively should be distinguished from *Joplin's neuroma* [195–197]. This is due to selective lesion to the medial plantar proper digital nerve to the great toe, which innervates the skin on the medial aspect of the great toe. Joplin's neuroma is often caused by trauma, bunion, callus, or biomechanical imbalances such as using tight or ill-fitting shoes. There is usually perineural fibrosis on pathological examination. The symptoms include pain and numbness in the medial great toe and, occasionally, Tinel's sign by percussion of the first metatarsophalangeal joint. Abnormality of the sensory NCS of the medial plantar proper digital nerve, using near-nerve recording at the ankle with surface stimulation at the great toe, was described but is not popular [198].

Evaluation and Diagnosis

The diagnosis of TTS is often made on clinical grounds with supports from ancillary testing such as EDX studies, plain X-rays, tomogram, bone scan, and MRI. Careful clinical evaluation of the ankle and foot is essential, and EDX studies are often necessary for correct diagnosis.

Electrodiagnostic Studies

Several EDX techniques are used to assess for TTS. Most of these involve assessing sensory or motor nerve fibers that traverse the medial or the lateral plantar nerves. The following are the most commonly utilized studies in patients with suspected TTS:

1. *Tibial motor NCSs recording from the abductor hallucis (medial plantar motor NCS) and the abductor digiti quinti pedis (lateral plantar motor NCS).* These are the first NCSs described to diagnose TTS [173]. Prolonged medial and/or lateral plantar distal latencies, using absolute values or by comparing to the contralateral asymptomatic limb, are considered diagnostic. Although these studies are easy to perform, they are not sensitive since they only assess tibial motor fibers; only about half of symptomatic limbs have abnormal tibial motor latencies [199].

2. *Mixed medial and lateral plantar NCSs.* These are the most widely employed studies for the evaluation of TTS [200, 201]. Mixed nerve action potentials of the medial and lateral plantar nerves are obtained by percutaneous (surface) stimulation of the medial and lateral plantar nerves on the sole of the foot while recording with surface electrodes over the tibial nerve posterior to the medial malleolus. These studies are the counterparts of the median and ulnar palmar mixed studies performed for the evaluation of carpal tunnel syndrome. Asymmetrical slowing of latency of the medial or lateral (or both) mixed nerve action potentials is considered abnormal. Another likely significant, though poorly localizing, abnormality is absent mixed plantar responses on the symptomatic side. Although this test is more sensitive than the tibial motor distal latencies (abnormal in about 2/3 of symptomatic limbs), it is plagued by many technical problems. It may be technically difficult to elicit these potentials in subjects with foot calluses on the plantar surface of the foot, ankle edema, foot deformities, or even in normal adults over 45 years of age.

3. *Medial and lateral plantar SNAPs.* NCS techniques for assessing solely the sensory fibers of the medial and lateral plantar nerves are reported. The orthodromic techniques consist of stimulating the first and fifth toes while recording from the tibial nerve proximal to the flexor retinaculum [188]. Antidromic studies stimulating the ankle and recording the toes are also possible. A variation of the orthodromic sensory NCS technique includes recording via needle electrode placed close to the tibial nerve and proximal to the flexor retinaculum [202]. Unfortunately, with any of these NCS procedures, the elicited SNAPs are extremely low in amplitude in normal subjects and require signal averaging. Moreover, in some healthy individuals, the responses cannot be evoked. As with the other plantar NCS techniques, prolonged latencies are sought. A possibly significant finding is absent SNAPs on the symptomatic side. This study is sensitive, reported to abnormal in over 90 % of symptomatic limbs [188, 199, 203]. The plantar SNAPs have not gained wide popularity.

Needle EMG examination of the muscles of the sole (such as abductor hallucis and abductor digiti quinti pedis) may be abnormal with TTS if axon loss has occurred. Also, MUAP loss, chronic neurogenic MUAP changes, and fibrillation potentials in various combinations may be found. A complicating factor is that these muscles are painful, difficult to activate, and may show denervation changes in asymptomatic patients, especially in the older age group, probably due to external trauma to the nerves and muscles of the foot [204].

An important task of the EDX studies is to differentiate TTS from peripheral polyneuropathy or S1/S2 radiculopathy, since all three entities result in abnormal tibial motor conduction studies and denervation of intrinsic muscles (Table 41.11). Distinguishing these three disorders is very difficult in the elderly patients in whom lower extremity SNAPs and H-reflexes are often absent.

The effect of surgical decompression of TTS on EDX studies has not been well studied. Improvement of EDX abnormalities has been noted postoperatively in about half of the patients with some residual findings [205, 206]. Thus,

Table 41.11 Electrophysiological differentiation of tarsal tunnel syndrome

	Tarsal tunnel syndrome	Chronic S1/S2 radiculopathy	Peripheral polyneuropathy
Nerve conduction studies			
Sural sensory study	Normal	Normal	Abnormal
Fibular motor study	Normal	Normal or low amplitude	Abnormal
Tibial motor study	Low amplitude and/or slow latency	Normal or low amplitude	Low amplitude and/or slow latency
Motor conduction velocities	Normal	Normal or slowed	Slowed
Plantar mixed nerve conduction studies	Slow latency or absent	Normal	Slow latency or absent
H-reflex	Normal	Abnormal	Abnormal
Upper extremity conductions	Normal	Normal	May be abnormal
Needle EMG			
AH/ADQP	Denervated	Denervated	Denervated
EDB	Normal	Denervated	Denervated
Medial gastrocnemius	Normal	Denervated	Denervated
Tibialis anterior	Normal	Normal	Denervated
Paraspinal muscles	Normal	Normal or fibrillations	Normal or fibrillations
Symmetry of findings	Asymmetrical[a]	Asymmetrical[a]	Symmetrical

[a]When bilateral, AH = abductor hallucis, ADQP = abductor digiti quinti pedis, EDB = extensor digitorum brevis

caution should be taken when interpreting the EDX abnormalities after surgery.

Imaging Studies

X-rays of the foot may reveal other causes of foot pain such as a bony spur, ankle or foot deformity, bony prominence from talocalcaneal coalition, or degenerative arthritis. MRI of the ankle is useful in identifying mass lesions within the tarsal tunnel such as ganglion cysts, dilated varicose veins, flexor hallucis longus tenosynovitis, fibrosis, or nerve sheath tumors [207, 208]. High-resolution MR neurography has recently shown promise in detecting focal nerve fibrosis in 90 % of patients [209].

Treatment, Management, and Prognosis

Conservative treatment should be initiated in all patients first. Sources of pressure, such as ill-fitting shoes, should be identified and eliminated. Other helpful measures include minimizing insole or lateral foot wedge. Nonsteroidal anti-inflammatory agents or local injection with long-acting corticosteroids may be also useful in alleviating tenosynovitis or arthritis.

Only a small proportion of patients requires surgical release of the flexor retinaculum. Satisfactory results are variable, ranging from 40 % to 90 % [206, 210–214]. Good results are achieved by selecting patients with documented entrapment who failed conservative treatment or those with identifiable space occupying lesions. Cases associated with foot comorbidities such as ankle trauma or deformities and patients with long duration of symptoms and longer tibial motor nerve conduction latencies have a poorer outcome [206, 210, 213]. Although, most patients improve with minimal sequelae, some may not or go on to develop chronic pain syndromes and features of complex regional pain syndrome.

Interdigital Neuropathy (Morton's Neuroma)

Etiology and Pathogenesis

Morton's neuroma (Morton's metatarsalgia) should be more correctly termed as *interdigital neuropathy* between the third and fourth toes. It is not a true neuroma. Interdigital neuropathies of the web space between the other toes may also occur. Morton's neuroma is caused by compression or entrapment of the interdigital nerve, against the deep transverse metatarsal ligament (Fig. 41.13b). Chronic repetitive compression of the interdigital nerve between the metatarsal heads is a likely mechanism, with hyperextension of the metatarsophalangeal joints being an exacerbating posture and resulting in angulation of the interdigital nerves. Most cases of Morton's neuromas are associated with fixed hyperextension of the metatarsophalangeal joints, which may be congenital or associated with wearing high heels or prolonged squatting. Rheumatoid arthritis, dystonia, and spasticity may also result in fixed hyperextension of these joints with subsequent development of interdigital neuropathies. At surgery, there is often a fibrous nodule of the interdigital nerve near the

metatarsal head which contains nerve fibers with varying degrees of demyelination.

Clinical Presentation

Morton's neuroma is a common source of forefoot pain [215, 216]. Middle-aged women comprise about 3/4 of patients. Foot pain particularly near the arch and the third and fourth toes is the most common presentation. The pain may radiate proximally to the ankle and calf. The pain is often lancinating, worse with weight bearing and relieved by rest. Numbness is not uncommon, often involving two adjoining toes. Involvement of the other interdigital nerves is less common.

The neurological examination reveals numbness in an interdigital nerve distribution. There is no weakness and the rest of the examination is normal. The most sensitive and specific clinical test is the *web space compression test:* while holding the dorsal and plantar aspect of the metatarsal head with the thumb and index fingers, a squeeze may reproduce the symptoms [217, 218]. Occasionally, a Tinel's sign may be also reproduced there.

Differential Diagnosis

Morton's neuroma may mimic other causes of foot pain, such as plantar fasciitis, bursitis, or arthritis. Tarsal tunnel syndrome may involve one plantar nerve only resulting in restricted numbness mimicking Morton's neuroma. However, palpation of the metatarsal heads does not usually reproduce the symptoms. It may be difficult to distinguish interdigital neuropathy from metatarsal joint disease, where the head itself (and not the space between two heads) is tender. Sensory loss and Tinel's signs are usually absent.

Evaluation and Diagnosis

The diagnosis of Morton's neuroma requires a high degree of suspicion, particularly when predisposing factors are present. Evaluation of the foot for deformities, congenital anomalies, or muscle imbalance is important. Web space compression and reproduction of the symptoms is an extremely useful sign [217, 218]. Local anesthetic block may be used as a diagnostic tool, but has no effect on surgical outcome. MRI scan and ultrasonography of the foot are the diagnostic studies of choice with conflicting results on their relative sensitivities [217–219]. MRI is very useful in showing the neuroma and excluding other cause of compressive nerve lesions, but may show neuroma in asymptomatic patients also [218]. Ultrasonography of the foot often shows an ovoid, hypoechoic mass oriented parallel to the long axis of the metatarsal bones. EDX studies are of value, in excluding other peripheral nerve causes of foot pain, such a lumbosacral radiculopathy or TTS. Sensory NCSs of the interdigital nerves, including near-nerve needle and signal averaging techniques, were described, are difficult to evoke, and, hence, have not been widely used [220, 221].

Treatment and Prognosis

Conservative treatment is often useful in alleviating the symptoms and is the first line of therapy [222]. Avoidance of high heels, changing to flat wear, and modification of shoes are often useful. Orthotic inserts or pads may prevent the repetitive compression on the interdigital nerve. Repeated corticosteroid injection may relieve the symptoms in more than half of patients and should be attempted before surgery [223]. Alcohol injection of Morton's neuroma has also been advocated with a high success rate [224]. Surgical neurolysis of the interdigital nerve often results in complete relief of symptoms and is the treatment of choice for many patients [225, 226]. Surgical excision of the neuroma is preferred by others and is indicated for patients who fail neurolysis [226–228]. Failure of neurolysis or neurectomy with persistent pain is reported in 5–10 % of patients [227, 228].

Sural Mononeuropathy

The sural nerve may be damaged at the ankle or calf. Less commonly, the lesion is at the popliteal fossa. Common causes include trauma including fractures, sprains, and lacerations. Mechanical compressions against hard ridges such as while sitting with crossed ankles, wearing tight high-topped boots, or elastic stockings were reported. Less common structural causes include schwannoma, ganglionic cysts, thrombophlebitis, bone tumor, neuroma, or Baker's cyst. Iatrogenic lesions of the sural nerve may follow vein stripping, ankle liposuction, ankle or knee arthroscopy, gastrocnemius muscle biopsy, and a variety of popliteal fossa surgical procedures [229–231].

The sural nerve is often used for nerve grafting and for diagnostic nerve biopsy. Immediate postoperative complications following this procedure, including infections or delayed wound healing, occur in up to 20 % of patients, particularly those with peripheral neuropathy or diabetes mellitus [232, 233]. Numbness and dysesthesia in sural sensory distribution occur in about half of the patient, decreasing over the next few years to a small area of hypesthesia [232, 233]. Delayed persistent pain (sural neuralgia) occurs in up to 30 % of patients and may be due to a neuroma formation [233]. An anterior fascicular sural nerve biopsy which preserves lateral heel sensation has been advocated with a reduction in the incidence of chronic foot pain [234].

The symptoms of sural mononeuropathy include pain and paresthesias in the lateral ankle and foot. Tinel's sign may be elicited along its course. The neurological examination reveals well-demarcated sensory loss in the sural nerve distribution with normal strength and reflexes. The sensory loss associated with sural neuropathy may mimic an S1 radiculopathy. However, lesions of the S1 root often results in absent or depressed ankle jerk with variable weakness of plantar flexion.

With EDX testing, sural nerve SNAP is usually absent or low in amplitude, while all other lower extremity NCSs and needle EMG are normal. In contrast, the SNAP in S1 radiculopathy is normal and there is often denervation in the gastrocnemius and other S1-innervated muscles. It should be noted that the sural SNAP may be difficult to evoke in the elderly or with ankle edema.

The treatment of sural mononeuropathy is directed toward the cause, such as removal of a mass lesion. Changing foot gear often improves the compressive symptoms. Patients with sural neuralgia may be treated with anticonvulsants, such as gabapentin and pregabalin, or antidepressants, such duloxetine and amitriptyline. Patients with a neuroma may respond to nerve excision and transposition of stump into bone or muscle.

The Femoral Nerve

Anatomy

The femoral nerve is formed by the combination of the posterior divisions of the ventral rami of L2, L3, and L4 spinal roots. The anterior divisions of the same roots form the obturator nerve. The femoral nerve, also called the anterior crural nerve, is a relatively short nerve. Soon after its formation in the pelvis, it innervates to the psoas muscle which receives additional separate branches from the L3 and L4 roots directly. The femoral nerve passes between the psoas and iliacus muscles and is covered by the tight iliacus fascia, which forms the roof of the iliacus compartment. The iliopsoas muscle and femoral nerve are the main constituents of this compartment.

The femoral nerve emerges from the iliacus compartment after passing underneath the rigid inguinal ligament in the groin. About 4–5 cm, before crossing the inguinal ligament, it innervates the iliacus muscle. Soon after passing underneath the ligament, the femoral nerve branches widely into (1) terminal motor branches to all four heads of the quadriceps (rectus femoris, vastus lateralis, vastus intermedius, and vastus lateralis) and sartorius muscles, and (2) three terminal sensory branches, the medial and intermediate cutaneous nerve of the thigh which innervate the skin of the anterior thigh, and the saphenous sensory nerve (Fig. 41.15).

The saphenous nerve travels the thigh, lateral to the femoral artery, by passing posteromedially from the femoral triangle through the subsartorial (Hunter's or adductor) canal. It gives off the infrapatellar branch that innervates the skin over the anterior surface of the patella. About 10 cm proximal and medial to the knee, the saphenous nerve becomes subcutaneous by piercing the fascia between the sartorius and gracilis muscles. Then, it crosses a bursa at the upper medial end of the tibia (pes anserinus bursa). In the lower third of the leg, it divides into two terminal branches to innervate the skin of the medial surface of the knee, medial leg, medial malleolus, and a small area of the medial arch of the foot (Fig. 41.15).

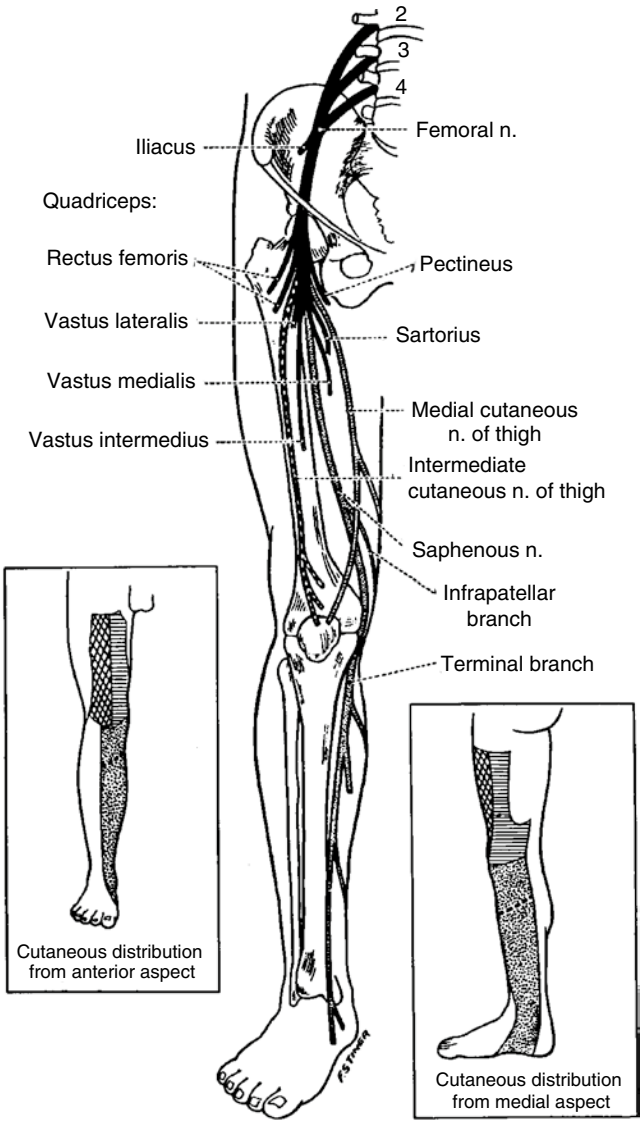

Fig. 41.15 The femoral nerve and its terminal motor and sensory branches and cutaneous distribution. The patterns of the cutaneous nerves are duplicated in the inserts. The broken line in the inserts represents the boundaries between the infrapatellar and terminal branches of the saphenous nerve (From Haymaker and Woodhall [393]. With permission)

Femoral Mononeuropathy

Etiology and Pathogenesis

Because of its short course, the main trunk of the femoral nerve is usually injured at one of the two sites: the retroperitoneal pelvic space or the inguinal ligament

Table 41.12 Common causes of femoral mononeuropathy

1. Compression in pelvis
By retractor blade during pelvic surgery
(Abdominal hysterectomy, radical prostatectomy, renal transplantation, etc.)
By iliacus or psoas retroperitoneal hematoma
(Anticoagulation (systemic or subcutaneous abdominal heparin), hemophilia, coagulopathy, ruptured abdominal aneurysm, femoral artery catheterization)
By pelvic mass (lymphadenopathy, tumor, abscess, cyst, aortic or iliac aneurysm)
2. Compression in the inguinal region
By inguinal ligament during lithotomy position
(Vaginal delivery, laparoscopy, vaginal hysterectomy, urological procedures)
By inguinal hematoma
(Femoral artery catheterization such as for coronary angiography)
During total hip replacement
By inguinal mass (e.g., lymphadenopathy)
3. Stretch injury (hyperextension, dancing, Yoga)
4. Others (radiation, laceration, misplaced injection)

Source: Adapted from Katirji [398]. With permission

(Table 41.12). Most femoral mononeuropathies are iatrogenic, occurring during intra-abdominal, intrapelvic, inguinal, or hip surgical or diagnostic procedures. The nerve injury often results from direct nerve trauma or poor leg positioning during the procedure but may be due to a compressive hematoma.

Iatrogenic nerve injury during pelvic surgical procedures is the most common cause of femoral mononeuropathy. This may occur following a variety of procedures including abdominal hysterectomy, radical prostatectomy, renal transplantation, colectomy, proctectomy, inguinal herniorrhaphy, lumbar sympathectomy, appendectomy, tubal ligation, abdominal aortic repair, and a variety of other intra-abdominal vascular, urological, or gynecological operations [235–245]. During these surgical procedures, the lateral blade of the retractor compresses the intrapelvic portion of the femoral nerve against the pelvic wall. Most cases occur following the use of self-retracting blades compared to the handheld blades [239, 245]. With an incidence of 7–11 % in patients undergoing abdominal hysterectomy; avoiding using retractors during gynecological operations decrease this incidence of femoral nerve injury by 93 % [245]. The incidence of femoral neuropathy after renal transplantation is about 2–3 % [236, 237]. In addition to retractor injury, femoral nerve ischemia is a possible mechanism since the incidence correlates with selection of iliac artery anastomosis and the duration of the arterial anastomosis [236]. In addition to possible ischemia, the postoperative femoral nerve lesions may be caused by postoperative retroperitoneal hematoma or inadvertent laceration or suturing of nerve [235, 246]. Stapling of the femoral nerve may also occur following laparoscopic inguinal hernia repair [241, 242, 247].

Femoral mononeuropathy may occur during surgical procedures of the hip joint [100, 102, 248–250]. Total hip replacement may result in iatrogenic femoral nerve injury in 0.1 to 2.4 % of patients [250]. The femoral injury is considered to be due to misplacement of the anterior acetabular retractors during the procedure, but recent experimental studies suggested that it is likely due to the incorrect use of instruments or implants (e.g., screws, cement, acetabular cup) [251]. Regardless of exact cause, these lesions are most frequent in revisions, anterolateral approach, and complicated reconstructions [248].

Acute hemorrhage in the iliacus compartment may lead to a compartmental syndrome which results in iliopsoas muscle or femoral nerve ischemia or both. Occasionally, the hematoma is large and extends into the psoas muscle or retroperitoneal space leading to a more extensive injury of the lumbar plexus or entire lumbosacral plexus. These hematomas may be a complication of anticoagulant therapy (heparin or warfarin), hemophilia or other blood dyscrasias, ruptured abdominal aortic aneurysm, pelvic operations, or traumatic rupture of the iliopsoas muscle [252–254]. Iatrogenic hemorrhage may occur following femoral artery (and less commonly femoral vein) catheterization for a variety of reasons, including coronary, cerebral, and aortic angiography [254, 255]. The prevalence of retroperitoneal hemorrhage is about 0.5 % of femoral artery cannulation for cardiac catheterization, but is probably on the rise, particularly with the increase use of thrombolytic agents. About a third of these hemorrhages result in femoral nerve injury or a lumbar plexopathy [254, 255].

Compression of the femoral nerve may occur at the inguinal ligament during lithotomy positioning for a variety of procedures. This often follows prolonged lithotomy positioning, particularly with extreme hip flexion and external rotation [256, 257]. The nerve is often kinked under the inguinal ligament but may also be stretched by excessive hip abduction and external rotation. These lesions are often associated with vaginal delivery and are likely underestimated since most are mild and recover rapidly. The reported incidence has declined, possibly due to the increased use of cesarean section and/or increased awareness of this complication, from about 4.7 % to about 2.8/100,000 deliveries (0.00028 %) [258]. Femoral mononeuropathy due to lithotomy positioning may also occur with other procedures including vaginal hysterectomy, prostatectomy, and laparoscopy [243, 259–261].

Pelvic mass lesions, other than hematomas, may also compress the femoral nerve. These include lymphadenopathy, abscess, cyst, enlarged iliac or aortic aneurysm, or tumor such as lymphoma and primary malignancy of colon, rectum, or ilium. Femoral nerve tumors, such as neurofibromas,

schwannomas, and neurogenic sarcoma, are relatively rare [262, 263].

Femoral nerve traumatic stretch may occur with hyperextension of the hip, such as in dancers, or with prolonged squatting such as during Yoga exercise [264, 265]. Selective injury of the motor branch to the vastus lateralis may also occur in athletes [266]. Femoral nerve injury may result from penetrating gunshot and stab wounds, lacerations, and contusions injuries associated with pelvic fractures.

A discussion of femoral neuropathy is incomplete without referring to the so-called diabetic femoral neuropathy. Earlier clinical reports suggested that selective femoral neuropathy may be a complication of diabetes mellitus. However, it is now clear that this is a misnomer. Diabetic patients actually have more extensive subacute peripheral nerve disease involving the lumbosacral plexus and spinal roots consistent with diabetic radiculoplexopathy, also known as diabetic amyotrophy or diabetic proximal neuropathy (see Chap. 31) [267, 268]. Although the brunt of weakness in these patients often falls on the quadriceps muscle, mimicking selective femoral nerve injuries, careful clinical and needle EDX examination reveal more widespread involvement of thigh adductors and sometimes foot dorsiflexors, muscles not innervated by the femoral nerve [269]. Despite the current knowledge, the term diabetic femoral neuropathy, unfortunately, has not completely vanished [270].

Clinical Presentation

Most cases of femoral mononeuropathies are unilateral, while bilateral lesions may occur, particularly after lithotomy positioning [244, 256, 264]. The clinical presentation of femoral nerve lesions is often acute, with thigh weakness and anterior thigh and leg numbness. Patients frequently complain that their leg buckles underneath them which may lead to falls. Acutely, groin or thigh pain is usually mild, while a deep delayed pain and hyperesthesia are not uncommon. An exception to this is in patients with retroperitoneal hematomas, who often complain of severe acute pain in the back, abdomen, groin, buttock, or anterior thigh and tend to keep their hip flexed.

The neurological examination reveals weakness of knee extension (quadriceps) with absent or depressed knee jerk. Thigh adduction and ankle dorsiflexion are, however, normal. Hip flexion (iliopsoas) is usually weak when the lesion is intrapelvic (such as during pelvic surgery), but spared when the lesion is at the inguinal region (such as during lithotomy positioning). Sometimes, it is difficult to examine hip flexion accurately because of groin or abdominal pain such as following recent pelvic surgery, vaginal delivery, or with iliacus hematoma. Hypesthesia over the anterior thigh and medial calf is common. A positive reversed straight leg test (pain in anterior thigh with extension of hip) may occur in femoral nerve lesion, particularly when associated with iliacus or retroperitoneal hematoma.

Differential Diagnosis

Quadriceps weakness with absent/depressed knee jerk and sensory manifestations in anterior thigh are manifestations shared not only by femoral neuropathy but also by an upper lumbar (L2, L3, and L4) radiculopathy (such as with disc herniation) and lumbar plexopathy (such as with diabetic amyotrophy). Careful examination of the thigh adductors, innervated by the L2, L3, and L4 roots via the obturator nerve, is extremely important, since weakness of these muscles is inconsistent with a femoral neuropathy and points to a lesion proximal to the femoral nerve. Also, weakness of ankle dorsiflexion (tibialis anterior), innervated by the L4 and L5 roots via the common fibular nerve, is highly suggestive of an L4 radiculopathy or lumbar plexopathy. Back and buttock pain and a positive reversed straight leg are common in upper lumbar radiculopathy, but may occur with lumbar plexopathy and femoral mononeuropathy, particularly when due to retroperitoneal hematoma or mass.

Sensory loss in the anterior thigh due to femoral neuropathy may occasionally be confused with meralgia paresthetica (lesion of the lateral femoral cutaneous nerve). This is particularly true in mild femoral nerve lesion when weakness of thigh muscles or depressed knee jerk may not be present. The sensory loss in meralgia paresthetica is lateral, does not extend beyond the knee, and rarely crosses the anterior midline of the thigh. In contrast, the sensory loss in femoral nerve lesions is anterior and often extends beyond the knee to include the medial leg (saphenous distribution).

Evaluation and Diagnosis

Since the majority of femoral nerve lesions are iatrogenic, a detailed history is extremely important. Acute quadriceps weakness, anterior thigh numbness, and depressed-absent knee jerk following abdominal surgery, particularly when using self-retractors, are highly suggestive of an intrapelvic femoral neuropathy. Similar manifestations, particularly when associated with severe pain and occurring in the setting of anticoagulation, coagulopathy, femoral vessel catheterization, or trauma, should raise the question of a femoral nerve injury due to an iliacus or retroperitoneal hematoma. Unilateral or bilateral quadriceps weakness following vaginal delivery, urological procedures, or laparoscopy, particularly when the iliacus muscle function is preserved, is often diagnostic of a femoral nerve compression at the inguinal ligament.

Electrodiagnostic Studies

The EDX testing in a patient with suspected femoral neuropathy is extremely useful in (1) confirming the presence of a selective femoral mononeuropathy, (2) excluding a lumbar plexopathy and radiculopathy, (3) localizing the site of femoral nerve injury, and (4) predicting the prognosis by assessing the primarily pathophysiological process (segmental demyelination or axonal loss).

The saphenous SNAP evaluates the postganglionic L4 sensory fibers and plays an important role in the differential diagnosis of femoral nerve lesions. It is often absent in femoral neuropathy and lumbar plexopathy but normal in L4 radiculopathy since the root lesion is intraspinal, i.e., proximal to the dorsal root ganglion. Rarely, the saphenous SNAP is normal in "purely" demyelinating femoral mononeuropathies where there is no Wallerian degeneration which is usually complete in 10–11 days in sensory fibers. The saphenous SNAPs should be studied bilaterally for comparison, since these potentials may be difficult to obtain in the elderly and obese patients and in patients with leg edema.

Femoral motor conduction studies are important in the assessment of the primary pathophysiological process and prognostication of femoral mononeuropathy [256, 271]. In contrast to many peripheral nerves, the femoral nerve may be only stimulated in the groin, allowing evaluation of a distal CMAP only. A femoral CMAP amplitude and/or area, obtained after 4 to 5 days from injury (the time needed for completion of Wallerian degeneration of motor axons), reflects, semiquantitatively, the primary pathophysiological process and predicts the prognosis. If the femoral CMAP amplitude and/or area is low or absent, in the presence of moderate or severe impairment of recruitment of quadriceps MUAPs, the lesion is primarily axonal. The prognosis is relatively protracted since it will depend on sprouting and reinnervation. Patients with CMAP amplitude more than 50 % of the contralateral side improve within 1 year, while fewer than half of the patients with a CMAP less than 50 % of the contralateral side improve [271]. In contrast, when the femoral CMAP amplitude and/or area is normal despite significant reduction of MUAP recruitment, the lesion is primarily demyelinating and the prognosis is excellent since it is dependent on remyelination. All patients with such findings recover in 6–8 weeks.

Needle EMG is essential in all patients with femoral mononeuropathy in order to localize the site of femoral nerve lesion and exclude a lumbar radiculopathy or plexopathy. Fibrillation potentials and decreased recruitment of MUAPs of quadriceps are common in all three entities. However, these changes are present in the thigh adductors (L2/L3/L4 – obturator nerve) only in patients with upper lumbar radiculopathy or plexopathy. Also, in L4 radiculopathy, similar neurogenic changes may be present in the tibialis anterior (L4/L5 – common fibular nerve). Since the branch to the iliacus muscle originates 4–5 cm above the inguinal ligament, sampling this muscle determines whether the femoral nerve lesion is distal (i.e., around the inguinal ligament) or proximal (i.e., intrapelvic). Fibrillation potentials are a poor quantitative measure of the extent of this axonal loss since they are identified whenever axonal loss occurs, even if minimal. Thus, these potentials identify the presence of axonal loss but do quantitate its extent, and are therefore, by themselves, poor indicators of the extent of peripheral nerve injury. The amplitude and/or area of the femoral CMAP is the best quantitative measure of motor axonal loss.

Imaging Studies

In patients with acute femoral mononeuropathy and severe pain, particularly in the setting of anticoagulation, coagulopathy, or femoral vessel catheterization, a retroperitoneal hematoma should be considered and confirmed (or excluded) urgently by a CT scan of the pelvis. CT or MRI of the pelvis is also useful in patients with suspected pelvic mass lesion or femoral nerve tumor.

Treatment, Management, and Prognosis

Most patients with femoral mononeuropathy are treated conservatively waiting for spontaneous remyelination and reinnervation. A knee-ankle-foot or knee only orthosis is helpful for patients with severe weakness of the quadriceps to assist in walking and prevent falls [272]. Anticonvulsants or antidepressants may be used for the delayed pain and hyperesthesia associated with femoral nerve lesions.

Hematoma evacuation in patients with iliacus or retroperitoneal hematoma at the time of the development of femoral neuropathy shortens the recovery period and results in rapid return of neurological function [252, 253]. Ideally, hematoma evacuation should occur as soon as it is detected and before signs of severe femoral nerve injury occur. Without operative treatment, the neurological deficit persists with a protracted leg weakness.

Compared to other peripheral nerve injuries, femoral mononeuropathy carries a relatively good prognosis due to its short length, even when the lesion is due to axonal loss. The quadriceps, which is the most clinically relevant muscle, is proximal and relatively near the injury sites at the inguinal ligament or in the pelvis. These optimal conditions often lead to effective sprouting and reinnervation in axonal loss lesions. As outlined, the femoral CMAP amplitude is the best estimate of the extent of axonal loss and is the only independent factor influencing prognosis [256, 271]. Demyelinating femoral nerve lesions often recover in 2 to 3 months by remyelination, whereas axonal lesions require one or more years. In general, compressive femoral mononeuropathies at the inguinal ligament following childbirth or laparoscopy tend to be demyelinating and recover rapidly, while lesions caused by iliacus hematomas are axonal with a more protracted recovery.

Prevention of iatrogenic femoral nerve lesions is essential. Eliminating retractors, particularly self-retractors, during pelvic surgery decreases the incidence of these lesions [239]. Compression at the inguinal ligament may be prevented by avoiding prolonged lithotomy positioning and extreme hip flexion and external rotation.

Saphenous Mononeuropathy

Saphenous mononeuropathies are usually iatrogenic occurring after vascular or orthopedic operations. Saphenous nerve damage occurs in up to 40 % of patients undergoing stripping of the long saphenous varicose vein, but only 6–7 % of patients have persistent and disabling sensory loss [273–276]. Also, harvesting the long saphenous vein for a coronary artery bypass is often complicated by damage to the saphenous nerve [277–279]. About 10 % of patients undergoing arterial operations in the thigh, such as superficial femoral thromboendarterectomies or femoropopliteal bypass grafts, develop saphenous mononeuropathy [280, 281]. Surgical operations on the knee, including meniscectomies and arthroscopic procedures, may injure the saphenous nerve or its infrapatellar branch [282–284]. Entrapment of the saphenous nerve may occur as it exits the subsartorial (adductor or Hunter) canal or by pes anserine bursitis [285–287]. The infrapatellar branch may be entrapped behind the sartorius tendon or injured with acute or repetitive medial knee trauma [288]. Schwannomas of the saphenous nerve or its infrapatellar branch are described [289].

Patients with saphenous mononeuropathy often complain of paresthesias or hyperesthesias of medial leg that may extend into the medial arch of the foot. Knee pain is common and may be the presenting symptom [288]. Leg pain with allodynia is also common and is sometimes referred to "saphenous neuralgia" [279, 281]. Selective infrapatellar branch entrapment often causes anterior, anteromedial, or anterolateral knee pain with minimal sensory loss confined to small patch below the knee. In entrapment of the saphenous nerve, tenderness or Tinel's sign may be elicited on percussion of the saphenous nerve at its subsartorial exits, four finger breadths above the medial condyle of the femur.

On EDX studies saphenous SNAP is the most important study. This study is technically difficult, especially in the elderly and obese patients [290, 291]. The study should be obtained bilaterally and a proximal technique should be done if the more common distal response could not be evoked bilaterally [290, 291]. Saphenous nerve lesions should be differentiated from L4 radiculopathy, lumbar plexopathy, or femoral mononeuropathy, and the EDX studies are useful in confirmation. Muscle strength and needle EMG of quadriceps, iliacus, and thigh adductors are normal in patients with saphenous mononeuropathy. Saphenous SNAP is often absent or low in amplitude in patients with saphenous or femoral nerve lesions but normal in L4 radiculopathy (see femoral nerve). The pain in patients with infrapatellar branch lesions mimics various pathology of the knee joint which should always be excluded.

Treatment of patients with saphenous nerve lesions depends on its causation. The circumference of the saphenous sensory loss becomes smaller with time in iatrogenic lesions [273, 274]. Topical lidocaine or capsaicin creams are fairly effective [292]. Saphenous nerve blocks may alleviate the symptoms in patients with entrapment at the subsartorial canal. Decompression of the saphenous nerve at this canal or the infrapatellar branch near the sartorius tendon may resolve the symptoms in patients with definite nerve entrapment.

Prevention of iatrogenic lesions is accomplished by a meticulous knowledge of the anatomy of the saphenous nerve and its infrapatellar branch [284, 293, 294]. During saphenous vein harvest, the most vulnerable area, which is the inferior third of the leg, should be avoided [293]. Saphenous nerve injury during stripping of varicose veins is significantly reduced by removal of only the femoral part of the vein or by downward (rather than upward) stripping of the long saphenous vein [275, 276].

The Lateral Femoral Cutaneous Nerve

Anatomy

The lateral femoral cutaneous nerve (lateral cutaneous nerve of the thigh, LFCN) is formed from sensory fibers originating from the ventral rami of L2 and L3 spinal roots (Fig. 41.16). The nerve travels within the lower abdominal muscles and crosses the iliacus muscle. The LFCN leaves the pelvis by passing underneath or within the inguinal ligament, 1.5 cm medial to its lateral insertion at the anterior superior iliac spine in 60 % of subjects. In 20 % each, the nerve exits the pelvis at or lateral to the anterior superior iliac spine [295, 296]. The LFCN, then, changes its direction from a horizontal to a vertical course and pierces the fascia lata a short distance below the inguinal ligament. Soon after, the LFCN divides into its terminal branches in the leg to innervate the skin of the lateral thigh. Although the sensory territory of the nerve is slightly variable between individuals, it does not extend beyond the knee and seldom across the anterior or posterior midline of the thigh.

Etiology and Pathogenesis

Mononeuropathy of the LFCN is the most common pure sensory mononeuropathy in the lower extremity. It is often referred to as *meralgia paresthetica* (Greek: mèros = thigh and algo = pain) or the Bernhardt-Roth syndrome. Meralgia paresthetica is often due to entrapment of the LFCN under or through the inguinal ligament where it is engulfed by multiple layers of fascia. This was confirmed histologically by the presence of focal demyelination, Wallerian degeneration, and internodal swellings at that site [297].

The majority of cases of meralgia paresthetica are idiopathic, though the disorder is frequently associated with pregnancy, diabetes mellitus, advancing age, and obesity [298–302]. The incidence rate of meralgia paresthetica is

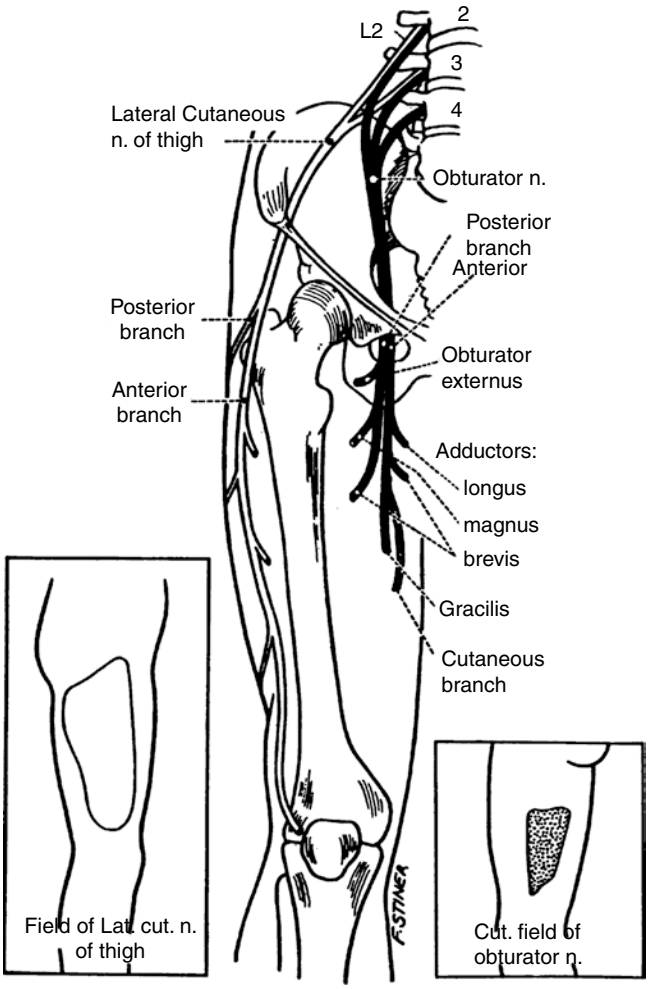

Fig. 41.16 The lateral cutaneous of the thigh and obturator nerves (From Haymaker and Woodhall [393]. With permission)

32.6 per 100,000 patient years and in the diabetic population 247 per 100,000 patient years (7½ times the general population). The association with diabetes is independent of body weight [298, 299]. It often manifests between the ages of 55 and 65 years. Compression of the nerve at the inguinal ligament may occur during occupational activities, such as wearing large tool belts, leaning against a tool bench or gymnastic bars, or simply by wearing tight clothing, low-cut trousers, body armor wears, or large pagers [303–306]. Iatrogenic lesions are described following iliac bone graft, misplaced injection, hip surgery, or pelvic surgery such as renal transplantation, gastric bypass, and laparoscopic herniorrhaphy [307–309]. Meralgia paresthetica may occur during anesthesia in the prone position such as for thoracolumbar spine surgery [310]. Although intrapelvic retractor injury explains many of the postoperative meralgia paresthetica, prolonged postoperative hip flexion following abdominal surgery or prolonged "frog-leg" positioning during vein harvesting for coronary artery bypass or during the relaxed postanesthesia period may explain some of these nerve lesions [311, 312]. Blunt trauma, such as avulsion fracture of the anterior superior iliac spine or seat belt trauma, or laceration may occasionally cause a lesion of the LFCN [313–315]. A pelvic or bone mass such as abdominal aortic aneurysm or metastatic tumor to the iliac crest may present with manifestations of a mononeuropathy of the LFCN [316–318].

Clinical Presentation

Almost all patients present with numbness and pain (hence the appropriate term meralgia paresthetica). The paresthesias may be unpleasant and annoying, often described to correlate with a trouser pocket area. Deep pain is rare while burning and stinging are common. Hyperesthesia and, sometimes, allodynia may occur. The symptoms may worsen with standing, walking, or turning in bed or improve with hip flexion. Despite transient symptoms, the neurological examination often detects a well-circumscribed area of sensory loss to touch and pin prick in the distribution of the LFCN, in its entirety, in a smaller area within the center of its territory, or in one of its terminal branches. In the majority of the patients, the sensory loss is in the lateral aspect of the thigh, but in 20 % the sensory loss extends or is exclusively in the anterior thigh [300]. Alopecia restricted to the area of sensory loss has been described [319].

Differential Diagnosis

Meralgia paresthetica may be confused with an upper lumbar radiculopathy, particularly L2 or L3 radiculopathy, a femoral mononeuropathy, or lumbar plexopathy. The sensory impairment in L2 or L3 radiculopathy is not well circumscribed, and there is often deep seated back, buttock, and groin pain. In femoral neuropathy and lumbar plexopathy, the numbness often involves the anterior thigh and does not respect the anterior thigh midline, often extending medially in the thigh and leg. Also, lower extremity weakness or depressed knee jerk often excludes meralgia paresthetica. Because of fluctuating pain, particularly if worsened by standing and walking, this disorder may be mistaken for lumbar spinal stenosis. However, the symptoms in spinal stenosis are often bilateral, the sensory manifestations not well demarcated, and there may be associated weakness or reflex changes.

Evaluation and Diagnosis

The diagnosis of meralgia paresthetica is straightforward to most neurologists, although it may be elusive to other physicians in more than 50 % of the patients [300]. Often, the patient is able to outline the exact area of sensory loss, which often correlates with the cutaneous distribution of the LFCN or one of its branches. A detailed history may reveal the precipitating cause such as weight gain or wearing tight pants. Imaging is often unnecessary except if an abdominal mass is suspected. Then, a CT scan of the pelvis is indicated.

EDX testing in meralgia paresthetica is important in excluding lumbar radiculopathy and plexopathy. SNAP of the LFCN

may be recorded antidromically or orthodromically, but may be absent in healthy subjects, particularly in women and obese individuals, or on the asymptomatic side in symptomatic individuals. Stimulating 4 cm distal rather than 1 cm medial to the anterior superior iliac spine evokes a response in 90 % of healthy subjects [320]. In patients with meralgia paresthetica, asymmetrically low-amplitude (at least half of the contralateral) or absent SNAP on the symptomatic side is the most specific EDX finding [300]. Somatosensory evoked potentials (SEP) of the LFCN are also possible. Dermatomal SEP (stimulating the lateral thigh) is more diagnostic than segmental SEP (stimulating the lateral femoral cutaneous nerve near the anterior superior iliac spine) [321, 322]. Absolute lateral femoral cutaneous SEP latency, absent response, and amplitude reduction (>50 % compared with the contralateral response) are considered diagnostic findings [323]. Comparison of the ipsilateral dermatomal SEP to the commonly studied tibial SEP is also useful in confirming the diagnosis of meralgia paresthetica with high sensitivity and specificity [324].

Treatment and Prognosis

Meralgia paresthetica is often a self-limiting disease with resolution of symptoms with time in the majority of patients. Pregnant women resolve after delivery and obese patients improve with weight loss. In diabetic patient, there is a tendency for slow improvement, though residual sensory loss in a smaller territory may persist for few years. Addressing compressive elements such as tight clothing or large belts is essential. Recurrence may occur with subsequent pregnancies or in diabetics.

Treatment should be initiated if neuropathic pain is intolerable. Antidepressants (such as tricyclics and duloxetine), anticonvulsants (such as carbamazepine, pregabalin, and gabapentin), or local treatment (such as capsaicin or lidocaine patch or cream) is often useful. Steroid injections may be helpful in resistant cases and are used as a prognostic indicator for the outcome of surgery [325]. Surgical decompression of the LFCN is indicated in patients with persistent pain and no precipitating risk factor [325–328]. Children tend to be more resistant to conservative treatment than adults and more often are treated surgically [329]. Neurolysis, decompression, and sectioning of the nerve (neurectomy) are all effective with 90–95 % success rate [325–328]. It should be noted that obesity has a poor outcome in general [328], and neither the lateral femoral SNAP nor the SEP has a predictive value on the outcome of meralgia paresthetica [330].

The Ilioinguinal Nerve

The ilioinguinal nerve originates from L1 spinal root, passes next to the lateral border of the psoas muscle, and follows the abdominal wall similar to an intercostal nerve. When the ilioinguinal nerve passes medial to the anterior superior iliac spine, it pierces the transverse and internal oblique muscles and runs along the inguinal canal with the genital branch of genitofemoral nerve and spermatic cord in men and the round ligament in women. The ilioinguinal nerve innervates the lower abdominal muscles and a strip of skin along the inguinal ligament to the base of penis and scrotum in men or labium majus in women (Fig. 41.17).

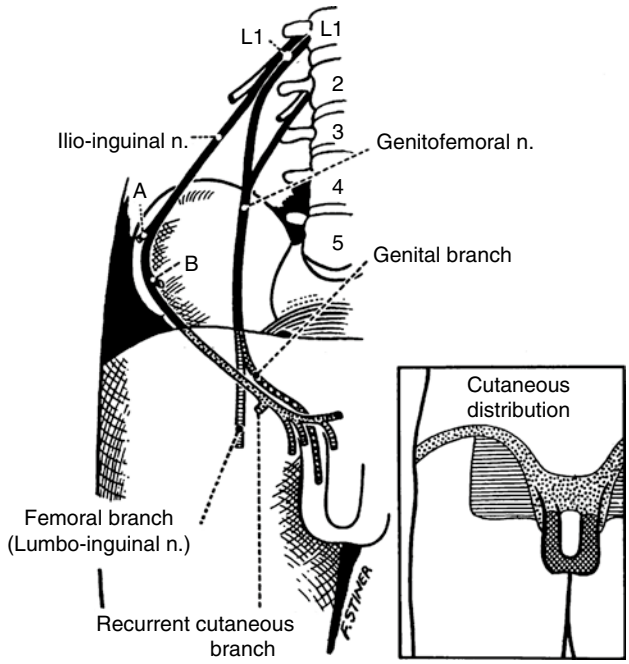

Fig. 41.17 The ilioinguinal and genitofemoral nerves. A and B are motor branches to the abdominal muscles (From Haymaker and Woodhall [393]. With permission)

Lesions of the ilioinguinal nerve are usually caused by iatrogenic nerve damage, trauma, or entrapment. Laparoscopic or open hernia repair is the most common cause of ilioinguinal nerve lesions [331, 332]. Chronic inguinal neuralgia after herniorrhaphy is likely caused by the entrapment of the sensory nerve in the scar tissue formed by the polypropylene mesh [333]. Other surgical operations, such as appendectomy, bladder suspension, iliac bone grafting, and gynecologic operations using the transverse (Pfannenstiel) incisions, may also injure the ilioinguinal nerve [334]. A blow to the lower abdomen may cause damage to the nerve. Entrapment of the ilioinguinal nerve may occur at the abdominal outlet medial to the anterior superior iliac spine.

Patients with ilioinguinal mononeuropathy often complain of burning pain in the lower abdomen radiating to the upper thigh and into the scrotum or labium majus. Sensory loss in the ilioinguinal nerve distribution is also common. The pain or sensory symptoms may worsen with extension of the hip, and the patients may be only comfortable in the flexed position. Tinel's sign may be induced by tapping the lower abdomen. A well-circumscribed trigger point medial and below the anterior superior iliac spine may be present in patients with entrapment of the ilioinguinal nerve. Bulging

of the lower abdominal wall, due to weakness of transverse and internal oblique muscles, may occur in severe lesions.

Ilioinguinal mononeuropathy should be differentiated from adjacent sensory mononeuropathies of the groin including iliohypogastric and genitofemoral nerve lesions (see below). Concomitant iatrogenic injuries of two or more of these nerves are common. High lumbar radiculopathies, such as L1 or L2 radiculopathy, cause groin pain and numbness and may be associated with ilioinguinal nerve lesions that may be mistaken as a frank hernia. Often, diagnostic nerve block is needed for confirmation [331, 334]. EDX studies, particularly the sensory nerve conduction studies, are not popular for technical reasons. However, needle EMG of lower abdominal muscles may reveal denervation [335]. Needle EMG of the upper lumbar paraspinal muscles is useful in excluding a high lumbar radiculopathy.

Treatment of ilioinguinal nerve lesion is often surgical. Nerve blocks may offer transient relief but are more important diagnostically. Surgical exploration with neurectomy (nerve section) is advocated with good results in over 3/4 of patients [336, 337]. Pulsed radiofrequency lesioning of the ilioinguinal nerve is also an alternate method [338]. Prevention of ilioinguinal nerve injury during abdominal operations is essential. In inguinal hernia repair, the ilioinguinal nerve should be displaced from the spermatic cord, and, in appendectomy, the incision should be more than 3 cm from the anterior superior iliac spine [339, 340]. There is a continuous debate as to whether division of the ilioinguinal nerve during inguinal hernia repair reduces the incidence of ilioinguinal nerve injury and chronic groin pain/neuralgia [341–343].

The Iliohypogastric Nerve

The iliohypogastric nerve originates from the L1 spinal root with occasional contribution from the T12 root. The nerve crosses the psoas and the quadratus lumborum muscles and the lower border of the kidney. Near the iliac crest, the iliohypogastric nerve passes through the transverse and internal oblique abdominal muscle after giving them off small motor branches. It then divides into two cutaneous terminal branches: a lateral branch which innervates a small strip of skin in the upper lateral buttock and an anterior branch which innervates a small area of skin above the pubis symphysis.

Isolated lesions of the iliohypogastric nerve are extremely rare and usually iatrogenic. More often the nerve is injured along with the ilioinguinal nerve because of their close anatomic relationship. Most cases occur after appendectomy, hernia repair, abdominoplasty, nephrectomy, or gynecologic surgery using the transverse (Pfannenstiel) incisions [337, 344]. Entrapment of the iliohypogastric nerve has not been described.

The clinical manifestations of iliohypogastric nerve lesions include pain above the symphysis and sensory loss in a small area above the symphysis. Bulging of abdominal wall is rare, often seen when there is concomitant involvement of the ilioinguinal nerve.

Iliohypogastric nerve lesions should be differentiated from other proximal sensory mononeuropathies around the groin, including ilioinguinal and genitofemoral nerves, and from L1 or L2 radiculopathy. Diagnostic nerve block is useful in confirmation of diagnosis. Nerve conduction studies of the iliohypogastric nerve have not been described. Needle EMG of lower abdominal muscles may reveal denervation, particularly when associated with ilioinguinal nerve lesion [335].

Neurectomy is the treatment of choice and is effective in the majority of patients, with the minority continuing to have pain in the groin [337]. Prevention of surgical trauma of the hypogastric nerve is advocated. Abdominal incisions (such as Pfannenstiel's suprapubic incision or lower paramedian incision) should pass at least 5 cm above to the inguinal ligament, and the nerve should be displaced carefully downward during oblique lumbar incisions, such as for nephrectomy [339]. Division of the iliohypogastric, ilioinguinal, or genitofemoral nerves during inguinal hernia does not always reduce the incidence of chronic inguinal neuralgia [340].

The Genitofemoral Nerve

The genitofemoral nerve is formed from the L1 and L2 spinal roots. It then passes through the psoas muscle and travels, vertically and retroperitoneal, along its lateral edge to reach the inguinal ligament. There, it divides into femoral and genital branches. The femoral branch passes under the inguinal ligament and innervates a small area of skin on the anterior aspect of the thigh. The genital branch travels medially, with the ilioinguinal nerve, to supply the cremasteric muscle and shares, with that nerve, the sensory supply of the scrotum or labium majus (Fig. 41.17).

The genitofemoral nerve may be injured mostly during appendectomy, but also following inguinal herniorrhaphy, laparoscopic varicocele ligation, nephrectomy, cesarean section, or blunt abdominal trauma [331, 345, 346]. Some cases are delayed, caused by adhesions and scarring. Because of proximity, damage of the genital branch often occurs with injuries of the ilioinguinal nerve at the inguinal ligament. Tumors and spontaneous genitofemoral neuralgia are exceedingly rare.

Clinically, genitofemoral neuralgia presents with pain and paresthesias in the medial inguinal area and scrotum or labium majus. The symptoms overlap significantly with ilioinguinal mononeuropathy such that some authors lump these

injuries into a common term, *"inguinal neuralgia"* [334, 347]. On examination there may be sensory loss in the genitofemoral distribution, often overlapping with the ilioinguinal distribution. Absent or diminished cremasteric reflex may occur on the affected side.

Genitofemoral mononeuropathy should be distinguished from ilioinguinal nerve lesion or L1 or L2 radiculopathy. Diagnostic nerve blocks are often necessary in patients with suspected ilioinguinal neuralgia. It is often useful to block first the ilioinguinal nerve at the lateral end of the inguinal ligament. If the symptoms are not relieved, then paravertebral blocks of L1 and L2 (genitofemoral nerve) should be attempted. Electrophysiological studies include motor conduction latency to the cremasteric muscle, needle EMG of the cremasteric muscle, and the cremasteric reflex [348, 349]. Delayed motor latencies have been reported in children with inguinal hernia [349]. These studies remain unpopular because of technical difficulties.

Once the diagnosis is made, neurectomy is effective in the majority of patients, which could be performed via laparoscopy [331, 337, 350]. Treatment of neuropathic pain with anticonvulsants or antidepressants is a useful adjunctive therapy [351].

The Posterior Femoral Cutaneous Nerve

The posterior femoral cutaneous nerve (posterior cutaneous nerve of the thigh, PFCN) arises from the S1 to S3 spinal roots. It exits the pelvis, with the inferior gluteal nerve, through the greater sciatic notch under the piriformis muscle, and enters the thigh near the sciatic nerve at the lower border of the gluteus maximus (Fig. 41.18). The PFCN innervates the skin of the lower buttock, posterior thigh, popliteal fossa, and proximal third of the calf. It also gives off branches to the perineum and scrotum in men or labium majus in women.

Lesions of the PFCN are rare [352–355]. Intramuscular injections in the buttock are the most common iatrogenic cause. Lacerations or gunshot wounds may selectively injure the PFCN, but often there is a concomitant lesion of the inferior gluteal nerve or sciatic nerve or both. Compression of the nerve by prolonged pressure on the buttock may occur during gymnastic exercises or long bicycle riding [355]. Pelvic mass lesions, such as colorectal tumors or venous malformations, and gluteal hematomas may cause mononeuropathy of the PFCN.

Paresthesias in the lower buttock and posterior thigh are the predominant features. Burning or throbbing pain may accompany the sensory symptoms and often radiates to the perineum, scrotum, or labium majus. The pain may be worse in the sitting or lying positions.

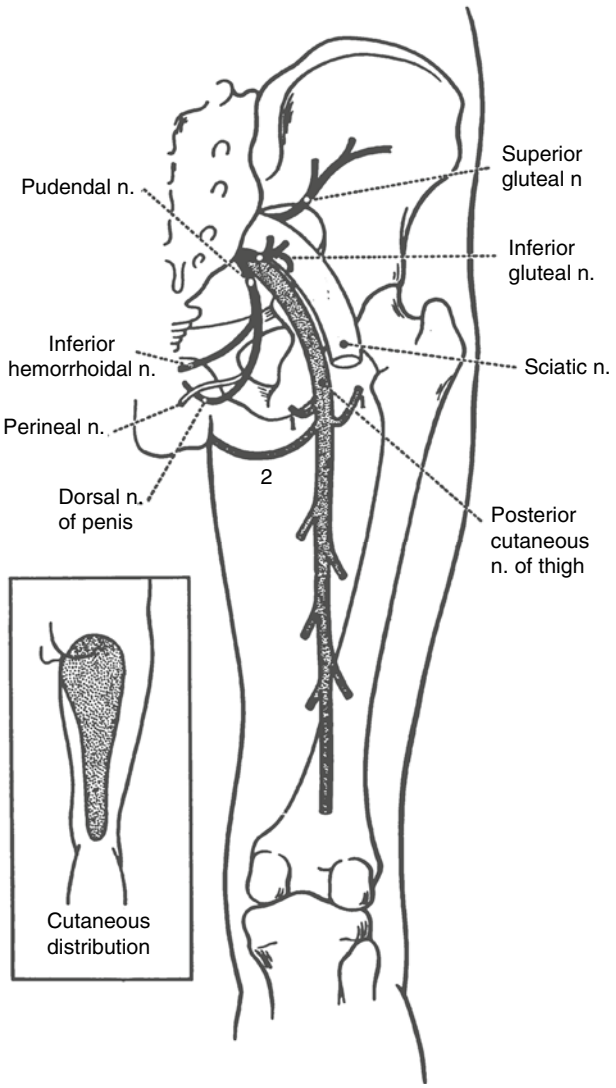

Fig. 41.18 The posterior cutaneous nerve of the thigh and its relation to the gluteal sciatic nerves (From Haymaker and Woodhall [393]. With permission)

A lumbosacral radiculopathy, particularly S1 or S2 radiculopathy, or a sacral plexopathy may mimic a lesion of the PFCN. Depressed or absent ankle jerk and calf or hamstring muscle weakness or atrophy help to exclude a PFCN lesion as a cause of posterior thigh pain ("sciatica") or numbness.

The diagnosis of mononeuropathy of the PFCN relies on a detailed history and typical sensory findings. CT or MRI of the pelvis is indicated if there is a suspicion of a pelvic mass such a colorectal cancer. SNAP of the PFCN is useful in confirming the findings, particularly when compared to the asymptomatic side [354, 356, 357].

The management of mononeuropathy of the PFCN is often conservative except with mass lesions which are often removed surgically. Avoiding pressure on the buttock and proper padding of bicycle seats are recommended.

The Obturator Nerve

The obturator nerve derives its fibers from the ventral divisions of L2, L3, and L4 spinal roots (the femoral nerve originates from the dorsal divisions of the same roots). The obturator nerve passes along the medial edge of the psoas muscle and over the sacroiliac joint before it reaches the obturator canal. The obturator nerve divides into an anterior and posterior branches, usually at the obturator canal, but sometimes proximal or distal to it [358], to innervate the thigh adductors, i.e., the adductor longus, adductor brevis, and adductor magnus (the latter receives additional innervation from the sciatic nerve). The obturator nerve also innervates a small area of skin in the inner thigh (see Fig. 41.16).

Obturator nerve lesions often accompany femoral mononeuropathies as a component of a lumbar plexopathy. Isolated obturator mononeuropathy may be a manifestation of obturator hernia, endometriosis, or a new or recurrent pelvic malignancy [359–363]. Pelvic trauma, particularly when associated with pelvic fractures, may injure the obturator nerve. Iatrogenic lesions occur during hip surgery or replacement, often caused by retractor blade injury, cement extrusion, or fixation screws [100, 102, 364, 365]. Genitourinary procedures and abdominal operations, such as aortofemoral bypass, oophorectomy, or laparoscopic pelvic lymphadenectomy, may also be associated with obturator nerve injury [366–372]. Vaginal delivery, particularly when forceps are used, may also damage the obturator nerve [373]. True entrapment of the obturator nerve by a thick fascia overlying the short adductor muscle is described in athletes [374]. Mass lesions, such as synovial cysts or schwannomas, ganglion cysts, or lipomatosis of the obturator nerve, have been described, but are rare [375–379].

The clinical presentations of obturator mononeuropathies are variable. Neuralgic pain in the medial thigh, worse with exercise, sometimes referred to as obturator neuralgia, is not uncommon particularly in athletes or patients with obturator hernia [360, 363, 372, 374, 380]. Numbness in the medial thigh is common, while subjective weakness and gait impairment are rare. In few patients, obturator nerve injury is only detected on clinical or EDX examination. The neurological findings are limited to weakness of thigh adduction, sometimes associated with sensory loss in the medial thigh. Circumduction of the weak leg, due to abnormal hip abduction, may result in a wide-based gait.

Obturator mononeuropathy may be mistaken as a lumbar radiculopathy, such as an L4 or L3 radiculopathy, or lumbar plexopathy, such as a diabetic amyotrophy. A radiculopathy or plexopathy is distinguished by the presence of quadriceps weakness, iliopsoas weakness, or depressed/absent knee jerk. Disorders of the symphysis or pubis may have referred pain in the medial thigh mimicking an obturator nerve lesion.

The diagnosis of obturator nerve lesions is straightforward when the typical findings are present. Patients with pain and subtle neurologic findings pose a problem in diagnosis. The needle EMG component of EDX studies is most useful since there is no motor or sensory conduction studies techniques available for the obturator nerve [363, 372, 381]. Needle EMG reveals fibrillation potentials, large MUAPs recruited rapidly, or both in the thigh adductors only. In contrast, needle EMG of the quadriceps, iliacus, and lumbar paraspinal muscles is normal. Patients with obturator mononeuropathy and no history of pelvic or hip surgery, or pelvic trauma, should undergo a pelvic CT or MRI to exclude pelvic malignancy [362].

Treatment of obturator nerve lesions depends on the cause and the patient's symptomatology. Correcting an obturator hernia is essential since the mortality from intestinal obstruction is high. Weakness and sensory loss improves in most patients. In those with disabling pain, obturator nerve blocks may be useful [382]. Surgical excision of the obturator nerve may also relieve the pain. The outcome of obturator neuropathy is good in the majority of patients [372, 381].

The Gluteal Nerves

The superior gluteal nerve originates from the L4, L5, and S1 spinal roots and exits the pelvis through the suprapiriform foramen. It then passes through the gluteus medius and minimus and innervates both muscles, before ending in the tensor fascia lata muscle. The inferior gluteal nerve originates from the L5, S1, and S2 spinal roots and exits the pelvis underneath the piriformis in close association with the sciatic nerve and the posterior femoral cutaneous nerve (Fig. 41.18). The inferior gluteal nerve innervates the gluteus maximus only.

Lesions of the gluteal nerves are rare and most are iatrogenic. Superior gluteal nerve injuries may occur with intramuscular injections [383]. This may result in lesions before or after the nerve supplies the gluteus medius and minimus muscles. Pelvic trauma may result in isolated superior gluteal nerve injuries [384]. The inferior gluteal nerve and the accompanying posterior femoral cutaneous nerve may be compressed by intrapelvic masses such as colorectal malignancy, or large iliac artery aneurysm [385, 386]. Both gluteal nerves may be injured after total hip replacement, irrespective of the approach (lateral or posterior) [387–390]. In fact, subclinical gluteal neuropathies are detected by needle EMG in about 3/4 of patients undergoing hip replacement [387]. Endometriosis has been described as a cause of superior luteal neuropathy [391]. Finally, the superior gluteal nerve may be entrapped by the anterior superior tendinous fibers of the piriformis muscle [392], while the inferior gluteal nerve may be compressed, with the sciatic nerve, as it passes under the piriformis muscle (see section "Piriformis Syndrome" above).

Weakness of abduction of the affected hip with a waddling gait is the main manifestation of a superior gluteal mononeuropathy. When the patient is asked to stand on one leg, there is a pelvic tilt toward the healthy side (Trendelenburg sign). Atrophy of buttock with weakness of hip extension is the common feature of inferior gluteal nerve lesions.

Gluteal mononeuropathies are difficult to diagnose without EDX confirmations. Close inspection and examination of the buttock is essential. Disorders of hip joint often mimic these lesions and should always be excluded. EDX studies are limited to needle EMG since the gluteal nerves are not accessible to nerve conduction studies. Fibrillations and loss of MUAPs in the tensor fascia lata and gluteus medius are features of superior gluteal nerve lesions. At times, the gluteus medius is spared when the lesion is distal such as with intramuscular injections. Isolated denervation of the gluteus maximus is the only finding in inferior gluteal mononeuropathy, although abnormal posterior femoral cutaneous SNAP or findings of sciatic nerve involvement may coexist. The EDX findings in gluteal mononeuropathies should be distinguished from L5 and S1 radiculopathy, where denervational changes are often more prominent in distal L5- or S1-innervated muscles such as the tibialis anterior or medial gastrocnemius, respectively.

Treatment of gluteal nerve lesions depends on its causations. Since these lesions are proximal, most partial lesions improve significantly without intervention. Nerve block may be useful in entrapments, and surgical intervention is rarely necessary [392].

Cranial Nerve Palsies

42

Vita Grynova Kesner and Christina Fournier

Introduction

The enumeration and naming of the cranial nerves represent a curious example of evolution in anatomical classification. The earliest classification was recorded by Galen during the second century A.D., and it included 7 pairs: optic (I); oculomotor (II); trigeminal (III); motor root of trigeminal (IV); facial and auditory (V); glossopharyngeal, vagus, and accessory (VI); and hypoglossal (VII) [1]. Progress in both anatomy and physiology resulted in numerous revisions of the nomenclature of cranial nerves. The current classification of 12 cranial nerves was developed by Soemmerring in 1778 as part of a doctoral thesis in medicine: olfactory (I), optic (II), oculomotor (III), trochlear (IV), trigeminal (V), abducens (VI), facial (VII), vestibulocochlear or acoustic(VIII), glossopharyngeal (IX), vagus (X), spinal accessory (XI), and hypoglossal (XII).

Trigeminal Nerve

Neuroanatomy

The fifth or trigeminal nerve is the largest cranial nerve and functions as a mixed motor and sensory nerve. Its fibers exit through the ventral surface of the mid-pons. The large trigeminal (gasserian) ganglion is positioned in the tip of the petrous bone, where the nerve divides into its three sensory divisions – ophthalmic, maxillary, and mandibular. These branches exit the skull through the superior orbital fissure, foramen rotundum, and foramen ovale, respectively. The motor fibers of the trigeminal nerve form a separate fascicle, which passes underneath the gasserian ganglion, merges with the mandibular division, and terminates in the muscles of mastication (Figs. 42.1 and 42.2).

Trigeminal Neuralgia ("Tic Douloureux")

The incidence of trigeminal neuralgia (TN) is approximately 4–5 in 100,000 [2]. TN manifests as episodes of severe unilateral paroxysmal facial pain, often described as stabbing, shock-like, or electrical in the distribution of one or more branches of the trigeminal nerve. The typical pain is lancinating or shooting. Atypical facial pain is usually constant and aching, burning, throbbing, or stinging. The most common pain location is along the nasolabial fold, innervated by the maxillary branch. It is followed in frequency by symptoms along the lower jaw, in the area of the mandibular branch, and the least common pain location is around the eye and forehead, areas innervated by the ophthalmic branch. Painful episodes may have a duration as brief as a few seconds or extend to several minutes in a continuous crescendo. They are often triggered by chewing, swallowing, talking, or light tactile stimuli. Patients may lose considerable weight due to impaired nutrition.

Classic TN should not be associated with any clinically evident neurologic deficits and can be either idiopathic or associated with vascular compression of cranial nerve V [3]. When a vascular source is identified, often an arterial loop from the superior cerebellar artery compresses the trigeminal nerve's sensory roots. Less often, vascular compression can occur from branches of the internal carotid artery, basilar artery, a primitive trigeminal artery, or rarely from an arteriovenous malformation or saccular aneurysm.

Symptomatic TN is due to a structural lesion other than vascular compression [3]. Demyelination of the proximal portion of the trigeminal sensory nerve root and ephaptic spread of excitation can cause TN in patients with multiple sclerosis [4]. Two to four percent of patients with TN have multiple sclerosis, and one to five percent of patients with

B. Katirji et al. (eds.), *Neuromuscular Disorders in Clinical Practice*,
DOI 10.1007/978-1-4614-6567-6_42,

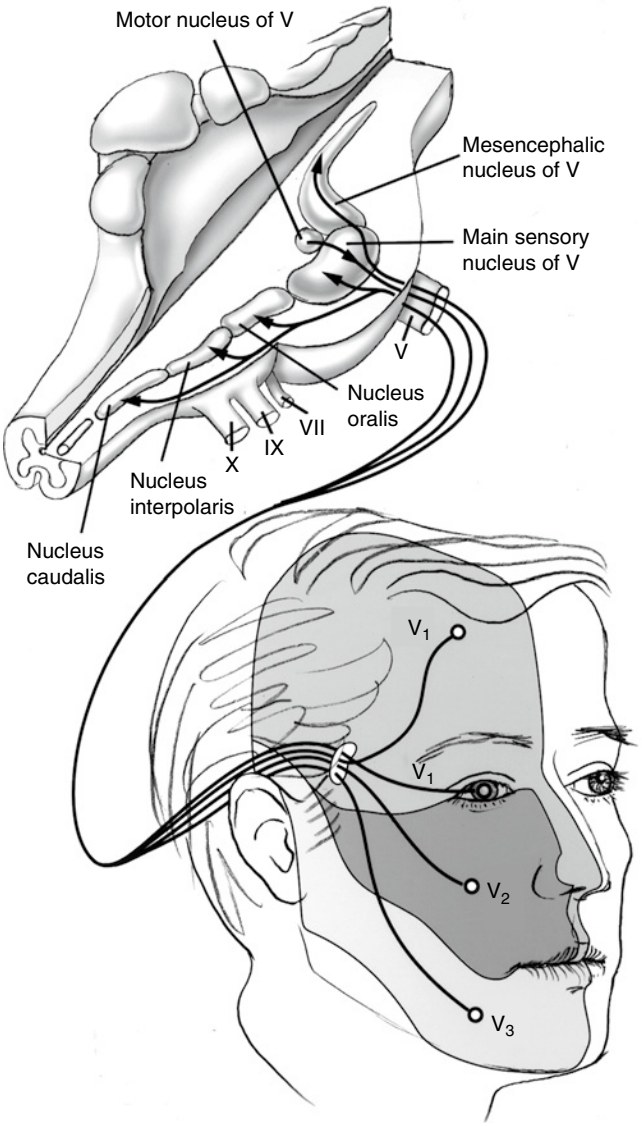

Fig. 42.1 The multiple subdivisions of the trigeminal nuclei occupy a significant rostrocaudal extent in the midbrain, pons, and medulla. Each branch of the trigeminal nerve (*V1* ophthalmic, *V2* maxillary, and *V3* mandibular) innervates a distinct area of the face, as indicated by the different shaded areas in the illustration. Note that the cornea is supplied by the ophthalmic division

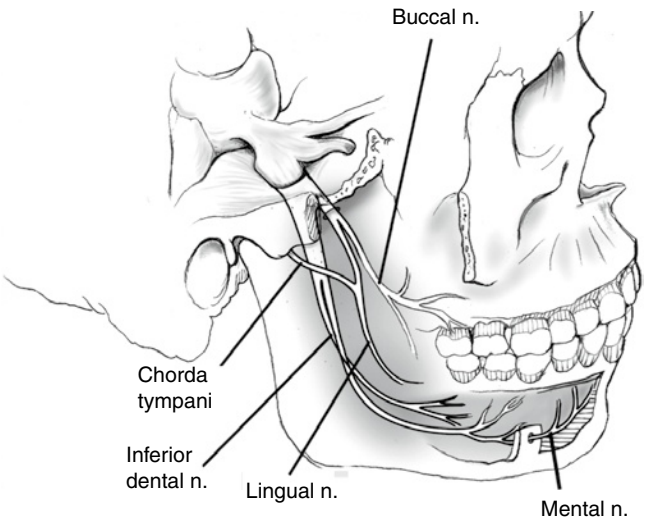

Fig. 42.2 Branches of the mandibular division of the trigeminal nerve

multiple sclerosis will develop trigeminal neuralgia, although the symptoms of multiple sclerosis often precede the onset of TN [5]. Cerebellopontine angle tumors, schwannomas of the trigeminal or vestibular nerve, meningiomas, and arachnoid cysts can less commonly cause trigeminal neuralgia. Younger patient's age, the presence of sensory deficits, or bilateral symptoms are thought to increase the risk of symptomatic TN.

Imaging in patients with TN identifies structural causes in up to 15 % of patients and should be pursued for evaluation. MRI of the skull base with gadolinium is preferred, and angiography can be helpful in the appropriate clinical context. Measurement of the blink reflexes, in which the latency and amplitude of ipsilateral and contralateral facial muscle contractions are recorded following the stimulation of the supraorbital branch of the trigeminal nerve, identifies symptomatic TN with a sensitivity of 59–100 % and specificity of 93–100 % [6]. With symptomatic trigeminal neuralgia, the ipsilateral R1 and R2 responses and contralateral R2 response are delayed or absent with ipsilateral trigeminal stimulation, while all three responses are normal with contralateral stimulation.

Medical treatment of TN usually involves anticonvulsant medications. Carbamazepine or oxacarbamazepine are effective in 60–80 % of patients and are recommended as first line treatment. Typical doses used include carbamazepine 200–1,200 mg/day or oxacarbamazepine 600–1,800 mg/day. Other medications including gabapentin, phenytoin, clonazepam, baclofen, lamotrigine, and valproate have been tried with variable success [7].

In patients who are refractory to medical treatment, several surgical options have been utilized including percutaneous Gasserian lesions, gamma knife surgery, and microvascular decompression. Methods of percutaneous Gasserian lesions include radiofrequency thermocoagulation, glycerol rhizotomy, and balloon compression. Although variance is noted between different publications, long-term satisfactory pain control in ablative Gasserian ganglion procedures and gamma knife is about 50 % [8]. Microvascular decompression may be superior to other procedures, with 70 % of patients being free of pain after 10 years [9]. The presence of typical lancinating pain (versus atypical and constant) is the only significant and independent predictor of outcome following microvascular decompression in patients with TN [10]. In this procedure, surgeons perform a suboccipital craniotomy, dissect the offending arterial loop, and separate the loop from the trigeminal root with Teflon. The mortality rate of this procedure is 0.2–0.4 %, and morbidity

varies based on institutional experience and volume. Other complications include aseptic meningitis, hearing loss, CSF leaks, infarcts, and hematomas.

Trigeminal Sensory Neuropathy

This is an uncommon clinical condition that results in facial paresthesias in the distribution of the fifth cranial nerve. The diagnosis of idiopathic trigeminal neuropathy can be made only after evaluation and exclusion of other causes, including drug intoxication from drugs such as oxaliplatin, trichloroethylene, and hydroxystilbamidine. Isolated chronic trigeminal sensory neuropathy may be a manifestation of connective tissue disorders such as Sjögren's syndrome, systemic lupus erythematosus, scleroderma, or mixed connective tissue disease. It is frequently bilateral and is not confined to individual nerve branches [11]. It affects patients of all age groups, independent of the etiology. Although a number of series report a benign course without other associated neurological defects and preserved corneal reflexes [12], other series describe frequent associations with tumors of the cerebellopontine angle, skull base, nasopharyngeal region, multiple sclerosis, or vasculitis [13]. Furthermore, sensory deficits in the face should always elicit inquiries about previous facial skin cancer because of the well-known tendency of squamous cell carcinomas to infiltrate along the perineurial sheathing of the cutaneous nerves [14]. Treatment with corticosteroids has limited efficacy in this condition.

Numb Chin and Numb Cheek Syndromes

Persistent numbness in the lower lip and chin (*numb chin syndrome*) may result from lesions of the mental nerve or the mandibular division of the fifth cranial nerve. This is also referred to as *mental neuropathy* and is often seen with metastatic cancer; it may be part of disease progression in advanced cases or the initial manifestation of a relapse in patients with known systemic cancer. Sometimes, it is the first symptom of an underlying malignancy. This occurs classically with nasopharyngeal carcinoma but is in fact most common with metastatic breast cancer, lymphoma, prostatic cancer, and lung cancer [15]. In more than half of the patients, this is due to invasion of the mandible and infiltration of the inferior alveolar nerve. In the rest, it is due to lesions of the base of the skull or leptomeningeal seeding [15]. Hence, the work-up should include imaging of the mandible by orthopantomogram or CT, and if negative, imaging of brain, base of skull, and CSF analysis. The prognosis is poor with a very high mortality in 6–12 months [15, 16]. In elderly patients with mandibular atrophy, impingement of the mental nerve at the mental foramen has been described [17] (Fig. 42.2).

On the other hand, numbness in the malar region (*numb cheek syndrome*) may be the initial manifestation of epithelial tumors (e.g., basal or squamous cell carcinomas of the face) or associated with incompletely treated neoplasms. Thus, persistent or progressive sensory deficits in the maxillary or mandibular divisions require thorough neuroimaging studies, laryngologic surgical evaluation, and careful clinical follow-up, as some neoplasms may initially be too small for detection.

Herpes Virus Infections

Infection by the herpes zoster virus is probably the most common lesion affecting the trigeminal ganglion. The ophthalmic division is involved in a ratio of 4:1 compared to lesions to the maxillary or the mandibular divisions. Clinically, patients describe a relatively rapid onset, with severe, constant, and disabling facial pain. Small vesicles often appear along the forehead and the eyebrow between the third and fifth days, followed by pronounced facial edema.

In contrast, infection caused by the herpes simplex virus (HSV), which results from persistent presence of HSV in the trigeminal ganglion, has a more indolent course. It affects all three trigeminal divisions equally and manifests as lifetime recurring episodes of mucous membrane lesions in the oral cavity and, most commonly, as "cold sores" in the lips.

Facial Nerve

Neuroanatomy

The seventh or facial nerve is a mixed motor and sensory nerve. It innervates the muscles of facial expression, the salivary and lacrimal glands, and the mucous membrane of the oral and nasal cavities. In addition, it conveys taste sensation from the anterior two-thirds of the tongue via the lingual and chorda tympani nerves and provides tactile sensation to a small but distinct area in the posterior external auditory canal (Hitzelberger's sign). The motor fibers originate in the facial nucleus located in the pons, sweep medially around the nucleus of the abducens nerve, and exit the ventral surface of the pons in the cerebellopontine angle. The facial nerve, along with the nervus intermedius and vestibulocochlear nerves, then passes from the brainstem into the temporal bone through the inner acoustic meatus. The seventh cranial nerve follows a tortuous course within the facial canal of the temporal bone exiting the skull through the stylomastoid foramen to supply the muscles of facial expression. The facial nerve also supplies the submandibular and sublingual glands (Fig. 42.3).

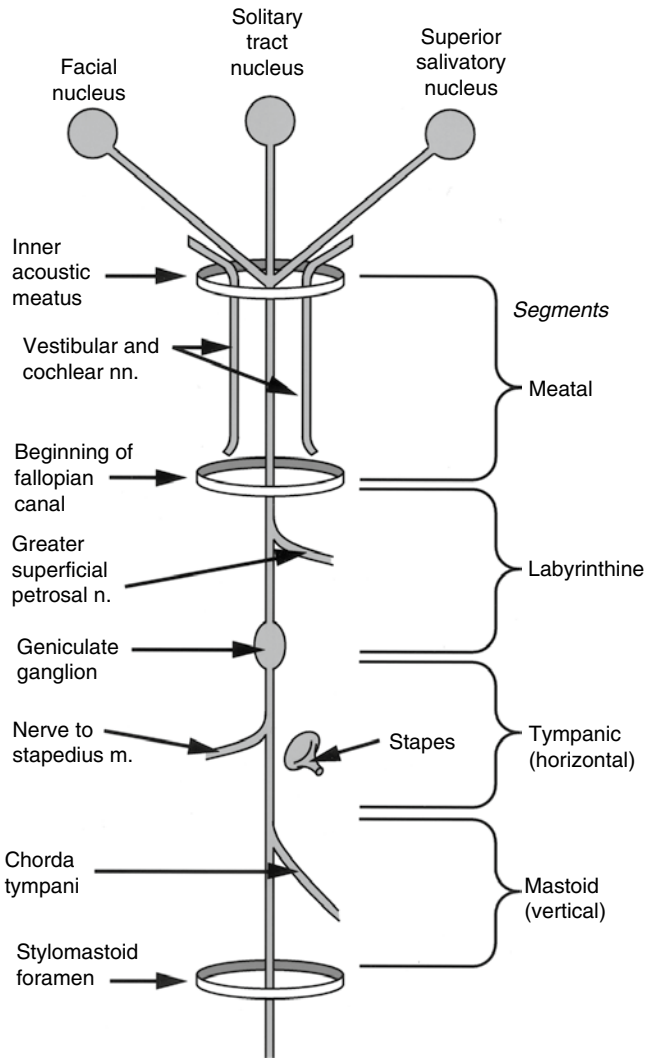

Fig. 42.3 The facial nerve contains fibers from the facial, solitary tract, and superior salivatory nuclei. It exits the skull through the inner acoustic meatus, in conjunction with the vestibular and cochlear nerves. Within each designated segment (labyrinthine, tympanic, and mastoid) of its complex trajectory, the facial nerve gives off a branch that can help in the clinical identification of the site of lesion

Given the close proximity of the genu of the facial nerve and the nucleus of the abducens nerve within the pons, facial palsies secondary to intrapontine lesions are almost always also associated with gaze or sixth nerve impairment, thus distinguishing them from more peripheral lesions. The anatomical branching pattern of the facial nerve sometimes allows for the localization of the lesion in the temporal bone (Fig. 42.3) [18]. Lesions of the most distal mastoid (vertical) segment affect the chorda tympani nerve, thus impairing taste sensation in the ipsilateral anterior two-thirds of the tongue. Lesions involving the tympanic (horizontal) segment within the middle ear result also in hyperacusis due to damage to the nerve to the stapedius muscle. Lesions of the most proximal labyrinthine segment result also in impaired ipsilateral lacrimation because of the involvement of the greater superficial petrosal nerve. Distal lesions of the facial nerve may affect individual motor branches, thus causing focal paresis of individual facial mimetic muscles. Such lesions can usually be confirmed by needle electromyographic examination.

Bell's Palsy

Idiopathic facial nerve palsy, or Bell's palsy (BP), is the most common lesion of the seventh cranial nerve. Clinically, patients frequently describe a dull pain in or behind the ipsilateral ear, suggestive of an ear infection as the initial manifestation. This is thought to be due to dysfunction of the sensory supply to portions of the external ear canal. A peripheral-type facial paralysis quickly follows and usually achieves maximum impairment in 48–72 h. In addition to facial paresis, patients may also describe impairment of taste and hyperacusis.

The site of injury to the facial nerve in BP is often in the proximal (and most narrow) portion of the facial canal [19]. The initial lesion is inflammatory in nature, causes segmental demyelination of motor axons, and disrupts the conduction of electric impulses. More severe lesions will result in direct injury to the axons, which can be detected on facial motor nerve conduction studies: there is a significant decrease of amplitude in the compound motor action potential (CMAP) recording the facial muscles in the involved side. The facial CMAP, performed after 7–10 days from the onset of facial weakness (time to complete Wallerian degeneration if any), has an important prognostic value [20]: If the CMAP of the involved side is 30 % or greater of that on the normal side, 84 % of the patients will have complete recovery. However, when the CMAP is 25 % or less of the normal side, there is an 88 % chance of incomplete recovery. In a small percentage of patients, delayed recovery with axonal loss can lead to aberrant regeneration of the remaining motor fibers.

The most common neurological sequelae of aberrant facial nerve regeneration results in synkinesis or contraction of the lower facial muscles on the previously involved side whenever there is an eye blink. Two very uncommon examples of abnormal regeneration patterns are so-called crocodile tears, i.e., lacrimation of the ipsilateral eye during chewing, and Marin-Amat syndrome, or "jaw-winking," manifested as closure of the ipsilateral eyelid when the jaw opens.

Although BP was classically defined as a unilateral peripheral facial palsy of unknown etiology, many studies support an association of acute facial palsy with herpes simplex virus (HSV). Latent HSV type-1 is isolated in the majority of the geniculate ganglia from autopsy samples [21]. Furthermore, HSV-1 genome was detected in 79 % of facial nerve endoneurial fluid in patients with BP, but not in normal

controls [22]. Others propose an immune etiology to BP, and in fact, recent studies suggest that treatment of BP with steroids alone provides the most benefit for facial muscle recovery and is superior to immunotherapy with antiviral medications. Treatment with both steroids and antiviral medications has not been clearly shown to confer additional benefit over treatment with steroids alone [23].

Herpes zoster infection of the geniculate ganglion (*Ramsay-Hunt syndrome, herpes zoster oticus with facial palsy*) is also increasingly recognized as a cause of facial palsy. Its incidence is 5/100,000 of the United States population with higher incidence in subjects older than 60 years. With zoster infections, in addition to pain, tinnitus, and decreased hearing, the appearance of vesicles in the external auditory canal and soft palate is characteristic [24]. Antibody titers against varicella-zoster virus (VZV) provide a useful adjuvant to the clinical diagnosis of Ramsay-Hunt syndrome. In a prospective study of 43 patients with facial nerve palsy, 75 % of patients with typical vesicular lesions (8 of 12) presented with antibody titers >1/10. In contrast, only 29 % (9 of 31) of patients without vesicular lesions presented with such high titers [25]. Oral antiviral agents are effective in patients with herpes zoster infection in general, by speeding up rash healing and decreasing pain duration. Although corticosteroids are mostly helpful in reducing the acute pain and the incidence of postherpetic neuralgia, their use in the Ramsay-Hunt syndrome remains anecdotal with no available controlled trials [26].

Bilateral Facial Palsy

Bilateral and simultaneous facial weakness (facial diplegia) is an uncommon event and often a diagnostic challenge. Although Guillain-Barré syndrome (GBS) is associated with facial diplegia in up to 60 % of the cases, bilateral facial weakness is a dominant neurological finding in the atypical forms of GBS such as the descending or the pharyngeal-cervical-brachial forms. Another rare GBS variant is characterized by facial diplegia only but is often associated with distal limb paresthesias, abnormal limb nerve conduction studies, and positive serology for a recent cytomegalovirus infection [27]. Neurosarcoidosis and accidental or intentional ingestion of the toxin, ethylene glycol ("antifreeze"), may also cause facial diplegia. The combination of facial diplegia, aseptic meningitis, and a slightly erythematous indurated face resembling painless cellulitis should trigger an investigation for Lyme disease. In Keane's seminal review of bilateral facial palsies, the most common cause was bilateral idiopathic BP (10 of 43 patients), followed closely by brainstem tumors (9 patients) and Guillain-Barre syndrome (5 patients) [28]. Less common causes of bilateral facial palsy include malignant lymphoma [29] and gelsolin-related familial amyloidosis, an autosomal dominant condition also associated with corneal lattice dystrophy and a generalized polyneuropathy [30].

Congenital Disorders

Unilateral or bilateral facial palsies in neonates are usually due to traumatic injuries versus congenital abnormalities. Traumatic facial nerve damage is usually associated with difficult forceps delivery and presents with periauricular ecchymosis, hemotympanum, and facial swelling. In contrast, congenital facial disorders often present with other systemic stigmata, e.g., microtia, external auditory atresia, limb deformity, or hypoplasia of the pectoral muscle. In particular, Möbius syndrome, which results from bilateral hypogenesis or agenesis of the nucleus of the sixth and seventh cranial nerves, is often associated with limb abnormalities. In the cardiofacial (Cayler's) syndrome ("asymmetric crying facies"), the neonate exhibits facial asymmetry when crying but not at rest. The cause of this motor deficit is isolated weakness of the depressor anguli oris and depressor labii inferioris [31].

Glossopharyngeal Nerve

Neuroanatomy

The ninth cranial or glossopharyngeal nerve receives contribution from several brainstem nuclear complexes (tractus solitarius [gustatory nucleus], nucleus ambiguus, inferior salivatory nucleus). Distinct subsets of the glossopharyngeal nerve fibers emerge from the medulla between the VIII and X cranial nerves. The nerve leaves the skull through the jugular foramen and reaches the lateral wall of the pharynx by following the inferior border of the stylopharyngeus muscle.

Isolated lesions of the IX nerve are very uncommon. Thus, multiple syndromes are described involving combined injuries to the nucleus or the peripheral fibers of the glossopharyngeal nerve and the other three lower cranial nerves (vagus, spinal accessory, and hypoglossal). However, isolated lesions of the glossopharyngeal nerve can manifest as slight difficulties with swallowing due to weakness of the stylopharyngeus muscle, taste disturbance in the posterior third of the tongue, reduced or absent gag reflex, or decreased parotid gland secretion.

Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia is a relatively rare neuralgia which presents as severe, sharp, and lancinating pain located in the lateral portion of the throat or tonsillar region, producing extreme discomfort. The pain often is referred to the

ipsilateral ear and external auditory canal. Trigger zones are usually located in the posterior and lateral pharyngeal and tonsillar fossa. Thus, talking, chewing, or swallowing can initiate the pain. Autonomic dysfunction (salivation, lacrimation, bradycardia, and syncope) may be associated with glossopharyngeal neuralgia. This condition may be idiopathic or secondary to a local structural lesion, such as a tumor of the peripheral nerve or a cerebellopontine angle tumor. Other reported causes include enlarged tortuous vertebral or posterior cerebellar arteries, oropharyngeal carcinoma, paratonsillar abscess, or elongated styloid process. Patients often lose considerable weight before treatment is initiated.

Treatment is targeted toward the underlying cause of secondary neuralgias. Medical treatment is similar to that of trigeminal neuralgia, and carbamazepine has been used as the initial line of treatment. Stereotactic radiosurgery and neurosurgical intervention may be effective in medically refractory cases [32, 33]. Surgical exploration often reveals aberrant vessels across the nerve, neurofibromas, or cholesteatomas adjacent to the nerve. The overall immediate success rate exceeded 90 % in patients treated with microvascular decompression, and long-term patient outcomes were best for typical glossopharyngeal neuralgia with pain restricted to the throat and palate. Nerve sectioning can be curative [34].

Glomus Jugulare Tumors

These are highly vascular erosive tumors that arise from the chemoreceptor cells in proximity to the jugular foramen. Their clinical manifestations result from compression of the adjacent IX, X, and XI cranial nerves. Patients often present with difficulties in swallowing, hoarseness in voice, and pulsatile tinnitus followed by conductive hearing loss. Patients may also present with symptoms of increased intracranial pressure due to compression of the jugular vein which results in impairing venous drainage. Treatment options for glomus jugulare tumors include subtotal resection with or without adjuvant postoperative radiosurgery, gross-total resection, or stereotactic radiosurgery alone [35].

Vagus Nerve

Neuroanatomy

The tenth cranial or vagus nerve has the longest and most widely distributed extracranial trajectory of all cranial nerves. The brainstem nuclear connections are similar to those of the glossopharyngeal nerve. The motor fibers originate from the nucleus ambiguus and the dorsal motor nucleus of the vagus. The sensory fibers are collected mostly at the jugular and the nodose ganglia. The vagus nerve, as do the glossopharyngeal and spinal accessory cranial nerves, exits the cranial vault through the jugular foramen.

Lesions of the vagus nerve lead to weakness of the palate and pharynx. Unilateral lesions cause defective elevation of the palate during phonation with deviation of the uvula to the contralateral side. Bilateral lesions result in nasal speech, nasal regurgitation with swallowing, and snoring. Pharyngeal paralysis results in varying degrees of dysphagia.

Clinically, two branches of the vagus nerve are of particular importance. The *superior laryngeal nerve* originates in the proximity of the nodose ganglion, and its branches innervate the cricothyroid and the inferior pharyngeal constrictor muscles, as well as the mucosa of the larynx and the various laryngeal glands. The *recurrent laryngeal nerve* controls all the intrinsic muscles of the larynx responsible for vocalizations. The right and left recurrent laryngeal nerves have different courses: On the right side, the nerve descends caudally with the main vagal trunk, loops underneath the subclavian artery, and redirects rostrally to innervate the larynx. The left recurrent laryngeal nerve loops underneath the aortic arch, thus following a longer course, and is therefore more vulnerable to lesions along its trajectory. The recurrent laryngeal nerves may be damaged by carcinoma of the thyroid, tumors of the mediastinum and lung, trauma, or iatrogenically in procedures such as thyroidectomy. Recurrent laryngeal neuropathy may also be a rare manifestation of idiopathic brachial plexopathy.

Recurrent laryngeal and superior laryngeal nerve lesions can be minimally symptomatic or lead to persistent hoarseness and dyspnea. They can also cause autonomic dysfunction with impairment of esophageal, gastric, and intestinal motility, as well as vagal cardiac activity. Intraoperative nerve monitoring has been utilized in attempts to reduce the risk of recurrent laryngeal nerve injury, but the benefits of these techniques remain uncertain [36].

Brainstem Lesions

Because of significant crossover of the supranuclear pathways to the nucleus ambiguus, only bilateral lesions are of clinical significance. Patients with such lesions, which can be caused by motor neuron disease, poliomyelitis, or primary brainstem tumors, have a pseudo-bulbar clinical presentation manifested as dysphagia and dysarthria.

Nuclear or intramedullary lesions can result from vascular infarcts (lateral medullary or Wallenberg syndrome), neoplasias, inflammatory lesions, syringobulbia, motor neuron disease, or poliomyelitis. Infranuclear lesions often occur as the vagus nerve exits the skull through the jugular foramen and are often associated with lesions of the glossopharyngeal and spinal accessory nerves. Peripheral lesions affecting the recurrent laryngeal nerve, usually the most common type of neurogenic laryngeal dysfunction, can result from trauma, surgical procedures in the neck region, and tumors of the

mediastinum and lung. Patients with acute unilateral injury to the recurrent laryngeal nerve often complain of difficulties in coughing forcefully ("bovine cough") and a hoarse voice.

Extramedullary Lesions

Posterior fossa or jugular foramen tumors can cause compression of the vagus nerve. Vagus nerve damage can also result from carotid artery aneurysm or dissection. Inflammatory and infectious processes responsible, such as sarcoidosis, Lyme disease, and Guillain-Barre syndrome, can affect the vagus nerve in conjunction with other cranial and peripheral neuropathies. Toxic causes and nutritional causes, such as alcohol-induced neuropathy, Beriberi or thiamine deficiency [37], and vincristine-induced nerve toxicity, have been implicated as causes of vagus neuropathies [38].

Spinal Accessory Nerve

Neuroanatomy

The eleventh or spinal accessory nerve is a purely motor cranial nerve and is composed of a smaller cranial part ("accessory" to the vagus nerve) and a larger spinal portion (C2-C6 ventral roots). The cranial part of the XI cranial nerve, in conjunction with the vagus and glossopharyngeal nerves, innervates muscles of the pharynx and larynx. The larger spinal portion innervates the sternocleidomastoid and upper portions of the trapezius muscles. The lower portions of the trapezius receive innervation from the ventral ramus of spinal roots C2-4.

Clinical Syndromes

A great diversity of lesions can injure the nerve fibers of the spinal accessory nerve, because the nerve follows a long course in the spinal canal, inside the cranial vault, and peripherally. Intraspinal lesions can result from motor neuron disease, poliomyelitis, syringomyelia, tumors, and external cervical trauma. Intracranially, masses such as meningiomas and neuromas may damage the neurons or the axons by direct compression. Arguably the most common type of lesion occurs in the periphery, between the jugular foramen and the nerve terminations in the trapezius muscle. Iatrogenic lesions, such as those resulting from radical neck dissections or lymph node biopsies in the neck region, are very common causes of injury (Fig. 42.4). Surgical exploration and nerve repair can be effective in the restoration of function in cases of nerve transection, and early operative intervention yields the best functional results [39]. Other etiologies include carotid endarterectomy [40], coronary artery bypass surgery, radiation damage, shoulder

Fig. 42.4 Left spinal accessory nerve lesion resulting in scapular winging following scalene nerve biopsy (Courtesy of Dr. Bashar Katirji)

dislocation, blunt trauma, and stretch and biting injuries [41]. In Vernet's syndrome, the spinal accessory nerve is injured in conjunction with the glossopharyngeal and vagus nerves as these three cranial nerves pass through the jugular foramen (Fig. 42.5). Neuralgic amyotrophy with involvement of cranial nerves IX, X, XI, and XII has been reported [42]. In addition, isolated unexplained lesions of cranial nerve XI can occur with spontaneous recovery. Motor nerve conduction studies of the spinal accessory nerve, particularly when asymmetry is noted in latency and amplitude with a unilateral lesion, and electromyography of the trapezius or sternocleidomastoid can be useful in confirming the diagnosis for CN XI lesions.

Patients with lesions of the spinal accessory nerve proximal to the branching point to the sternocleidomastoid muscle have weakness in turning the head toward the unaffected side. Furthermore, attempts of neck flexion in the supine position may show a head deviation to the affected side. Lesions of the motor branches to the trapezius muscle result in significant wasting of muscle mass, and the affected shoulder is notably lower than the healthy counterpart. At rest the scapula is displaced laterally, with the inferior angle rotated medially. Scapular winging is further accentuated by attempted abduction of the arm. In contrast, in scapular winging associated with weakness of the serratus anterior muscle, which can result from injuries to the long thoracic nerve, the scapula is displaced medially, and winging is accentuated by forward flexion or protraction against resistance.

Clinical Anatomy of the Jugular Foramen

There is a unique anatomical relationship between the last four cranial nerves (glossopharyngeal, vagus, spinal accessory, and hypoglossal) and the jugular foramen (JF) which

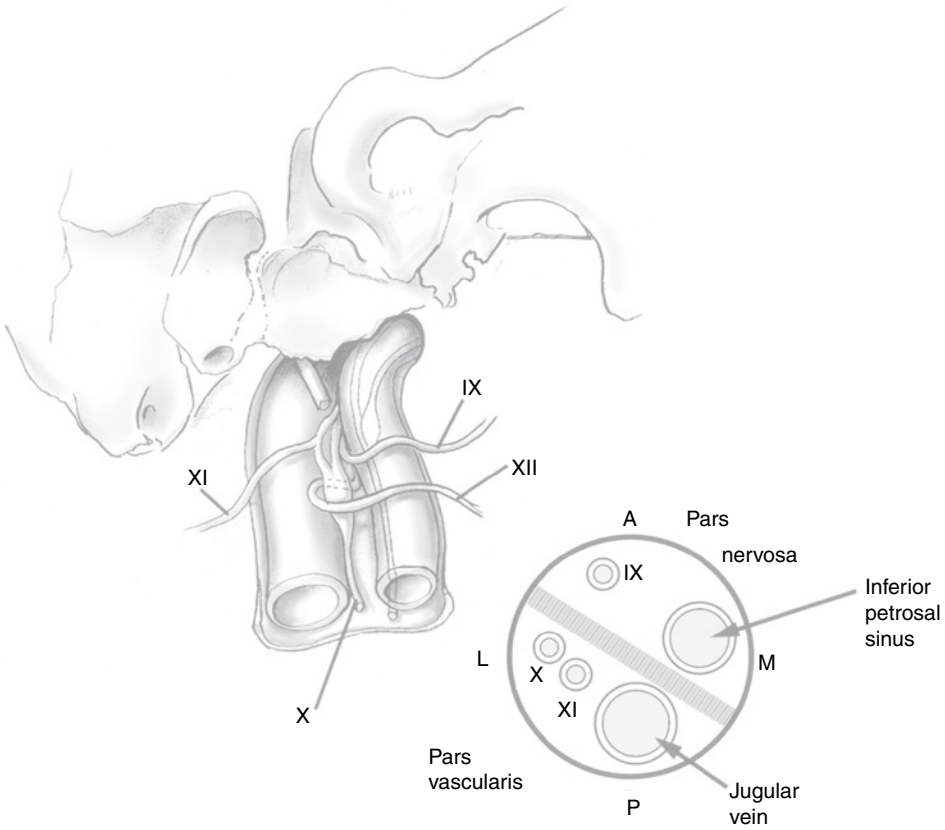

Fig. 42.5 Regional anatomy of jugular foramen and associated cranial nerves

explains the observed clinical syndromes (Table 42.1). Thus, a more detailed examination of this anatomical region is warranted (Fig. 42.5). Three cranial nerves (IX, X, and XI) exit the base of the skull through the JF. The hypoglossal nerve passes through the hypoglossal canal, which lies immediately medial to the JF. The JF is divided in two compartments by a fibrous or bony septum: *pars nervosa* (anteromedial) and *pars vascularis* (posterolateral). Despite the nomenclature, only the glossopharyngeal nerve goes through the smaller pars nervosa together with the inferior petrosal sinus. The pars vascularis contains the vagus and the accessory nerves, as well as the jugular vein.

The close proximity of the last four cranial nerves often results in combined nerve lesions. Clinical presentations of such lesions generally include hoarseness or loss of voice strength, nasal speech, and difficulties in swallowing.

The *Vernet's syndrome* manifests as deficits of the cranial nerves (IX, X, XI) that traverse the jugular foramen. Sparing of the hypoglossal nerve and the cervical sympathetic chain often suggests the intracranial nature of the lesion causing this syndrome. In contrast, all four lower cranial nerves are impaired in the *Collet-Sicard syndrome* (Table 42.1). Although an intracranial lesion can result in this combination of cranial nerve deficits, a more parsimonious explanation is an extracranial lesion just outside of the jugular foramen affecting the nerves that pass through the JF (IX, X, XI) and the nearby hypoglossal nerve as it exits through the separate hypoglossal canal. An intracranial lesion extensive enough to cause a Collet-Sicard syndrome would very likely distort the lower brainstem and the cerebellum, thus causing pyramidal and cerebellar signs. The inclusion of a Horner's syndrome to the impairment of the last four cranial nerves constitutes the clinical presentation of the *Villaret's syndrome*. This always indicates an extracranial lesion, usually in the area of the posterior nasopharynx, as it affects the sympathetic chain, which

Table 42.1 Brainstem lesions and clinical syndromes

Syndromes	Cranial nerve involvement	Clinical presentation
Tolosa-Hunt	III,IV,V,VI	Multiple cranial nerve palsies
Millard-Gubler	VI,VII	VI and VII palsies and contralateral hemiplegia
Foville's	VI,VII	VI and VII palsies, contralateral hemiplegia, and gaze palsy to the side of the lesion
Vernet's	IX,X,XI	Ageusia (1/3 posterior tongue); paralysis of vocal cords, palate, and pharynx; paralysis of trapezius and sternocleidomastoid
Schmidt's	X,XI	Paralysis of soft palate, pharynx, and larynx; paresis of ipsilateral trapezius and sternocleidomastoid
Tapia's	X,XII	Paresis of pharynx and larynx; paralysis and atrophy of tongue
Jackson's	X,XI,XII	Paresis of pharynx and larynx; paresis and atrophy of tongue; paresis of ipsilateral trapezius and sternocleidomastoid
Collet-Sicard	IX,X,XI,XII	Anesthesia of palate; paresis of vocal cords and palate; weakness of trapezius and sternocleidomastoid; paresis and atrophy of tongue; hemianesthesia of pharynx and larynx
Villaret's	IX,X,XI,XII, and cervical sympathetic	Same as above plus Horner's syndrome

does not traverse the jugular foramen, and the extracranial portion of the lower cranial nerves.

Hypoglossal Nerve

Neuroanatomy

The twelfth or hypoglossal nerve is a purely motor nerve that controls the extrinsic and intrinsic muscles of the tongue. The hypoglossal nucleus is located in the floor of the fourth ventricle, close to the midline, and the fibers traverse the cross-section of the caudal medulla before exiting through the ventral surface of the brainstem, between the pyramidal tract and the olivary eminence. The nerve leaves the skull base through the hypoglossal canal and courses briefly with the IX, X, and XI cranial nerves before it separates at the mastoid level and innervates the tongue. A unilateral lesion of the hypoglossal nerve results in ipsilateral paresis and wasting of the tongue.

Clinical Syndromes

A common cause of isolated hypoglossal nerve damage occurs as a complication of carotid endarterectomies [43], particularly due to variability in location between the hypoglossal nerve and the carotid bifurcation [44]. However, peripheral lesions may also result from radiation therapy, local tumor (e.g., salivary gland neoplasm), carotid artery aneurysm and dissection, internal jugular vein cannulation, glomus jugulare resection, and trauma to the face (Fig. 42.6). Clinically, patients with unilateral injuries to the hypoglossal nerve have unilateral atrophy of the tongue and mild difficulties manipulating food. The tongue deviates toward the side of the lesion due to the unopposed action of the healthy contralateral genioglossus muscle (see Fig. 42.6). There is tremendous difficulty moving the tongue from side to side. However, only with bilateral nerve injuries will patients encounter significant difficulties in swallowing, talking, and respiration, because the tongue falls backward and obstructs the upper airways.

Motor neuron disease, poliomyelitis, syringomyelia, tumors [45], and infarcts may cause lesions to the neurons of the hypoglossal nucleus. An infarct may assume the presentation of the medial medullary syndrome [46] (i.e., ipsilateral tongue paresis associated with a contralateral corticospinal tract lesion causing paresis of the arm and leg and medial lemniscus involvement leading to diminished proprioceptive and tactile sensation). Basilar meningitis or intracranial metastases can occasionally affect CN XII but most commonly will do so in conjunction with other lower cranial nerve lesions. Hypoglossal nerve palsy has also been reported in association with infectious mononucleosis [47] and due to subluxation of the odontoid process with rheumatoid arthritis [48].

Peripheral Nerve Tumors

43

Loyola V. Gressot, Kim Islup, David G. Kline, and Daniel H. Kim

Peripheral nerve tumors encompass neoplasms originating in peripheral nerves and those originating from tissues extrinsic to the peripheral nerves with consequent neural compression. Although much less common than nerve entrapment or nerve injuries, these peripheral nerve tumors are not rare, as several thousand cases are diagnosed annually [1–4]. Physicians undertaking the management of these lesions must have experience with the anatomy of the area involved by the tumor as well as a fundamental understanding of the internal structure of the involved nerve itself [5, 6]. Surgical resection is the treatment for most peripheral nerve tumors and can be quite complex with the risk of serious neurologic deficit. The pathologic diagnosis of these lesions can be difficult as well, and misinterpreted histology can result in incorrect treatment and serious disability. Physicians who are not comfortable in the diagnosis and treatment of these lesions should refer peripheral nerve tumors to a medical center with surgeons and pathologists with experience in such cases in order to maximize patient satisfaction and good outcomes.

Diagnosis

Peripheral nerve tumors have a broad and complex range of histopathology. The differential diagnosis of a mass or pain encompasses a wide range of etiologies, and peripheral nerve tumor is frequently overlooked. Commonly encountered neoplasms, such as schwannomas, neurofibromas, plexiform neurofibromas, and neurogenic sarcomas, have classic clinical presentations and characteristic gross and microscopic features [7]. The prototypically clinical presentation of a peripheral nerve tumor is a mass which can be mobilized perpendicular to the course of the nerve but not longitudinal to the nerve (Fig. 43.1a) [8]. Patients may also report induced paresthesia in the nerve distribution upon percussion of the nerve by the examiner. Once a peripheral nerve tumor is suspected, it is imperative to seek out evidence of other nerve tumors and von Recklinghausen's disease (neurofibromatosis 1-NF1). Though MRI is not particularly helpful in managing patients with nerve injuries, MRI together with computed tomographic (CT) scanning is most useful in delineating the true extent of the tumor or identifying additional lesions diagnostic of NF1 (Fig. 43.1b). Angiography and myelography are occasionally required to fully evaluate complex lesions [9]. Any tumor located in close proximity to the spine should have the medial extent of the tumor carefully defined by such studies. Unfortunately, no imaging modality can conclusively differentiate schwannoma from neurofibroma or malignant versus benign peripheral nerve tumors with certainty. The diagnosis depends on histopathological evaluation of tumor tissue.

Once the diagnosis of a peripheral nerve tumor is made on clinical grounds, the clinician cannot determine at that point whether the diagnosis is a schwannoma, a neurofibroma, or a malignant nerve tumor. Depending on the physician's experience with nerve tumors, it may be best to refer a patient to an appropriate medical center with experience in managing these complex patients where a definitive diagnosis can be made and, if necessary, definitive surgery can be performed. A partial or suboptimal resection may lead to clinical worsening.

Peripheral nerve tumors may be classified into benign and malignant tumors. The benign tumors may further be divided into those that are of neural sheath origin and those that involve the peripheral nerves but are not of neural sheath origin. Malignant tumors can be categorized as those of neural sheath origin, including neurogenic sarcomas, and malignancies of non-neural origin compressing or directly involving nerve by either direct extension or metastasis.

Benign Neural Sheath Tumors

Schwannomas

Schwannomas are the most common benign neural sheath tumor. The incidence of schwannomas is higher in females than males for reasons not fully understood [10]. The typical presentation of a schwannoma is a painless but palpable mass which may occur throughout the upper or lower extremities (Tables 43.1, 43.2, and 43.3). Percussing over the mass usually generates paresthesias in the distribution of the affected nerve (Tinel's sign). In one series of 85 schwannomas, all patients but one had a Tinel's sign [11]. Rarely, a schwannoma may present with a neurologic deficit or abnormal electrodiagnostic studies [12]. If the patient presents after a biopsy or an attempted resection of a schwannoma, symptoms then are more likely to be pain, paresthesias, neurologic deficit, or a combination of these symptoms. Occasionally, schwannomas can develop in patients with NF1 although neurofibromas are the most likely diagnosis in this population [13]. Schwannomatosis has recently been proposed as a separate syndrome in patients with multiple schwannomas but no stigmata of NF2 such as vestibular schwannomas[14]. Symptomatic tumors should be removed, provided that the patient is an acceptable surgical candidate.

Schwannomas most likely originate from Schwann cells, but the exact origin of these tumors has previously been disputed [15–17]. Histopathology reveals a tumor composed only of Schwann cells without fibroblasts or perineural cells. The tumor consists of two distinct cellular patterns. Antoni A tissue is characterized by hypercellular compact elongated cells which may demonstrate Verocay bodies made up of alternating parallel rows of tumor cells forming palisading region. Antoni B tissue is characterized by loosely arranged, hypocellular regions (Figs. 43.2 and 43.3). Lipid-laden cells may be found in either Antoni A or B tissue. The vasculature of schwannomas is often thickened, hyalinized, and may even be thrombosed. The compact Antoni type A tissue of a schwannoma must be differentiated from the less compact and more myxomatous matrix of a neurofibroma. Antoni type B tissue has a somewhat loose stroma and may be distinguished from a neurofibroma by mucopolysaccharide stain. Schwannoma matrix does not stain for mucopolysaccharide but neurofibroma matrix does. Schwannomas will demonstrate strong S 100 positivity and frequently also show positivity for podoplanin, calretinin, and SOX 10 [18–21].

Schwannomas are well encapsulated and displace adjacent nerve fascicles laterally. Larger schwannomas tend to stretch and elongate the fascicles but do so at such a slow rate

NF Neurofibroma, *NF-NF1* Neurofibroma in patient with von Recklinghausen disease

that neurological function is typically preserved [10]. Generally, one or two nerve fascicles enter the tumor proximally and emerge distally. Electrical stimulation across these fascicles does not produce a nerve action potential (NAP); thus, surgical resection is therefore possible without interrupting functional nerve fibers. Operative removal is usually indicated based upon expectant improvement of pain, improvement or stabilization of motor symptoms [9], or to prevent the tumor from enlarging to the point at which such symptoms would develop. MRI can provide information regarding the relationship of the tumor to the surrounding structures [22, 23] but has not been reliably able to distinguish between schwannomas and neurofibromas [11].

Operative Procedure

The patient is positioned so that the involved limb's response to electrophysiologic stimulation can be observed (Fig. 43.4). The anesthesia providers should be instructed to avoid muscle relaxant medications. Surgical exposure includes nerve and related structures both proximal and distal to the lesion itself (Fig. 43.5). Exposure may be limited if resecting a schwannoma involving the pelvic plexus or the proximal spinal nerve level of the brachial plexus where exposure either proximal or distal to the lesion may be difficult. The schwannoma is usually found surrounded by nerve fascicles [16]. As a schwannoma increases in size, it may bulge out of the nerve in a concentric manner, leaving fascicles asymmetrically arrayed

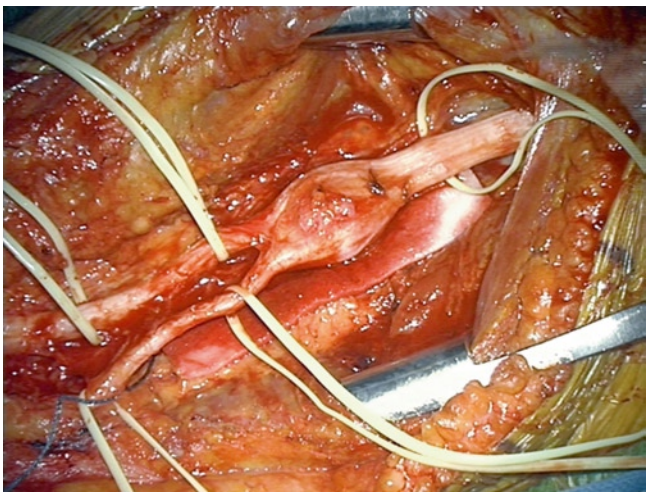

Fig. 43.5 Surgical exposure of right sciatic schwannoma with both proximal and distal anatomy exposed

Fig. 43.4 Positioning and incision for left sciatic nerve tumor resection. Note leg is positioned to allow observation of motor response upon stimulation

around the tumor itself. Schwannomas are encapsulated; thus, by dissecting longitudinally along the mass, the fascicles can then be gently dissected away from the tumor capsule (Fig. 43.5). Further dissection at the proximal and distal poles of the tumor usually reveals a relatively small nerve fascicle entering and leaving the tumor. When these fascicles are stimulated across the tumor, no NAP is conducted yielding a flat recording [11]. Stimulation of the proximal or, rarely, distal tumor fascicle alone may generate muscle contraction in the distribution of the nerve. This is the result of retrograde stimulation of healthy fascicles not of conduction across the fascicles entering the tumor. The entering and exiting nerve fascicles are divided which allows the en bloc removal of the tumor with its capsule intact as a single mass (Fig. 43.6). When unable to perform an en bloc resection, the capsule of

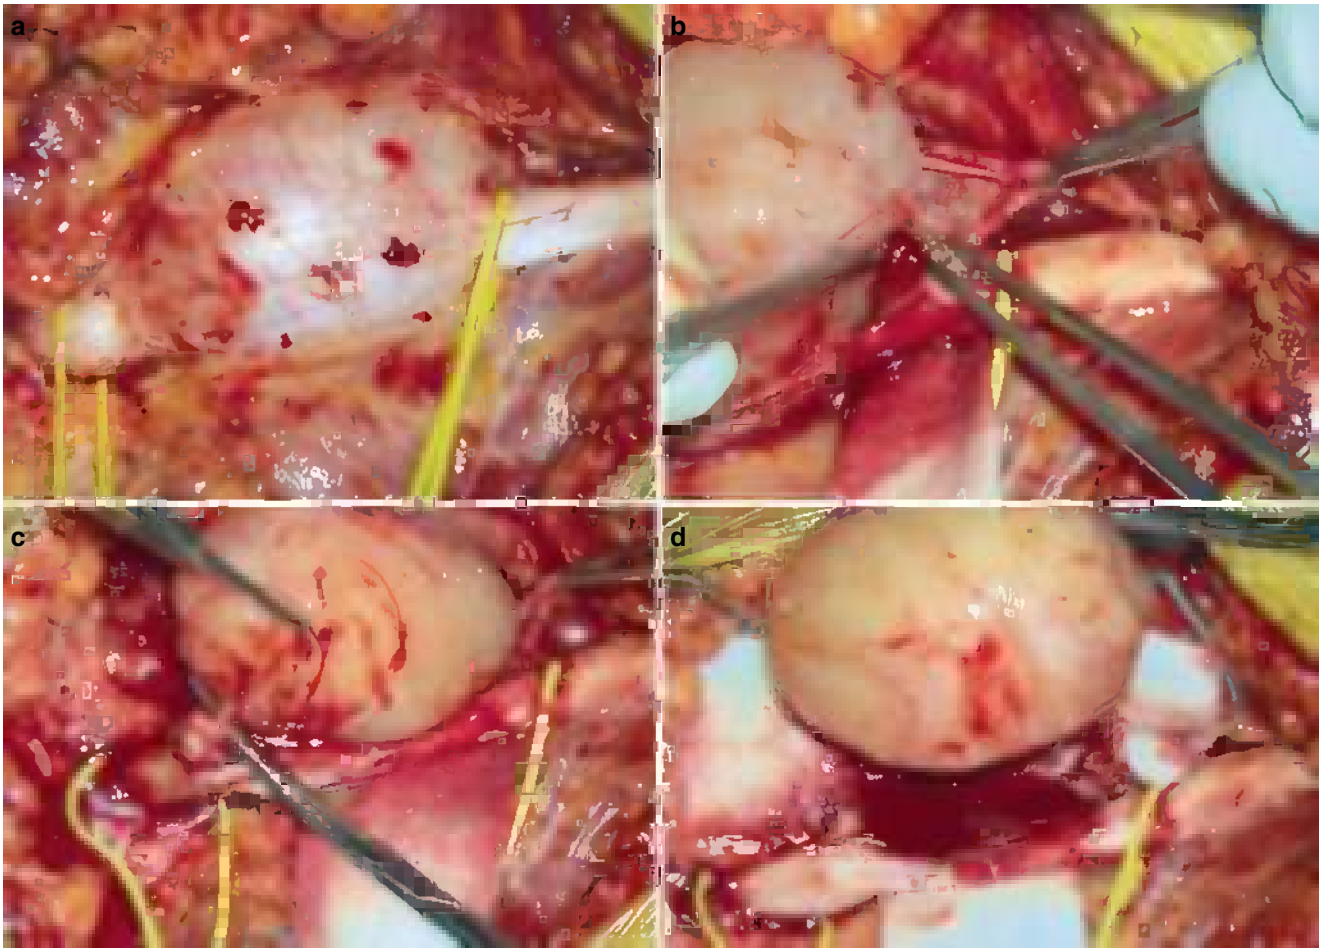

Fig. 43.6 Surgical resection of sciatic nerve schwannoma. (**a**) Dissection of tumor with proximal and distal involved nerve, (**b**) dissection along longitudinal axis of nerve, (**c**) continuation of dissection, and (**d**) removal of tumor en bloc with capsule intact

the schwannoma can be opened longitudinally, and its relatively soft, usually homogenous, sometimes cystic contents can be evacuated. Following internal debulking of the tumor, the capsule can be gently dissected away from the fascicles. If this method is utilized, it should be done thoroughly to reduce the incidence of recurrence. Large schwannomas may extend beyond the immediate nerve tissue making resection more difficult and increasing the possibility of recurrence [24]. Following careful resection, the presenting symptoms of schwannomas usually resolve. Eighty-seven percent of patients had improved or stable motor function in one series, and 85 % of patients who presented with pain had either total or partial resolution of this symptom [11].

Solitary Neurofibromas

Local or radicular pain is more likely to occur as a presenting symptom with solitary neurofibromas than with schwannomas [16]. In one large series, pain was associated with neurofibromas in 47 % of cases versus 31 % of schwannoma cases [11]. Solitary neurofibromas are less common than neurofibromas associated with NF1. As with schwannomas, these tumors can generally be displaced perpendicular to the course of the nerve of origin but not longitudinally. A neurologic deficit is slightly more likely to be present at the time of presentation than with a schwannoma but is greatly increased in neurofibroma patients who have had a prior biopsy or attempted but incomplete removal [25]. Solitary neurofibromas produce symptoms due to local axonal compression and are likely to be fusiform rather than plexiform in non-NF1 patients [10]. Tinel's sign is present in most cases; one series of 197 neurofibromas reported a positive test in all patients [11].

For unclear reasons, solitary neurofibromas are found more frequently on the right side of the body than the left [10]. As with schwannomas, neurofibromas can occur throughout the upper or lower extremities (Tables 43.1, 43.2, and 43.3), but unlike schwannomas, they are more likely to arise from the motor portion of the nerve than the sensory

portion [10]. The female predominance of neurofibromas is even greater than that of schwannomas by mechanisms that are not well understood [10].

Neurofibromas originate from cells believed to be more primitive than a Schwann cell, likely arising from the perineural fibroblast [26]. Compared to a schwannoma, the tumor's histological background is less compact and more myxomatous, contains mast cells and lymphocytes, and stains more positively with a mucopolysaccharide stain, such as Alcian blue (Figs. 43.7 and 43.8). The myxo-collagenous background of a neurofibroma also usually stains intensely with a reticulum stain as opposed to a schwannomas where this is not seen. Fewer Schwann cells are present in neurofibromas than schwannomas and are mixed together with distorted myelinated and unmyelinated axons. The vasculature in neurofibromas is less likely to be thickened and hyalinized than in schwannomas. Neurofibromas can occur as a localized mass or can involve longer segments of nerves. No histologic difference exists between a solitary neurofibroma and one associated with NF1. Unlike schwannomas, neurofibromas involve the entire cross-section of the nerve, resulting in the absence of cleavage planes between normal nerve and tumor. This makes gross total resection of the tumor without removal of normal nerve impossible.

The optimal management for neurofibromas is guided by patient symptoms. Patients without symptoms with known neurofibromas can be managed expectantly with observation. Resection of neurofibromas is reserved for tumors causing pain, progressive neurologic deficits, or those in which the diagnosis is uncertain or malignancy is suspected. MRIs are useful to define the anatomic location and extent of the tumor [23]. In cases where the neurofibroma is on a proximal nerve, imaging studies of the spine should be performed to assess for intraspinal tumor extension [27].

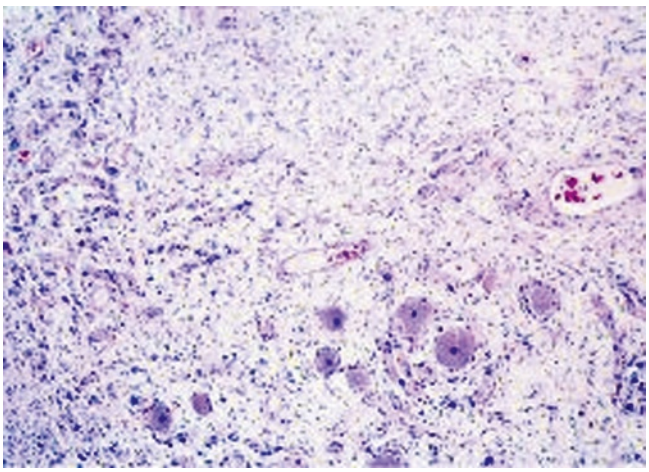

Fig. 43.7 Neurofibroma involving dorsal root ganglion: neoplasm composed of Schwann, perineurial-like and fibroblastic cells (neurons surrounded by satellite cells are residual from the infiltrated dorsal root ganglion)

Operative Procedure

The initial surgical approach is similar to that for a schwannoma. In most cases, the nerve fascicles are "basketted" around the main tumor mass and must be carefully dissected away. Neurofibromas usually have a capsule which is often more adherent to the central mass of the tumor than a schwannoma. The key steps for removal of a neurofibroma include dissecting out the fascicles at both ends of the tumor. If solitary, the fascicle entering and leaving the neurofibroma is larger than that seen in a comparable sized schwannoma. In other lesions, several fascicles approach and leave the tumor. It is more efficacious at times to section an entering or leaving fascicle or fascicles at one or the other pole and then gently elevate the mass away from the tumor and dissect beneath it to clear the mass away from the fascicles and the capsule left on the underside. NAP recording obtained across the tumor by stimulating the entering fascicle(s) is usually flat, indicating nonconducting fascicles that can be sectioned just as in a

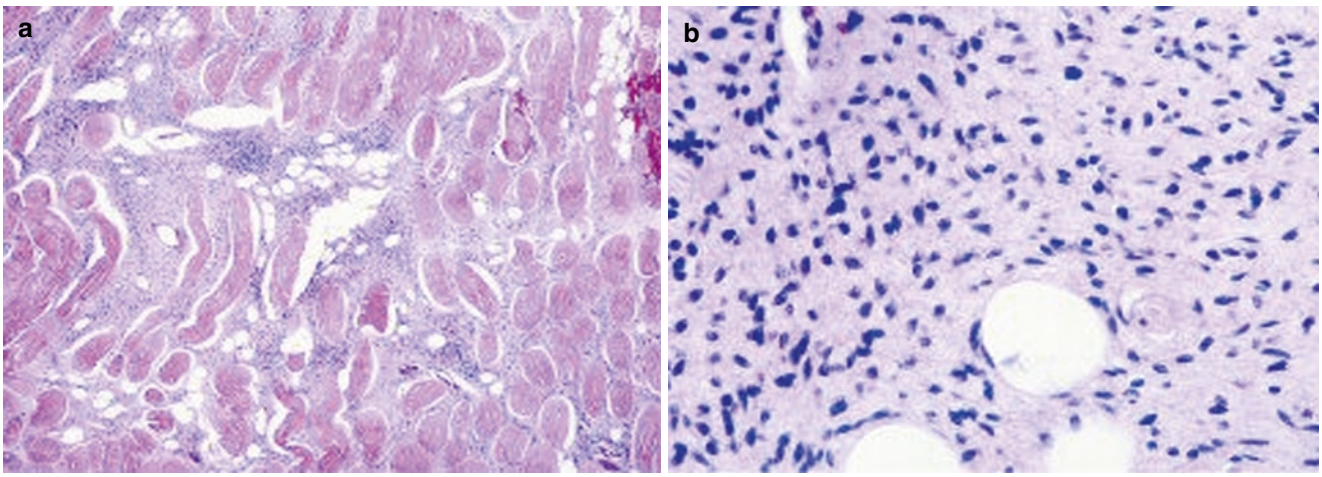

Fig. 43.8 Diffuse neurofibroma (**a**) low-power view and (**b**) high-power view. There is a disordered proliferation of relatively small spindle to stellate-shaped tumor cells, infiltrating adipose tissue and skeletal muscle

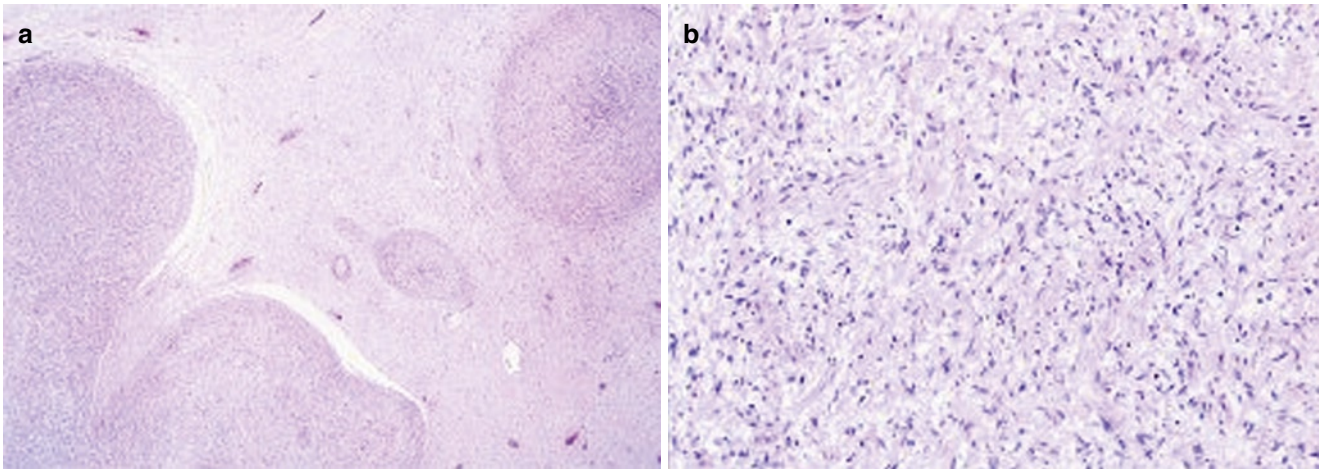

Fig. 43.9 Plexiform schwannoma, low-power view (**a**): multiple, well-circumscribed tumor nodules involving dermis. (**b**) High-power view showing well-circumscribed tumor nest, spindle cells arranged in a typical fascicles and palisades

schwannoma [11]. NAP recording after the mass is removed can be used to confirm maintenance of most function just as in a schwannoma. Occasionally, the neurofibroma requires partial graft repair after resection, particularly when loss of function is a concern or when functional fascicles were sacrificed to gain complete tumor resection. Donner et al. reviewed their series of 123 neurofibromas occurring in 121 patients without NF1, noting that 90 % had stable or improved motor function and 88 % had partial or complete resolution of pain [11].

Neurofibromas Associated with Neurofibromatosis 1 (NF1)

Neurofibromatosis 1 (NF1), also known as von Recklinghausen disease, is a phakomatosis defined in part by multiple neurofibromas. NF1 is inherited on chromosome 17 in an autosomal dominant pattern with full penetrance but variable expression. The overall incidence of NF1 is approximately one per 300 individuals, with many afflicted patients showing mild symptoms with limited number of tumors [2]. NF1-associated neurofibromas are more evenly divided between males and females and are seen equally on both sides of the body [10]. Additionally, NF1-associated neurofibromas are more likely to present at an earlier stage than solitary neurofibromas [10]. The range of neurofibromas in NF1 includes tumors in small cutaneous nerves to larger lesions in larger proximal nerves [10]. Most cases of NF1-associated solitary neurofibroma can be excised without serious deficit, even when the tumor involves a major nerve. The technique is the same as that for a non-NF1 neurofibroma described above. In NF1 patients, there is a 15 % risk of malignant degeneration of the neurofibroma [28, 29]; thus, every attempt should be made to remove all tumor fragments intraoperatively.

Patients with NF1-associated neurofibromas do not have as high a rate of resolution of symptoms as patients with sporadic neurofibromas due to the more difficult dissection of neurofibromas in patients with NF1. A series of 48 patients with NF1 who had neurofibromas resected noted that 83 % had stable or improved motor function and 74 % had partial or complete resolution of pain symptoms [11]. However, 16 % of patients experienced new but usually mild pain syndromes. Since neurofibromas in NF1 patients are more likely to be plexiform, the incidence of total resection is 60 % as compared to 80 % for solitary neurofibromas [11].

Plexiform Neurofibromas

Plexiform neurofibromas are histologically identical to solitary neurofibromas (Fig. 43.9) but involve a length of nerve in an interweaving fashion [11]. Plexiform tumor masses lack a capsule and can be both intrafascicular and extrafascicular. These tumors present an operative challenge, but resection is possible, though complete resection is generally not feasible without incurring a neurological deficit. Indications for surgery include symptomatic tumors involving sensory nerves or branches. Even an attempt at a partial resection of a plexiform tumor may lead to a neurological deficit. Nerve section, both proximal and distal to such a lesion and repair of the gap, which is usually lengthy, does not usually restore function [30, 31]. Decompression and debulking of the tumor may provide a benefit in patients with severe pain as a dominant symptom or with large tumors. In selected cases, it may be possible to reduce pain by decompressing a nerve through a neurolysis. Tumors involving less important sensory nerves or branches, such as antebrachial cutaneous, superficial sensory radial, sural, or saphenous nerves, can be removed in total, along with the nerve of origin.

Plexiform neurofibromas are very likely to be associated with NF1 but rarely may be also encountered as sporadic, solitary non-NF1 associated lesions. A sizable plexiform tumor

can be accompanied by hundreds of smaller neurofibromas involving the nerve of origin of the larger lesion. These associated tumors involve the nerve proximal to and distal to the large lesion and, occasionally, other nerves in the same limb, a syndrome called regionalized NF1, or neurofibromatosis type 5 [32]. Only a palliative operative procedure can be performed in these situations. If the plexiform tumor is large and firm, removal can be considered to ensure that malignant transformation is not present, a process that occurs in 5 % of plexiform neurofibromas, usually marked by significant pain and rapid growth [33]. Secondary operations for neural sheath tumors for which repair are necessary require frozen section biopsy of nerves or elements of origin to ensure that residual tumor is not incorporated in the repair.

In one series, nine patients with plexiform neurofibromas were treated either by partial excision ($n=5$), internal neurolysis with gross total excision ($n=1$), internal neurolysis with subtotal excision ($n=1$), or division of the nerve both proximal and distal to the tumor with nerve grafts ($n=2$) [13]. Tumors recurred in four patients with the time to symptomatic recurrence being 4–19 months. All four of these patients had worse motor exams, and three of the four developed new pain syndromes. MRI is useful in monitoring the rate of growth of plexiform neuromas as rapid growth and development of pain may herald malignant degeneration [34].

Neurothekeoma

Neurothekeomas are benign nerve sheath tumors that generally occur in the first three decades of life [35]. They are soft mobile tumors often based in the dermis. The cell of origin for these tumors was believed to occur in either the Schwann cell line or the perineural cell line, and tumor cells are often arranged in fascicles bounded by myxoid stroma. Recent investigations have shown that these tumors are positive for vimentin, CD10, NKI/C3, and at times focal reactivity for smooth muscle actin, yet are negative for S 100 and GFAP [36]. It is postulated that neurothekeomas may actually be of fibroblastic origin [36]. Treatment is symptomatic, with most neurothekeomas removed suspected to be schwannomas perioperatively. A gross total resection can almost always be performed with only rare recurrences.

Other Benign Peripheral Nerve Tumors

Several types of tumors occur less frequently than lesions of neural sheath origin but can be responsible for pain and, in some instances, loss of nerve function (Table 43.4). Some of these are favorable lesions as they tend to cause symptoms from nerve compression rather than originating within neural tissue [10]. On occasions, these lesions may be adherent to the epineurium making resection difficult and recurrence rate high [37]. The following is a discussion of the more common lesions.

Desmoids and Myositis Ossificans

Desmoids are lesions believed to arise from muscle and can involve soft tissue and compress, incorporate, or adhere to major nerves. They originate from a mesenchymal origin and are benign in the sense that they do not metastasize to other parts of the body, but they are rarely cured due to their invasiveness of soft tissue. Recurrence after a presumed gross total resection is common [4]. Desmoids are most common on the abdominal wall, but they can be present in the neck, shoulder, or extremities as well. Operative treatment involves a relatively wide exposure of the lesion and early identification of any nerve or nerves involved. The desmoid usually needs to be sharply dissected away from the nerve and involved epineurium usually requires resection. Both the firmness of these lesions and their adherence to nerves and vessels make removal without deficit difficult unless great care is taken during the dissection. As a result, recurrence is common. Desmoids are associated with patients with familial adenomatous polyposis, a condition caused by a mutation of the APC gene, and studies are showing that certain APC mutations will generate a desmoid phenotype [38, 39].

Myositis ossificans is a poorly defined disorder that may be related to previous trauma or surgery. It usually produces a firm to hard mass of tissue with calcification and, like a desmoid, can envelope contiguous soft tissues, including bone. Symptoms develop due to neural compression, vascular compression, or both. Removal of these masses can be technically difficult. Complete resection is rarely possible and usually not indicated as neurolysis of the nerve often dramatically improves symptoms.

Myoblastomas and Lymphangiomas

These two pathologic entities have similar behavior and somewhat similar appearance during surgery. Myoblastomas consist of plump and somewhat angular cells in a compact arrangement with acidophilic granules, whereas lymphangiomas have cells of a lymphoid nature. These tumors tend to spread as a sheet of tumorous tissue and are less likely to form a globular mass than are a desmoid tumor or a hemangioma [4, 32]. Both tumors can also become adherent to or envelope nerves leading to neurological symptoms. Treatment involves a wide surgical exposure to determine normal anatomy distal and proximal to the lesion prior to skeletonizing the involved nerve away from the lesion.

Table 43.4 Benign tumors of non-neural sheath origin involving peripheral nerve

Lipomas and Lipohamartomas

Lipomas are fatty lesions that usually occur solely in the subcutaneous region thus rarely involve the major nerves. Rarely, a large lipoma envelops or compresses nerve, or originates deep to the subcutaneous tissues in a limb and thus compresses or entraps nerve producing neurologic symptoms [4]. Common sites include the forearm or popliteal region, with resultant posterior interosseous or fibular (peroneal) nerve palsy, respectively. Larger lipomas in the supraclavicular fossa can involve the brachial plexus, while those in the buttock, leg, or arm can potentially compress the median, sciatic, or ulnar nerves.

Lipohamartomas are also composed of fatty tissue and are intrinsic to nerve and usually involve the median nerve at the wrist or palmar levels [32]. When median nerve lesions present with pain and paresthesias, treatment is sectioning of both the transverse carpal ligament in the palm, its extension covering the nerve and the lipomatous mass at the wrist level. When serious loss of median function occurs, more extensive surgery consisting of internal neurolysis with reduction of the bulk of the tumor from around individual fascicles can be performed. More focal lipohamartomas can be treated with resection and repair.

Hemangiomas, Hemangiopericytomas, and Vascular Malformations

Vascular lesions including hemangioma, hemangiopericytomas, as well as aneurysms and arteriovenous fistulae, originate close to nerves and can compress or elevate them [40]. An operation for these lesions, especially if the nerve is involved, is never easy. Preoperative angiography is of some help in planning surgery. Intraoperatively, it is imperative to isolate vessels on the periphery of the lesion and ligate or clip them if they are not the major supply to the extremity. Nerves are carefully dissected away from the lesion while

protecting them as much as possible. Occasionally, a hemangioma, hemangioblastoma, venous aneurysm, or fistula directly involves nerve or appears to originate in it. If the clinical situation warrants proceeding with surgical resection, a careful interfascicular dissection is necessary for removal. Each fascicle or group of fascicles needs to be stripped of the abnormal vascular tissue to assure adequate resection of the vascular lesion.

Hemangiopericytomas, which usually arise in the mediastinum and secondarily involves the brachial plexus, can behave in a malignant fashion and metastasize to other sites, including, rarely, the brain. It cannot usually be removed entirely, and the surgeon must be content with a subtotal procedure to decompress the brachial plexus.

Ganglions and Epidermoid Cysts

Most ganglions arise from joints and at sites that do not usually involve nerves, such as the dorsum or the side of the wrist [41]. Occasionally, this tumor arises from a region of the wrist joint that compresses the thenar sensory branch of the median nerve, the ulnar palmar branch, or the main trunk of the median or ulnar nerves. Other sites where these ganglions are clearly of joint origin include the forearm, where they arise from the radioulnar joints and compress the posterior interosseous nerve; the knee, involving the fibular (peroneal) nerve [42]; the ankle, involving the posterior tibial nerve; and the hip, involving the sciatic nerve. Ganglions at the elbow level can involve radial and, less frequently, median and ulnar nerves, whereas those in the shoulder can involve the brachial plexus, particularly the suprascapular branch in the region of the scapular notch. Ganglion cysts usually present as a tender mass resulting in pain or paresthesias in the distribution of the nerve involved [10]. Occasionally, they result in a motor and sensory deficit or both. Another type of ganglion does not appear to have a connection with a joint, such as those found in the deep fibular (peroneal) nerve over the head of the fibula [43, 44]. It is likely that these lesions originate from the superior tibiofibular joint after disruption of its capsule, allowing dissection of the synovial fluid along the articular branch of the fibular nerve reaching the epineurium of the nerve. The previous connection with the joint is often then obliterated. Intraneural ganglia may extend great distances along the course of the nerve, such as the fibular (peroneal) division of the sciatic nerve, resulting in motor or sensory deficit [4].

Most localized lesions are resectable without serious loss of function. For ganglions extrinsic to nerve but compressing it, the surgeon must dissect around such lesions after carefully identifying, dissecting away, and protecting the involved nerve. The origin of the cystic lesion should be ligated or secured in some other fashion close to the joint to reduce recurrence. For intraneural ganglions, interfascicular dissection seems to work best because fascicles are cleared of the cyst and then its capsule. For larger lesions, it may be necessary to evacuate the synovial-like contents of the cysts and dissect the capsule away from the decompressed and split fascicles. Occasionally, larger lesions require several operations before they are obliterated.

Epidermoid cysts usually do not arise within nerve itself but may compress an adjacent nerve. Common locations for the epidermoid cysts involve the sciatic nerve close to the sciatic notch or behind the knee, involving the posterior tibial nerve [4]. These cysts can be resected as a solitary mass after performing neurolysis on and gently retracting involved nerves. Occasionally, a large lesion at the hip or pelvic level requires initial evacuation and then dissection of the capsule away from adjacent tissues, including nerves.

Hypertrophic Neuropathy or Onion-Whorl Disease

Hypertrophic neuropathy is a rare disease of unknown etiology and pathogenesis. Fascicles and individual nerve fibers become encased by connective tissue in a circular fashion, as if the endoneurium has proliferated. This results in a hypertrophic nerve with an "onion-whorl" appearance to its nerve fibers. Histologically, there is proliferation of perineural cells, endoneurial fibrosis, fibrotic replacement of the perineurium, and significant reduction in myelin [10].

Hypertrophic neuropathy primarily affects children or young adults with a predilection for the fibular (peroneal) nerve in the leg or the median nerve in the arm [45, 46]. Less commonly, it can also be found in the brachial plexus as well as the ulnar, radial, and sciatic nerves [4, 45, 47]. The lesion usually involves a lengthy segment of nerve resulting in a progressive loss of function. It does not spread to other nerves in the body. Some of its histologic features suggest either a contusive stretch injury or a chronically compressive etiology, but a history of significant trauma is usually absent, and no obvious entrapment or irritative environment is found on surgical exploration.

Pain or progressive loss of function warrants exploration. Function is usually partially spared distal to the lesion, and NAPs across the lesion are often present. External or external and internal neurolysis is usually performed. Manipulation of the lesion, particularly by internal neurolysis, may produce additional and even complete loss of function, despite the fact that neurolysis is less invasive than resection. An alternative is to proceed with resection, despite the attendant loss, and to replace the lost segment by grafts. Since the disease usually involves a significant segment of nerve, the grafts are likely to be long.

Table 43.5 Malignant neural sheath tumors

	No. of cases	NF1	Avg. F/U (month)	Deaths (%)
Neurogenic sarcomas				
Brachial plexus	14	4	50	29 %
Sciatic	6	1	17	0
Fibular (peroneal)	1	0	18	0
Tibial	1	1	30	0

Malignant Neural Sheath Tumors

Malignant neural sheath tumors (MNST) are a group of neoplasms consisting of malignant schwannomas and malignant neurofibromas, commonly grouped as neurogenic sarcoma and fibrosarcomas (Table 43.5) [27, 48]. The differentiation between malignant schwannomas and malignant neurofibromas can be difficult, a positive mucopolysaccharide stain favoring the latter. Histopathologic analysis reveals mitotic activity, cellular pleomorphism, necrosis, and hemorrhage in most cases (Figs. 43.10, 43.11, 43.12, and 43.13). Heterogeneous cell lines are present in 15 % of MNSTs and are generally found in patients with neurofibromatosis [48]. Approximately half of MNST arise in patients with NF1 [48] but can occur as solitary lesions in patients without NF1 [49]. Spontaneous malignant degeneration of solitary benign schwannomas is rare except in patients with NF1 [7]. Malignant degeneration of a plexiform neurofibroma in a patient with NF1 is not uncommon [18]. There is no gender preference in MNST and no specific laterality. Prior treatment with radiation therapy is a risk factor in the development of approximately 10 % of cases of MNST [48, 50]. MNST can be suspected if a mass increases rapidly in size and is associated with a progressive loss of function [51]. These lesions are often firmer than benign neural sheath tumors and are also relatively adherent to surrounding structures.

MNST usually manifests as pain with or without progressive loss of neurological function. Other common findings of MNST include a mass with irregular borders, a rapid increase in size, and a large size at presentation [10]. On rare occasion, patients with MNST present with metastasis to lung, bone, liver, or other organs [10]. MR imaging (Fig. 43.14a, b) is useful in defining the anatomy of the tumor as well as to screen for metastasis [22]. The 5-year survival for patients with MNST can approach 50 % but is much lower in patients with NF1 [52].

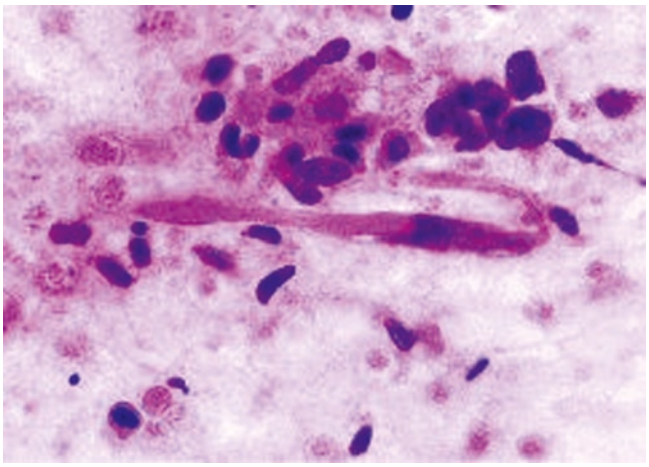

Fig. 43.13 Malignant neural sheath tumor, with divergent (rhabdomyosarcomatous) differentiation (high-power view of H and E stained smear): atypical elongated cell with eosinophilic cytoplasm myofibrillar bands

Despite preoperative symptoms and findings suggesting malignancy, the clinician cannot be certain of the diagnosis without a biopsy, which usually requires an operation. If prior biopsy was performed with a diagnosis of MNST, then a metastatic evaluation needs to be performed including a chest x-ray, CT or MR scan, abdominal CT, and bone scan. Following this and based on the extent of metastatic disease, options include the following:

1. Perform wide local resection, including removal of adjacent as well as adherent soft tissues (Fig. 43.15a, b). Resection should include a several-centimeter margin of entering and exiting nerve shown to be free of malignant changes on frozen and subsequent permanent sections. At that time, some surgical oncologists favor placement of tissue rods for irradiation locally, whereas others favor external radiation. Chemotherapy may also be added.
2. Amputate the limb well above the level of the lesion. Proximal upper limb lesions can also be managed by forequarter amputation of shoulder and arm above the level of the plexus or spinal nerves. Proximal lower limb lesions may require hip disarticulation with section of the proximal sciatic and femoral nerves.
3. Irradiate the limb with or without adjuvant chemotherapy in patients who refuse surgery beyond an attempt to remove the lesion or in patients with widely metastatic disease.

A critical step in managing these lesions is to obtain as thorough a neuropathologic examination of as much tissue as possible. As a result, further treatment depends heavily on the nature of the malignancy as determined by permanent sections. The recurrence rate is high, even after wide local excision and irradiation, but some patients survive beyond 5 years with proper management [53]. Although patients have died despite forequarter amputation or hip disarticulation when results for metastasis were negative, the largest percentage of survivors beyond 5 years is in this category [27].

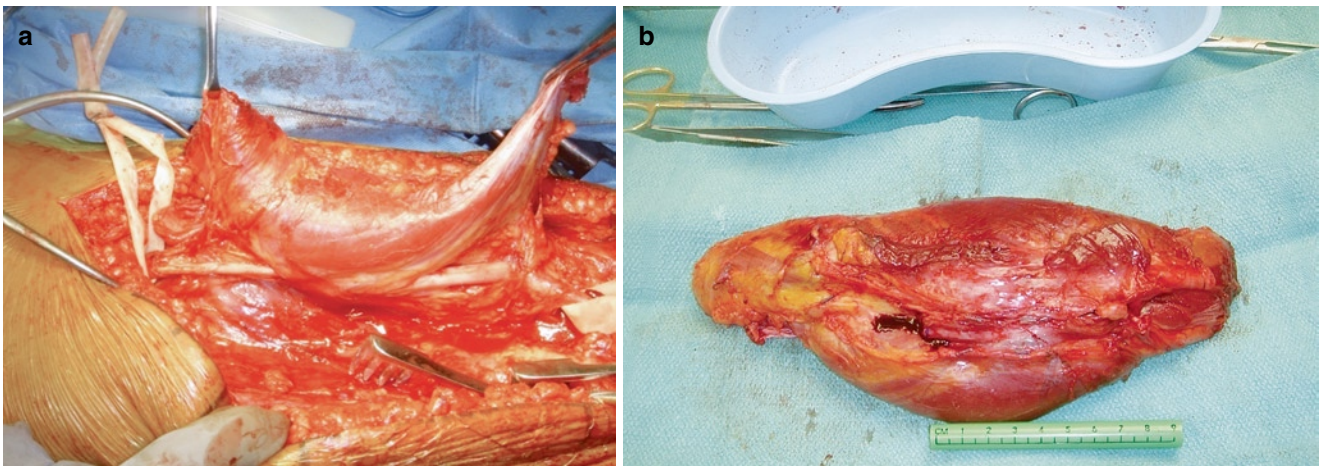

Fig. 43.15 Surgical resection of malignant peripheral nerve sheath tumor of sciatic nerve. (**a**) Note adherent biceps femoris to tumor and wide local resection to remove adjacent and adherent tissue. (**b**) Resected tumor with wide margin or tissue and visible proximal and distal stump of sciatic nerve

In recent years, however, limb-sparing procedures, including wide local resection, placement of x-ray rods, and sometimes external x-ray treatment, in conjunction with chemotherapy in carefully selected patients resulted in good to excellent survival rates [54–56]. Therefore, limb-sparing surgery is an accepted form of treatment in many patients with MNST.

Metastatic Carcinoma

This diverse group of tumors usually involves nerves by direct extension from the primary site. Occasionally, a malignancy may metastasize to nerve or tissues adjacent to it. Treatment plans must be individualized given the wide scope of variability in presentation and extent of involvement with each particular cancer. Breast carcinoma is the most common metastatic lesion involving nerve [4, 27]. Metastases to nerves have also been described with lung, melanoma, thymoma, pancreatic, and prostate cancer [8, 27, 57–59]. Most of these metastases occur in the brachial plexus. Metastasis located at an infraclavicular axillary level appears to present by direct extension, while metastasis located at the supraclavicular plexus is more likely with breast cancer disseminated through the lymph nodes. Most of these patients had prior mastectomy followed by irradiation, making differentiation between neoplastic plexopathy with metastatic breast cancer and radiation plexopathy more challenging (see Chap. 46) [60, 61].

If a mass is palpable or seen on scan in a patient with a history of breast cancer, then decompression of involved neural elements is reasonable. Unlike malignant neural sheath tumors, the nerve involved by metastasis can be treated with external neurolysis and careful removal of tumor from involved nerve. As much of the adjacent mass as possible is also removed. Metastases do not typically invade nerve beyond the epineural level, but exceptions exist. In cases of invasion of the neural elements by metastatic lesions, resection of the involved neural elements may be considered for pain control as a palliative procedure.

Metastatic lung cancer also commonly involves nerve and particularly the brachial plexus. Lung cancer may involve the brachial plexus by direct extension and most often produces a *Pancoast syndrome*. If pain is a severe problem, a posterior subscapular resection of the first rib and subtotal resection of the apical tumor to decompress the lower elements of the plexus may be performed as a palliative procedure. This procedure combined with cervical laminectomy for associated epidural metastatic disease is also palliative. Occasionally, a high contralateral open cervical cordotomy also helps control the pain associated with a Pancoast syndrome. The main focus for this palliative operation is adequate decompression of the compressed or entrapped nerve [62].

True metastatic disease involving nerve is seen with lymphoma, bladder cancer, and melanoma, although it is less common than breast or pulmonary cancer. With melanomas involving the plexus, removing the tumor from any epineural attachment has sufficed. The surgical procedure is then followed by local irradiation. A similar approach is also sufficient, at least for palliative purposes, for lymphoma.

Cervical Radiculopathy

44

Kerry H. Levin

Anatomy

The cervical spinal column is comprised of 7 vertebral bodies. The first (the atlas) is a ring of bone without a body; the second (the axis) has a bony process (the odontoid) that extends upward and around which the axis rotates. Neural foramina are formed between each pair of vertebral bodies and are bounded superiorly and inferiorly by pedicles, anteriorly by intervertebral disc and vertebral body, and posteriorly by facet joint (Fig. 44.1). Through the neural foramina pass the spinal nerve roots, recurrent meningeal nerves, and radicular blood vessels. The number designation of the exiting cervical spinal nerve root corresponds with the number of the vertebral body below it, except at the C7–T1 intervertebral level, where the exiting root is numbered C8.

The blood supply to spinal nerve roots is provided by a capillary network derived from the radicular arteries. In the rat, in the transitional region between the peripheral and central nervous system (the root entry zone), blood vessels are positioned on the surface of rootlets and in interradicular spaces, but not in rootlets themselves. The density of capillaries is very high in the ventral nerve root entry zone [1]. Distal to the rootlets in rats, at the proximal and distal root levels, ventral root capillary density is higher than at the dorsal roots [2].

The spinal canal is bounded posterolaterally by laminae and the ligamentum flavum, anterolaterally by pedicles, and anteriorly by intervertebral discs and vertebral bodies. The maximal anterior-posterior dimension of the canal at the C1–C3 levels ranges from 16 to 30 mm and at the C4–C7 levels from 14 to 23 mm. The diameter of the spinal cord at C1 is about 11 mm, at C2–C6 about 10 mm, and at C6–C7 about 7–9 mm. The cervical canal diameter is reduced by 2–3 mm with extension.

Facet joints are true synovial joints that link adjoining vertebral bodies, and provide spinal column directional stability during spine movement, based on the specific plane of the facet joint articulation. Facet joints are innervated by branches of the posterior primary ramus of the spinal nerve root. Spondylotic degenerative change at facet joints produces osteophyte formation that leads to neural foraminal and canal stenosis.

Intervertebral discs provide both support for the spinal column and mobility of the spine. Discs account for up to 30 % of the total height of the spinal column. They are composed of a gelatinous nucleus pulposus, surrounded by a containing ring of elastic collagen (the annulus fibrosus). The nucleus, which is about 90 % water, desiccates through life, fills with fibrous tissue, and loses its elasticity. Disc material and the ligamentum flavum do not contain nociceptors, but the posterior ligament, which lies next to the disc, does. This arrangement makes it most likely that disc herniation through the annulus fibrosus in itself does not produce pain, although the subsequent pressure on the posterior ligament and the nerve root does. In a clinical study of patients under local anesthesia, compression of a nerve root produced limb pain, while pressure on the disc produced pain in the neck and the medial border of the scapula. Intradiscal injection and electrical stimulation of the disc also suggested that neck pain was referred by a damaged outer annulus [3].

Historical Features of Cervical Radiculopathy

The association of arm pain with cervical disc protrusion and cervical spondylosis was not clear before the middle of the twentieth century. Arm pain was attributed to conditions such as neuritis, fibrositis, and scalenus anticus syndrome. Pathological reports in the early 1900s described cervical disc herniations as "chondromas," often associated with spinal cord compression. In 1934, Mixter and Barr reported disc

herniation as the cause of sciatica in the lumbar region, but it was not until 1943 that Semmes and Murphey reported cervical disc herniation as the cause of radiculopathy in the absence of myelopathy. However, even into the 1950s it was commonplace for patients to undergo section of the scalenus anticus for treatment of symptoms that now would be recognized as classical cervical radiculopathy.

Risk Factors and Epidemiology of Cervical Radiculopathy

Research regarding risk factors in low back pain is much more plentiful than for acute neck pain. Factors strongly associated with low back pain such as prior back injury, age, and job satisfaction/emotional distress do not seem readily transferrable to acute neck pain. In one study, factors associated with acute neck pain included heavy lifting at work, cigarette smoking, and frequent diving from a diving board [4]. Risk factors for slow recovery from whiplash have been studied and include female gender, older age, having dependants, and not having full-time employment [5]. In an epidemiological study of cervical radiculopathy in Rochester, Minnesota, physical exertion or trauma preceded onset of radiculopathy in almost 15 % of their 561 patients, most often the result of snow shoveling in the winter and playing golf in the summer [6]. Motor vehicle accidents were responsible for radiculopathy due to spinal fracture, but not due to disc protrusion, and 41 % of patients had had prior lumbar radiculopathy, and 31 % had had prior cervical radiculopathy.

Cervical radiculopathy is a common condition with a male to female ratio of 1:7. In the Rochester study, the annual age-adjusted rate was 83.2 cases per 100,000, with a peak frequency of 202.9 per 100,000 per year for the 50–54-year age group [6]. The C7 root was involved in 46 % of cases, the C6 root in 17.6 %, and the other levels each in less than 10 % of cases. The cause of radiculopathy was disc protrusion in 22 % and spondylosis, disc, or both in 68 %. Surgical treatment was subsequently performed on 26 %, but at last follow-up, 90 % of all patients were asymptomatic or only mildly incapacitated by their radiculopathy. There are no studies that provide information about the factors on initial evaluation that predict prognosis.

Pathophysiology of Cervical Spondylosis

Pathology of Spondylosis

Spondylosis literally refers to a condition of the spine. In common medical parlance, it signifies age-related degenerative changes in the disc, the vertebral body, the facet joints, and points where they come in contact with each other in the spine. Damage to the nervous system occurs as the result of degenerative change at three main points: the disc, the uncovertebral joints, and the zygapophyseal (facet) joints. Resulting bony overgrowth (osteophytes) or disc herniation at these points may directly impinge on spinal nerve roots or the spinal cord, or their effect may be primarily to produce instability and misalignment of the spine that in turn produces

pain and neurological sequelae. It is not known whether changes in these different structures are causally interrelated or occur independently.

One school of thought suggests that the cascade of spondylotic changes is led by degenerative change in the nucleus pulposus of the disc. With age there is gradual narrowing of the disc space coincident with changes in disc proteoglycan composition. Later, cracks develop in the disc, and deposits of gas and calcification may form. Eventually the disc material becomes desiccated and friable. Age-related changes also occur in the annulus fibrosus, which becomes more fibrotic and less elastic. Fissures develop and calcium is deposited. As the disc shrinks and the intervertebral disc space narrows, the annulus tends to buckle out.

As the disc degenerates, changes are seen at the vertebral body end plates adjacent to the disc. The marrow undergoes fibrovascular change or fatty marrow replacement. Finally end-plate sclerosis develops. Osteophyte formation occurs at the margins of the vertebral bodies. What triggers osteophyte formation is unclear, although spinal movement at ligamentous attachment sites and loss of buffering tissues between bony surfaces likely play roles. Osteophyte production appears to slow as advancing spondylosis leads to decreasing spinal movement [7].

Uncovertebral joints are not true joints but may represent a slit in the intervertebral disc at the point where the uncinate process makes contact with the disc and vertebral body above. As disc substance decreases, there is more contact between the uncinate process and adjacent bone, leading to osteophyte formation (Fig. 44.2). At the cervical levels, dorsal protrusion of these osteophytes narrows the adjacent neural foramen (where spinal nerve roots exit); lateral protrusion may lead to impingement of the vertebral artery. These changes are greatest at the C5–6 and C6–7 levels, where cervical movement is greatest.

Facet joint degeneration may not be as directly related to the above spondylotic changes but often coexists. One study suggested that disc degeneration predominates at the lower cervical levels, while facet joint change predominates at the upper levels [8]. Disc degeneration is likely to put additional weight-bearing strains on facet joints, which are not weight-bearing structures. With unnatural movement of the spine, the synovial joint bears more structural burdens, degenerates, and develops osteophytes. These osteophytes grow into the posterior aspect of the neural foramen (Fig. 44.3).

Fig. 44.3 Cervical radiograph demonstrating facet joint osteophyte encroaching into neural foramen (*arrow*)

Pathophysiological Mechanisms of Nerve and Cord Impingement

There is no universally accepted classification system for pathological disc changes. Basically, an abnormal disc may be described as bulging or herniated. Herniations may be classified as protrusions, extrusions, or free fragments. A bulging disc extends beyond the margin of the vertebral end plate but does not affect the integrity of the encircling annulus fibrosus. A disc protrusion is described when disc material extends focally through a defect in the annulus, although the outer fibers of the annulus remain intact. A disc extrusion extends through the entire annulus but may remain anterior to the posterior longitudinal ligament or extend through it. The extruded disc remains connected with its

parent disc material. In contrast, a free (or sequestered) fragment is an extrusion that is completely separated from its main disc, although it may be either anterior or posterior to the posterior longitudinal ligament. A free fragment may migrate up or down from the cervical level of its origin. The size and lateral location of the disc protrusion or extrusion will determine whether a spinal nerve root becomes impinged and which particular level will be affected. Because cervical spinal nerve roots tend to exit horizontally from the cord to their neural foramina, a paramedian or lateral disc herniation will likely entrap the nerve root corresponding to the number of the vertebral body directly below it.

Neural foraminal stenosis occurs on a chronic basis from osteophyte growth directed posteriorly from uncovertebral joints or anteriorly from facet joints. A very laterally placed disc herniation or free fragment may also impinge the nerve root at this site. Especially at upper cervical levels (C4–5, C5–6), there may be dorsal root ganglion impingement, as the DRG may occupy relatively intraspinal locations at those levels [9]. Osteophytes from facet joints may exert more impingement acutely with neck extension.

Concentric cervical canal stenosis may develop on the basis of a number of underlying pathological changes. Chronic spondylosis and the combination of disc herniation, facet, and uncovertebral osteophyte formation may all act in combination to narrow the canal at one or multiple levels. Hypertrophy of the posterior longitudinal ligament and the ligamenta flava will further decrease central canal size. Ossification of the posterior longitudinal ligament is a degenerative condition significantly associated with narrowing of the cervical canal and compressive myelopathy. It tends to occur in some ethnic groups more than others and is a pathological feature in 27 % of cases of cervical myelopathy in the Japanese population. All the above changes will produce premature cervical canal stenosis in those with a congenitally narrowed canal, usually on the basis of shortened pedicles.

A host of other intraspinal disorders can act to produce cervical nerve root and spinal cord impingement. Infections and inflammatory disorders (such as tuberculosis and sarcoidosis), extradural and intradural tumors (malignant, metastatic, or benign such as neurofibromas and schwannomas), dural fistulae, and arteriovenous malformations can produce clinical pictures identical to those seen with spondylotic changes.

Clinical Examination in Cervical Radiculopathy

The initial diagnosis of cervical radiculopathy rests upon the clinical assessment, based on the history and physical examination. The anatomic localization can be inferred in some cases by the neurological examination, but the precise structural cause can only be determined by neuroimaging procedures. In cases that are not straightforward clinically, in cases where significant weakness is present, and in cases where the neuroimaging findings are complex or confounding, electrodiagnostic testing (EDX) can aid in improving the degree of diagnostic certainty.

Patient History

Obtaining a history consistent with cervical radiculopathy requires exploring the major symptoms of arm pain, paresthesia, numbness, and weakness. Pain is present in virtually all patients with acute cervical radiculopathy, but it is seldom of localizing value. The diagnosis of cervical radiculopathy is supported by the presence of radicular pain emanating from the neck or shoulder, with extension into the arm (sometimes in a specific dermatomal distribution). The diagnosis is further supported when the symptoms are exacerbated by Valsalva maneuvers (cough, sneeze, or strain), indicating stretching of the dura at an intraspinal point of compression.

Paresthesia and numbness are present less often than pain and are usually nonspecific and therefore not of great localizing value, but they are symptoms that are seldom present with non-radicular causes of neck and arm pain. The patient may report intensification of paresthesia with Valsalva maneuvers or lateral head positioning.

If the patient describes Lhermitte's symptoms (spinal or radicular tingling, shock-like paresthesia with neck flexion), there is support for dysfunction of the posterior columns of the spinal cord, possibly due to spondylotic cord compression but also potentially due to intraspinal mass lesions or intramedullary processes such as multiple sclerosis. The presence of bowel or bladder urgency or incontinence, or new constipation or urinary retention, resulting from cervical spinal cord compression, may accompany multiple cervical radiculopathies in the setting of severe cervical spondylosis.

The patient may provide important information regarding the underlying cause of the symptoms. Recent or remote trauma should be explored, including whiplash incidents and injuries during contact sports. Prior episodes of spine pain, prior spine surgery, and a family history of spine disease should be sought. A general medical review of systems and past medical history are important to exclude other possible factors, such as the presence of malignant disease, collagen vascular disease, or infection.

Clinical Examination

The initial part of the examination should be a limited general physical examination as dictated by the findings during

Table 44.1 Typical clinical attributes of solitary cervical root lesions

Root	Pain	Numbness	Weakness	Reflex loss
C5	Neck, shoulder	Axillary distribution	Shoulder abduction, external rotation, elbow flexion, forearm supination	Biceps, brachioradialis
C6	Neck, shoulder, lateral upper arm, lateral forearm, thumb and lateral hand	Lateral forearm, thumb and index	Shoulder abduction, external rotation, elbow flexion, forearm supination and pronation	(Biceps, brachioradialis)
C7	Neck, shoulder, middle finger, hand	Index and middle finger, palm	Elbow and wrist (radial aspect) extension, forearm pronation, wrist flexion	Triceps
C8	Shoulder, medial forearm, fourth and fifth digits, medial hand	Medial forearm, fourth and fifth digits, medial hand	Finger extension, wrist (ulnar aspect) extension, distal finger flexion, distal thumb flexion, finger abduction and adduction	Triceps
T1	Medial arm and forearm, axillary chest wall, medial forearm	Medial forearm, fourth and fifth digits	Thumb abduction, distal thumb flexion, finger abduction and adduction	

the historical interview. The general neurological examination should include gait assessment, screening mental status testing, cranial nerves II–XII, motor testing in all four extremities, testing for increased tone in the extremities, sensory testing in all four extremities, coordination testing in all four extremities, deep tendon reflexes in all extremities, plantar stimulation, and inspection and percussion of the spine.

The specific examination for radiculopathy forms the core of a comprehensive general neurological examination. A classification of the typical neurological attributes of solitary cervical root lesions is listed in Table 44.1.

Specific bedside clinical maneuvers for the provocation of symptoms of cervical radiculopathy have come in to use, although their accuracy and safety have not been carefully studied. *Lhermitte's sign* can be elicited by actively flexing the patient's head and observing for the development of tingling paresthesia down the cervical spine or into the symptomatic arm. *Spurling's* test (the neck compression maneuver or foraminal compression test) is performed by extending and rotating the neck to the side of the pain, followed by applying downward pressure on the head [10]. This maneuver may produce limb pain or paresthesia, as neck extension causes posterior disc bulging, while lateral flexion and rotation cause narrowing of the ipsilateral neural foramina [11]. It may be safer to perform this maneuver by asking the patient to actively extend the neck, then laterally flex and rotate toward the side of the pain, followed by application of pressure through the examiner's hands on the vertex of the head [12]. When radiating pain or limb numbness develops, the maneuver should be stopped. This maneuver is rather specific but not sensitive. The *shoulder abduction relief sign* (or shoulder abduction test) is performed by asking the patient to lift the symptomatic arm over the head, resting the hand on the top of the head [13]. This may be a useful therapeutic maneuver as well as a diagnostic one for lower cervical radiculopathy [14].

One study reviewed the various provocative and relief signs and reported that for roots C6–8 the neck compression maneuver had a specificity of 100 % for radicular pain and 92–100 % for neurological and radiological signs, respectively. For the shoulder abduction maneuver, the specificity was 100 % for neurological signs and 80 % for radiological signs. The sensitivity of these tests for radicular symptoms, neurological signs, and radiological signs ranged from about 40 to 60 % [15]. Neither of these maneuvers was useful for C4–5 radiculopathies. A systematic review of the diagnostic accuracy of provocative tests of the neck for diagnosing cervical radiculopathy identified only six studies that met evidence-based methodological criteria for review [16]. After their review, lack of evidence precluded firm conclusions regarding diagnostic value of these tests. However, the review suggested that when consistent with the history and physical findings, a positive Spurling's test, traction/neck distraction, and Valsalva maneuver might be indicative of a cervical radiculopathy, while a negative upper limb tension test might be used to exclude it.

Of all the elements of the clinical examination, the identification of weakness in a specific myotomal distribution has the greatest localizing value for the diagnosis of a solitary cervical (or lumbar) spinal nerve root lesion. Arm weakness provides the most reliable correlation with the structural level of cervical spinal nerve root involvement. The presence of weakness is strong support for a neurological disorder, but the examination seldom fully differentiates radiculopathy from brachial plexopathy, or mononeuropathy in some cases. True neurogenic weakness may be difficult to distinguish clinically from reduced voluntary effort due to pain.

Clinical Localization of Radiculopathy

Clinicians use reference charts to guide them in the correlation of specific distributions of weakness with the likely anatomical level of nerve root involvement. Such charts have been constructed by a number of researchers in the field, and they tend to vary from one another in regard to the

correlation between specific muscles and nerve roots. The lack of agreement from one myotomal chart to another relates to anatomical variations in humans and differences in the nature of the research material used in the collection process. Anatomic charts have been derived by tracing root and peripheral nerve innervations of muscles from cadaver studies. Clinical charts have been derived by correlating the distribution of clinical muscle weakness in patients with specific traumatic lesions. Electromyographic charts have been derived from patterns of muscle denervation in patients with focal nerve root lesions.

The most complete descriptions of the myotomal innervations in man have come from the work of the Dutch anatomist Louis Bolk, beginning in 1894. His work was based on the anatomy of a single 3-year-old boy. Bolk postulated that any anatomic structure contains innervation elements from several adjacent root segments, explaining the anatomical variability seen from one individual to another [17]. Although we recognize errors in some of Bolk's myotomal innervations, his work formed the core of all modern myotomal charts. There are several reasons why one published myotomal chart may vary somewhat from others. First, as noted above, segmental innervation of dermatomes and myotomes is variable from one individual to another, owing to the overlapping nature of segmental innervation from adjacent root segments. Any one chart will necessarily be a composite of the segmental possibilities. Second, there are inherent shortcomings in any single technique of segmental anatomical study. Clinical studies rely on the spectrum of traumatic lesions producing the nerve damage; these may be partial lesions so that the extent and distribution of involvement will vary from one case to another. Anatomical studies rely on the tracing of nerve twigs to muscles, but do not take into account the physiological contribution of innervation. The physiological aspects of the segmental innervation of motor units are best traced by electromyographic myotomal charts, which carry the additional value of precise localization of individual, affected muscles, not possible in clinical studies where motor actions cannot always be defined in terms of the activation of individual muscles (see below).

Electrodiagnosis of Cervical Radiculopathy

For the patient with a solitary cervical spinal nerve root compression in whom the clinical examination is straightforward and neuroimaging studies are entirely consistent, no further workup is required. However, for situations in which the age of the deficits is unclear, the degree and nature of active motor axon loss is in question, or the clinical findings and neuroimaging studies are complex or not consistent with each other, electrodiagnostic testing is useful. It can provide valuable information regarding the physiology of the neurological symptoms (the presence, the severity, and the activity of motor axon loss), as well as the anatomical localization of the lesion. Electrodiagnostic studies will also exclude other disorders that may masquerade as radiculopathy.

Clinical Neurophysiology of Radiculopathy

Cell bodies of the motor nerve fibers reside in the anterior horns of the spinal cord, while those of the sensory nerve fibers reside in the dorsal root ganglia (DRG). DRG are in general located within the neural foramina and are therefore not strictly speaking intraspinal. The preservation of sensory nerve action potentials (SNAPs) is a cornerstone of the electrodiagnostic presentation of radiculopathy. Axon loss lesions occurring within the intraspinal canal will affect both sensory and motor root fibers and will produce both sensory and motor symptoms, but will only produce peripheral wallerian degeneration along the motor fibers, as long as the DRG are distal to the site of nerve root damage. Peripheral sensory axons do not degenerate when they remain connected to their cell bodies.

However, there is a tendency for DRG to reside within the spinal canal at some segmental levels. While this is especially true at the L5 and S1 levels, it is also seen in the cervical region, especially at the C5 and C6 levels [9].

Nerve root fibers are vulnerable to the same types of injury as other peripheral nerves: entrapment, compression, infiltration, necrosis, and transection. Mild damage may result in focal demyelination leading to conduction block or conduction velocity slowing along nerve root fibers. Axon loss at the root level results in wallerian degeneration along the whole course of affected nerve fibers. Both conduction block and axon loss produce symptoms and signs of sensory loss and weakness if a sufficient number of nerve fibers are affected. Conduction velocity slowing alone is insufficient to produce weakness or significant sensory loss, although sensory modalities requiring timed volleys of impulse transmission along their pathways, such as vibration and proprioception, can be altered.

Nerve Conduction Studies

A number of factors reduce the sensitivity of NCS in the diagnosis of radiculopathy. First, most radiculopathies are due to compression from disc protrusion or spondylosis and result in damage to only a fraction of nerve root fibers, producing limited motor and sensory deficits. Second, in the acute setting, radiculopathy manifests itself most commonly by symptoms of pain and alteration of sensory perception. Sensory radiculopathy can only rarely be reliably localized segmentally by electrodiagnostic techniques. This is the case

because symptoms of pain and paresthesia are mediated through C-type sensory fibers that are too small to be studied by routine electrodiagnostic techniques, and because the peripheral processes of sensory root fibers remain connected to their cell bodies in intraspinal lesions, so sensory nerve action potentials (SNAPs) remain normal. Third, the intraspinal location of most lesions makes it impossible to perform direct nerve conduction studies (NCS) on the nerve root proximal to the damaged segment, preventing the diagnosis of conduction block and focal conduction velocity slowing across the damaged segment of the root.

Routine Studies

Sensory NCS performed along peripheral nerve trunks are characteristically normal in radiculopathy. The SNAP distal latency and nerve conduction velocity are never involved in radiculopathy. The SNAP amplitude may be abnormal if DRG are affected in the pathological process. In pathological processes that infiltrate or extend from the intraspinal space into the neural foramen, such as malignancy, infection, and meningiomas, DRG are damaged and wallerian degeneration along sensory axons occurs, resulting in SNAP amplitude loss. When DRG reside in an intraspinal location, as mentioned above, they become vulnerable to compression by disc protrusion and spondylosis.

Motor NCS are relatively insensitive in the diagnosis of motor radiculopathy for several reasons. First, most radiculopathies interrupt only a fraction of the total number of motor root fibers, while loss of close to 50 % of motor axons in a nerve trunk is required to reliably establish a significant reduction in the compound muscle action potential (CMAP) amplitude, when compared to the same response on the uninvolved side [18]. Second, to identify an abnormality of CMAP amplitude in a motor radiculopathy, the muscle belly from which the CMAP is generated must be in the myotome of the injured root. For example, a severe C8 radiculopathy would be expected to produce some change in the ulnar CMAP amplitude, recording from either the abductor digiti minimi or the first dorsal interosseous. In the C5 myotome, the musculocutaneous and axillary nerve trunks can be stimulated to assess CMAPs from the biceps and deltoid muscles, respectively. However, in the C6 and C7 myotomes, there are no major peripheral nerve trunks that carry only C6–7 fibers, and there are no isolated muscle bellies from which to assess the CMAP amplitude.

Late Responses

Late responses are evoked motor potentials that can be used to measure the travel time of propagated nerve action potentials from a distal point of electrical stimulation along a peripheral nerve trunk, to the spinal cord, and then back down the limb to a muscle belly innervated by the same peripheral nerve trunk. Theoretically, they make possible the assessment of conduction through the damaged segment of a nerve root, but there are a number of limitations. First, because the traditional measurement is latency, the sensitivity is low because even severe slowing over a short segment will not usually prolong the total latency enough to be significant. Second, as long as a few nerve fibers conduct normally through a damaged segment, a normal "shortest" latency will be recorded, even in the presence of severe nerve root damage. Finally, late responses such as F waves are of limited value in the diagnosis of radiculopathy because they are not recorded along sensory nerve fibers, and are useless in the assessment of sensory symptoms.

The F wave was first described by Mc Dougal and Magladery in 1950 and was so named because they were originally recorded from foot muscles. The F wave is a motor response often recorded from a muscle belly after stimulation of the peripheral nerve trunk innervating the muscle. It is thought to arise from the "backfiring" of motor neurons as impulses arrive antidromically from a peripheral site of nerve trunk stimulation. The F wave occurs after the CMAP, but as the point of nerve trunk stimulation is moved more proximally, the CMAP latency lengthens and the F wave latency shortens, indicating that the impulse eliciting the F wave travels away from the recording electrodes toward the spinal cord before returning to activate distal muscles. Traditionally, the shortest latency of at least eight consecutive discharges is measured. The absence of an F wave response from stimulation of the median, ulnar, or tibial nerve in the presence of normal evoked CMAPs from the same muscle suggests conduction block or very recent (less than 5–8 days) axon loss somewhere along the nerve trunk proximal to the point of nerve stimulation. This is most often encountered in the setting of acute demyelinating polyneuropathy but could conceivably be a feature of isolated radiculopathy when occurring in a single myotomal distribution. The F amplitude and duration and the range of F wave latencies have not been of clinical value in the diagnosis of focal radiculopathy. A measure of the interval between the shortest and longest F latency in a consecutive series of stimuli is described as chronodispersion and can be abnormally increased in demyelinating polyneuropathies, but does appear to have significant application to focal radiculopathy.

The H reflex is a monosynaptic spinal reflex first described by Hoffmann in 1918. Traditionally, this response is obtained by stimulating the tibial nerve at low voltage in the popliteal fossa to preferentially activate Ia sensory afferents, whose fibers terminate directly on motor neurons in the same spinal cord segment, completing a reflex arc that ends in an H wave recorded over a distally recorded muscle in the tibial nerve distribution, such as the soleus muscle. In clinical practice, only the tibial H reflex is routinely performed. When elicited from the tibial nerve, the H reflex is the electrophysiological equivalent of the Achilles tendon muscle stretch reflex.

The H reflex can be elicited from other nerve trunks. In the presence of corticospinal tract disease, the H reflex can be elicited from many nerve trunks, as a result of loss of the normal central inhibitory influences on motor neuron pools. Under normal circumstances, aside from the tibial H reflex, the H reflex can be elicited reliably only from the median nerve, recording over the flexor carpi radialis. Abnormalities of the median H reflex may be seen in patients with C6–7 radiculopathy; one study identified 11 of 25 patients with absence of the median H reflex and 6 of the remaining 14 with prolonged H reflex latency [19]. The upper limit for the median H reflex has been reported as 20 ms, but nomograms taking into account the effect of arm length allow more precision in diagnosis.

Somatosensory Evoked Potentials

Theoretically, somatosensory evoked potentials (SEPs) should be a valuable tool in the assessment of conduction abnormalities along sensory fibers at the root level. Electrical stimuli are delivered on the skin surface to a mixed sensory and motor nerve trunk, a sensory nerve trunk, or the skin in a specific dermatomal distribution. Responses are recorded over the spine and scalp, and latencies are measured to assess the conduction time along large-diameter sensory fibers across various segments of the peripheral and central conduction pathways primarily subserving proprioception and vibratory sense.

Unfortunately, a number of limitations diminish the value of this technique. First, amplitude measurements are too variable in normal individuals to have clinical significance; thus, the assessment of partial axon loss lesions and partial conduction block is not reliable. Second, focal slowing in the root segment is diluted by normal conduction along the rest of the sensory pathway. Third, nerve trunk stimulation often simultaneously activates nerve fibers belonging to more than one root segment, masking the abnormality in the abnormal root in question [20].

Given the above-mentioned limitations, SEPs obtained from nerve trunk stimulation are of little diagnostic value. In patients with signs of cervical radiculopathy, with or without signs of myelopathy, nerve trunk stimulation may yield abnormal SEPs [21]. However, in these studies the abnormal SEP results contributed little to electrodiagnosis, because the patients in general also demonstrated clear electromyographic features of cervical radiculopathy.

Cutaneous sensory nerves have more specific and isolated root innervations, and thus, SEPs derived from cutaneous nerve stimulation have a potential diagnostic advantage. Scalp-recorded cutaneous SEPs were abnormal in 57 % of 28 cases of cervical and lumbosacral radiculopathy in one report, based on findings of abnormal amplitude and waveform configuration [22]. Overall, SEPs do not have the specificity or sensitivity of other electrodiagnostic techniques, such as the needle electromyography (EMG) examination, to recommend them at this time for the routine diagnosis of radiculopathy.

The Needle EMG Examination

For cervical radiculopathy, a systematic evidence-based literature review concluded that needle EMG examination provided confirmatory evidence of cervical root pathology in 30–72 % of patients presenting with appropriate symptoms or signs. Needle EMG abnormalities were highly correlated with weakness. Good agreement between imaging studies and needle EMG was seen in 65–85 % of cases [23, 24].

General Concepts

Although the needle EMG assesses only the motor component of radiculopathy, it is the most specific and sensitive of the electrodiagnostic tests for the identification of axon loss radiculopathy. In many cases the needle EMG may provide information regarding the root level of involvement, the degree of axon loss present, the degree of ongoing motor axon loss, and the chronicity of the process. Several general comments can be made. In most laboratories, patients with arm pain receive a general needle EMG survey that samples all major root and nerve trunk distributions in the limb in question. If abnormalities are identified, the examination is modified to focus on the cause for the abnormality. If there is a symptom in a specific region of the limb, such as the shoulder girdle, muscles in that region are also examined. Table 44.2 outlines the screening NCS for nonspecific arm symptoms. Table 44.3 outlines the screening needle EMG for nonspecific arm symptoms.

The localization of a nerve root lesion requires the identification of neurogenic abnormalities in a distribution of muscles that shares the same root innervation. The abnormalities may include increased insertional activity in the form of positive waves or sharp spikes, abnormal spontaneous activity in the form of fibrillation potentials, reduced (neurogenic) recruitment of motor unit action potential (MUAP) firing, and features of chronic MUAP reinnervation, such as increased duration, increased amplitude, and polyphasia.

The timing of the needle EMG is important. In acute radiculopathy, fibrillation is the abnormality most likely to confirm the presence of a motor radiculopathy. Fibrillation seldom develops before 2 weeks has elapsed from the onset of symptoms and in some patients may not appear until 4–6 weeks after the onset of symptoms. To utilize the EMG most effectively, the needle EMG should be delayed for at least 3 weeks after the onset of symptoms.

Table 44.2 Screening nerve conduction studies for arm pain

Sensory
Distal amplitude and latency:
Median
Ulnar
Radial
Motor
Distal latency, distal and proximal amplitudes, conduction velocity, and F latency:
Median (recording from thenar eminence)
Ulnar (recording from hypothenar eminence)

Table 44.3 Screening needle EMG survey for arm pain

Muscle	Root level	Nerve trunk
Abductor pollicis brevis	T1 (C8)	Median
First dorsal interosseus	C8 (T1)	Ulnar
Flexor pollicis longus	C8 (T1)	Anterior interosseous (median)
Extensor indicis proprius	C8	Posterior interosseous (radial)
Pronator teres	C6–7	Median
Triceps	C6–7	Radial
Biceps	C5–6	Musculocutaneous
Deltoid	C5–6	Axillary
C7 paraspinal	Overlap	

Root Localization by Needle EMG

The choice of muscles for the needle EMG must be tailored to the clinical question and specific symptoms but must be comprehensive enough to maximize diagnostic certainty. The particular muscles showing neurogenic changes in the myotome in question will vary from case to case because most root lesions are partial and not all muscles in the myotome will be affected equally. During the needle EMG, the more muscles identified as abnormal in the myotome, the more secure the electrodiagnosis. To make a reliable diagnosis of a single-root lesion, at least two muscles in that myotome should be found with neurogenic changes, and they should not share the same peripheral nerve innervation. In myotomes where it is possible, involvement of proximal and distal muscles should be sought to increase the certainty of the diagnosis and exclude peripheral mononeuropathy as the cause for the abnormalities. To complete the needle EMG in an individual with an identified single-root lesion, muscles in the myotomes framing the involved root level should be examined to verify that those myotomes are normal. For example, the biceps and first dorsal interosseous muscles should be normal in a patient with a C7 radiculopathy.

Paraspinal muscle involvement should always be sought, as it adds important support for the diagnosis of an intraspinal lesion and essentially rules out plexopathy and peripheral mononeuropathy as the cause of extremity muscle involvement. However, a number of factors reduce their value. First, paraspinal muscle fibrillation can be seen not only in disorders of the root but also in processes affecting the anterior horn cells and in muscle disorders such as necrotizing myopathy. Second, paraspinal muscle involvement cannot precisely localize the segmental level of root damage because the segmental innervation of paraspinal muscles can overlap by as much as 4–6 segments [23]. Third, clear evidence of paraspinal denervation with cervical (and lumbosacral) radiculopathies is seen in only about 50 % of cases [24]. Likely causes include the overlapping segmental innervation of paraspinal muscles and the tendency for muscles close to the site of the nerve lesion to reinnervate sooner and more completely than muscles at greater distance from the point where nerve regeneration begins. Finally, in paraspinal muscles that are close to a prior laminectomy site, fibrillation potentials may persist indefinitely due to iatrogenic denervation. In routine practice, we do not examine paraspinal muscles in areas of prior surgery.

Anatomically and clinically derived myotomal charts are not entirely applicable to the needle EMG. Muscles are chosen for the needle EMG because of specific attributes of root innervation and accessibility. Some muscles, such as the anconeus, pronator teres, and brachioradialis, are not easily isolated in the clinical examination but are easily isolated by the needle EMG and are important in root localization. Thus, electromyographically derived myotomal charts are useful in the electrodiagnosis of radiculopathy [24]. Figure 44.4 is an electromyographically derived myotomal chart for the cervical root segments.

Defining an Acute Radiculopathy

In an axon loss radiculopathy, determining the age of the lesion requires combining information about the duration of the symptoms with needle EMG findings. When MUAPs are of normal configuration and size, the presence of abnormal insertional or spontaneous activity (fibrillation) in the form of trains of brief sharp spikes or positive waves indicates recent motor axon loss. Abnormal insertional activity alone suggests that the process may be only several weeks old. The presence of spontaneous activity in the form of fibrillation potentials indicates a process at least 3 weeks of age.

While electrodiagnostic testing for radiculopathy is most valuable when significant axon loss has occurred, indirect evidence on the needle EMG may support the presence of a prominent conduction block lesion at the root level as the cause for weakness. When examining a muscle whose CMAP is of normal amplitude, the presence of a reduced recruitment pattern of MUAPs, in the absence of fibrillation potentials and chronic neurogenic MUAP changes, suggests conduction block. If this pattern is seen in multiple muscles of a specific myotome, a diagnosis of radiculopathy can be made. This diagnostic strategy is not reliable if the onset of weakness is less than 4 weeks prior to the electrodiagnostic study, since acute axon loss lesion may not clearly manifest fibrillation potentials for 3 or more weeks after onset of symptoms.

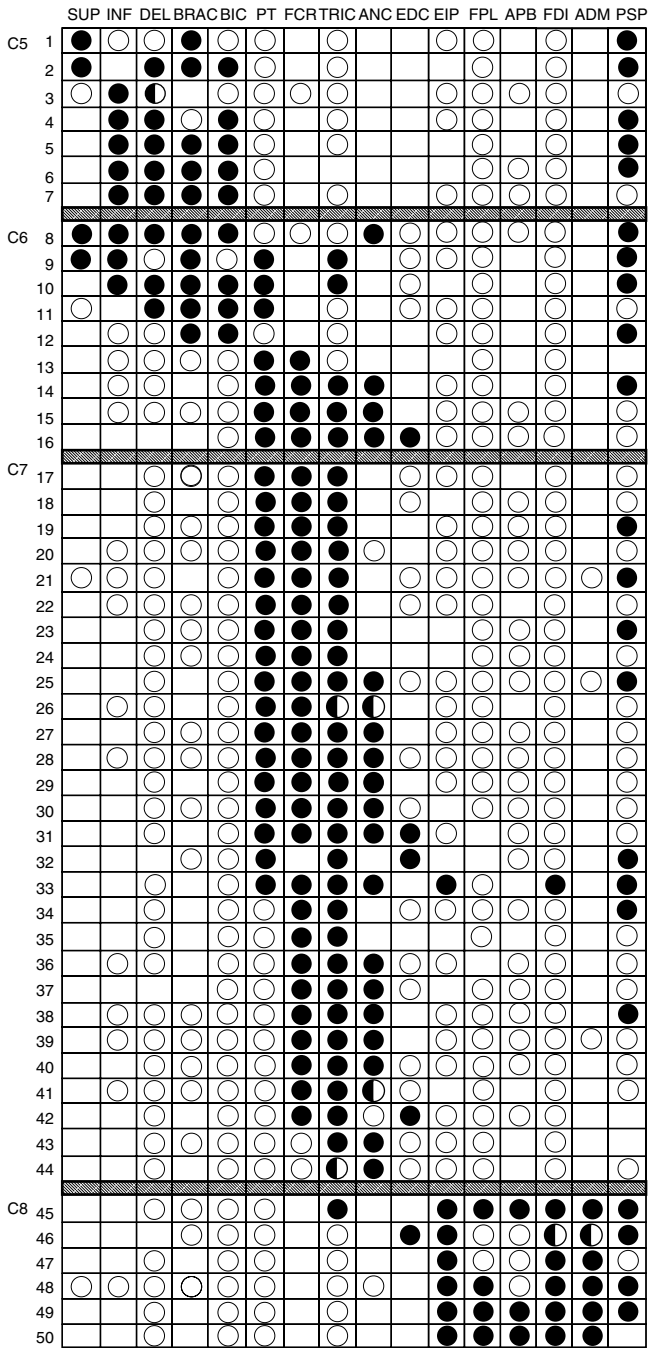

Fig. 44.4 Electromyographically derived myotomal chart for the cervical root segments, based on cases of isolated single-root lesions confirmed surgically. *Closed circle* positive waves or fibrillation potentials, with or without neurogenic recruitment and motor unit changes; *half-closed circle* neurogenic recruitment changes only; *open circle* normal examination. *SUP* supraspinatus, *INF* infraspinatus, *DEL* deltoid, *BRAC* brachioradialis, *BIC* biceps, *PT* pronator teres, *FCR* flexor carpi radialis, *TRIC* triceps, *ANC* anconeus, *EDC* extensor digitorum communis, *EIP* extensor indicis proprius, *FPL* flexor pollicis longus, *APB* abductor pollicis brevis, *FDI* first dorsal interosseus, *ADM* abductor digiti minimi, *PSP* paraspinal muscle (Reprinted from Levin et al. [24] with permission)

Defining a Chronic Radiculopathy

The diagnosis of a chronic/active or a chronic/remote root lesion is based on the observation of neurogenic MUAP changes, in the presence or absence of evidence of fibrillation potentials. In the early stages of reinnervation of denervated muscle fibers, between 6 and 26 weeks after nerve root injury, collateral sprouting from surviving nerve fiber terminals to denervated muscle fibers gives rise to MUAPs which are polyphasic and show moment-to-moment variation in morphology. As more time elapses, reinnervation becomes more complete, moment-to-moment MUAP variation resolves, and MUAPs develop the characteristic features of increased duration and amplitude, the typical electrodiagnostic signature of a chronic lesion. A needle EMG demonstrating these chronic neurogenic MUAP changes without fibrillation indicates the residuals of a remote lesion. These MUAP changes are permanent, reflecting the histopathological changes in the reinnervated muscle, and will remain unchanged unless the motor unit is injured again. After a significant motor axon loss process has occurred, MUAPs never return to their pre-injury morphology.

Chronic lesions can be classified into a chronic/active category if there are both fibrillation potentials and chronic neurogenic MUAP changes. In root distributions where the myotome includes muscles in both distal and proximal regions of a limb (in the arm only the C5–6 segments qualify), the presence of a chronic and ongoing axon loss process can be even more clearly defined when fibrillation potentials are seen in both distal and proximal muscles in the root distribution. In lesions where fibrillation potentials are seen in distal muscles only, the presence of an ongoing axon loss process is less certain. Some inactive but severe axon loss processes never fully reinnervate, especially in muscles farthest from the injury site, leaving some muscle fibers denervated indefinitely. The needle EMG findings at progressive stages of axon loss radiculopathy are summarized in Table 44.4.

Defining the Severity of a Radiculopathy

The severity of an axon loss process can be assessed during the needle EMG by the degree of motor unit loss in the root distribution. This is determined by a subjective measurement of the degree of reduced recruitment of MUAPs. While there is a correlation between the degree of reduced MUAP recruitment in a neurogenic process and the degree of weakness, reduced recruitment is not necessarily due to axon loss unless the CMAP elicited from the same muscle is also reduced in amplitude. Thus, defining the severity of an axon loss radiculopathy requires evaluation of both the CMAPs in the myotome in question (when possible) and the degree of reduced recruitment of MUAP activation. Measuring the number of fibrillation potentials present in a muscle is highly subjective and does not correlate as well with the degree of axon loss.

Table 44.4 Findings in the needle EMG examination at progressive stages of axon loss radiculopathy

	RECRUIT	INSERTION	PSP	FIB	POLY/VAR	NEUR	MTP/CRD
<3 weeks	++	+/+	+				
3–6 weeks	++	++	++	+++			
6–26 weeks	++	+	+/−	++	+++		
Chronic/active	++		+/−	+	++	++	
Chronic/remote	+/++					+++	+

RECRUIT neurogenic recruitment of myotomal motor units, *INSERTION* abnormal insertional activity in myotomal muscles, *PSP* paraspinal fibrillation, *FIB* fibrillation potentials in myotomal muscles, *POLY/VAR* polyphasic motor unit potential changes/motor unit potential variation, *NEUR* neurogenic motor unit potential changes (increased duration and amplitude), *MTP/CRD* myotonic discharges/complex repetitive discharges, +/− equivocal amount, + mild amount, ++ moderate amount, +++ greatest amount

Individual Root Lesions

Individual root lesions can be diagnosed with precision in many cases by a comprehensive needle EMG. By establishing familiarity with the electrical presentation of single-root lesions, it is often possible to identify radicular patterns when confronted with more complex combinations of root lesions in polyradiculopathies.

The most complete clinical study of specific cervical root lesions was carried out by Yoss et al. [25]. According to that study, clinical and radiographic evidence of radiculopathy occurs at the C7, C6, C8, and C5 levels 70 %, 19–25 %, 4–10 %, and 2 % of the time, respectively. The following needle EMG data on individual cervical radiculopathies comes from a study of isolated single-root lesions based on confirmed surgical localization [24] (see Fig. 44.4).

C5 radiculopathy produces a rather stereotyped pattern of muscle involvement, affecting the spinati, biceps, deltoid, and brachioradialis with about equal frequency, but not all of them together in each patient. The pronator teres is never involved in C5 radiculopathy [24]. Because the rhomboid major muscle has prominent C5 innervation, it should be examined in unclear cases. The upper trapezius, with its prominent C4 innervation, is spared in C5 radiculopathy. NCS are not likely to be helpful, although severe lesions may be associated with axillary and musculocutaneous CMAP amplitude loss.

C7 radiculopathy produces a rather stereotyped pattern of muscle involvement, affecting particularly the triceps but also the anconeus, flexor carpi radialis, and pronator teres. The triceps muscle is affected in essentially all cases of C7 radiculopathy [24]. Because the extensor carpi radialis is not reliably affected in most C7 radiculopathies, it is not usually part of the routine needle EMG survey for radiculopathy. An important part of the clinical diagnosis of C7 radiculopathy rests upon the finding of a diminished triceps deep tendon reflex, but several studies have shown that the reflex is abnormal in less than 70 % of patients [24, 25]. There are no reliably performed motor NCS that can be used to generate CMAPs from C7-innervated muscles.

With *C6 radiculopathy* there is no single characteristic pattern of muscle involvement. Rather, two patterns are discernible: the first very similar to the C5 pattern, with additional involvement of triceps and pronator teres in some; and the second similar to the C7 pattern. The pronator teres is abnormal in 80 % of patients with C6 radiculopathy but is also abnormal in 60 % of the cases of C7 radiculopathy [24]. The triceps is abnormal in over half the cases of C6 radiculopathy. Thus, significant electromyographic overlap occurs between C5 and C6 radiculopathy and between C6 and C7 radiculopathy. There are no reliably performed motor NCS that can be used to generate CMAPs from C6-innervated muscles.

C8 radiculopathy produces a stereotyped pattern of muscle involvement, including the ulnar-innervated muscles, extensor indicis proprius, and flexor pollicis longus. Abductor pollicis brevis is involved less often and to a lesser degree than other muscles. Of all the root lesions, C8 radiculopathy is the most clearly identified by needle EMG because of the limited myotomal overlap. NCS are not likely to be helpful, although severe lesions may be associated with ulnar (recording from the abductor digiti minimi or first dorsal interosseous) CMAP amplitude loss.

Although not strictly speaking a cervical radiculopathy, T1 root lesions present as upper extremity disorders. They are the most uncommon isolated root lesion affecting the arm. Although all C8 muscles of the hand are said to have T1 contributions, the abductor pollicis brevis muscle appears to be the only muscle with predominantly T1 innervation [26]. A single case of T1 radiculopathy with neuroimaging and intraoperative confirmation has been reported. The EMG picture showed chronic and active denervation limited to the abductor pollicis brevis [27].

Value of Electromyography in the Diagnosis of Radiculopathy

The lack of an established reference standard for the diagnosis of radiculopathy, other than the observation of nerve compression at surgery for structural radiculopathy, and the subjective nature of electromyographic data collection and analysis make a comparison of sensitivity and specificity of

various diagnostic tests studied in the scientific literature difficult. As a result few electrodiagnostic scientific studies have been able to meet the traditional standards set for class I or II evidence of effectiveness. Those studies that do meet evidence-based guidelines in systematic literature reviews often do not directly answer the question of clinical utility that is important to have in daily clinical care of patients.

For cervical radiculopathy, a systematic evidence-based literature review concluded that needle EMG examination provided confirmatory evidence of cervical root pathology in 30–72 % of patients presenting with appropriate symptoms or signs. Needle EMG abnormalities were highly correlated with weakness. Good agreement between imaging studies and needle EMG was seen in 65–85 % of cases [28]. One study retrospectively analyzed 47 patients with a clinical history compatible with either cervical or lumbosacral radiculopathy who were evaluated with both an EMG and a spine MRI. Among these patients, 55 % had an EMG abnormality and 57 % had an MRI abnormality that correlated with the clinically estimated level of radiculopathy. The two studies agreed in a majority (60 %) of patients, with both normal in 11 and both abnormal in 17; however, only one study was abnormal in a significant minority (40 %), suggesting that the two studies were complementary diagnostic modalities. The agreement was higher in patients with abnormal findings on neurologic examination [29].

Neuroradiology of the Cervical Spine

Neuroimaging of the cervical spine has been revolutionized by the availability of MRI technology. This has markedly reduced the use of invasive techniques such as myelography, except for those patients with implanted defibrillators and pacemakers, those with inconclusive MRI studies due to prior surgery, and those who are above the weight limit of the MRI examination table.

Neuroradiological studies are not required for all patients with neck pain and radiculopathy. In straightforward cases where there are minimal neurological deficits, conservative therapy without extensive diagnostic workup is the standard of care. When symptoms do not resolve over time or when there are significant neurological deficits, there is a greater need to understand the underlying anatomical changes, and neuroimaging should be undertaken.

Plain radiographs are of no use in the visualization of neural structures. Their use now is in the evaluation of the spine in the setting of acute trauma. They may also be used for localization during radiological, anesthetic, and surgical procedures.

Computed tomography (CT) imaging does permit visualization of neural structures and is useful in distinguishing nerve root compression due to disc versus osteophyte. CT is superior to MRI in the assessment of bony changes at the lateral recesses and neural foramina. When CT follows myelography, the resolution of cord and nerve root compression syndromes is excellent.

Disadvantages of CT include the effects of partial volume averaging, the slow acquisition time for multiple thin sections, streak artifacts in areas of dense bone such as the shoulder, and changes in configuration of the spine occurring between successive motion segments [30].

MRI technique is clearly superior in most cases to all other imaging modalities for the spine. In the cervical spine, MRI correctly predicts 88 % of the surgically proven lesions, in comparison with 81 % for post-myelogram CT, 58 % for myelography, and 50 % for CT [31]. Small osteophytes are not consistently identified on MRI scans so that in the setting where a distinction between disc and osteophyte is required, plain radiographs are an ideal additional study for identification of the osteophytes.

Specific MRI protocols differ from one institution to another, but certain basic sequences are needed to maximize the evaluation [32]. T1-weighted two-dimensional spin-echo images provide best contrast between dark CSF and high-signal-intensity bone marrow. Two-dimensional or three-dimensional spin-echo T2 or gradient-echo T2 imaging provides high-signal-intensity CSF to assess for anterior extradural disease, producing a myelogram-like effect. With a history of prior surgery, gadolinium-DTPA administration with T1-weighted sagittal and fat-saturation axial images will help assess for epidural scar, which enhances immediately following contrast injection, regardless of the time since surgery. Gadolinium-enhanced studies are also useful to assess epidural inflammatory disease in patients with possible vertebral osteomyelitis.

When bony metastatic disease is to be evaluated, screening can be carried out with a T1-weighted sagittal study. T1-weighted axial images are required to exclude epidural disease and cord compression. To assess the presence of intradural or leptomeningeal disease, sagittal and axial T1-weighted images before and after gadolinium enhancement are necessary.

Management of Cervical Radiculopathy

In any medical condition, the treatment plan should correspond to the severity of the symptoms and signs. The management approach for cervical radiculopathy covers the gamut from avoidance of heavy lifting to cervical laminectomy and fusion. No outcome studies have been published that compare specific modalities of medical care or that compare medical and surgical treatments in a similar patient population. For cervical radiculopathy, the goals of treatment should be the reduction of pain, the stabilization or amelioration of neurological deficits, and the stabilization or prevention of cervical spinal cord complications.

The initial management of acute neck pain must be directed toward an understanding of the likely pathophysiology. In the presence of a history of recent trauma or serious underlying medical illness, more aggressive evaluation is warranted. The presence of acute and progressive neurological dysfunction is an urgent medical problem. This is especially so when there is clinical evidence of bilateral neurological dysfunction, increasing the likelihood of involvement of the spinal cord. Manifestations include bilateral leg weakness and sensory symptoms, and loss of bowel or bladder control. Such symptoms should trigger an urgent workup that should include MRI studies and possible neurosurgical consultation.

A number of reports have performed systematic reviews of the literature regarding aspects of management, including diagnosis, medical treatment, and surgical interventions. Few studies have reached the level 1 or 2 significance by evidence-based criteria [33, 34].

Acute Nonspecific Neck Pain

There is general agreement that patients with nonspecific acute neck pain or nonlocalizable cervical radiculopathy without neurological signs or significant neurological symptoms require only conservative medical management. Radiographs of the spine are not indicated unless there is a significant history of trauma. Patients should abstain from heavy lifting, but bed rest is not helpful. Recommended medications include nonsteroidal anti-inflammatory drugs such as ibuprofen or aspirin. If there are complaints of muscle spasm, muscle relaxants such as cyclobenzaprine may be used. Narcotic analgesia should, in general, be avoided.

Patients suffering from cervical whiplash injuries constitute the only group that has been systematically studied. The Quebec Task Force recommended early mobilization of the neck, return to usual activities, and avoidance of bed rest and inactivity [35]. Cervical collars are not recommended because they prevent early mobilization of the cervical spine. Based on a review of the literature, another study concluded that manual therapies such as mobilization, exercises, and massage are beneficial for patients with mechanical cervical pain, but did not distinguish these therapies from more forceful manipulation, including thrust procedures [36]. A literature review identified reports that supported early mobilization but none that assessed the value of manipulation [37]. Therefore, it appears that data are not available to support the use of cervical manipulation for acute neck pain.

Patient education is an important part of the therapeutic effort. First, acute neck pain is very common, and the likelihood of spontaneous recovery is in the range of 80–90 %. Most patients are able to return to normal activities within 1–6 months. Second, prolonged inactivity will delay recovery. Third, potential causative activities should be avoided acutely, and perhaps indefinitely, such as heavy lifting, diving from a diving board, and possibly smoking.

There should be a follow-up visit with the patient within a month of the first visit. If significant symptoms persist, the patient's condition has moved into a subacute or chronic phase. If not already initiated, physical therapy evaluation and exercises should begin. In the absence of contributing psychosocial issues, the possibility of underlying structural or systemic causes should now be considered. After 4–7 weeks of an unimproved state, neuroimaging studies of the spine should be considered. Acute or chronic spine pain may be related to serious underlying medical illness. Warning signals that a medical illness may be at cause include prior history of cancer; unexplained weight loss; lack of pain relief with bed rest; failure to improve with conservative therapies; history of intravenous drug use; recent infection of the skin, urinary tract, or heart valve; and presence of risk factors for vertebral compression fractures.

Acute Cervical Radiculopathy with Focal Features

Acute Radiculopathy with Sensory Features Only

Patients with clear radicular pain and symptoms of paresthesia or numbness in a segmental distribution should be treated as though they have a focal intraspinal lesion. Such symptoms are often increased with specific provocative maneuvers during the examination. The prognosis for these patients is as favorable as for the group with nonspecific symptoms, regardless of the treatment plan. Management should consist of the avoidance of provocative activities, use of nonnarcotic analgesics, muscle relaxants if symptoms suggest a component of spasm, and early mobilization. Prolonged inactivity is not beneficial. If tolerated, gentle exercises, massage, and mobilization are beneficial, but spinal manipulation is not. If the suspicion is strong for nerve root impingement by disc protrusion or spondylosis, a high-dose, fast-taper course of corticosteroids can be used. A typical course would be prednisone 60–80 mg daily for 5–7 days, followed by a fast taper to discontinuation over the next 7–14 days. Prophylaxis against gastritis is recommended, and special precautions are needed in diabetics, but otherwise, the short course of treatment is not likely to produce complications.

With the clinical setting outlined, neuroimaging is not indicated unless there are specific historical features that suggest myelopathy or recent trauma. Patients with acute symptoms in the absence of significant neurological deficits are very likely to respond to conservative management, and surgery is not indicated. Treatment with cervical traction and spinal manipulation is not recommended in the presence of spinal cord compression or large disc protrusion and should not be considered unless the intraspinal anatomy has already been defined by neuroimaging.

In the patient with acute cervical radiculopathy due to neural foraminal stenosis from facet or uncovertebral osteophytes, cervical traction may provide temporary relief by modestly increasing the separation between vertebral bodies. This therapy can be self-administered with a pulley-system traction device. The initial counterweight should not exceed 5–7 lb but can be increased as tolerated to 15 or more pounds. 15–20-min episodes of traction should be repeated through the day as needed. Reports indicate that during cervical traction and for some minutes after, some anterior cervical vertebral separation does occur. In one study greater separation appeared with 50 lb than with 30 lb of traction, but traction applied for over 7 s at a time provided no further separation [38]. With 7 s of 30 lb of applied traction alternating with 5 s of rest, maximal separation occurred at 25 min, but the effect was lost within 20 min of the last applied traction. The efficacy of cervical traction has not been proven, but it is a standard therapy, and a number of patients claim benefit. If traction induces increased symptoms or pain, it should be discontinued.

Acute Radiculopathy with Neurological Deficits

Even patients with neurological deficits, such as segmental distributions of weakness, segmental loss of sensation, and reflex changes, are likely to have significant spontaneous recovery. The initial approach to their treatment need not be different from that outlined for the patient with radicular sensory symptoms only. Reliable outcome studies are not available that establish guidelines for medical versus surgical treatment in this patient group. However, the risk is clearly greater in this group for progression of the neurological deficits and residual neurological impairment if spinal nerve root compression persists. In the presence of a significant motor deficit, it is important to understand the underlying structural cause, first of all, in order to identify lesions that are amenable to surgical correction and, second, in order to exclude the additional (and at times subclinical) presence of spinal cord compression. Thus, early MRI studies in this setting are appropriate.

Management should consist of the avoidance of provocative activities, use of nonnarcotic analgesics, and muscle relaxants if symptoms suggest a component of spasm. Prolonged inactivity is not beneficial, and mobilization should be encouraged once symptoms stabilize. Gentle exercises, massage, and mobilization are beneficial, but spinal manipulation is not. If the suspicion is strong for nerve root impingement by disc protrusion or spondylosis, a high-dose, fast-taper course of corticosteroids can be used, as noted above.

Shoulder abduction over the head, with the hand and wrist resting on the vertex, has been used as a supportive sign of cervical radiculopathy but may also be used for temporary relief of sensory symptoms [14].

Chronic Cervical Radiculopathy and Chronic Neck Pain

When symptoms of radiculopathy extend beyond 4 weeks, in the presence of neurological deficits that are fixed or worsening, reassessment of the underlying cause of the symptoms and treatment options is necessary. A number of alternative nonsurgical approaches are also available, although their efficacy has not been proven. Physical therapy evaluation and the use of exercises to promote ideal posture, the use of transcutaneous electrical nerve stimulation (TENS) units, and continued cervical traction all have their advocates, and patients appear to respond to one or more of these maneuvers.

Epidural corticosteroid injections at the cervical levels have been performed for several decades, but not to the extent of epidural injections at the lumbar levels. Epidural injection of a combination of corticosteroid and anesthetic can lead to temporary reduction of pain in some patients. The few studies that have been performed have not been well controlled, and patient accession into the studies was not highly selective. Nevertheless, injections performed at the C5–6 and C6–7 interspaces produced "good or better" pain relief for 1 month or longer in 38 % of patients [39].

One retrospective study of 100 patients attempted to identify a patient profile that predicted response to cervical epidural injection of a combination of corticosteroid and anesthetic [40]. Based on clinical outcomes determined by subjective reports of pain relief and return to activities of daily living, only the presence of radicular pain predicted a better outcome from epidural injection. Other measured predictors, including age, abnormal sensory examination, change in deep tendon reflexes, motor changes on examination, and abnormal electromyographic findings, were not found to be significant. Predictors of a poor outcome included normal radiological examination findings and the presence of a herniated disc. In those whose pain relief amounted to 50 % or more, the response occurred irrespective of the cervical level involved. In patients with symptoms and neurological signs of true radiculopathy, whether or not a structural abnormality was seen radiographically, the probability of at least 50 % improvement was 62 %, while the probability was only 35 % for patients with only radicular pain symptoms and radiological structural changes. The poorest probability was seen in patients with radicular symptoms without structural changes and in patients with nonspecific axial pain symptoms.

Another local injection procedure, selective nerve root block, has been used for both diagnostic and therapeutic purposes at both the lumbosacral and cervical levels. This diagnostic technique has been used when there is lack of agreement between clinical and neuroimaging findings, when there is atypical limb pain, and when there is a history

of failed surgery at the level in question. Their use is contraindicated in the presence of systemic infection, local infection, or bleeding diathesis. For the therapeutic procedure at the cervical level, it is standard practice to use a combination of 0.5 cc of a 1 % xylocaine and a long-acting corticosteroid. The therapeutic injection is preceded by a localization procedure under fluoroscopic guidance, using a nonionic contrast medium to outline the selected nerve root. Contrast injection is also critical to exclude intravascular needle positioning, epidural positioning, and positioning at the sinuvertebral; injection at the latter two positions would no longer assure a selective nerve root block. The sinuvertebral nerve, derived from sympathetic fibers from the ramus communicans and fibers from either the primary anterior or posterior ramus, provides innervation over several segments to adjacent dura, posterior longitudinal ligament, and annulus. A further drawback of this technique is the placebo response rate, reported to be as high as 38 % [41]. Although reports have studied the efficacy of selective nerve root block at the lumbosacral levels, no studies have directly addressed the value of selective nerve root block in the treatment of cervical radiculopathy.

Chronic neck pain resulting from whiplash injury is a difficult therapeutic problem. A small number of patients who have suffered whiplash injuries have pain that persists 6 months or more after onset. In about half of these patients, the pain is thought to originate in the cervical zygapophyseal (facet) joints [42]. This chronic pain disorder does not appear to have specific clinical or radiological hallmarks, but it responds to local anesthetic block to the nerves supplying the painful joint. Although a controlled trial showed that intra-articular injections of corticosteroids offered no particular benefit, percutaneous radiofrequency neurotomy of the medial branch of the cervical dorsal ramus that innervates the joint provided pain relief for up to 263 days, compared to 8 days in the placebo group [43]. Patient selection was based on double-blind controlled trials of local anesthetic to the medial branches of the cervical dorsal rami at the levels of clinical involvement. Return of pain after a successful radiofrequency procedure was thought to represent regeneration of nerve branches to the joint and was treated with repeat neurotomy, with variable results.

A small number of patients fail to respond to all the above-mentioned therapeutic interventions. Some of these patients have chronic spine pain without evidence of structural intraspinal pathology, others have had previously treated structural lesions, and some have had multiple previous surgical interventions, a condition described as the failed spine syndrome. The goal in such patients is to improve the ability to perform activities of daily living and refocus attention away from pain perception.

A number of nonmedical factors play a role in the triggering and perpetuation of pain behavior. These include psychosocial issues such as job dissatisfaction, family stresses, and underlying psychiatric disorders. In other cases patients develop and ingrain a behavior of pain avoidance and fear of pain. Patients with chronic pain are best treated in dedicated centers for the rehabilitation of patients with multifactorial pain syndromes. Pain programs concentrate on the reeducation of the patient to diminish fear of activities of daily living through graded exercise programs, the exploration of psychosocial stressors, and the nonnarcotic treatment of pain.

Surgical Management of Cervical Spinal Disease

The factors that increase the likelihood that surgery will be performed for cervical radiculopathy include an obvious neurological deficit, progression of the deficit over time, unresolved pain, identification of an anatomic lesion that corresponds with the neurological picture, and spinal cord compression on neuroimaging in the presence of associated myelopathic neurological deficits. The general surgical approach to several different clinical scenarios will be presented.

A common surgical scenario is that of a large disc protrusion giving signs and symptoms of a unilateral C6 nerve root compression. When asked how to approach such a patient, four surgeons rendered four different opinions [44]. The opinions included anterior discectomy with fusion, anterior discectomy without fusion, anterior discectomy with anterior plating and screw fixation, and standard partial hemilaminectomy and foraminotomy to remove the disc fragment, without fusion. The last choice is favored because the disc space is not entered and recurrence and complications are rare [44, 45]. This procedure has been further refined with microdiscectomy techniques [46].

In the patient with osteophyte in the uncovertebral region causing nerve root compression, hemilaminectomy and foraminotomy as noted above are usually successful. This approach is also appropriate for the common combination of osteophyte and extruded disc at the C5–6 or C6–7 level.

The surgical treatment of spondylotic spinal cord compression and myelopathy is more involved. In the presence of a normal cervical lordosis, multilevel laminectomy is a satisfactory approach, allowing the spinal cord to migrate posteriorly. In the presence of reversal of the cervical curvature or overt kyphosis, multilevel fusion, internal fixation, and corpectomy are favored to reestablish stability.

The recurrence of symptoms after surgery may be due to a number of issues: inappropriate patient selection, insufficient decompression or disc removal, nerve root trauma, residual free fragment, and postoperative hematoma and infection. Postoperative symptom recurrence requires repeat clinical evaluation and repeat neuroimaging. The

identification of a retained disc fragment or a recurrent disc extrusion will likely lead to reoperation. Recurrent disc extrusions at the same level suggest the need for a fusion at that level. The presence of epidural scar is not in general an indication for reoperation.

A Cochrane systematic review of surgery for cervical radiculopathy or myelopathy identified only two studies out of 52 that met evidence-based medicine criteria for review [47]. Methodological flaws also occurred in these studies such as risk of bias, and neither study provided reliable evidence on the effects of surgery. It was unclear whether the short-term risks of surgery were outweighed by long-term benefits. There was low-quality evidence that surgery may provide pain relief faster than physical therapy or hard collar immobilization, and there was little or no evidence of such over the long term.

Differential Diagnosis of Cervical Radiculopathy

Acute Disorders

A number of other peripheral neuropathic disorders can present clinically or electrodiagnostically as acute cervical radiculopathy. The most likely to cause confusion in my experience is neuralgic amyotrophy. This disorder may best be described as a regional mononeuropathy multiplex. Although usually predominant in a single limb, in over 25 % of cases, there is either clinical or electrodiagnostic evidence of bilateral involvement. Classically the disorder begins with severe pain in the scapula or shoulder, preventing sleep in the recumbent position. Over subsequent days, weakness develops and reaches a maximum over hours to days. The pain usually subsides over several weeks but can persist. The motor disorder often takes the form of some combination of the spinal accessory, suprascapular, long thoracic, axillary, and musculocutaneous nerve trunks. Most cases involve nerve trunks around the shoulder girdle, but the clinical and electrodiagnostic picture can be extremely patchy, selectively affecting median nerve branches to the pronator teres muscle or the anterior interosseous nerve trunk. Rarely cranial nerves are involved. Sensory involvement is rare, perhaps owing to the fact that the disorder has a predilection for nerve trunks around the shoulder girdle, which are purely or mainly motor. Some patients describe numbness over the lateral aspect of the forearm, and this may coincide with loss of the lateral antebrachial cutaneous sensory nerve action potential. The pathophysiology is axon loss, but few comprehensive pathological studies have been performed because the disorder is always self-limited and rarely reaches bulbar or respiratory structures. Significant recovery is the rule, although atrophy and weakness may persist in severely affected muscles. Because the usual combination of nerve trunk involvement affects muscles with C5–6 segmental innervation, differentiating radiculopathy at those levels can be extremely difficult unless the EMG findings are clear cut. Neuroimaging is often required to completely exclude radiculopathy.

Acute brachial plexopathy can also mimic cervical radiculopathy. Traumatic lesions may occur to any of the trunks or cords, and the more selective the damage (such as isolated upper or lower trunk, lateral or medial cord), the more likely the confusion with radiculopathy. Lesions affecting the whole plexus produce weakness in the C5 through T1 distributions, an unlikely pattern in unilateral cervical radiculopathy. Electrodiagnostic studies will almost always exclude cervical radiculopathy because of abnormalities of sensory nerve action potentials, with the exception of some upper trunk lesions where C5 damage is not reflected in any of the dermatomes studied with routine sensory nerve conduction.

Severe trauma to the neck, shoulder girdle, or arm can produce enough traction on cervical nerve roots to cause avulsion from the spinal cord at the root entry zones. The clinical presentation includes profound weakness and anesthesia in the distributions of the avulsed root segments. Electrodiagnostic studies show absent compound motor action potentials in the affected myotomes, but the corresponding sensory responses are normal, as the dorsal root ganglia have been avulsed along with the sensory axons, maintaining ganglion-axon integrity.

Acute musculoskeletal conditions can masquerade as radiculopathy. Rotator cuff tears prevent full shoulder abduction and external rotation, a pattern often confused with C5 or C6 radiculopathy, but the EMG will be normal. Subacromial bursitis and acute intrinsic shoulder joint disease may also pose a diagnostic problem early on.

Chronic Disorders

Several neurogenic disorders can be confused with cervical radiculopathy early in their course. When amyotrophic lateral sclerosis (ALS) or progressive muscular atrophy (the pure lower motor neuron form of ALS) has its onset in a unilateral upper extremity distribution, root disease is often considered first. This is especially true when it begins in the C8–T1 segments. Another disorder, multifocal motor neuropathy with conduction block, is characterized by a primarily upper extremity presentation without clinical or electrodiagnostic sensory abnormalities. Early on in its course, nerve trunk involvement is patchy and may appear to conform to a specific root distribution. Electrodiagnostic testing may show a root or isolated motor nerve trunk pattern of neurogenic recruitment, with or without conduction block on nerve conduction studies and with or without chronic motor axon loss features on the needle EMG examination.

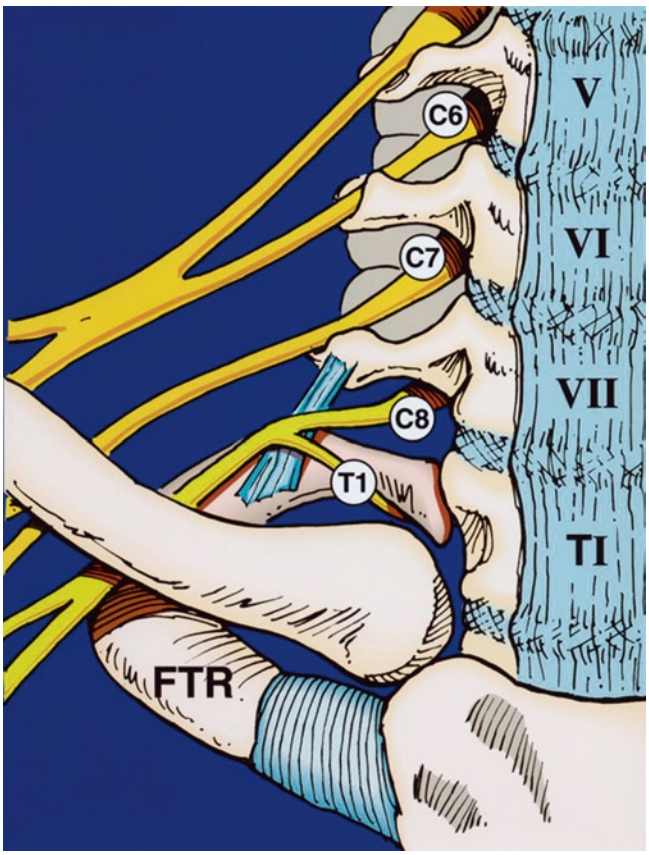

Fig. 44.5 Diagram depicting the likely anatomic relationship between the T1 and C8 nerve roots and the offending ligamentous band in neurogenic thoracic outlet syndrome, showing entrapment of the T1 and C8 nerve trunks. *Roman numerals* indicate vertebral body levels, *circled numbers* indicate root levels, and *FTR* indicates first thoracic rib (Reprinted from Levin et al. [26] with permission)

Uncommonly, individual mononeuropathies may resemble radiculopathy. This is especially true of pure motor ulnar neuropathies in the hand, radial neuropathies, and posterior interosseous, axillary, musculocutaneous, and suprascapular neuropathies.

At times, other intraspinal disorders may produce damage to a single or several spinal nerve roots. Leptomeningeal deposits of malignant cells, epidural abscess, and schwannoma can masquerade as uncomplicated root disease.

Disorders of Anterior Primary Rami

Extraspinal radiculopathy (focal damage to anterior primary rami) constitutes an unusual group of disorders that is difficult to diagnose. Two such disorders have traditionally been categorized as types of brachial plexopathy, but electrodiagnostic evidence suggests that they are more likely to represent damage to extraspinal root distributions affecting the anterior primary rami. First, neurogenic thoracic outlet syndrome, long considered a type of lower trunk brachial plexopathy, produces most severe damage in the abductor pollicis brevis muscle and the medial antebrachial cutaneous SNAP, both sharing principally T1 root innervation [26]. In most cases lower trunk/C8 structures are affected to a much lesser extent. Second, median sternotomy brachial plexopathy, a condition that occurs in the course of coronary artery bypass graft and cardiac valve repair procedures and also considered a type of lower trunk brachial plexopathy, produces most severe damage in the ulnar and C8 root distribution, with little involvement of T1-innervated structures. These two lesions show distributions of involvement that, in their purest forms, may be mutually exclusive: the abductor pollicis brevis and the medial antebrachial cutaneous response with neurogenic thoracic outlet syndrome, and C8 muscles and the ulnar sensory response with median sternotomy brachial plexopathy. However, the nerve fibers innervating all these structures travel together in the lower trunk of the brachial plexus. Therefore, neurogenic thoracic outlet syndrome and median sternotomy brachial plexopathy more likely represent, respectively, extraspinal T1 and C8 root lesions proximal to the formation of the lower trunk, as diagramed in Figs. 44.5 and 44.6.

Table 44.5 Differential diagnosis of polyradiculopathies

	Polyradiculopathy	Polyneuropathy	Myelopathy
Disorders with true root involvement

Polyradiculopathies

The term polyradiculopathy indicates damage to multiple root segments simultaneously or in progressive order, occurring in a single limb, or more frequently bilaterally and sometimes diffusely. The causes are diverse and at times unclear. In general this is a process that affects the lumbosacral segments and the cervical segments later on or not at all. In some neurological disorders polyradiculopathy coexists with lesions in distal peripheral nerves, or lesions in the central nervous system, or both. The following discussion will be limited to those disorders that are likely to be associated with significant root involvement at the cervical levels. Table 44.5 lists some causes of cervical polyradiculopathy and disorders that fall into the differential diagnosis.

Compressive Polyradiculopathies

Spondylosis of the spine is often multifocal, and multiple roots may suffer compressive damage concurrently. This is especially true at the lumbosacral level, where spondylosis causes lumbar canal stenosis and multilevel neural foraminal stenosis. At the cervical level, bilateral compressive polyradiculopathy usually occurs due to diffuse spondylosis, perhaps associated with congenital narrowing of the intraspinal canal or hypertrophy of the ligamentum flavum. This condition is often associated with cervical myelopathy. The immediate cause of the myelopathic deficits and motor axon loss in root distributions may not be compressive but rather venous congestion in the spinal cord arising from the compression, causing ischemia and infarction of long tracts and anterior horn cells. This mechanism would explain how a focal lesion in the proximal spinal cord could produce anterior horn cell loss at a distance from the actual site of compression [49].

When the cervical polyradiculopathy is chronic and active, the clinical and EMG pattern may be difficult to distinguish from early to mid-stage progressive motor neuron disease (ALS), especially in patients who have changes in the lower extremities limited to upper motor neuron signs. There are several EMG features that may help distinguish one disorder from the other. Compressive polyradiculopathy is a more chronic process, and there may not be much evidence of fibrillation potentials, while in mid-stage ALS, fibrillation potentials are prominent, as is MUAP configuration instability as a feature of ongoing active reinnervation. Second, the degree of motor unit dropout is usually greater in ALS than in most radiculopathies.

Other Causes of Polyradiculopathy

The polyradiculopathy associated with diabetes can be among the most disabling of all the neuropathic complications of that condition. Although almost always confined to the thoracic, lumbar, and sacral segments, the cervical myotomes may also affected in severe cases [50, 51]. Although usually associated with underlying diabetic polyneuropathy, diabetic polyradiculopathy may be seen in isolation in as many as 25 % of cases [52].

Processes that infiltrate or compress nerve roots lead to polyradiculopathy. Infectious causes include Lyme disease, tuberculosis, syphilis, and fungal infections. While these processes usually begin at the lumbosacral levels, they may also affect cervical levels subsequently or in the initial phase of disease. Malignancy produces polyradiculopathy by compression and invasion. Malignancies with a predilection for bone are especially likely to cause polyradiculopathy, myelopathy, or both, because of their tendency to spread into contiguous regions. Malignant cells may also gain entry into the intraspinal canal by hematogenous spread.

Myelopathy

Intramedullary processes produce motor axon loss in myotomal distributions when anterior horn cells are damaged. There may or may not be sensory symptoms and signs, but as long as the process remains strictly intramedullary, electrodiagnostic studies will show preservation of sensory nerve action potentials. The clinical picture of motor axon loss may mimic ALS, both in terms of the distribution of peripheral motor axon loss features, and because of the concomitant presence of corticospinal tract deficits. Examples include cervical syringomyelia, radiation radiculomyelopathy, severe demyelinating disease, intramedullary glioma and other malignancies, and spinal muscular atrophy. Juvenile amyotrophy of the upper extremity is considered an isolated form of lower motor neuron disease [53], but the same slowly progressive picture can be seen with arteriovenous malformations affecting the cord [54].

Polyradiculoneuropathies

The diagnosis of polyradiculoneuropathy indicates the presence of coexisting features of polyradiculopathy and peripheral polyneuropathy. The clinical presentation includes weakness in both proximal and distal root distributions of the legs (and in some disorders the arms as well), often in a distal to proximal gradient, associated with features of sensory axon loss. Electrodiagnostically the picture is characterized by loss of sensory responses, combined with features of motor axon loss, or demyelinating conduction block in multiple root distributions, or both. The leading causes include acute inflammatory demyelinating polyradiculoneuropathy (Guillain-Barre syndrome), chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), and diabetes. We now recognize both demyelinating and pure axon loss forms of inflammatory polyradiculoneuropathy [55]. Guillain-Barre syndrome may occasionally present in a relatively isolated distribution affecting cervical root distributions.

Uncommonly hereditary disorders produce a picture of polyradiculoneuropathy. Hereditary neuropathy with tendency to pressure palsy (HNPP) has been reported to present in this fashion [56]. Alpha-lipoprotein deficiency (Tangier disease) produces motor and sensory neuronopathy in a progressive segmental pattern that often affects the upper extremities first, and mimics a pattern of polyradiculopathy [57, 58]. Porphyric polyneuropathy is characterized by marked proximal and distal weakness, sometimes asymmetric and affecting the arms more than the legs. Sensory responses are variably affected, but the clinical presentation is predominantly motor.

Lumbosacral and Thoracic Radiculopathies

45

Elizabeth M. Raynor, Scott A. Boruchow, Rachel Nardin, and Galit Kleiner-Fisman

Introduction

Radiculopathy, particularly of the lumbosacral region, is one of the most common clinical problems seen by neuromuscular clinicians and among the leading reasons for referral to electrodiagnostic laboratories. While the term sciatica was first introduced by Hippocrates, its connection to intervertebral disc disorders was not widely appreciated until Mixter and Barr's 1934 work describing lumbosacral radiculopathy resulting from disc herniation [1]. It was still later that there was general recognition of thoracic radiculopathy as a distinct clinical entity, following a series of work on the subject in the early 1950s [2].

General Anatomy

Lumbosacral Spine and Spinal Nerves

The lower spine is comprised of 5 lumbar, 5 sacral, and 4 coccygeal vertebrae and their associated intervertebral discs and facet joints, with the facet joints being formed by the articular processes of the pedicles. The intervertebral foramina are formed by notches in the superior and inferior surfaces of adjacent pedicles. The disc is anterior and medial to the foramen, while the facet joint is posterior. The ligamentum flavum is attached to the articular processes of the facet joints and forms part of the posterior aspect of the spinal canal (Fig. 45.1).

The spinal cord terminates at the lower edge of L1, forming the conus medullaris. Arising from the conus is the cauda equina, which gradually separates into the individual lumbosacral nerve roots. Of the 31 pairs of dorsal and ventral roots arising from the spinal cord, there are 5 lumbar, 5 sacral, and 1 coccygeal. Ventral roots arise from motor neurons in the anterior and lateral gray columns of the spinal cord (Fig. 45.2). Dorsal roots extend proximally from sensory neurons in the dorsal root ganglia (DRG), which lie within the neural foramen. The ventral and dorsal roots join one another just distal to the DRG, forming a spinal nerve; upon exiting the foramen, the nerve divides into dorsal and ventral rami. The dorsal rami supply the paraspinal muscles and skin overlying the paraspinous region, while the ventral rami form the lumbosacral plexus, which branches into the individual peripheral nerves that supply the lower limb and sacral region. The cauda equina is contained within the arachnoid membrane, which continues along individual nerve roots to form a portion of the root pouch or nerve root canal, along with a short sleeve of dura mater which covers the nerve root within the foramen (Fig. 45.2).

Inherent disparity in the lengths of the vertebral column and the spinal cord creates a situation in which the spinal segments are relatively higher than the corresponding vertebral spinous processes. This translates into a difference of approximately two segments in the thoracic region and three segments in the lumbosacral region. In contrast to the cervical and thoracic roots, the lumbosacral nerve roots comprising the cauda equina traverse a long intraspinal course before exiting at some distance from their corresponding spinal segment. Also, the thoracic and lumbosacral nerve roots exit below their correspondingly numbered vertebrae

(i.e., L4 nerve root exits between the L4 and L5 vertebrae) (Fig. 45.3).

The muscles innervated by a single spinal segment constitute a myotome; the skin region innervated by a single spinal segment is a dermatome. There is significant variability in individual myotomal and dermatomal representation for a particular muscle or skin region. Each muscle receives innervation from multiple contiguous nerve roots, and each dermatome overlaps extensively with neighboring dermatomes.

Localization of nerve root disorders is often complicated, in part due to the intricate anatomic relationships between the nerve roots and surrounding structures. For example, a disc herniation at a single level may injure different nerve roots, depending on its location. If a disc herniates in a posterolateral direction, which is the usual tendency, it will compress the nerve root that is situated in the lateral recess as it descends to exit one level below that disc. Thus, an L4–5 disc herniation will compress the L5 nerve root in the lateral recess (Fig. 45.4). Less often, a far lateral disc herniation will compress the nerve root exiting through the foramen at that level, i.e., a far lateral L4–5 disc herniation will compress the exiting L4 root (Fig. 45.5). A particularly large disc prolapse may compress the two adjacent nerve roots by both of these mechanisms. A posterior or central disc herniation may compress multiple nerve roots in the central aspect of the cauda equina (Fig. 45.6).

Thoracic Spine and Spinal Nerves

Twelve pairs of thoracic spinal nerves innervate all of the muscles and skin of the trunk except for the lumbar paraspinal muscles and overlying skin. As in the lumbosacral spine, each spinal nerve is formed from a dorsal and ventral root,

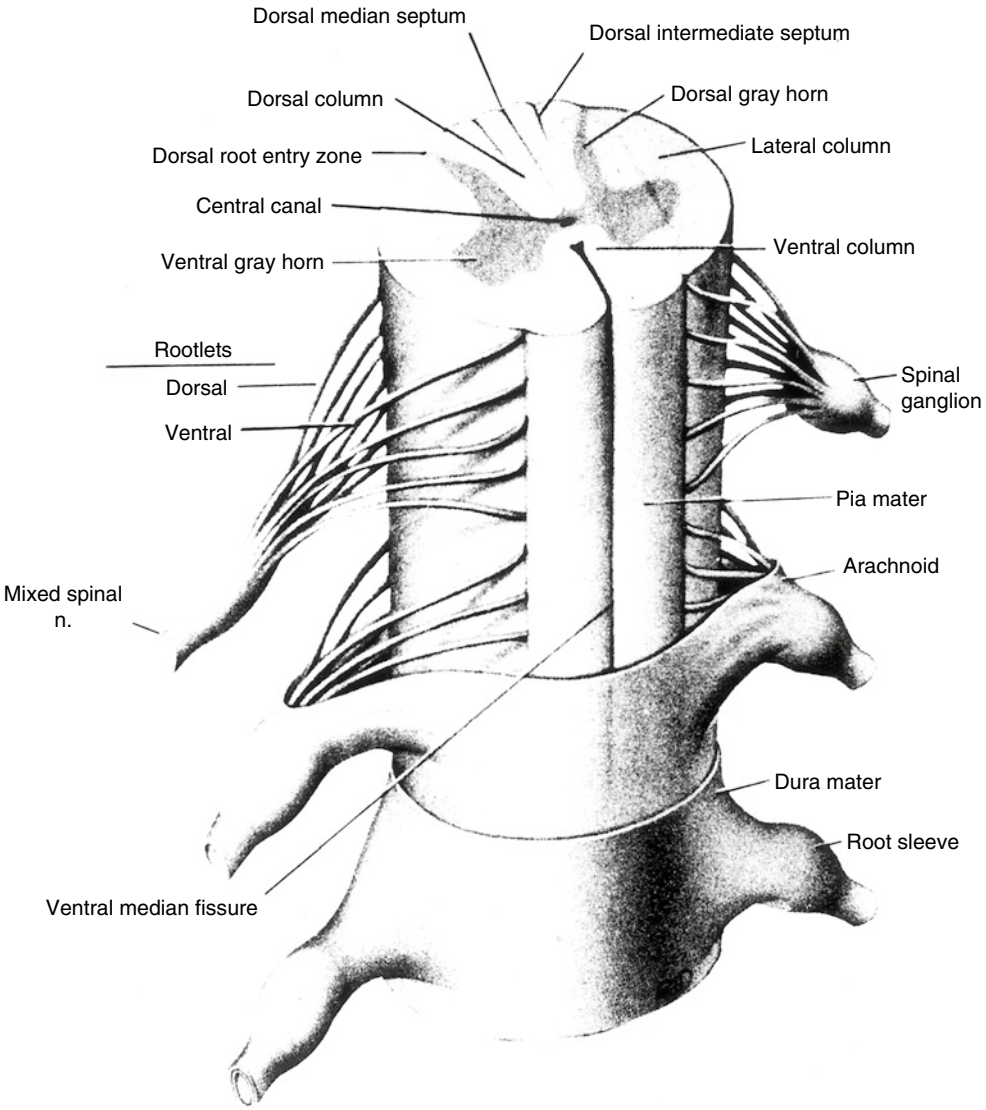

Fig. 45.2 The spinal cord, nerve roots, and meninges. Each nerve root emerges as a series of rootlets; each spinal nerve is formed by the joined dorsal and ventral nerve roots. The spinal or dorsal root ganglion contains the nerve cells whose axons make up the dorsal roots. Individual nerve roots are covered by a root sleeve formed by the dura mater (Reproduced with permission from Moore [3])

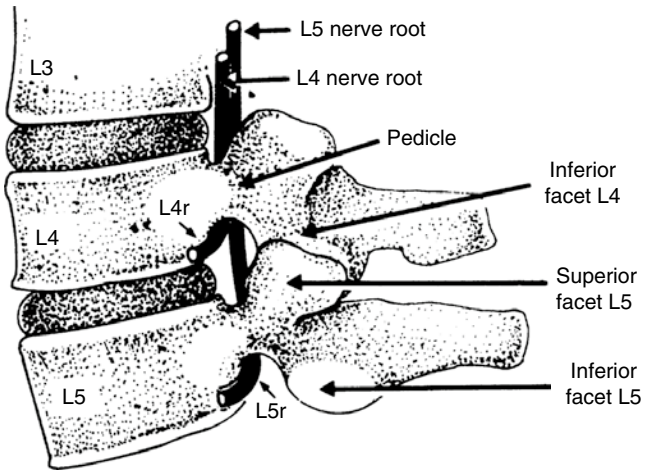

Fig. 45.3 The L4 nerve root exits the intervertebral foramen formed by the inferior facet of L4 and the superior facet of L5, i.e., the L4–5 disc space. The L5 nerve root, situated medially, descends to exit one level below (Reproduced with permission from Stewart [4])

arising from the spinal cord approximately two segments above the corresponding vertebral level. The spinal nerves divide into dorsal and ventral rami after exiting the neural foramina. The dorsal rami proceed posteriorly to innervate the adjacent paraspinal muscles and overlying skin. In the thoracic region, the ventral rami do not form large nerve plexuses but run individualized courses. In general, they may be categorized into three groups: T1, T2–6, and T7–12. The T1 ventral ramus gives off a large branch which joins C8 to form the lower trunk of the brachial plexus and, a smaller branch, the first intercostal nerve. Ventral rami from T2–6 form the intercostal nerves; T7–11 ventral rami form the thoracoabdominal nerves. The intercostal nerves curve around the chest wall between the intercostal muscles, giving off the lateral cutaneous nerves of the thorax about midway around the chest and then terminating as the anterior (medial) cutaneous nerves of the thorax (Fig. 45.7). The thoracoabdominal nerves (T7–12) also run along the intercostal spaces but

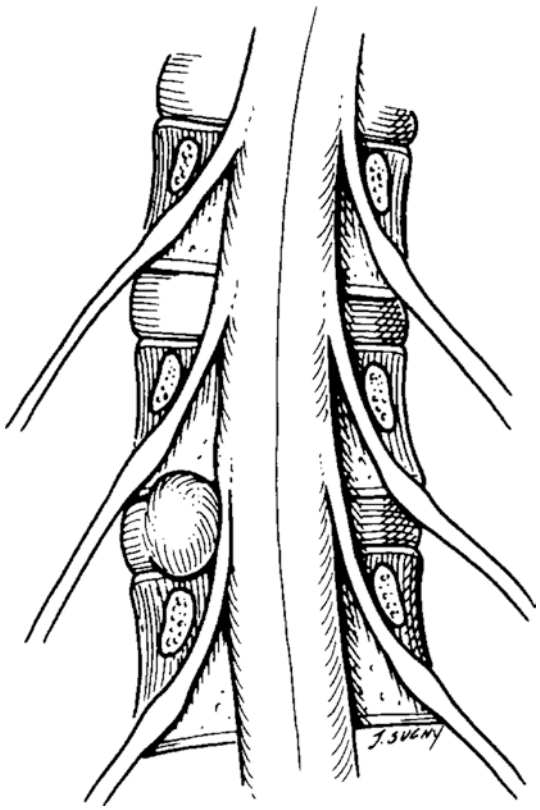

Fig. 45.4 A posterolateral disc herniation compresses the nerve root descending to exit the intervertebral foramen one level below the corresponding vertebrae (i.e., an L4–5 disc herniation compressing the L5 nerve root) (Reproduced with permission from Hardy and Plank [5])

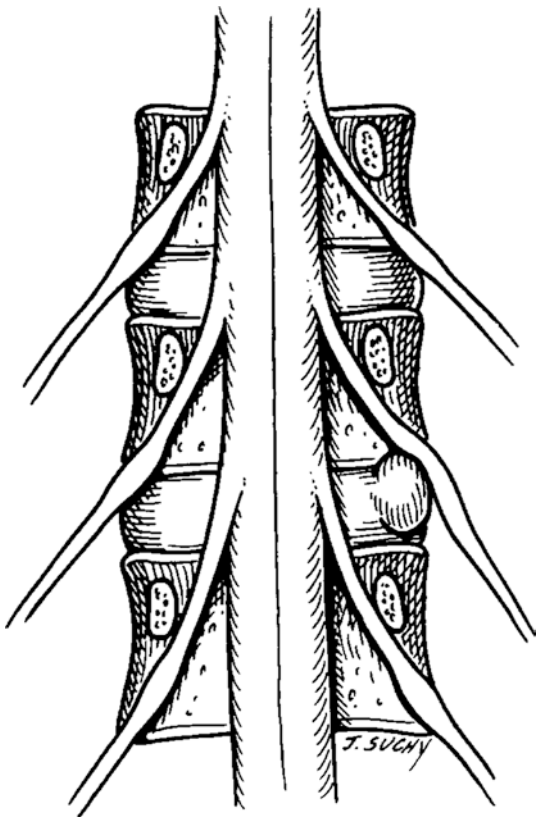

Fig. 45.5 A far lateral disc herniation compresses the nerve root exiting through the foramen at that vertebral level (i.e., an L4–5 disc compressing the L4 nerve root) (Reproduced with permission from Hardy and Plank [5])

pursue a longer course into the abdomen, giving off lateral cutaneous branches before continuing as the nerves supplying the rectus abdominis and other abdominal wall muscles, and anterior (medial) cutaneous branches of the abdomen. The thoracic and upper lumbar spinal nerves also carry preganglionic sympathetic fibers.

Pathophysiology

The pathophysiology of nerve root injury depends upon the underlying cause. Both direct trauma involving nerve roots and indirect trauma involving nearby or contiguous structures, such as the lumbosacral plexus, will result in mechanical disruption, either stretching or compression of the nerve roots. On the other hand, nontraumatic lesions may either be structural, thereby likely to cause compressive injury to the nerve root, or inflammatory/infiltrating lesions, therefore likely to cause injury by either ischemic, metabolic, or other mechanisms which are nonmechanical in nature. Compression

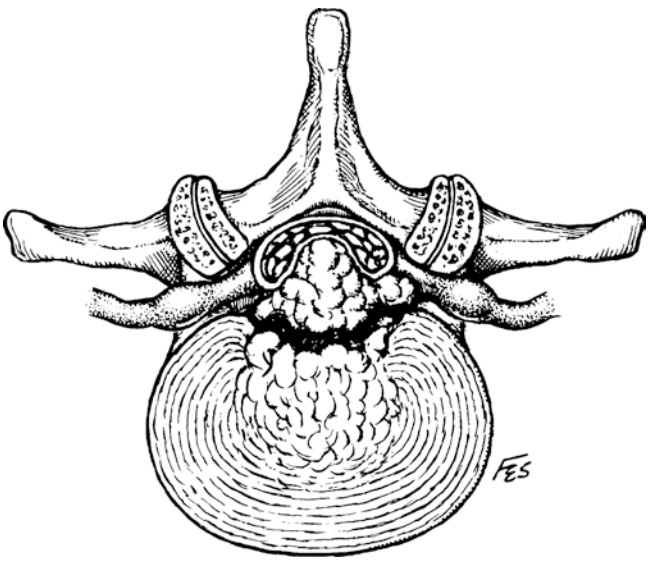

Fig. 45.6 Cross-sectional view demonstrating midline cauda equina compression by large lumbar disc herniation (Reproduced with permission from Fager [6])

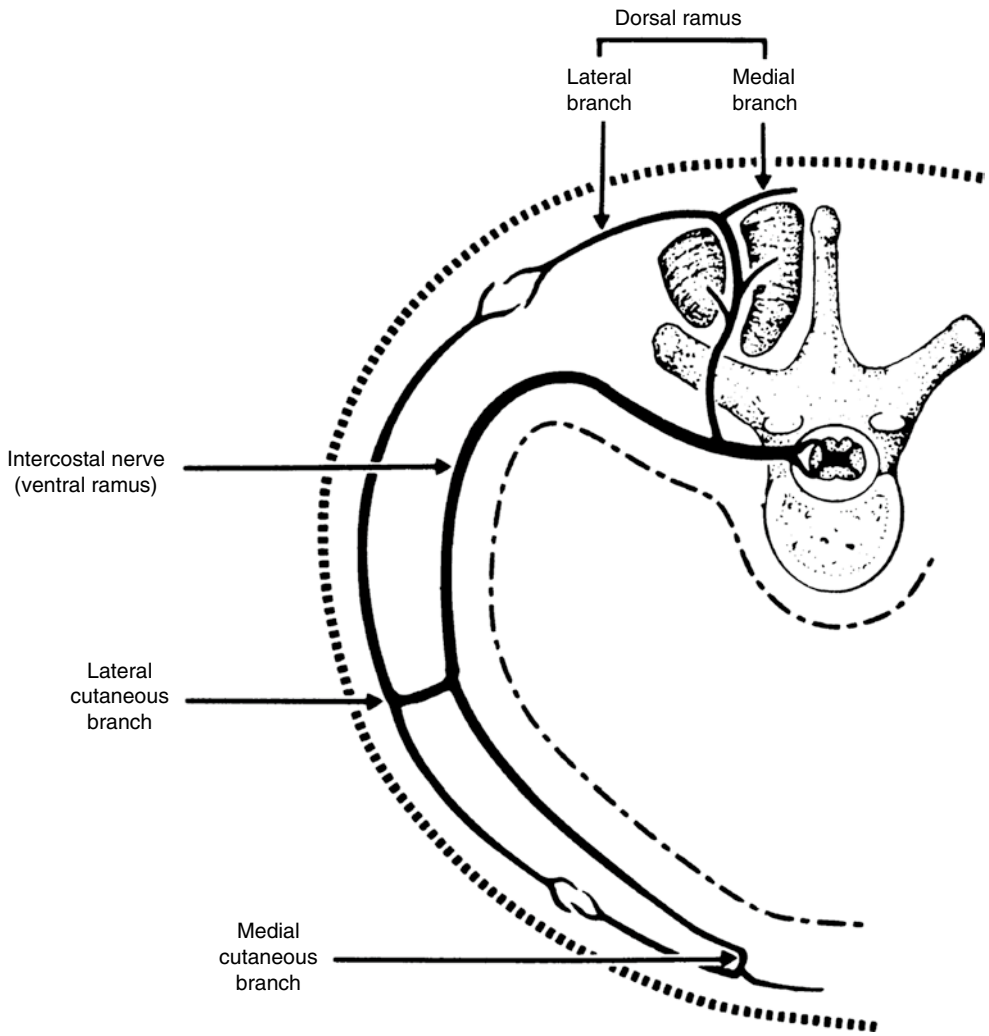

Fig. 45.7 Course and branches of a thoracic spinal nerve. Thicker, *outer stippled line* represents skin; *inner stippled line* is the pleura or peritoneum (Reproduced with permission from Stewart [7])

is the most common mechanism of nerve root injury. Compared to peripheral nerves, nerve roots have a paucity of endoneurial collagen and no epineurium, leaving the axons with considerably less surrounding fat and connective tissue, thus increasing their vulnerability to compression [8]. The absence of perineurium in the nerve roots also results in markedly increased susceptibility to the effects of stretching and compression compared to the rest of the peripheral nerve [8]. Thus, major trauma causing stretch injury to various plexus elements may result in overt avulsion of the nerve roots from the spinal cord. Fortunately, lumbosacral nerve root avulsion is relatively rare, due to the secure arrangement of the nerve roots and plexus elements within the pelvis. In addition to providing tensile strength, the perineurium provides a barrier against attack from infectious and inflammatory agents, and its absence in the nerve roots increases their susceptibility to injury by nonmechanical mechanisms [8].

Ultimately, regardless of the initial mechanism of injury, the pathophysiologic consequence of nerve root insults is either segmental demyelination or axonal loss in the fibers of the nerve roots; in the majority of injuries, there is a combination of both. The clinical and electrodiagnostic (EDX) features of a given lesion will be determined by the predominant physiologic mechanism as well as the type, size, and overall number of nerve fibers involved. One important physiologic consideration is the relationship of nerve root injury to the DRG. Regardless of the underlying etiology, nearly all nerve root injuries occur in a location proximal to the DRG. Thus, the peripheral sensory fibers will be spared, regardless of the severity and nature of the injury to the central processes of the DRG. This has very important implications for the EDX findings in radiculopathy.

Clinically, injury to nerve roots most often affects sensory fibers only, followed by combined motor and sensory

fibers; rarely are motor fibers affected in isolation [5]. Paresthesias, reflex changes, and weakness reflect damage to larger-diameter fibers, while pain reflects involvement of smaller myelinated and unmyelinated fibers. A lesion causing pure focal demyelination with slowed conduction alone would not be expected to result in significant clinical weakness or sensory loss, although reflex changes might occur. Lesions causing axonal loss or demyelinative conduction block affecting a large number of fibers are clinically indistinguishable, as both are associated with fixed sensory or motor deficit and deep tendon reflex (DTR) abnormalities; only the EDX findings would help differentiate these two processes.

Clinical Presentation

Localization of Radiculopathy

Lesion localization is of critical importance and is based primarily on clinical and EDX examination. It is on the basis of these findings that the relevance of any imaging or other laboratory abnormalities is determined. Localization depends upon demonstration of a segmental myotomal and/or dermatomal distribution of abnormalities, which requires knowledge of the neurological deficits produced by lesions at individual segmental levels. In most cases, the primary differential diagnostic considerations include lesions of the plexus, peripheral nerves, and possibly the spinal cord. A useful, though rare, clue on physical examination that a lesion is at the nerve root level is finding sensory loss over the paraspinal region innervated by the dorsal ramus of the involved root. In the lumbosacral and thoracic regions, lesions may involve a single-root level (monoradiculopathy) or multiple, usually contiguous, root levels (polyradiculopathy). Involvement of the cauda equina tends to cause polyradiculopathy and is often associated with lesions of the conus medullaris. Lesions of this region will be considered separately.

In general, radiculopathy is characterized by pain. Although dermatomal radiation of the pain may indicate which nerve root is involved, more reliable is the distribution of any accompanying paresthesias or sensory loss demonstrable on neurologic examination. Notably, an entire dermatome is rarely affected, with a tendency for distal portions to be more involved. Weakness may similarly involve only the more distal muscles in the myotome, thus making differentiation from plexus or peripheral nerve lesions difficult. DTRs are generally reduced but elicitable, unless multiple nerve roots are involved.

Lumbosacral Monoradiculopathy

Table 45.1 outlines the typical neurological examination findings with lumbosacral radiculopathies at each level. Differential diagnostic considerations depend on the particular nerve root involved but include mononeuropathies and lumbosacral plexopathies (Table 45.2).

In the lumbosacral region, the most common causes of radiculopathy are disc herniation and compression of nerve roots by spondylotic bony lesions. These lesions are almost always manifested by symptoms of pain in the lower back and/or leg (i.e., sciatica). Pain radiating into the leg is one of the signs of nerve root irritation; paresthesias radiating into a particular dermatomal region are a more specific localizing sign. Both of these symptoms may be aggravated by Valsalva maneuvers. Other signs of nerve root irritation include positive findings on straight leg and reverse straight raising maneuvers.

The straight leg raise maneuver has a number of different eponymous characterizations, but the basic test maneuver always involves stretching of the sciatic nerve and its associated L5 and S1 nerve roots in an attempt to produce radiating

Table 45.1 Neurologic findings in lumbosacral monoradiculopathies

Root level	Pain	Sensory loss (paresthesias)	Motor abnormalities/weakness	Deep tendon reflex abnormalities
L1	Inguinal region	Inguinal region	None	None
L2	Groin, anterior thigh	Anterolateral thigh	Iliopsoas	None
L3	Anterior thigh to knee	Medial thigh and knee	Quadriceps, iliopsoas, hip adductors	Knee jerk
L4	Anterior thigh to medial foreleg	Medial leg	Tibialis anterior, quadriceps, hip adductors	Knee jerk
L5	Lateral thigh and leg to dorsum foot	Lateral leg, dorsum foot, and great toe	Toe extensors, ankle dorsiflexors, everter and inverters, and hip abductors	None (unless S1 involved)
S1	Posterior thigh, calf, heel	Sole, lateral foot and ankle, lateral two toes	Toe flexors, gastrocnemii, hamstrings, gluteus maximus	Ankle jerk
S2–4	Medial buttocks	Medial buttocks, perineal and perianal region	None unless S1–2 involved	Bulbocavernosus and anal wink (ankle jerk if S1 involved)

Table 45.2 Differential diagnosis of lumbosacral monoradiculopathies

Root level	Nerve lesion	Plexus lesion	Differentiating features
L1	Ilioinguinal neuropathy Genitofemoral neuropathy	Unlikely	Sensory loss outside single nerve territory
L2	Lateral femoral cutaneous neuropathy (meralgia paresthetica); femoral neuropathy	High lumbar plexopathy	Strength normal in meralgia paresthetica; quadriceps more involved with femoral neuropathy
L3	Femoral neuropathy	High lumbar plexopathy; diabetic amyotrophy	Adductor weakness not seen w/femoral neuropathy
L4	Femoral neuropathy; common peroneal neuropathy	Mid-lumbar plexopathy	Tibialis anterior, hip adductors not involved in femoral neuropathy; quadriceps not involved in peroneal neuropathy
L5	Common peroneal neuropathy	Mid-lumbar plexopathy	Ankle inversion and hip abduction not involved in peroneal neuropathy
S1	Sciatic neuropathy; tibial neuropathy	Lower lumbosacral plexopathy	Hamstrings not involved in tibial neuropathy; glutei not involved in sciatic neuropathy

pain. The painful leg is flexed at the hip and extended at the knee with the patient supine. Pain at less than 70° is considered a positive test. Variations include reproduction of pain upon straight leg raising of the unaffected leg or aggravation of pain with forceful dorsiflexion of the involved ankle or firm pressure in the popliteal fossa. Reverse straight leg raise testing evaluates the upper lumbar roots (L2–4) and involves hip extension with the patient prone. Pain in the anterior thigh and/or lower back is considered a positive test. Although useful clinically, these maneuvers are not specific for radicular lesions and may be seen in lumbosacral plexopathies, femoral neuropathies, and diseases of the hip joint. Similarly, sciatic-type pain, usually not extending distal to the knee, may occur in the setting of mechanical lower back injuries. The clinical presentation of monoradiculopathies at individual levels is discussed briefly.

L1 Radiculopathy

L1 radiculopathy is rare as disc herniation at this level is extremely uncommon. Pain and paresthesias are the presenting complaints, with associated sensory loss in the inguinal region. There is no specific myotomal representation and no associated DTR for this segmental level. The differential diagnostic considerations include ilioinguinal and genitofemoral neuropathy.

L2 Radiculopathy

L2 radiculopathy is also rare and disc herniation a very uncommon cause of radiculopathy at this level. L2 radiculopathy presents as paresthesias with or without sensory loss in the anterolateral thigh and weakness of the iliopsoas muscle; DTRs are normal. In the absence of motor involvement, the primary differential diagnosis is lateral femoral cutaneous neuropathy (i.e., meralgia paresthetica); additional considerations include femoral neuropathy or high lumbar plexopathy, especially if motor weakness is present. However, femoral neuropathy is more likely to cause quadriceps weakness and loss of the knee jerk.

L3 Radiculopathy

Disc herniation is more likely to occur at this level than the higher levels but significantly less likely than at the L4–S1 levels. L3 radiculopathy is most often confused with femoral neuropathy, as the quadriceps muscle is predominantly affected in both. Iliopsoas weakness may be present in either. Additional involvement of hip adductor muscles, which are innervated by the L3 nerve root via the obturator nerve, indicates a plexus or root lesion. Paresthesias and/or fixed sensory deficits occur predominantly in the medial thigh and knee. The knee jerk may be reduced or absent. In addition to femoral neuropathy, the differential diagnosis includes upper lumbar plexopathy, including diabetic amyotrophy.

L4 Radiculopathy

Unlike the higher lumbar levels, disc herniation is the most common cause of radiculopathy at this level. As with L3 radiculopathy, there may be significant quadriceps weakness, leading to confusion with femoral neuropathy; however, additional involvement of tibialis anterior (peroneal nerve), as well as hip adductors, helps localize the lesion to the L4 root level. Alternatively, foot drop may be the initial clinical presentation. Sensory abnormalities occur primarily in the medial leg (saphenous nerve territory). The knee jerk is often reduced. Lumbosacral plexopathy, including diabetic amyotrophy, is the primary differential diagnostic consideration.

L5 Radiculopathy

Significant L5 radiculopathy is most likely to present with foot drop with or without "toe drop," secondary to involvement of the tibialis anterior and extensor hallucis longus, respectively. Subtle weakness of these muscles may be elicited by having the patient walk on their heels. Sensory loss is prominent over the lateral lower leg and great toe. There is no easily elicitable DTR for assessment of L5 root integrity; however, concomitant involvement of S1 will cause a reduced ankle jerk. The primary lesion which mimics L5 radiculopa-

thy is common peroneal neuropathy. Although both have weakness of ankle eversion (subserved by peroneal-innervated L5 muscles), additional weakness of ankle inversion (subserved by tibial-innervated L5 muscles) excludes a common peroneal nerve lesion and localizes the lesion more proximally. Determination of ankle inversion strength is critical to the clinical examination and should be documented in all cases of foot drop. Sciatic neuropathy and lower lumbosacral plexopathy are differential diagnostic considerations once the lesion has been localized proximal to the peroneal nerve. Weakness of the gluteus medius (hip abduction) places the lesion proximal to the sciatic nerve but does not differentiate L5 radiculopathy from lumbosacral plexopathy.

S1 Radiculopathy

Isolated S1 radiculopathy results in weakness of gastrocnemius and soleus muscles, as well as hamstrings and glutei. Subtle weakness of these muscles may be difficult to determine on examination. Difficulty of toe-walking or rising on the toes of one foot is useful for demonstrating gastrocnemius/soleus weakness. Gluteus maximus is best tested by having the patient extend the leg at the hip while prone. Involvement of gluteal muscles is an important indicator of a lesion proximal to the sciatic nerve. Sensory loss involves the sole and lateral aspect of the foot and lateral three toes. The ankle jerk is asymmetrically reduced or absent in unilateral S1 radiculopathy; in patients with bilateral S1 lesions or polyneuropathy, ankle jerks may be reduced or absent bilaterally. The differential diagnostic considerations include tibial and sciatic neuropathies as well as lumbosacral plexopathy.

Lower Sacral Radiculopathy: S2–S4

Radiculopathy involving lower sacral nerve roots is uncommon; typically, S2–5 are involved together, given their close anatomical relationship. Often, these roots are involved with central disc herniations causing pressure on the midline region of the cauda equina. The presenting symptoms are pain and sensory loss involving the perineal region and medial buttocks ("saddle region"), along with urinary retention and fecal incontinence. Physical examination demonstrates sensory loss in a variable distribution within the S1–4 dermatomes, reduced or absent anal sphincter tone, and absence of the anal wink and bulbocavernosus reflexes. Gluteal muscle weakness is associated with S1–2 involvement. Ankle jerks may be reduced or absent bilaterally or unilaterally if S1 root is involved.

Lumbosacral Polyradiculopathy and Cauda Equina Syndromes

Multiple, contiguous, and ipsilateral radiculopathies may result from disorders affecting several individual nerve roots (i.e., multilevel neural foraminal stenosis, multiple disc herniations) either in the vertebral canal or the nerve root foramina or from lesions of the cauda equina. Cauda equina lesions should be considered when more than two contiguous nerve roots are involved. Multiple, bilateral lumbar and/or sacral radiculopathies are most suggestive of lesions of the cauda equina.

The clinical presentation of lesions involving the cauda equina is variable and depends upon the nature and location of the particular lesion, as well as the time course over which it develops. Generally, two important syndromes are recognized: midline cauda equina/conus medullaris syndrome secondary to compression and intermittent neurogenic claudication due to central spinal stenosis.

Midline cauda equina syndrome usually results from compression of the nerve roots lying within the central aspect of the cauda equina. They may develop either acutely or gradually. Acute compression is most commonly due to large, central disc herniations, usually involving the L4–5 disc. Because the sacral nerve roots lie medially in the cauda equina, they are most often involved, leading to a clinical picture of sacral polyradiculopathy. However, in more extensive lesions, lumbar nerve roots may be involved as well. The syndrome is typically one of acute pain and paresthesias in sacral dermatomes, accompanied by objective sensory loss in these dermatomes ("saddle anesthesia") as well as bladder and bowel dysfunction. Depending on the extent of the lesion, leg weakness may develop either early or later in the course; ultimately, this can result in paraplegia if multiple nerve roots are involved. Often, the syndrome is progressive and early recognition is crucial, as bladder dysfunction and leg weakness are often permanent once they are fully developed.

The term *intermittent neurogenic claudication* (or cauda equina claudication) is used to describe a syndrome of lower back and leg pain brought on by walking and relieved with rest. Occasionally, the pain is brought on merely by standing but is exacerbated by walking. This syndrome is a common presentation of lumbar spinal stenosis. Lower back and leg pain and paresthesias develop over increasingly shorter distances; once pain symptoms develop, further exercise only increases the pain and may be accompanied by sensory loss or weakness. Eventually, the patient is forced to stop and rest, with relief of symptoms after several minutes. Sitting down or raising one leg results in more rapid relief. Also, bending at the waist may offer some relief. Pain is usually bilateral but may be unilateral.

The neurologic examination of patients with intermittent neurogenic claudication is frequently normal. Occasionally, neurological signs, including reflex, sensory, and motor abnormalities, are demonstrable only after a period of walking [5]. Alternatively, the neurologic examination may show evidence of a patchy polyradiculopathy involving the lower extremities.

Thoracic Radiculopathy

The typical clinical presentation of lesions involving thoracic nerve roots involves pain and/or paresthesias radiating from the posterior thorax, in the approximate dermatomal distribution of the involved root level. However, the pain may involve only a portion of a given dermatome and may not have a clear radicular quality, leading to confusion with pain of abdominal or cardiac origin. Sensory deficits may be demonstrated in all or only a portion of the involved dermatome, depending on the location, nature, and extent of the lesion. Muscle weakness is often subtle but may sometimes be demonstrated by having the patient cough or attempt a sit-up, which will produce bulging of a weak intercostal or abdominal muscle, which may be observed or palpated.

Etiology

The vast majority of lesions causing lumbosacral radiculopathy are compressive in nature and due to either disc herniation or spondylosis. However, as listed in Table 45.3, the differential diagnosis of lesions producing lumbosacral radiculopathy is broad and includes a variety of neoplastic, infectious, and inflammatory disorders.

Unlike the lumbosacral region, acute disc herniations and spondylotic lesions in the thoracic spine cause radiculopathy only infrequently and are much more likely to cause spinal cord compression which dominates the clinical picture. Thus, compressive thoracic radiculopathy is relatively rare compared to lumbosacral radiculopathy and is more likely to be caused by a non-compressive lesion. Table 45.4 lists the differential diagnosis of lesions producing thoracic radiculopathy.

Table 45.3 Causes of lumbosacral radiculopathy

Monoradiculopathy	Polyradiculopathy or cauda equina syndrome
Degenerative spine disease	Degenerative spine disease
Disc herniation	Disc herniation—usually large, central
Spondylosis/lumbar spinal stenosis	Spondylosis/lumbar spinal stenosis
Neoplastic disease	Neoplastic disease
Primary spinal tumors	Leptomeningeal metastases
Epidural and vertebral metastases	Carcinomatous meningitis
Infectious disease	Infectious disease
Spinal epidural abscess	Polyradiculopathy in HIV/AIDS
Herpes zoster	CMV, HSV, syphilis
Lyme radiculoneuropathy (early, late)	Herpes zoster Lyme radiculoneuropathy (early, late)
Diabetic radiculopathy	Diabetic polyradiculopathy (amyotrophy)
Complication of epidural/spinal anesthesia	Complication of epidural/spinal anesthesia
Spinal epidural hematoma	Spinal arachnoiditis
Spinal cysts	Tethered cord syndrome
Traumatic nerve root injury	Hypertrophic nerve roots in CIDP, HMSN I

Degenerative Spine Disease

Lumbosacral Disc Herniation

In patients under age 40–50 years old, disc herniation is the most common cause of lumbosacral radiculopathy. The most common levels of disc herniation are L4–5 and L5–S1; consequently, L5 and S1 radiculopathy are most frequent, L4 is less common, and herniation at the higher lumbar levels is distinctly unusual. Herniation of the nucleus pulposus (HNP) may leave some of the fibers of the annulus fibrosis intact (prolapsed or bulged disc) or may rupture through the annulus fibrosis (extruded or herniated disc) and be contained by the posterior longitudinal ligament (PLL); occasionally, the disc ruptures through both the annulus and the PLL and floats freely within the spinal canal (sequestered disc). Sequestered disc fragments may migrate in the epidural space; rarely, herniated discs may penetrate the dura.

The pathogenesis of radiculopathy from acute HNP appears related to both mechanical and ischemic-metabolic injury to the nerve root, due to the combined effects of compression and local inflammation [9, 10]. Mechanical injury is related to physical stretching or compression of the nerve root by the herniated disc, with associated disruption of axons and/or myelin. Ischemic-metabolic injury is the result of several interrelated factors. Compression of the nerve root impairs intraneural blood flow, leading to ischemia, in addition to altering vascular permeability. Altered vascular permeability results in endoneurial edema, which further jeopardizes the microcirculation [9]. Partial arachnoid block may also contribute to metabolic injury through interference with local cerebrospinal fluid (CSF) flow, a potentially important nutritional support system for the nerve roots [11]. Finally, ischemic-metabolic injury may be compounded by acute inflammatory substances released by the extruded disc contents, which further alters vascular permeability and intraneural blood flow [10].

Table 45.4 Causes of thoracic radiculopathy

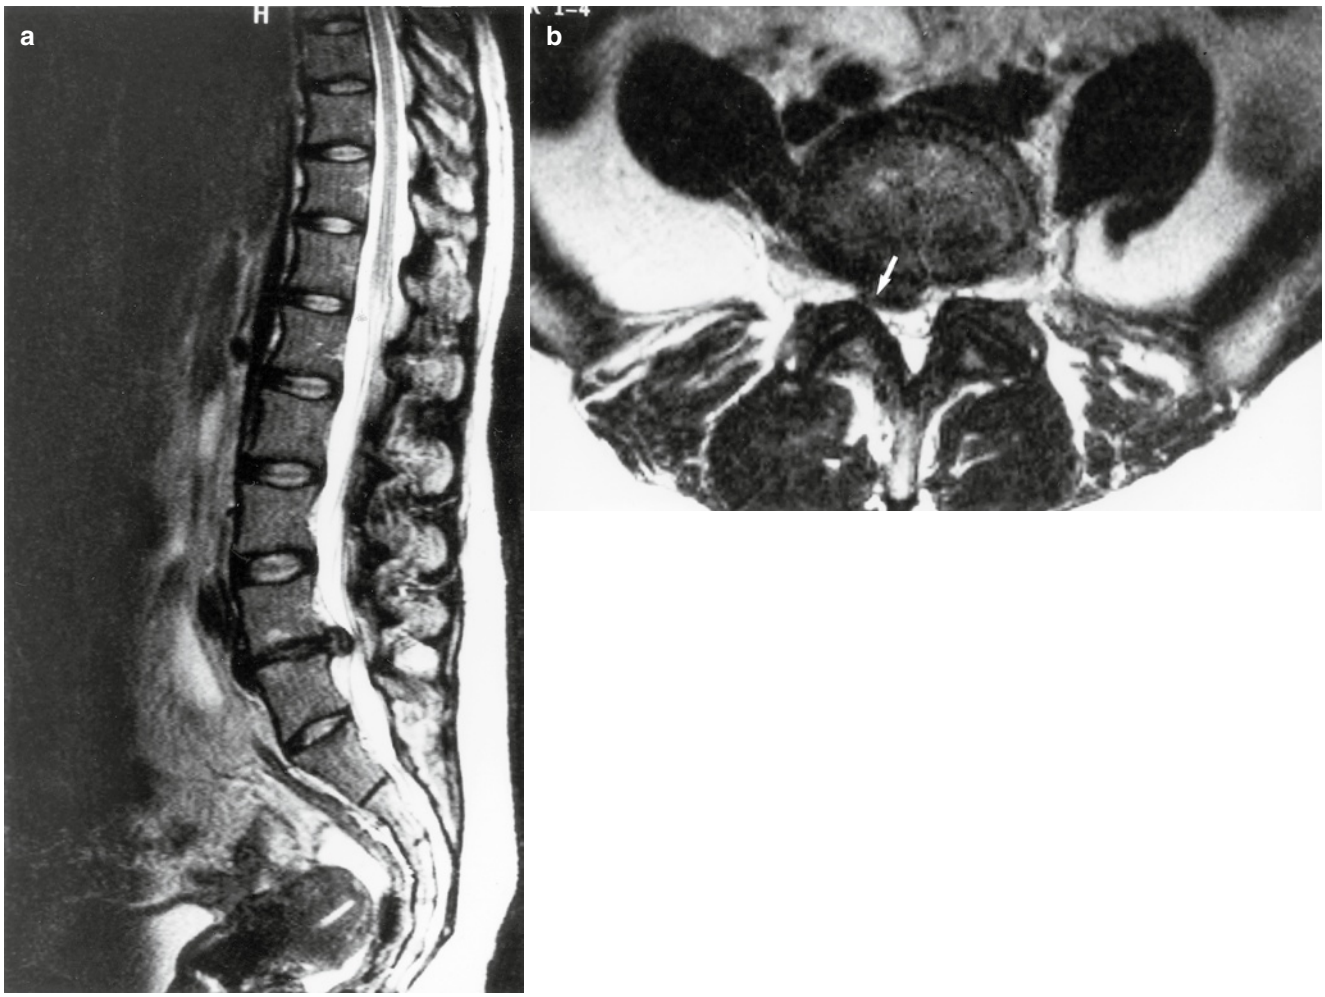

Fig. 45.8 Lumbosacral disc herniation causing nerve root compression. (**a**) Sagittal, T2-weighted MR image of the lumbosacral spine showing a large herniated disc at the L4–5 level. (**b**) Axial, T2-weighted MR image of the same patient at the L4/5 disc level showing the right, paracentral disc herniation (*white arrow*) obliterating the lateral recess and compressing the descending L5 nerve root on the right

The level and severity of nerve root injury is determined by the direction and vertebral level of the disc herniation, as well as its size and the location of any free fragments. Figure 45.8 shows a large paracentral disc herniation compressing the descending L5 nerve root. Because disc herniation at a given vertebral level may produce radiculopathy at more than one root level, the clinical syndrome cannot reliably determine the level of the disc lesion.

Pain in the low back, with or without sciatica, is a hallmark of acute HNP. Pain is characteristically of abrupt onset and severe but may be minor, usually precipitated by bending over or lifting. Patients may complain of sciatica without low back pain. Aggravation of pain with movement, particularly forward or lateral bending, or with Valsalva maneuver, is typical; pain is relieved with recumbency. Patients maintain a rigid upright posture, generally stooped forward, with associated paraspinal muscle spasm. In addition to pain, patients frequently report paresthesias in the involved dermatome. They may note fasciculations and/or weakness in muscles of the involved myotome. The physical examination is aimed towards determining the presence of radiculopathy as well as identifying its anatomic level and severity. Straight leg raising maneuvers (Lasegue test) are nearly always positive with a sensitivity of 91 % but specificity of only 26 % in pooled analysis. In contrast, crossed straight leg raising test has a sensitivity of 29 % but specificity of 88 % for a herniated disc [12, 13]. The reverse straight leg raise (also called the femoral tension sign) has a high sensitivity (84–95 %) for an upper to mid-lumbar radiculopathy, but unknown specificity [14]. Motor, sensory, and reflex changes depend on the level of radiculopathy (see section "Lumbosacral Monoradiculopathy"). Acute HNP may cause monoradiculopathy or polyradiculopathy at two contiguous levels; alternatively, a large, central disc herniation may produce bilateral, usually asymmetrical, lumbosacral radiculopathies or an acute cauda equina syndrome. Urinary retention or fecal incontinence suggests cauda equina compression and should prompt urgent evaluation and decompression, as

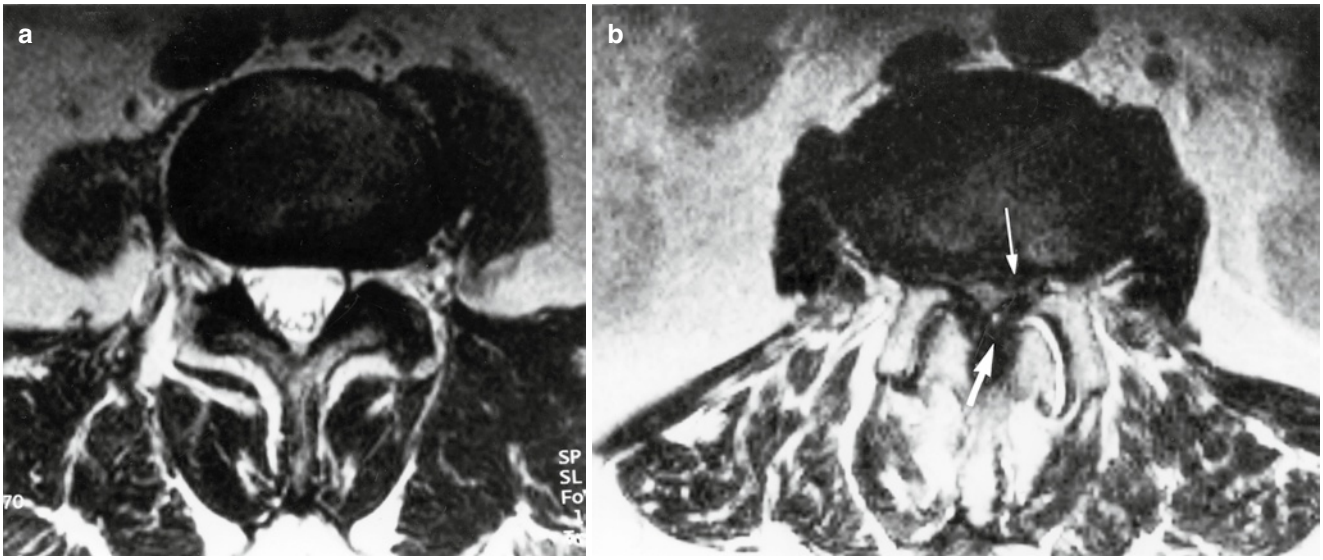

Fig. 45.9 Lumbar spinal stenosis. Axial, T2-weighted MR images at the L3/4 level. (**a**) Normally, the nerve roots of the cauda equina can be distinctly seen in the thecal sac, surrounded by CSF, which appears bright. (**b**) Spinal stenosis, due to hypertrophy of the ligamentum flavum posteriorly (*large arrow*) and to disc bulge anteriorly (*small arrow*). These structures have compressed the thecal sac into the characteristic trefoil configuration, crowding the cauda equina so that the individual nerve roots can no longer be distinguished

delayed decompression is associated with poor recovery of sphincter function [15].

Lumbosacral Spondylosis and Spinal Stenosis

Compression of nerve roots secondary to degenerative changes in the lumbosacral spine is the most common cause of radiculopathy in patients over the age of 40–50 years. Degenerative changes in the spine involve the facet joints as well as the intervertebral discs and intraspinal soft tissues. Hypertrophic changes of the facet joints lead to partial subluxation with narrowing of the lateral recess and/or nerve root foramen. Associated loss of disc height further narrows the foramen vertically. The enlarged facet joints encroach on the posterolateral aspect of the spinal canal, creating a trefoil appearance in cross section (Fig. 45.9). Hypertrophic changes in the soft tissues, notably the ligamentum flavum, further reduce the diameter of the spinal canal. Degeneration of the facets is also associated with spondylolisthesis or forward movement of one vertebra over another. Spondylolisthesis, which most commonly affects L5 on S1, contributes to narrowing of the foramina and abnormal stress on the discs.

Developmental anomalies, such as congenital spinal stenosis or fused vertebrae, may be contributing factors; these conditions are most likely to become symptomatic after superimposed degenerative changes occur. Lumbar spinal stenosis most commonly affects L4–5, followed by L3–4, L5–S1, and L1–2 in descending order [16].

As in acute radiculopathy, the pathogenesis of chronic radiculopathy is likely related to both ischemic and mechanical factors. For instance, in neurogenic claudication secondary to spinal stenosis, lumbar extension reduces the cross-sectional area of the central canal as well as the neural foramina, increasing pressure on the venules surrounding the nerve roots, with subsequent engorgement and ischemic nerve impairment. This may explain the alleviation of symptoms by forward flexion of the spine [17].

In spondylotic disorders, compressive radiculopathy may occur as a result of bony nerve root entrapment in the spinal canal, either in the lateral recess or the intervertebral foramen, or as a result of central spinal stenosis. In the former situation, lumbosacral nerve roots may be affected at single or multiple levels, either unilaterally or bilaterally, producing either lumbosacral monoradiculopathy or polyradiculopathy. Central spinal stenosis typically produces either cauda equina compression or intermittent neurogenic claudication. The most common symptom with lumbar spinal stenosis is neurogenic claudication—discomfort classically brought on by walking and improved with sitting; typically, the pain radiates from the spine into buttocks, thigh, or lower leg, but leg pain may predominate [17]. Radicular symptoms, i.e., pain radiating from lower back into buttocks, thigh, or lower leg, are a fairly sensitive indicator of lumbar spinal stenosis (sensitivity 88 %), though of low specificity (34 %). A more specific and sensitive symptom is one of back pain while standing which is relieved by sitting (specificity 93 %, sensitivity 46 %) [17, 18]. Radicular and claudicant syndromes may coexist, although one typically dominates the clinical picture. Additionally, disc herniation may complicate any of these syndromes [19].

Although degenerative spondyloarthropathies are most common, there are a number of chronic disorders associated with inflammatory spondyloarthritis. These include rheumatoid arthritis, psoriasis, ankylosing spondylitis, ulcerative colitis, Crohn's disease, Whipple's disease, and Behcet's disease. The clinical syndromes associated with nerve root compression for these disorders are similar to those seen in degenerative disease of the spine.

Thoracic Disc Herniation and Spondylosis

Symptomatic intervertebral thoracic disc herniations are distinctly uncommon. With improved imaging techniques, greater numbers of thoracic disc herniations are being diagnosed than previously recognized, and many are identified incidentally [20]. Most occur in the lower thoracic region, from T8–T11 [21]. When symptomatic, the usual clinical picture is that of midline back pain and myelopathy due to spinal cord compression from a centrally herniated disc. Radicular pain is reported in less than half of patients, and pure radicular signs are even less commonly reported. In nearly all symptomatic patients, a radiculomyelopathy is seen, with variable motor, sensory, and bowel/bladder deficits [21]. The diagnosis is often delayed, in part due to lack of a characteristic clinical syndrome. The symptoms are chronic (greater than 6 months) in most patients.

Degenerative spondyloarthropathy of the thoracic spine is common in the elderly and rarely causes myelopathy. Symptomatic radiculopathy from thoracic spondylosis is almost never seen.

Neoplastic Disease

Primary Tumors

Radiculopathy may result from a tumor located anywhere within the spinal canal; most often, extramedullary lesions are responsible. The primary spinal tumors are mostly intradural, while metastatic lesions are mostly extradural [22, 23]. In general, primary spinal tumors tend to occur singly, while spinal metastases are frequently multiple. Infrequently, extraspinal tumors may involve segmental spinal nerves, simulating radiculopathy. While the mechanism of injury due to spinal tumors is likely multifactorial, the primary pathophysiologic process is one of direct mechanical compression [23, 24].

Among primary spinal tumors, the anatomic site of tumor is most frequent in spinal cord (approximately 70 %), followed by spinal meninges (approximately 25 %) and cauda equina (approximately 5 %); the most common tumor types are meningioma, ependymoma, and schwannoma [25]. Intradural tumors are rare; the majority are extramedullary, with meningiomas and nerve sheath tumors seen with highest frequency. Neurofibromatosis I (NFI or von Recklinghausen's disease) is identified in 35–45 % of patients with spinal nerve sheath tumors; multiple tumors are a hallmark of NF1 [26]. Intramedullary tumors are uncommon, mostly comprised of low-grade astrocytomas and ependymomas [26].

In the thoracic spine, meningiomas are seen most frequently. However, the intrinsic tumors that most often involve the lumbosacral nerve roots are myxopapillary ependymomas and neurofibromas arising from the cauda equina. Less common cauda equina tumors include schwannomas, meningiomas, lipomas, and dermoid tumors; hemangioblastomas, paragangliomas, ganglioneuromas, osteomas, and lymphomas/plasmacytomas are rare [27]. Clinically, primary spinal tumors are frequently confused with disc herniation or spondylosis, with similar symptoms including pain, weakness, paresthesias, incoordination or balance difficulty, and urinary incontinence [25]. Back pain, with or without sciatica, is the earliest and most common presenting symptom; onset may be sudden or gradual. The pain related to tumor, unlike disc disease, usually becomes unremitting and increasingly severe over time. Notably, the pain tends to be worse when lying down and is often most troublesome at night, causing sleep disturbance [27]. The nature of the pain is the most helpful clinical feature in differentiating tumor from other causes of radiculopathy [27]. Motor and sensory symptoms typically follow the onset of pain by weeks or even years. Sphincter and sexual dysfunction from radiculopathy indicate involvement of the cauda equina. Rarely, these lesions present with intermittent neurogenic claudication or spinal subarachnoid hemorrhage; ependymomas have the highest propensity for bleeding [28]. The physical examination demonstrates varying abnormalities consistent with individual or multiple radiculopathies, dependent upon the tumor location. With cauda equina lesions, straight leg raise testing may be positive. There may be tenderness to gentle percussion over the involved vertebrae.

Epidural and Vertebral Metastases

Metastatic tumor is the most common type of neoplasm involving the spinal canal. An estimated 5–10 % of patients with cancer will have spinal metastasis, and epidural spinal cord compression is the initial manifestation of malignancy in 20 % of these [29]. While epidural, intraspinal, or leptomeningeal metastases may involve nerve roots, epidural metastases do so most commonly. The vertebrae are the most frequent site of skeletal metastasis, in part due to facilitation of hematogenous spread via Batson's venous plexus [30]. Epidural metastases nearly always result from the direct extension of metastatic vertebral tumor. Less commonly, extension of paravertebral tumor through the intervertebral foramina occurs. Rarely, tumors metastasize directly to the epidural space [31]. Most often, vertebral neoplasms cause radiculopathy by direct compression of nerve roots within

the foramen or compression of the conus medullaris/cauda equina. Less commonly, vertebral tumors may compress the entire cauda equina secondary to pathologic fracture or compress individual spinal nerves via extension into the paravertebral area [23, 30]. Metastatic lesions generally remain confined to the extradural space, with the dura providing a relatively effective barrier against extension into the subdural or subarachnoid space.

The tumors most frequently responsible for vertebral metastases in adults are breast, lung, and prostate cancer; other tumors seen with relatively high frequency are melanoma, renal cancer, sarcoma, and multiple myeloma. Lymphoma has a predilection for metastasis to the paravertebral lymph nodes [23, 32]. Tumors of the pelvic region, including colon and prostate cancers, preferentially metastasize to the lumbosacral region of the spine [32]. Overall, the thoracic spine is the most frequent site of metastasis (70–80 %), followed by the lumbosacral (20 %) and cervical spine (10 %) [30, 33]. Hence, myelopathy secondary to spinal cord compression is the most typical clinical finding, but radicular symptoms and signs are often associated. Weakness is present at diagnosis in over two thirds of cases [29]. Physical examination findings are dependent upon the level and extent of involvement of the tumor, and prognosis is closely correlated with degree of neurological dysfunction at diagnosis.

As with primary tumors of the spine, pain is the most frequent initial symptom, with motor and sensory symptoms developing later, over a variable time course. Back pain is present in approximately 90 % of cases of spinal metastases, reported an average of 7 weeks before onset of neurologic deficits. Symptoms reported in the thoracic region, where disc herniation and spinal stenosis are uncommon, heighten suspicion for malignancy [29]. Local pain near the site of the lesion is nearly universal; radicular pain is more variable. Percussion tenderness at the site of the lesion is characteristic.

Radicular pain from lesions in the thoracic region is usually bilateral and may be described as a squeezing sensation around trunk or abdomen but may be unilateral or bilateral with lumbosacral lesions. When present, radicular pain is usually localizing within one or two vertebral segments [32]. As with primary tumors, the pain is characteristically worse with recumbency and Valsalva [32]. Herpes zoster has been reported to affect patients at the level of spinal cord involvement, presumably secondary to activation of virus by tumor involvement in the DRG [32]. Rarely, patients present with painless leg weakness with variable sensory or sphincter involvement. Although most patients with metastatic spinal lesions have known malignancy, in a small percentage, spinal metastasis is the presenting syndrome. MRI is highly sensitive and specific (>90 %) for detecting lesions causing metastatic epidural spinal cord compression [29]. Median survival after diagnosis is 3–6 months, with primary tumor type and ambulatory status being the most significant prognostic indicators [29]. Thus, the importance of maintaining a high index of suspicion for spinal metastases in patients with known malignancy cannot be overemphasized.

Leptomeningeal Metastases and Meningeal Carcinomatosis

Cancer cells from primary systemic or central nervous system tumors may seed the meninges via CSF pathways, creating multifocal deposits of nodular tumor or diffuse leptomeningeal involvement (meningeal carcinomatosis). Generally, malignant cells gain entry to the subarachnoid space through hematogenous dissemination but may also spread from adjacent bone via the dural sinuses or epidural plexus. Less often, direct extension occurs from a brain metastasis, or systemic tumor spreads along nerve or perineural lymphatics into the subarachnoid space [34]. Previously considered rare, leptomeningeal metastases are reported with increasing frequency, likely due to improved survival of patients with systemic cancer as well as earlier recognition of the clinical syndrome. While any systemic cancer can seed the meninges, certain malignancies have a propensity to do so. Carcinoma of the breast and lung (particularly small-cell type), acute leukemia, lymphoma, and melanoma have the highest incidence of meningeal carcinomatosis [30, 31]. Of the primary CNS tumors, medulloblastomas have the highest incidence of leptomeningeal metastasis.

In general, meningeal carcinomatosis is a late manifestation of systemic cancer, associated with relapse of disease elsewhere in over 70 % of cases but occurring during a disease-free interval in 20 % of cases and as the first manifestation of cancer in 5–10 % [35]. Typically, cranial and spinal leptomeninges are involved; extension into the brain parenchyma is less common [30]. The nerve roots of the cauda equina are the most heavily involved, likely due to the influence of gravity on tumor dissemination in the CSF [36].

The clinical manifestations of meningeal carcinomatosis reflect diffuse involvement of the central nervous system (CNS), specifically involving three areas: cranial nerves, spinal nerve roots, and brain. Patients have diverse complaints including headache, memory or concentration difficulty, and gait disturbance in addition to specific symptoms referable to cranial or spinal nerve involvement, the latter most often involving the cauda equina. Typically, radicular symptoms include pain, weakness, or paresthesias; bowel/bladder dysfunction is uncommon. Physical examination findings include cranial neuropathies, frequently multiple, as well as evidence of patchy lumbosacral polyradiculopathy, dependent upon tumor distribution and extent. Signs of meningeal irritation may also be present [30].

CSF examination reveals an elevated protein, low glucose, and normal or mildly increased cell count. The diagnosis is established by demonstration of malignant cells on CSF cytologic examination. Large volumes and repeated lumbar punctures may be required [30]. CSF cytology is diagnostic in approximately 50 % of cases on the first lumbar puncture, 70–80 % after the second, and 70–85 % after three CSF examinations; however, CSF cytology may be persistently negative in 10–15 % of patients [37, 38]. CSF flow cytometry is particularly useful in evaluating hematologic malignancies [35]; numerous biochemical markers, including carcinoembryonic antigen, lactate dehydrogenase, alkaline phosphatase, b-human chorionic gonadotropin, creatine kinase, monoclonal immunoglobulins, b2-microglobulin, and vascular endothelial growth factor, have been studied but noted to have poor sensitivity and specificity [34].

MRI may reveal contrast enhancement of the basal meninges or ependyma; diffuse or nodular enhancement of the cauda equina is also characteristic. A study of 61 patients with meningeal carcinomatosis comparing the diagnostic utility of MRI and CSF cytologic examinations found a sensitivity of 75 % for CSF versus 76 % for Gad MRI, while the diagnostic specificity of CSF cytology was 100 % compared to Gad MRI 77 % [39].

Infectious Disease

In general, infectious diseases cause radiculopathy either by their presence in the epidural space, creating a compressive syndrome at one or more levels, or by diffuse involvement of the leptomeninges, causing polyradiculopathy. The latter situation is most often associated clinically with cauda equina syndrome, due to meningeal inflammation in the caudal sac. Herpes zoster is the most frequently encountered infectious radiculopathy and causes symptoms by destructive inflammation, rather than active infection, years after the primary infection.

Herpes Zoster

Acute herpes zoster (HZ), or shingles, is the clinical syndrome associated with reactivation of varicella-zoster virus which infects the dorsal root ganglia during the primary attack of chickenpox. HZ is a common disorder, with a dramatically increased frequency in adults over age 50 years old and in the immunocompromised. HZ most often involves the thoracic region, causing a radicular and cutaneous syndrome involving one or two dermatome segments [40]. Burning, aching, itching, or electric shock-like pain in the distribution of the involved dermatome is the overwhelming complaint and usually precedes the vesicular eruption by several days [41]. Pre-herpetic neuralgia has been reported to precede the rash by up to several months; rarely, cutaneous lesions never develop (zoster sine herpete) [42]. In the majority of patients, pain improves gradually as the vesicles crust over. In approximately 10–15 %, pain persists beyond 3 months following resolution of the rash, a condition known as postherpetic neuralgia (PHN) [41, 42]. Patients over the age of 50 years have a significantly higher prevalence of PHN.

In most cases, HZ affects only the dorsal roots, with cutaneous and sensory manifestations. In a small percentage of cases, the ventral rami and/or anterior horn cells are involved, causing weakness in a myotomal distribution, a condition known as segmental zoster paresis (SZP) [40]. Typically, weakness involves one or two contiguous myotomes, correlating with the root level of the cutaneous involvement; however, rare cases are described in which the motor and sensory levels are dissociated [40, 43a]. Motor weakness is nearly always preceded by skin lesions, by an average of 2–3 weeks. The diagnosis may be difficult in those cases where weakness precedes the cutaneous eruption. Reported SZP most often involves lumbosacral and cervical nerve roots; however, the subtle findings associated with thoracic involvement (i.e., abdominal muscle weakness) may result in significant underreporting. Good functional recovery is expected in the majority of patients.

Spinal Epidural Abscess

Acute and chronic bacterial infections are most likely to cause radiculopathy through development of spinal epidural abscesses (SEA) or granulomas, which are rare, but appear to be increasing in incidence. The thoracic and lumbosacral regions are most frequently affected in acute and subacute SEA, with chronic lesions more often reported in the thoracic region [44, 45]. Increasing frequency of lumbosacral lesions is likely related to complications of epidural anesthesia and paraspinal injections. Fourteen to 22 % of cases of epidural abscess occur in relation to spinal surgery or percutaneous spinal procedures, though these are rare complications, with a reported incidence of 1 in 2,000 epidural catheterizations. An indwelling catheter increases risk of developing abscess substantially. PMID 20060254 *Staphylococcus aureus* is the commonest organism but gram-negative rods, anaerobes, mycobacterium, and fungus are being reported with increasing incidence [46]. Until recently, tuberculosis of the spine was the commonest cause of SEA; it usually causes a subacute or chronic syndrome. Tuberculous spondylitis (Pott's disease) is still relatively common in countries where tuberculosis is prevalent and may cause spinal cord or cauda equina compression.

The clinical syndrome associated with SEA is dependent in part on the location and extent of infection, with some common presenting features. Severe back pain is nearly universal (85–90 % of patients); associated neurological deficits (70–80 %) and fever (35–70 %) are less frequent at time of presentation. Radicular pain and signs of spinal cord or cauda

equina compression develop if the disorder remains untreated. Erythrocyte sedimentation rate or C-reactive protein is elevated in over 90 % of patients, while peripheral white blood cell count is elevated in only 50–60 %. The causative organism is identified in blood cultures in 50–70 % of cases and tissue cultures in 90 % [47]. A high index of suspicion should be maintained in patients at risk. Risk factors for development of SEA include diabetes mellitus, history of intravenous drug abuse, spinal surgery, spinal or paraspinal injection, epidural catheter placement, and immunocompromised status [45]. T1-weighted MRI scanning with contrast is currently the diagnostic procedure of choice for SEA.

Polyradiculopathy in Human Immunodeficiency Virus (HIV) and AIDS (Acquired Immunodeficiency Syndrome)

Acute lumbosacral polyradiculopathy is a rare and devastating disorder that occurs in patients with AIDS. Early recognition of the syndrome is important as many cases improve with appropriate treatment. The clinical presentation is distinctive, consisting of a rapidly progressive cauda equina syndrome. The majority of cases are secondary to cytomegalovirus (CMV) infection of the nerve roots and, rarely, compression from infectious or other masses in the conus medullaris [48]. Other etiologic considerations include lymphomatous infiltration of nerve roots, syphilitic polyradiculopathy, herpes simplex virus (HSV), HIV-related polyradiculopathy, and cryptococcal and mycobacterial infections [48, 49]. Patients present with rapidly ascending leg weakness and paresthesias, often accompanied by sphincter dysfunction and perineal/perianal numbness, leading to flaccid paraplegia with urinary retention and obstipation over several weeks [48]. Severe low back pain is frequent. Findings include lower extremity areflexia, asymmetric motor, and sensory loss with frequent involvement of lower sacral dermatomes [50]. Significant CSF pleocytosis with polymorphonuclear (PMN) predominance and elevated protein, and low glucose is characteristic; EDX studies demonstrate evidence of lumbosacral polyradiculopathy with acute denervation [50]. Cytomegalovirus culture of CSF is positive in only 50 % of cases, but detection of CMV by polymerase chain reaction analysis of CSF has a sensitivity of 92 % and specificity of 94 % in CMV-associated polyradiculopathy [51]. In patients with AIDS, CSF anti-CMV antibody production is a nonspecific finding [50]. In less than half of patients, MRI may demonstrate gadolinium enhancement of the leptomeninges [50].

Acute anogenital infection with HSV 2 may produce a superficially similar clinical syndrome due to involvement of the sacral motor neurons or nerve roots. The main differentiating characteristic is the early and almost exclusive involvement of sacral dermatomes. Physical examination may reveal the primary herpetic lesions. CSF pleocytosis, predominantly lymphocytic, is common. EDX reveals active denervation in the involved myotomes. Depending on the dermatomes involved, sensory responses may be abnormal due to dorsal root ganglionitis.

Lyme Polyradiculoneuropathy

Lyme neuroborreliosis (LNB) is the neurologic disease associated with infection with *Borrelia burgdorferi*, a spirochete closely related to *Treponema pallidum*, the causative organism in syphilis. Neurologic symptoms complicate Lyme infection in approximately 5–10 % of patients [52]. Radicular signs and symptoms associated with LNB are most frequently encountered within the first few months of the infection, often as part of a triad including cranial neuropathy, particularly facial palsies, and lymphocytic meningitis (Bannwarth syndrome) [53]. The classic rash of erythema migrans may be seen acutely. In the early meningeal syndrome, protracted radicular pain is followed by motor and/or sensory symptoms and signs in a distribution that is typically multifocal and asymmetrical but may involve single nerve roots. While cranial neuropathy, specifically facial palsy, is the predominant clinical presentation in the United States, radicular syndromes occur twice as often as cranial neuropathies in European patients. Radicular syndromes may be underrecognized in the USA due to patients without accompanying meningeal symptoms or rash [54]. When a classic skin rash is reported, it typically precedes meningeal symptoms by weeks or months. CSF usually demonstrates a lymphocytic pleocytosis and elevated protein; intrathecal production of specific antibody can usually be demonstrated and PCR is often positive [53]. The acute infection is typically self-limited, although antibiotic treatment likely speeds recovery. Improvement occurs over the course of months, and symptoms may fluctuate but ultimately resolve [54].

In contrast to acute radiculoneuritis, a rare syndrome of chronic radiculoneuropathy related to Lyme disease usually presents months to years after initial untreated infection, is clinically mild, and is unassociated with meningitis or cranial neuritis. Patients typically present with one of two symptom complexes—either intermittent symptoms of mild, distal paresthesias or complaints of radicular pain, often involving multiple body segments. Of these two, the radicular pain syndrome is least common in the USA but is more prevalent among older European patients [52, 55]. Regardless of the presenting symptoms, the physical examination findings are generally subtle and mostly sensory, with minimal motor or reflex changes. The EDX findings in both groups are similar and suggest a polyradiculoneuropathy with predominantly axonal features and radicular patterns on needle EMG examination; the findings may also suggest a mononeuropathy multiplex [54, 55]. CSF protein may be elevated but pleocytosis is distinctly uncommon.

Diabetic Radiculopathy

Radiculopathy associated with diabetes typically presents as a subacute, painful, asymmetric, predominantly motor syndrome, involving multiple nerve roots, lumbosacral plexus, or proximal nerves, usually in the high lumbar or thoracic region. The lumbar disorder, often called *diabetic amyotrophy or diabetic radiculoplexus neuropathy*, is fairly well recognized (see Chap. 31). However, diabetic thoracoabdominal neuropathy is less common and probably less well recognized, leading to inappropriate GI and cardiac evaluation in some cases. These disorders are most commonly seen in patients over 60 with fairly well-controlled type II diabetes. Associated weight loss (10 lb or more) is frequent. The chief presenting complaint is nearly always pain, which has a radicular and/or neuropathic quality and is usually worse at night; allodynia may be severe. Involvement of multiple nerve roots is most common, frequently involving noncontiguous myotomes and spreading from one limb to another. Weakness is prominent and occurs early in the course. Paresthesias and sensory loss are often inconspicuous.

Physical examination findings include weakness involving myotomes corresponding to the dermatomal distribution of pain, usually lower thoracic and high lumbar (L1–3); often, weakness is more widespread than the distribution of pain indicates. In thoracoabdominal neuropathy, weakness of iliopsoas or quadriceps muscles is a common finding [56]. Thoracoabdominal weakness may be difficult to demonstrate. Sensory loss or hyperesthesia is a variable finding; when present, it usually involves the symptomatic dermatome. Reflexes are diminished in affected dermatomes. However, in many cases, there is only stocking sensory loss and reflex changes secondary to underlying polyneuropathy. Sphincter involvement is noticeably absent.

Electrodiagnostic studies demonstrate evidence of polyradiculopathy with moderate to marked active denervation at multiple, bilateral paraspinal levels as well as involved limbs or abdominal muscles [56]. Often the findings are more extensive than predicted clinically. Evidence for underlying, distal axonal polyneuropathy is seen in most patients. CSF protein is elevated without associated pleocytosis. The underlying pathological process is probably altered immunity and microvasculitis of nerve rather than metabolic derangement [57].

Complications of Epidural and Spinal Anesthesia

Neurologic deficits complicating epidural and spinal anesthesia are rare; the true incidence is difficult to determine due to probable underreporting [58, 59]. In a prospective study of over 100,000 French patients following spinal and epidural anesthesia, neurologic complications occurred in only 34 of them, and recovery was complete within 3 months in 19 patients. Needle trauma and local anesthetic neurotoxicity were the most common neurologic complications [60]. Spinal cord compression, cauda equina syndrome, and isolated lumbosacral monoradiculopathies have been described [58, 59]. Mechanisms of injury include epidural hematoma, toxic effects of anesthetic agents, direct injury to nerve roots from needle or catheter, inadvertent subarachnoid injection of medication during epidural anesthesia, and epidural abscess [59]. Very rarely, adhesive arachnoiditis has been described as a complication of spinal anesthesia; review of most of these cases suggests contamination of anesthetic medication with detergents or other chemical irritants [58]. Hemorrhagic complication rates are estimated to be less than 1:150,000 epidural and less than 1:220,000 spinal anesthetics. Infectious complications such as arachnoiditis, meningitis, and abscess following spinal or epidural anesthesia are rare; three cases of meningitis were reported in one combined series of more than 65,000 spinal anesthetics [60].

Factors which appear to increase the risk of neurologic complications of these types of anesthesia include the presence of lumbar spinal stenosis, the inadvertent subarachnoid injection of high volumes and dosages of medication intended for epidural administration, the combination of general and epidural anesthesia, and increased age [59]. Continuous delivery spinal anesthetics have a higher incidence of complications compared with single-dose techniques [60]. The majority of patients with radicular syndromes have good functional recovery; however, severe, permanent neurologic sequelae may persist in a small number [58, 59]. A meta-analysis of 32 studies from 1995 to 2005 found permanent neurological injury after spinal and epidural anesthesia ranged from 0 to 4.2:10,000 and 0 to 7.6:10,000, respectively [61].

Spinal Arachnoiditis

Adhesive arachnoiditis is the end result of an inflammatory response that leads to fibrosis of the arachnoid membrane, compromise of meningeal blood vessels, and atrophy of nerve roots. The lumbosacral region is most often affected, but any spinal region may be involved [62]. Causes include surgical trauma, infections, and intrathecal irritants such as contrast agents, steroids, or anesthetics. Generally, there is insidious development of low back pain and/or leg pain, anywhere from days to years after the initial insult, which becomes fairly constant over time. Pain is exacerbated by activity and unrelieved with rest. Neurologic deficits are dependent on the extent of involvement; typically, multiple nerve roots are involved but the severity is highly variable. Physical examination reveals evidence of polyradiculopathy with variable sensory, motor, and reflex deficits. CSF protein

may be normal or elevated, particularly in the setting of spinal subarachnoid block [62].

Tethered Cord Syndrome

Tethered cord syndrome (TCS) presenting in adulthood is uncommon. The most common causative lesions are tight thickened filum terminale, intradural fibrous adhesions, dermal sinus tracts, diastematomyelic septae, intradural lipomas, (lipo)myelomeningoceles, bone spicula, fibrous adhesions, and adhesive arachnoiditis. The physiologic changes are due to stretching of the filum terminale and spinal nerves causing reduced regional blood flow, disruption of oxidative metabolism, neuronal membrane changes, and progressive fibrosis [63]. While the pathologic lesions are the same as those seen with children, the clinical syndrome is distinct [64]. In adults, pain is the most common presenting feature, often localized to the anal, perineal, or gluteal region or diffuse over one or both extremities; typical radicular pain is uncommon. The neurologic picture is one of a variable cauda equina and conus medullaris syndrome, with frequent motor, sensory, and bladder dysfunction. Physical examination findings correspond to the level and extent of involvement; Babinski and other long track signs may be present, as well. Unlike children, the majority of adults have no cutaneous lesions suggestive of spinal dysraphism (subcutaneous lipomas, hair tufts, sacral dimple), although these should be sought. Progressive scoliosis and pes cavus, also common in children, are rare. Patients may develop symptoms after an acute precipitating event producing significant stretch of the conus or following the development of acquired spinal stenosis. MRI is diagnostic, with evidence of a thickened filum, often with associated lipoma, and low conus medullaris. Surgical resection is usually effective for relief of pain and good functional improvement of motor and sensory deficits; however, bladder dysfunction is often refractory [63, 64].

Unusual Compressive Lesions

The following lesions are described as rare causes of compressive radiculopathy. Surgical excision and/or spinal decompression lead to improvement of symptoms in many cases. However, given their rarity, surgical treatment should be considered only if disabling or progressive manifestations are clearly attributable to these lesions.

1. Cysts. Spinal cysts that may cause nerve root compression include synovial cysts (arising from facet joints), cysts of the ligamentum flavum, and perineural cysts, also called Tarlov's cysts [28]. Tarlov's cysts are focal outpouchings of the dural root sleeves, usually occurring in the sacral region. Generally, when symptomatic, cysts are associated with spinal dysraphism or cord compression. Unlike Tarlov's cysts, the other types are found most often in the lumbar region and may present with lumbosacral radiculopathy or cauda equina compression [28].
2. Vascular Lesions. These include epidural and subdural spinal hematomas, spinal arteriovenous malformations, vertebral hemangiomas, spinal epidural cavernous hemangiomas, aortic aneurysms, and ligamentum flavum hematomas. Epidural hematomas may occur spontaneously or after lumbar puncture, epidural anesthesia, epidural injections, or spinal surgery. One third of cases are associated with anticoagulant therapy [65]. Patients with inferior vena cava obstruction may develop epidural venous plexus enlargements presenting with back pain and radiculopathy [66].
3. Demyelinating Polyneuropathy. Hereditary motor and sensory neuropathy type I (HMSN I) and chronic inflammatory demyelinating polyneuropathy (CIDP) may be associated with symptomatic radiculopathy secondary to compression of abnormal, hypertrophic nerve roots [67, 68]. In the lumbosacral region, the symptoms are primarily a result of cauda equina dysfunction with pain, bladder disturbance, and intermittent neurogenic claudication described [67, 68]. In CIDP patients, immunosuppressive therapy leads to improvement in symptoms in most cases.
4. Spinal Epidural Lipomatosis (SEL). The deposition of excessive amounts of normal adipose tissue in the spinal canal may cause compression of the spinal cord or nerve roots. SEL is associated with exogenous steroid use and, less commonly, with obesity and Cushing syndrome [69].
5. Sarcoidosis. Rarely presenting as a polyradiculopathy and often associated with central nervous system sarcoidosis, the lesions typically involving thoracolumbar or lumbosacral roots. Symptoms may progress rapidly, mimicking Guillain-Barre syndrome. Imaging, chest radiographs, and/or CSF are typically diagnostic [70].

Evaluation and Diagnosis

Evaluation of a patient with a suspected lumbosacral or thoracic radiculopathy begins with the question of whether any diagnostic testing is needed at all. The most important aspect of the initial evaluation is a careful history and neurologic examination, with specific attention to risk factors for etiologies other than degenerative disorders. In patients with typical sciatica, in whom the cause is likely to be disc herniation or spondylosis, a course of conservative therapy with close follow-up is usually appropriate, with further evaluation only if patients do not improve as expected after 6–8 weeks. Patients need more urgent evaluation if there has been spinal trauma, if tumor or infection is suspected, if cauda equina

Table 45.5 Clues that a radiculopathy needs urgent evaluation

Suspect cancer or infection if	Suspect spinal fracture if	Suspect cauda equina syndrome if
History of cancer	History of significant trauma	Acute urinary retention or overflow incontinence
Unexplained weight loss	Prolonged use of steroids	Fecal incontinence or reduced anal sphincter tone
Chronic immunosuppression	Age over 70	Saddle anesthesia
Urinary or other infection		Widespread, bilateral lower extremity weakness
History of intravenous drug use		
Age over 50		
Fever		
Pain not improved with rest		

Table 45.6 Sensitivity of diagnostic tests in lumbosacral radiculopathy

Test	Reported sensitivity range (%)	Comment	Selected references
Needle EMG	41–82	Sensitivities appear higher with more severe or predominantly motor radiculopathy	[71–75]
Late responses	26–50		[71, 74, 75]
SEPs	10–70	Most reported sensitivities <50 %, except for cutaneous SEPs in L5 root lesions	[71, 76]
Neuroimaging	57–86		[71–73, 75, 77]

syndrome is present, or if there is a severe or progressive neurologic deficit or a pattern of deficits inconsistent with a monoradiculopathy. Table 45.5 lists some red flags which suggest the need for immediate evaluation. Because of the relatively reduced likelihood of degenerative spine disease in the upper lumbar and thoracic regions, early evaluation of upper lumbar and thoracic radiculopathies is reasonable.

The most common diagnostic tests are electrodiagnostic (EDX) studies and neuroimaging studies. Table 45.6 shows the relative sensitivities of these two other tests. In patients at risk for more unusual causes of radiculopathy, additional studies such as blood work (e.g., complete blood count, erythrocyte sedimentation rate, blood glucose, Lyme titer, and HIV antibody), lumbar puncture, or tissue biopsy may be needed. A careful history aimed at identifying the presence of diabetes, immunocompromise, cancer, or risk factors for infections such as Lyme or HIV will help identify the patients in whom a more extensive work-up is indicated.

Electrodiagnostic (EDX) Studies

EDX studies are best utilized as an extension of the clinical examination. They help confirm the diagnosis of radiculopathy, provide information about its severity and chronicity, and exclude an alternative cause for the patient's symptoms, such as a mononeuropathy or plexopathy. Routine EDX studies include motor and sensory nerve conduction studies, late responses, and needle electromyography (EMG). Less commonly used studies are somatosensory evoked potentials (SEPs) and motor evoked potentials (MEPs). Though historically performed for evaluation of radiculopathy, the sensitivity and specificity of SEPs are too low for them to be worthwhile in equivocal cases where other tests are normal [71, 78] (Table 45.6). MEPs are essentially a research tool and will not be discussed further.

Conventional Nerve Conduction Studies

Routine motor nerve conduction studies (NCS) are usually normal in lumbosacral radiculopathies [79]. If focal demyelination is the primary pathology, they are normal because the routine stimulation sites are distal to the root lesion. If axon loss is the primary pathology, the studies remain normal unless the axon loss is severe in the distribution of the recorded muscle. Even then, the reduction in the compound muscle action potential (CMAP) amplitude is usually mild because of the contribution to the recorded CMAP from neighboring intact roots. Routine peroneal and tibial motor NCS provide information about the L5 and S1 nerve roots, respectively. Uncommon motor NCS can be done to assess other thoracolumbar roots, such as a femoral motor NCS and the saphenous sensory NCS, to assess the L2, L3, and L4 nerve roots; however, this is not always necessary as the diagnosis may often be clearly established with needle EMG.

Sensory nerve conduction studies are the single most useful EDX parameter for differentiating radiculopathies from mononeuropathies and plexopathies. The sensory nerve action potential (SNAP) amplitude is almost always normal in compressive radiculopathies, whether the lesion is axonal or demyelinating, because the lesion lies proximal to the dorsal root ganglion. SNAP amplitudes may be abnormal with the rare compressive lesion which extends into the neural foramen [80] or with inflammatory radiculopathies which also involve the dorsal root ganglion (e.g., herpes zoster). The SNAP may be less helpful in distinguishing a radiculopathy from a distal peripheral nerve lesion in individuals over age 60 or in patients with polyneuropathy in whom SNAP amplitudes may be reduced or absent in the lower extremities. Saphenous sensory potentials are difficult to obtain, even in normal individuals, complicating the distinction of a lumbar plexopathy or femoral neuropathy from an L4 radiculopathy. Comparison of SNAP amplitudes from the contralateral, asymptomatic limb is often helpful.

Late Responses

F responses provide an assessment of proximal motor pathways. Unfortunately, the sensitivity of F responses in radiculopathy appears low. This may be because F responses are mediated by more than one nerve root (i.e., L5/S1). It may also be due to fact that most radiculopathies are partial, leaving some motor axons intact to result in a normal minimum F latency; for this reason, a prolonged minimum-maximum latency range may be more a more sensitive measure [79]. F responses also have a low specificity, as axon loss or demyelination anywhere along the entire length of the motor fiber being studied may prolong the F latency.

The H reflex assesses both sensory and motor pathways. However, it provides information about the S1 nerve root only. It has an advantage over EMG in diagnosing acute radiculopathies (3 days to 3 weeks) since it becomes abnormal within days of an injury. However, once a reflex is lost, it may not return with resolution of the clinical syndrome, which makes it difficult to differentiate an acute from a chronic S1 radiculopathy. H reflexes are also limited in specificity because they can be abnormal with pathology anywhere along the course of the tibial and sciatic nerves. They can also be bilaterally prolonged or absent with a generalized polyneuropathy.

Needle Electromyography

Needle EMG is the most reliable of all electrodiagnostic methods for detecting radiculopathy. The EMG diagnosis of lumbosacral radiculopathy is based on finding evidence of ongoing denervation and/or chronic reinnervation in at least two muscles innervated by the same root, but by different peripheral nerves. In order to make the diagnosis of a monoradiculopathy, muscles innervated by adjacent roots should be normal.

The presence of denervation in the paraspinal muscles is an important localizing finding, as this provides evidence that the lesion is at the root level, proximal to the takeoff of the dorsal ramus. Because thoracic myotomes contain few muscles, and examination of intercostal and abdominal muscles carries the risk of perforating a viscus, the EMG diagnosis of thoracic radiculopathy usually rests entirely on demonstrating ongoing denervation in the thoracic paraspinal muscles.

The absence of paraspinal denervation does not rule out a radiculopathy, however. Paraspinal muscles may be spared in an incomplete root lesion or may be reinnervated in chronic lesions. Because the paraspinal muscles are innervated by multiple roots, denervation may also be missed with limited sampling. In the largest study describing paraspinal examination in patients with surgically proven radiculopathy, paraspinal denervation was present in only approximately 50 % of cases [81]. Similarly, the presence of paraspinal denervation is not specific for radiculopathy. Paraspinal denervation can be seen in other conditions, such as motor neuron disease, inflammatory myopathy, diabetic neuropathy, acid maltase deficiency, and after lumbar laminectomy. Mild paraspinal denervation, consisting of a few runs of positive sharp waves, or even occasional fibrillations in people over age 40, may be seen in the lumbosacral paraspinal muscles of normal, asymptomatic individuals, likely reflecting asymptomatic root injury as part of age-related degeneration of the spine [82].

The myotomal distribution of EMG abnormalities indicates which nerve root is injured. Because most muscles are innervated by more than one root, however, it is sometimes impossible to determine electrophysiologically which of two contiguous roots is involved. This is especially true of the L2, L3, and L4 roots because they overlap extensively in their muscular innervation. It is also impossible to determine the level of spinal pathology by needle EMG, because a single root may be compressed by a disc or osteophyte at more than one level, depending on its size and location.

Lesions of the cauda equina are most often associated with EMG findings of polyradiculopathy, with involvement of bilateral nerve roots at multiple levels. Sacral radiculopathies from any cause are often bilateral, and the S2, S3, and S4 roots are usually involved together. EMG of the anal sphincter can provide supportive evidence for involvement of this group of nerve roots. Involvement of multiple roots is also commonly seen in lumbar spinal stenosis, with half of patients demonstrating chronic, bilateral lumbosacral radiculopathies at multiple levels and most of the remaining having bilateral single-root lesions or an isolated radiculopathy [78]. In patients with chronic reinnervation and ongoing denervation in multiple lumbosacral myotomes bilaterally, it may be necessary to examine cervical, thoracic, and/or cranial muscles to exclude a more widespread degeneration of motor neurons.

The EMG diagnosis of radiculopathy is subject to several limitations. First, the findings on EMG are the result of loss of motor axons, and thus, EMG cannot detect sensory root injury. Second, the needle EMG is generally normal in lesions producing primarily demyelination at the root level; although severe demyelinating conduction block may lead to reduced recruitment of motor unit action potentials (MUAPs), this is rarely severe or widespread enough at the root level to allow detection by needle EMG. Third, detectable abnormalities may be minimal unless the injury is extensive, even with lesions causing axon loss, due to the broad myotomal overlap in innervation of individual muscles. Finally, the needle EMG findings also depend on the timing of the EMG in relation to the root injury. Because fibrillations may not develop in the paraspinal muscles for 7–10 days, and in the limb muscles for 3–6 weeks, an EMG done early in the course may show only reduced recruitment of MUAPs, or be entirely normal. Reinnervation proceeds in a proximal to distal

fashion, with chronic changes appearing in proximal muscles by about 2–3 months and in distal muscles by about 3–6 months. With injury to especially long nerve roots, such as L5 and S1, reinnervation may be prolonged or incomplete, and fibrillation potentials may be found in distal muscles of these myotomes 12–18 months after a static lesion. Findings of chronic reinnervation with long-duration, high-amplitude, and polyphasic MUAPs are often most prominent in, or even limited to, distal muscles of an involved myotome. Notably, needle EMG studies may be negative if performed early, before evidence of denervation has developed or in subacute lesions, after denervation has resolved and reinnervation is incomplete.

Neuroimaging

In general, imaging studies are used in the evaluation of radiculopathy when the clinical picture suggests an etiology requiring urgent intervention, such as trauma, tumor, or infection, or when patients with suspected degenerative spine disease is associated with unremitting pain and/or severe clinical deficits are potential candidates for surgery or epidural steroid injection [83]. Imaging studies such as plain radiographs or bone scans, which are used in the evaluation of patients with back pain, are rarely useful in the assessment of patients with radiculopathy, as the identification of spondylosis, spondylolisthesis, tumor, or infection can be made as easily with tests that provide better anatomic detail of the nerve roots themselves. Standard methods for imaging the thoracic and lumbosacral spine include myelography, computed tomography (CT), CT-myelography, and magnetic resonance imaging (MRI).

Recent studies using surgical findings as a gold standard suggest that MRI and CT-myelography have roughly equivalent sensitivities and specificities in the diagnosis of lumbar disc herniation as a cause for suspected nerve root compromise, although MRI may be a bit more sensitive [84]. All three methods are superior to plain myelography [77, 84]. One exception may be those radiculopathies due to discrete degenerative abnormalities in the lateral recess, where plain myelography appears to be an important supplemental study and may have superiority to both MRI and CT-myelography [85]. MRI and CT-myelography appear to provide similar diagnostic accuracy in the diagnosis of spinal stenosis, with both superior to plain myelography [86, 87].

In general, MRI is the preferred initial study for patients with lumbosacral radiculopathy [88, 89]. This is based on the evidence that MRI is comparable to CT in diagnosing herniated discs and most other degenerative spine abnormalities but provides superior ability to diagnose other inflammatory, malignant, or vascular etiologies [88, 90]. CT may be most appropriate when fractures or other bone abnormalities are suspected and is acceptable as an initial study when the diagnosis of disc or spinal stenosis is fairly certain clinically. CT-myelography is probably best reserved for the occasional preoperative patient in whom a specific technical question remains unanswered [91]. MRI performed with an intravenous contrast agent such as gadolinium-DTPA is the most sensitive study for diagnosing paravertebral soft tissue abnormalities, intradural pathology (e.g., tumor, metastasis, cyst, infection, or arachnoiditis), and intrinsic cord lesions. It is the most useful study for differentiating recurrent disc herniation from postoperative fibrosis [89].

Table 45.7 Prevalence of asymptomatic intervertebral disc herniations on imaging studies

Imaging modality	Prevalence (%)	Mean age (years)	References
Myelography	24	51	[92]
CT	20	40	[93]
MRI	28	42	[87, 94]

The significance of any spine abnormality seen on neuroimaging must be interpreted in the context of the patient's clinical syndrome, given the high prevalence of abnormalities seen on imaging studies of the lumbosacral spine in asymptomatic individuals, especially with advancing age [87]. Table 45.7 summarizes the prevalence of asymptomatic disc herniations with various imaging modalities. Less significant disc abnormalities, such as degeneration or bulging, have been seen on MRI in 93 % of subjects over age 60 [95]. Asymptomatic disc herniations and bulges are common in the thoracic spine as well, with a prevalence of 37 and 53 %, respectively [96]. These findings emphasize the need for interpreting imaging abnormalities in light of their potential clinical relevance.

Diagnostic Utility of EMG Versus Neuroimaging

EMG and imaging studies are complementary in the diagnosis of lumbosacral radiculopathy. These two types of studies differ in that EMG provides information about nerve root function, whereas imaging studies provide information about the anatomy of the nerve roots and surrounding structures. Neither study is completely sensitive. As Table 45.6 illustrates, comparative studies in patients with clinical radiculopathy suggest that the sensitivity of EMG is comparable to that of myelography, CT, and MRI, with sensitivities for both studies for the most part varying from 50 to 85 %, depending on the patient population studied [72, 73, 78]. EMG appears to have a very low false-positive rate [73, 78] compared with the high incidence of false-positive abnormalities seen with imaging modalities. The relative sensitivity of the two studies in thoracic radiculopathy is unknown.

As a general rule, EDX studies should be performed when confirmation of the clinical diagnosis of radiculopathy is needed. This includes patients whose history or examination are limited, whose presentation could also be consistent with a mononeuropathy or plexopathy, or in whom the clinical significance of an imaging abnormality is unclear. Imaging studies should be performed when the etiology of a radiculopathy is in question or when surgical intervention or steroid injections are being contemplated. There is no compelling evidence that routine imaging within the first 6 weeks affects treatment decisions or improves outcomes over clinical assessments alone [97].

Approach to Thoracic Radiculopathies

The diagnosis of thoracic radiculopathy is usually suspected on clinical grounds. The diagnosis can be confirmed by needle EMG. As reviewed above, the EDX of thoracic radiculopathy is usually made based on the presence of denervation in the form of fibrillation potentials in the paraspinal muscles. As degenerative spine disease is less common in the thoracic than in the lower lumbar spine, imaging studies are appropriately obtained early in the course, to exclude an unusual compressive lesion. Serum glucose testing is indicated if a compressive lesion is not found, to exclude diabetes, a common cause of thoracic radiculopathies.

Management and Prognosis

Degenerative Spine Disease

Lumbosacral Disc Herniation

Management options for lumbosacral disc herniations include surgical and nonsurgical ("conservative") treatments. Long-term outcome, based on pain, working capacity, and neurologic deficits, appears no different for patients treated conservatively than for those treated surgically, although the short-term outcome may be better following surgery [98–100]. Furthermore, the natural history of most patients is for improvement within the first 6 weeks with noninvasive management. Thus, the common practice of a 4- to 6-week trial of conservative therapy is reasonable for most patients. Nonetheless, there are certain patients in whom early, if not urgent, surgical treatment is necessary. These include patients with marked or progressive leg weakness and acute cauda equina syndromes, because of the risk of permanent sphincter dysfunction or leg weakness if left untreated. A relative indication for early surgery is intolerable pain which cannot be controlled with medications. In patients who are still symptomatic after a 6-week trial of conservative therapy and whose symptoms and signs are not intolerable or functionally limiting, consideration of surgical intervention is appropriate [101].

Conservative therapy includes a number of different modalities. Early mobilization is often recommended for patients with lumbar radiculopathy; an aerobic exercise program that minimizes stress on the back, and conditioning exercises that strengthen trunk muscles, may be helpful. However, specific recommendations are lacking on type, duration, and benefit of early activity, physical therapy, or spinal manipulation; evidence-based reviews remain inconclusive [100, 102].

Medications are generally required for symptomatic relief of the acute episode. Acetaminophen and nonsteroidal anti-inflammatory agents are comparable in pain relief. Muscle relaxants may be used in selected patients with pronounced paraspinal muscle spasm but may be limited by adverse effects, primarily sedation. For severe pain, opioid analgesics or tramadol is often necessary but should be used on a time-limited basis due to risk of dependency. Medications typically prescribed for neuropathic pain, including anticonvulsants such as gabapentin and pregabalin, selective serotonin reuptake inhibitors, and tricyclic antidepressants, are probably of some benefit in treating the pain of radiculopathy, though results are mixed and high-quality evidence for their role in management is lacking [14, 103, 104]. Systemic corticosteroids are generally not recommended for pain relief [105, 106].

Injections of steroids and anesthetic agents may be used in selected patients with focal irritative symptoms referable to a single segmental level in whom oral analgesics are ineffective. The procedure involves the injection of a concentrated drug dose of medication into the epidural space, close to where the nerve root enters the intervertebral foramen, with the objective of reducing swelling, inflammation, and pain. Epidural injections provide short-term pain relief but do not improve the long-term outcome (beyond 3 months) as far as impairment of function or pain relief, nor do they alter the need for eventual surgery [107, 108].

Other conservative therapies include trigger point injections, biofeedback, lumbar corsets, transcutaneous nerve stimulation, and acupuncture. However, there is little available evidence regarding the efficacy of these methods of treatment for low back pain with radiculopathy [109]. In 60–90 % of patients treated conservatively for radiculopathy due to lumbar disc herniations, symptoms resolve satisfactorily without surgical intervention within approximately 6–12 weeks, though there may be continued improvement following this period [13, 110, 111]. However, there may be recurrent painful episodes throughout the patient's lifetime [14].

Several surgical approaches are available, all aimed at reducing pressure on the nerve root. These approaches include conventional laminectomy, microdiscectomy, percutaneous discectomy, or arthroscopic disc excision. Alternatively, elimination of nerve root irritation may be

achieved by preventing movement between adjacent spinal segments through spinal fusion [111]. In the appropriate patient population, the success of surgery using modern techniques for relief of radiculopathy due to lumbosacral disc herniation is favorable (85–95 %); however, there are no evidence-based recommendations to guide decision-making in individual cases [109, 112]. The largest randomized study to date examining surgical versus nonoperative treatment, prospectively examined 501 patients with radiculopathy of at least 6 weeks duration and lumbar disc herniation confirmed by imaging. While the "as-treated" analysis showed favorable effects of surgery, significant flaws in the study design considerably limit the generalization of results [113]. Other studies have also suggested hastened recovery from radiculopathy following surgical treatment but without change in long-term outcomes compared to conservative treatment [101, 114–116].

Lumbar Spinal Stenosis

In patients with lumbar spinal stenosis resulting in neurogenic claudication or foraminal nerve root entrapment, it is reasonable to begin with a trial of conservative therapy in patients without significant compromise of activities of daily living or in patients with significant medical comorbidity for whom surgery poses high risks. The regimen of conservative therapy is similar to that used for management of disc herniations and includes physical therapy aimed at strengthening the abdominal musculature and improving spinal mechanics, analgesic and anti-inflammatory medications, as well as epidural injections of steroids or anesthetic agents for pain relief [17]. Patients may respond to conservative measures but symptoms often recur as the disease is generally slowly progressive [16].

The decision to undergo surgical intervention for relief of neurogenic claudication or radiculopathy is based upon the severity of functional limitation and neurologic deficits. There are multiple surgical options, all involving decompression of nerve roots, including laminectomy, facetectomy, foraminotomy, and laminotomy. If extensive decompression is performed or if the lumbar stenosis is accompanied by degenerative scoliosis, kyphosis, or spondylolisthesis, arthrodesis may be needed for spinal stabilization [5]. Decompressive surgery provides modest but consistent improvement in functional ability compared to nonoperative measures, with good results and return to premorbid activity levels reported in 60–85 % of pooled cases [16]. Patients with claudicant symptoms are most likely to benefit; those with chronic neurologic deficits such as muscle atrophy are less likely to achieve full recovery, and those with paraspinal low back pain, which may be due to underlying degenerative arthritis rather than entrapment radiculopathy, often fail to improve [16]. Less favorable outcomes may be associated with congenital stenosis, tight canal stenosis, and multilevel decompression [117]. Furthermore, advantages in pain reduction and functional status for surgical versus conservatively treated patients narrow over the course of follow-up, and symptoms may recur, necessitating further operations, typically with diminishing results [17, 118, 119]. Among nearly 100 patients with lumbar spinal stenosis completing 8- to 10-year follow-up in the Maine Lumbar Spine Study, low back pain relief, predominant symptom improvement, and satisfaction with the current state were similar in patients initially treated surgically or nonsurgically, though leg pain relief and greater back-related functional status continued to favor those initially receiving surgical treatment [119]. Given the limitations of current evidence, a shared decision-making approach between physicians and patients is recommended when discussing treatment options for lumbar spinal stenosis.

Thoracic Disc Herniation

Surgical decompression is usually indicated for thoracic disc herniation causing symptomatic spinal cord compression. Most patients with thoracic disc herniation causing radiculopathy without myelopathy are managed conservatively. The approach is similar to the conservative management of lumbosacral disc herniation and includes analgesic and anti-inflammatory medications, physical therapy, and epidural steroid injections. Although most patients respond to conservative therapy, surgical decompression may be necessary if radicular complaints persist. In one series, 27 % of patients with thoracic disc herniation demonstrated by MRI required surgery after a trial of medical management [20].

Thoracic Spondylosis

Thoracic spondylosis is relatively rare. The only clear indication for surgery in thoracic spondylosis is the presence of canal narrowing sufficient to cause myelopathy. The indications for surgical decompression in thoracic radiculopathy due to spondylosis have not been studied sufficiently, but surgery is likely appropriate for patients with incapacitating pain not responding to conservative management or for patients with T1 radiculopathies and resultant hand weakness.

Neoplastic Disease

Primary Tumors

The initial treatment of primary spinal tumors is almost always surgical [22]. Total resection is generally possible as these are discrete masses. With incomplete resection, residual tumor foci may result in recurrence. Radiation therapy has an established role in the treatment of incompletely excised tumors, recurrent tumors, and tumors with malignant histology and is more often performed in patients with

lymphoma/plasmacytoma, astrocytoma, and occasionally with ependymoma [25, 120].

Epidural and Vertebral Metastases

Treatment for metastatic vertebral body disease is selected based upon extent of neurologic compromise and vertebral body destruction [121]. Additional considerations include the anticipated survival time and general health of the patient. Therapy objectives are usually palliative. Patients with pain and radiculopathy without significant bony involvement should undergo radiotherapy as their primary therapeutic modality, particularly when the tumor is highly radiosensitive (e.g., lymphoma or myeloma). Metastatic lesions from lung, kidney, breast, colon, and prostate tumors also respond to radiotherapy, chemotherapy, or both [22, 121]. In patients with vertebral collapse resulting in spinal instability, spinal cord compression, or intractable pain, spinal decompression and stabilization may be necessary.

Whenever there is resultant neurologic dysfunction due to spinal metastases, high-dose corticosteroids should be given intravenously as soon as possible. Prognosis is closely correlated with degree of existing neurological dysfunction, so early diagnosis is crucial. The primary therapy now offered to patients with metastatic epidural disease is radiotherapy. Surgical decompression should be considered when the diagnosis is in doubt or in patients with progressive neurologic deterioration despite radiation and steroids, with radioresistant tumors, with symptomatic spinal instability, or with intractable pain [31]. There is some evidence that early surgical intervention may be superior to radiation therapy in selected cases [29]. The most radiosensitive tumors are breast, prostate, small-cell lung cancer, lymphoma, and multiple myeloma. Renal cell carcinoma and melanoma are extremely radioresistant [122].

Chemotherapy may play a role in patients who are poor surgical candidates due to widespread metastatic disease and for those who have previously undergone radiotherapy [33]. Surgical morbidity ranges from 10 to 15 %. In appropriately selected patients, approximately 80 % have improved neurologic function and pain relief, although the overall prognosis remains poor. In one study, two thirds of patients were able to ambulate following surgery compared to one third preoperatively [123].

Leptomeningeal Metastases and Meningeal Carcinomatosis

The goal of therapy is to improve neurologic status and prolong survival time. Because tumor cells disseminate widely throughout the subarachnoid space, therapy must reach the entire neuraxis. Treatment consists of intrathecal chemotherapy in combination with radiation to the affected areas; methotrexate is the drug of first choice in almost all patients. Radiation therapy can rapidly relieve pain, stabilize neurologic function, and improve CSF flow, making subsequent intrathecal chemotherapy more effective [34]. Without therapy, median survival time is 4–6 weeks, with death usually a result of progressive neurologic dysfunction. Treatment increases median survival to 3–6 months [124].

Infectious Disease

Herpes Zoster and Postherpetic Neuralgia

Treatment with oral acyclovir, famciclovir, or valacyclovir, if started within 72 h of the onset of zoster eruption, is effective in accelerating cutaneous healing of lesions and reducing acute neuritis [125]. Although there is evidence to suggest that early treatment with these antiviral agents reduces the risk of PHN, this has not been confirmed in large epidemiologic studies [125, 126]. The addition of corticosteroids appears to accelerate healing of acute lesions but does not reduce the incidence of PHN; they should be considered as adjunctive early therapy in high-risk (e.g., older) patients with severe pain in whom there is no contraindication [125, 127]. There is evidence suggesting that low-dose amitriptyline, started when herpes zoster (HZ) is first diagnosed, results in a 50 % reduction in the incidence of PHN; however, this is not a common clinical practice [41, 128].

Once PHN is established, tricyclic antidepressants, gabapentin, pregabalin, opioids, and lidocaine patches are effective in reducing pain (Level A, class I, II evidence) [41, 129, 130]. Though opiates are efficacious, they are not recommended as first-line treatment due to concerns of misuse and dependency. Topical capsaicin is also efficacious but adverse effects are a major limitation in most patients [129, 130]. Combination therapy with medications such as nortriptyline and gabapentin may be more successful than monotherapy [130]. The majority of patients with PHN have spontaneous resolution of symptoms over months or years; however, a small number are incapacitated by chronic pain.

Varicella zoster vaccine is a live vaccine FDA approved for use in immunocompetent adults over age 60, regardless of a prior episode of HZ. Because it contains live virus, the vaccine is contraindicated in immunocompromised patients. In a large randomized, double-blind, placebo-controlled trial, the vaccine reduced the incidence and burden of illness of HZ by over 50 %, as well as reducing the incidence of PHN by over 60 % [131]. Vaccination is recommended in nonimmune children and adults, as well as all immunocompetent adults ≥60 years of age; low-dose acyclovir is recommended for prophylaxis in patients receiving immunosuppressive regimens [132].

Spinal Epidural Abscess

Treatment of spinal epidural abscess (SEA) must be initiated urgently, following the collection of blood cultures, with

empirical antimicrobial therapy covering both gram-positive cocci including MRSA as well as gram-negative bacilli in patients at risk [133]. The mainstay of treatment for pyogenic SEA is surgical decompression of the thecal sac and abscess drainage [47, 133]. After surgical drainage, parenteral antibiotics are recommended for at least 2–4 weeks followed by 4 weeks of oral therapy, although precise recommendations on duration of treatment vary [46, 133, 134]. Medical management alone may be appropriate in selected patients in whom the organism has already been isolated and the location of the abscess poses little risk to the spinal cord or cauda equina, in whom there is no neurologic deficit, or in whom the risks of surgery are unacceptable due to comorbid illness. These patients require 8–12 weeks of intravenous (IV) antibiotics followed by 2–3 months of oral agents. Close monitoring is necessary and urgent surgical decompression is performed if neurologic compromise develops [46, 47].

In contrast to bacterial SEA, the mainstay of treatment for spinal tuberculosis is antituberculous chemotherapy, although surgical debridement may be required in some cases. The development of neurologic compromise constitutes an important indication for surgery. Drug regimens for spinal tuberculosis are identical in composition to those used for pulmonary tuberculosis but are administered for 12 months.

Polyradiculopathy in HIV and AIDS

The natural history of untreated CMV polyradiculopathy is one of rapid progression of ascending paralysis, with death usually occurring within 8 weeks of symptom onset [50]. When CMV polyradiculopathy is suspected, an empiric course of ganciclovir should be initiated while awaiting microbiologic confirmation, based on CMV PCR. Alternative therapy with foscarnet or cidofovir, either alone or in combination with ganciclovir, should be instituted in patients already receiving ganciclovir for systemic CMV infection or CMV retinitis or in patients who worsen despite treatment, as this may indicate ganciclovir resistance [50, 135]. The overall prognosis, based on retrospective studies of patients prior to the development of protease inhibitors, is fairly poor, even with treatment [50]. A minority of patients make significant functional recovery, and their survival time, with treatment, is only 3–5 months [50].

Lyme Radiculoneuropathy

Evidence-based guidelines for the management of Lyme borreliosis have been published by numerous North American and European expert groups in recent years and are largely in agreement on recommendation [52, 136]. The choice of treatment regimen for Lyme neuroborreliosis is based upon the clinical presentation. Intravenous ceftriaxone (2 g daily) is recommended for patients with acute neuroborreliosis associated with central nervous system involvement, i.e., encephalitis or myelitis, or patients with late neuroborreliosis and vasculitis. Oral doxycycline (100 mg twice daily) has been found in a number of studies to be as effective as intravenous ceftriaxone (2 g twice daily) in patients with acute neuroborreliosis confined to the meninges, cranial nerves, nerve roots, or peripheral nerves and is the currently recommended treatment [52, 136, 137]. Recommended treatment duration is 14 days as longer courses of treatment have not shown superior outcomes [52, 136]. Only a limited number of class III and IV studies have addressed the treatment of the rare syndrome of late neuroborreliosis presenting as chronic, mild neuroradiculopathy. Based on the available evidence, current recommendations are to treat as for acute neuroborreliosis syndromes involving the peripheral nervous system (including radiculopathy, diffuse neuropathy, mononeuropathy multiplex, cranial neuropathy with normal CSF), i.e., with oral doxycycline [136]; however, in late neuroborreliosis, a 3-week regimen is recommended [52, 136, 138].

Since it takes time for damaged nerves to recover, improvement typically occurs over a few months, often with some fluctuation, but patients ultimately return to baseline. Antibodies remain detectable in the serum for some time after successful treatment so are a poor indicator of treatment response [54, 136].

Persistent symptoms following accepted courses of antibiotic treatment, including fatigue, arthralgias, myalgias, headache, paresthesias, poor sleep, irritability, and concentration difficulties, are referred to as post-Lyme disease syndrome (PLS). There is compelling class I evidence that PLS is not due to active Borrelia infection and is not responsive to further antibiotic therapy, particularly with respect to overall health-related quality of life and cognitive and depressive symptoms. As prolonged courses of antibiotics do not improve the outcome of PLS and are potentially associated with adverse events, they are not recommended (Level A recommendation) [136].

Diabetic Radiculopathy

Management of these painful syndromes is symptomatic with the use of analgesics, tricyclic antidepressants, or anticonvulsants, including carbamazepine, phenytoin, and gabapentin. Transcutaneous nerve stimulation has also been used with variable success [139]. This painful condition is generally self-limited and in most cases the pain resolves in 6–24 months [56, 139]; however, patients may be left with some motor deficit. Methylprednisolone and IVIG have shown some therapeutic potential, mostly insofar as pain relief, but larger, controlled studies are needed, particularly given the toxicity of these agents in diabetic patients [140]. Polyradiculopathy recurs in approximately 20 % of patients [56, 139].

Spinal Arachnoiditis

Unfortunately, few effective treatment options are available for spinal arachnoiditis; even symptomatic pain relief is elusive in most cases. Recognition and avoidance of iatrogenic causes of arachnoiditis is an important aspect of management. Symptomatic treatment of neuropathic pain with tricyclic antidepressants and anticonvulsants, such as gabapentin, is appropriate. Excision of extradural scar and performance of a foraminotomy may provide pain relief in some cases. Intradural lysis is not advised, however, as there is no way to prevent reformation of scar [141]. Implantation of a spinal cord stimulator (SCS) may be another consideration; however, this involves several surgical procedures and long-term pain control achieved with SCS is often incomplete [142]. Neuroablative procedures, such as dorsal rhizotomy and dorsal root ganglionectomy, do not provide benefit and are not recommended [143].

Brachial Plexopathies

46

Mark A. Ferrante and Bryan E. Tsao

Introduction

The brachial plexus, which innervates the upper extremity and most of the shoulder, is the most complex structure in the peripheral nervous system (PNS). Its susceptibility to trauma, especially closed-traction injury, is directly related to its large size, superficial location, and position between two highly mobile structures (i.e., the neck and upper extremity) [1, 2]. In addition, it is vulnerable to indirect injury from disorders involving structures adjacent to it (e.g., lymph nodes, major blood vessels, lung tissue) [3] (Fig. 46.1). These susceptibilities explain why the incidence of brachial plexopathies is many times higher than the combined incidence of cervical, lumbar, and sacral plexopathies. Accurate diagnosis and management requires that the examining physician integrate anatomic, pathophysiologic, and neuromuscular knowledge with the clinical features, thereby permitting localization and initial characterization of the lesion, which, in turn, dictates the appropriate management of the patient and permits accurate prognostication.

Anatomy

The brachial plexus is a triangular-shaped structure that extends in an inferolateral direction from the spinal cord (its base) to the axilla (its apex). It has an average extraforaminal length of 15.3 cm [4], is composed of connective and neural tissue in a 2:1 ratio [4–6], and consists of several elements: 5 roots (classically, C5 through T1), 3 trunks (upper, middle, and lower), 6 divisions (3 anterior and 3 posterior), 3 cords (lateral, posterior, and medial), and several terminal nerves (Fig. 46.2). The brachial plexus contains over 100,000 individual nerve fibers [2]. Of these, 25 % enter via C6, 25 % via C7, and 25 % via C8; the C5 and T1 roots are the conduits for the other 25 % [4]. The percentage of sensory and motor fibers composing each root varies: the C5 and C6 roots contain the highest percentage of motor fibers (the C7 and T1 roots contain the lowest percentage), and the C7 root contains the highest percentage of sensory fibers, followed in descending order by C6, C8, T1, and C5 [6, 7].

Roots

After exiting the spinal cord, the dorsal and ventral rootlets fuse to form the dorsal and ventral roots, respectively, which then traverse the intraspinal canal to enter the intervertebral foramen. Just distal to the dorsal root ganglion (DRG), the dorsal and ventral roots fuse, to form a spinal nerve (it also is termed a *mixed* spinal nerve because it contains sensory and motor nerve fibers). After exiting the intervertebral foramen, the spinal nerve gives off a posteriorly directed branch (the posterior primary ramus) and then continues peripherally as the anterior primary ramus (APR) (Fig. 46.3). The APR emerges from between the anterior and middle scalene muscles. Nerves arising from the APR include the nerves to the scalene and longus colli muscles (C5–C8); the long thoracic nerve, which innervates the serratus anterior (C5–C7 APR); a portion of the phrenic nerve, which innervates the diaphragm (C5 APR); and a portion of the dorsal scapular nerve, which innervates the levator scapulae and the rhomboideus major and minor muscles (C5 APR) [8]. In addition, preganglionic sympathetic fibers exit from the APR, via white rami communicantes, to reach the sympathetic ganglia. The sympathetic ganglia then send postganglionic fibers, via gray rami communicantes, to the C5–T1 spinal nerves. The preganglionic sympathetic autonomic fibers that

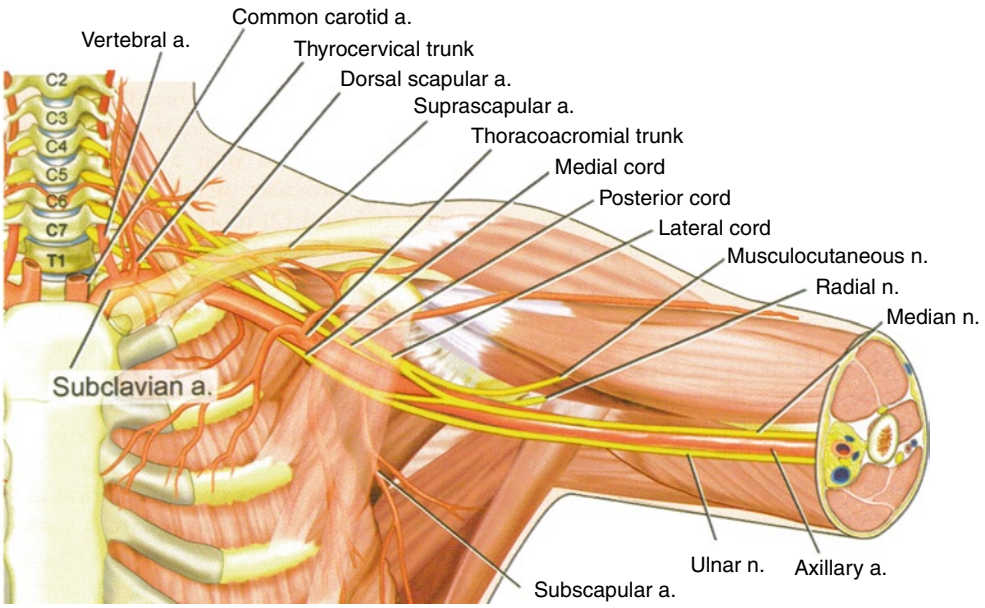

Fig. 46.1 The relationship between the brachial plexus and its neighboring structures

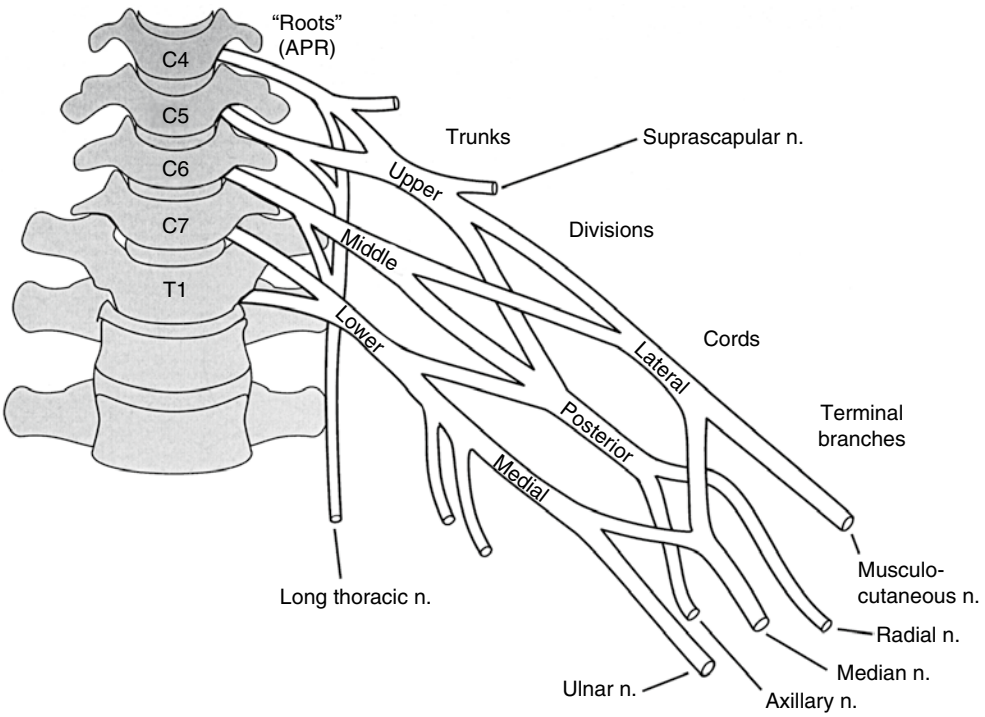

Fig. 46.2 The brachial plexus

supply the head and neck travel with the C8 and T1 spinal nerves to reach the inferior cervical ganglion. Thus, brachial plexus lesions associated with Horner syndrome must be located at or proximal to the spinal nerve level. In its classic formation, the brachial plexus consists of motor and sensory fibers derived from the C5 through T1 anterior horn cells (AHCs) and DRG, respectively [8, 9]. Vertical variations in its composition are not uncommon, such as expansions related to contributions from C4 or T2 or vertical shifts one level upward or downward. Whenever the C4 contribution is large and the T1 contribution is small, the brachial plexus is said to be *prefixed* (C4 through C8), whereas it is considered *postfixed* whenever the C5 contribution is small and the T2 contribution is large (C6 through T2) [10]. It is important to realize that these one-segment shifts do not affect the arrangement of the plexus – it still consists of 5 roots, 3 trunks, 6 divisions, 3 cords, and 5 terminal nerves – and, for this reason, the clinical examination still accurately localizes the lesion. Infrequently, the C7 root may contribute fibers to the ulnar nerve [4]. A final point concerns the

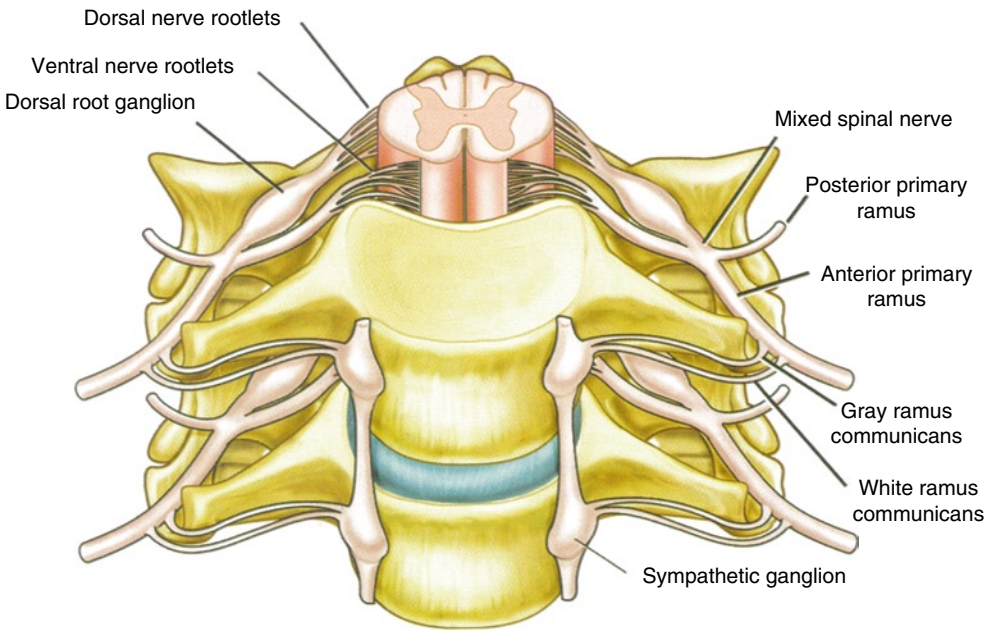

Fig. 46.3 The proximal elements of the brachial plexus

definition of the term *root*. Although anatomists consider the root of the brachial plexus to be the APR, most physicians and surgeons dealing extensively with brachial plexus define the root as the APR, posterior primary ramus, spinal nerve, and all of the dorsal and ventral roots and rootlets contributing to them (i.e., the PNS elements proximal to the trunk) [2]. With the latter definition, the roots have intraspinal canal and intraforaminal and extraforaminal segments, and avulsion injuries are brachial plexopathies. Because of its clinical utility, the more expansive definition of root is used in this chapter.

Trunks

The trunks are named for their relationship to each other – upper, middle, and lower. They are formed from the APR at the lateral borders of the scalene muscles and traverse the anteroinferior region of the posterior cervical triangle of the neck (behind the clavicle and sternocleidomastoid muscle) relatively superficially. Classically, the C5 and C6 APR join to form the upper trunk, the C7 APR continues as the middle trunk, and the C8 and T1 APR coalesce to form the lower trunk. The trunk elements are infrequently anomalous – the upper trunk is of classical formation more than 90 % of the time, the middle trunk is a direct continuation of the C7 APR 100 % of the time, and the lower trunk is of classical formation more than 95 % of the time [11]. The lower trunk is adjacent to the apex of the lung and lies very near the subclavian artery. Two branches derive from the trunk level of the brachial plexus – the nerve to the subclavius muscle and the suprascapular nerve [8].

Divisions

With the body situated in the anatomic position, the divisions lie between the midportion of the clavicle and the first thoracic rib (i.e., they are retroclavicular). In general, the divisions do not give off any nerve branches [8]. Each trunk element divides into two processes, one directed anteriorly and the other posteriorly, thereby generating three anterior divisions and three posterior divisions. The anterior divisions primarily supply flexor muscles, whereas the posterior divisions primarily supply extensor muscles. Although the anterior and posterior divisions of the upper trunk are similar in caliber, the posterior division of the middle trunk is much larger than its anterior division (because the C7 motor fibers innervate more extensor muscles than flexor muscles), whereas the anterior division of the lower trunk is much larger than its posterior division (because the C8 and T1 motor fibers innervate more flexor muscles than extensor muscles) [6]. Following division formation, the segmental nature of the root and trunk elements is lost and, for this reason, the clinical deficits associated with infraclavicular lesions are in the distribution of one or more peripheral nerves or nerve branches.

Cords

The cords, which form at or just beyond the clavicle, are named for their relationship to the second segment of the axillary artery to which they typically are bound (see Fig. 46.1). They are the longest elements of the brachial plexus and lie in the proximal portion of the axilla, near the

axillary lymph node chain [8, 12–15]. The anterior divisions of the upper and middle trunks join to form the lateral cord, the posterior divisions of all three cords unite to form the posterior cord, and the anterior division of the lower trunk continues as the medial cord. The lateral cord, which contains C6 and C7 sensory and C5–C7 motor fibers, gives off the lateral pectoral and musculocutaneous nerves before terminating as the lateral head of the median nerve. The posterior cord, which contains C5–C7 sensory and C5–C8 motor fibers, gives off the subscapular and thoracodorsal nerves before terminating as the axillary and radial nerves. The posterior cord delivers the C5 sensory fibers via the upper and lower lateral brachial cutaneous nerves (branches of the axillary and radial nerves, respectively). The medial cord, which contains C8 and T1 sensory and motor fibers, gives off the medial pectoral, medial brachial cutaneous, medial antebrachial cutaneous (MABC), and ulnar nerves before terminating as the medial head of the median nerve. Cord formation anomalies may produce unexpected findings. For example, when the C7 root or lateral cord contributes motor fibers to the ulnar nerve, lesions of the C7 root or lateral cord can be associated with abnormalities in ulnar nerve-innervated muscles [4, 14, 16, 17]. Although the posterior cord occasionally contains T1 fibers, when present, they account for less than 5 % of its fibers [4, 18]. Nerves usually do not arise from the cord elements of the brachial plexus.

Terminal Nerves

The terminal nerves are situated in the distal portion of the axilla and are the most distal components of the brachial plexus. They number from three (median, ulnar, radial) to five (when musculocutaneous and axillary are included), depending on the author. Since all five of these structures are cord-derived and enter the upper extremity, we consider them to be five terminal nerves. Except for the median nerve, which is derived from two cords (lateral and medial), the terminal nerves originate from a single cord: the musculocutaneous nerve from the lateral cord, the radial and axillary nerves from the posterior cord, and the ulnar nerve from the medial cord. The terminal nerves continue distally as the peripheral nerves of the upper extremity and bear the same name (e.g., the radial terminal nerve of the brachial plexus becomes the radial nerve proper of the upper extremity). There is no anatomical change to demarcate their point of transition, and thus, this point has been defined in different ways by different authors. Narakas defined the transition point as 3 cm distal to the cord [19], but this is challenging to identify clinically. Wilbourn defined the transition point as occurring where the nerves exit the axilla, which is more clinically appreciable [15]. The other cord-derived nerves – the lateral pectoral nerve from the lateral cord, the thoracodorsal nerve from the posterior cord, and the medial pectoral, medial brachial cutaneous, and medial antebrachial cutaneous nerves from the medial cord – like the previously listed APR- and trunk-derived nerves, are not considered as terminal nerves.

Classification

Brachial plexus lesions can be classified in a number of ways. Because of its vast size, most brachial plexus lesions are focal in nature. Consequently, like other lesions of the nervous system, brachial plexus lesions are best classified anatomically. Based on its relationship to the clavicle, the brachial plexus is divided into *supraclavicular* (roots and trunks), *retroclavicular* (divisions), and *infraclavicular* (cords and terminal nerves) plexuses. This subdivision has significant clinical relevance because supraclavicular and infraclavicular plexopathies differ in their incidence, severity, and prognosis. Supraclavicular lesions have a higher incidence, tend to be more severe, and, when severe, have an overall worse prognosis than infraclavicular ones [2, 20, 21]. Their greater severity reflects the greater force associated with their production and the higher incidence of closed-traction injuries (e.g., obstetric paralysis and vehicular accidents), which often produce lengthy and more severe lesions (e.g., nerve root avulsion). Consequently, overall, supraclavicular plexopathies tend to have a worse prognosis [2, 20–23]. The lesion types observed in these two regions also differ. Lesions commonly involving the supraclavicular plexus include closed-traction injury (e.g., obstetric paralysis, vehicular accidents, and burner syndrome), malpositioning (e.g., classic postoperative paralysis), rucksack palsy, neoplastic processes (especially lung or breast cancer), and true neurogenic thoracic outlet syndrome, whereas infraclavicular plexopathies are more frequently related to trauma (gunshot and stab wounds, humerus fractures and dislocations), radiation, medial brachial fascial compartment syndrome, crutch use, and iatrogenicity (e.g., following shoulder operations, shoulder arthroscopy, axillary arteriograms, axillary regional anesthetic blocks, and postmedian sternotomy) [3].

The supraclavicular plexus is further divided into three regions: the upper plexus (upper trunk and C5 and C6 roots), the middle plexus (the middle trunk and C7 root), and the lower plexus (the lower trunk and C8 and T1 roots) (Fig. 46.4). This division also has clinical utility in regard to incidence, severity, and prognosis. Upper plexus lesions have the highest incidence, tend to occur in isolation, and usually are traumatic in etiology (especially closed traction); however, most large series of brachial plexus lesions are compiled by surgeons and, thus, have an etiologic bias [15, 24]. Middle plexus lesions, which rarely occur in isolation, usually are traumatic in etiology and related to traction injury [25, 26].

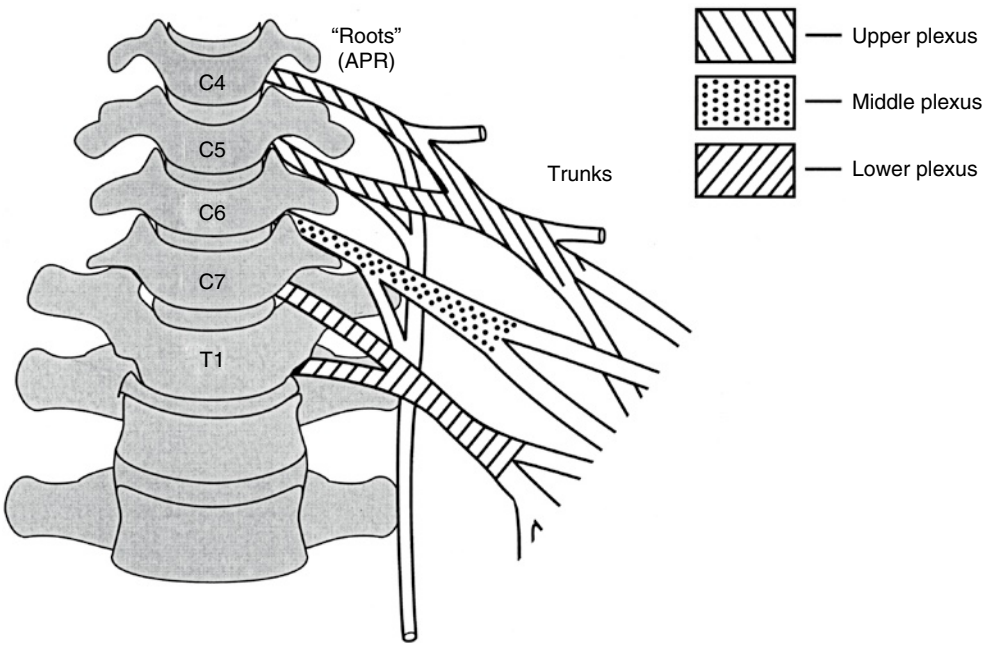

Fig. 46.4 The upper, middle, and lower plexuses

Lower plexus injuries have the lowest incidence. In general, upper plexus lesions are less severe than lesions of the lower plexus because they (1) more frequently are demyelinating conduction block (remyelination is more complete than axon regeneration), (2) usually are located more proximate to the muscles that they innervate (more amenable to reinnervation via axon regrowth), and (3) more frequently are extraforaminal (more amenable to surgical intervention) [2]. For these reasons, upper plexus lesions tend to have a better prognosis. Consequently, a remote process that originally involved all three supraclavicular regions equally may subsequently appear as an isolated lower plexus lesion. Retroclavicular plexopathies rarely occur in isolation. For example, when clavicular fractures damage the underlying divisions, they usually cause concomitant traction injury to the supraclavicular plexus. Unlike the supraclavicular plexus, the infraclavicular plexus is not further divided anatomically because lesions affecting it do not show significant regional differences in incidence, severity, prognosis, or lesion type [3].

Because most clinicians assessing brachial plexus disorders first attempt to localize the lesion, this classification system has clinical utility. Moreover, because many brachial plexus disorders are site specific, this approach also helps establish a differential diagnosis, especially when considered in relation to the lesion itself. For example, forearm flexion weakness following a stab wound to the supraclavicular fossa is most likely associated with a supraclavicular process, whereas following pacemaker placement, an infraclavicular plexopathy is more likely. Finally, this classification system facilitates communication among physicians, especially in the acute setting, when there are examination limitations (e.g., pain, mental status changes, or nonneural injuries with a higher priority for assessment) or prior to diagnostic testing. This is particularly true for the subdivisions of the supraclavicular plexus. For example, it is much easier to discuss a patient with a lesion involving the upper plexus than to commit to one of its internal elements (i.e., upper trunk, C5 root, C6 root).

Pathology and Pathophysiology

Although the nerve fibers composing the brachial plexus may be injured in a countless number of ways, their pathologic and pathophysiologic responses are limited. Regardless of cause, axon disruption causes the nerve segment distal to the disruption site to degenerate. This pathologic process is termed Wallerian degeneration, after Augustus Waller, who first described it [27]. It is also referred to as axon degeneration or axon loss. Seddon utilized Greek terms to pathologically classify nerve trauma into three levels of severity: *neurapraxia* (nonaction of nerve) was applied to lesions restricted to the myelin coating of the nerve (termed demyelination), *axonotmesis* (a "cutting of the axon") to lesions restricted to the axon, and *neurotmesis* (a "cutting of the nerve") when the nerve was either completely severed or so severely disorganized by scar tissue that regeneration was not feasible (e.g., following laceration or ischemic injuries, respectively) [28]. Sunderland later introduced a system that included the degree of connective tissue injury [29]. In his system, *grades I and II* are equivalent to neurapraxia and axonotmesis, respectively, and represent grades of neural involvement, whereas *grades III–V* are equivalent to neurotmesis and represent degrees of connective tissue disruption. A *grade III* lesion

involves the myelin, axon, and endoneurium; a *grade IV* lesion also involves the perineurium; and a *grade V* lesion also involves the epineurium (see Chap. 39). Pathophysiologically, with axon loss, *conduction failure* occurs because the distal nerve fiber segments can no longer conduct impulses. With demyelination, action potentials either traverse the disruption site at a slower rate (demyelinating conduction slowing) or, with more significant degrees of demyelination, are unable to traverse it (demyelinating conduction block). Each of these pathophysiologies has unique EDX manifestations. In order to perform an EDX assessment of the brachial plexus (discussed later in this chapter), these manifestations must be understood. These classification systems also have clinical merit. With neurapraxia, the prognosis for complete recovery is excellent, as it often is with axonotmesis, especially when the Schwann cell tubes are spared. With increasing connective tissue layer involvement, the prognosis for recovery progressively worsens. In general, it is good when disruption is restricted to the endoneurium, extremely poor with perineurial involvement, and nil with epineurial involvement. Unfortunately, the degree of connective tissue involvement cannot be determined clinically or by EDX testing, and in addition, PNS lesions (especially those caused by trauma) often produce a combination of these grades.

Electrodiagnostic Manifestations

Axon Loss

Most brachial plexus lesions are axon loss in nature and result in conduction failure. Thus, the affected sensory and motor nerve fibers do not contribute to the sensory nerve action potential (SNAP) and compound muscle action potential (CMAP), respectively. The recorded amplitude and negative area under the curve (AUC), which reflect the total number of conducting fibers, are decreased. In contrast, the latencies and conduction velocities (CVs) reflect the conduction rate along only the fastest conducting fibers (i.e., those with the largest diameters and the thickest myelin sheaths) and, thus, only reflect a small percentage of the stimulated nerve fibers. Consequently, these values do not become abnormal until all or most of the fastest fibers are affected. Therefore, even with severe axon loss lesions demonstrating low CMAP amplitudes, whenever some of the fastest fibers remain unaffected, latency and CV values remain normal. In summary, *the amplitude and negative AUC values are by far the most sensitive nerve conduction study (NCS) parameters for identifying axon loss lesions, whereas the latency and CV values are fairly insensitive until the lesion is quite severe*. On needle electromyography (EMG) examination, axon disruption causes motor unit action potential (MUAP) dropout and fibrillation potentials. MUAP dropout, which is present from the time of motor axon disruption, is proportional to the number of disrupted motor axons. Because it typically is only apparent when the motor response is 50 % or less than that recorded from the contralateral asymptomatic side, it is usually not apparent on needle EMG unless the lesion involves at least 50 % of the motor axons (i.e., is moderate to severe in severity). Because most extremity muscles have an innervation ratio of several hundred or more, a large number of fibrillation potentials are produced per disrupted motor axon. These potentials typically appear around day 21, are preceded approximately 7 days earlier by insertional positive waves, and can be quite prominent, even when the lesion is only minimal in degree. As successful reinnervation occurs – via progressive distal advancement of the proximal motor fiber stumps from the disruption site to the denervated muscle fibers (*proximodistal regeneration*) or via *collateral sprouting* from the unaffected intramuscular motor fibers – the affected motor response normalizes, and the MUAPs show chronic neurogenic changes (e.g., prolonged durations and increased amplitudes).

Unlike the focal nature of myelin disruption, which persists until remyelination occurs, axon disruption becomes nonfocal because it triggers Wallerian degeneration, which affects the entire distal stump. Once this process of degeneration is complete (see The Timing of the EDX Studies), the entire distal stump is incapable of generating or conducting nerve fiber action potentials. For these reasons, regardless of stimulation site (proximal to, at, or distal to the lesion), the recorded response only reflects the unaffected fibers, and consequently, all of the responses have the same size and appearance (i.e., they are uniform).

Demyelination

Like axon loss lesions, demyelinating lesions may be focal, multifocal, or generalized. Of these, only focal and multifocal (e.g., multifocal motor neuropathy, radiation injury) are pertinent to this chapter. Unlike axon loss lesions, myelin disruption does not induce distant nerve fiber changes (i.e., it remains focal). Thus, the nerve fiber segments proximal and distal to the site of myelin disruption conduct normally and, for this reason, focal demyelination can only be observed on NCS when the stimulating and recording electrodes bracket the lesion (i.e., stimulation current must traverse it). Consequently, *focal demyelinating lesions are localizable by NCS*. Because physiological dispersion causes the sensory responses to decay when recorded over long nerve fiber segments – a reflection of their small size (microvolts), their shorter duration (1–2 ms), and their broader range of CVs (about 25 m/s difference between the fastest and slowest fibers) – focal demyelinating lesions typically are sought

during performance of the motor NCS by moving the stimulating electrodes more and more proximally until the morphology of the recorded waveform changes. The most proximal site utilized by surface stimulation in a patient with suspected brachial plexopathy is the supraclavicular fossa, which can detect focal lesions at or distal to the mid-trunk level. Lesions located proximal to the mid-trunk level are not detectable by surface stimulation. With mild degrees of myelin disruption, the propagating motor nerve fiber action potentials are slowed (demyelinating conduction slowing), whereas with more severe degrees of myelin disruption, they are blocked (demyelinating conduction block). When the motor nerve fibers are slowed to the same degree (uniform slowing, synchronous slowing), their relative rates of conduction across the lesion remain the same. Consequently, the morphology of the recorded waveform appears normal. The only abnormality is that its arrival time is delayed, and thus, either the distal latency is prolonged or the calculated proximal nerve CV is reduced, depending on whether the lesion is located distal to the most distal stimulation site or between the two stimulation sites, respectively. Uniform demyelinating conduction slowing is commonly observed among patients with early carpal tunnel syndrome. When the lesion slows action potential conduction along the affected motor nerve fibers to differing degrees (nonuniform slowing, nonsynchronous slowing), the morphology of the recorded waveform changes – the duration of the negative phase increases, resulting in negative and positive phase cancelation among the dispersed action potentials. Consequently, the negative AUC and amplitude values decrease. Nonuniform conduction slowing may be accompanied by paresthesias but not fixed sensory loss or weakness. The calculated motor CV may be normal (when some of the fastest conducting fibers are spared) or reduced (when all of the fastest conducting fibers are involved). Nonuniform demyelinating conduction slowing is commonly observed among patients with ulnar neuropathies at the elbow. Demyelinating conduction slowing of either form has no effect on the needle EMG and, because it produces neither weakness nor sensory loss, is rarely observed among patients with brachial plexus lesions.

With demyelinating conduction block, the NCS response is normal with stimulation below the lesion, but with stimulation above the lesion, it is either unelicitable (complete lesion) or reduced in size (partial lesion). When the lesion lies proximal to the standard stimulation sites, its presence can be inferred when a clinically weak muscle generates discordance on the motor NCS (normal or nearly normal motor response) and the needle EMG (markedly decrease recruitment of rapidly firing MUAPs). Most significant demyelinating conduction block lesions disrupt at least a few axons and are therefore often accompanied by at least some fibrillation potentials. When demyelinating conduction block is noted among patients with brachial plexus lesions, it typically accounts for a minority of the nonconducting motor fibers, with the majority of the affected fibers being due to axon disruption. Unlike demyelinating conduction slowing, demyelinating conduction block lesions are symptomatic (static sensory deficits or weakness) because the action potentials cannot traverse the lesion site. Most of the brachial plexus lesions that are predominantly demyelinating conduction block are associated with acute trauma, recover via remyelination, and are referred to as *neurapraxia* or as *neurapractic* lesions. Although most demyelinating conduction block lesions of the brachial plexus have a good prognosis, there are at least two that do not – those due to radiation and those attributable to multifocal motor neuropathy. The demyelinating conduction block associated with the early and middle stages of radiation-induced plexopathy tends to persist, to progressively involve more nerve fibers, and to convert to axon loss. With multifocal motor neuropathy and its variants, slow progression and conversion to axon loss also occur.

The Timing of the EDX Studies

The transected distal segments of the affected nerve fibers initially retain their ability to conduct, and therefore, the recorded sensory and motor responses initially appear normal with stimulation below the lesion despite the clinical presence of sensorimotor deficits. With stimulation above the lesion, however, the action potentials cannot traverse the lesion site, and the recorded response is reduced in size (partial axon loss lesion) or absent (complete axon loss lesion). For this reason, prior to Wallerian degeneration, the recorded responses have an appearance identical to that observed with demyelinating conduction block – the response recorded with stimulation proximal to the lesion site is diminished in size in comparison to the one recorded with stimulation distal to the lesion site (partial demyelinating conduction block) or is absent (complete demyelinating conduction block). This phenomenon has been referred to by many terms but will be referred to as *transient axonal conduction block* in this chapter. The time period over which this phenomenon is observable differs due to the different techniques utilized in their recording. On motor NCS, stimulation below the lesion prior to Wallerian degeneration results in a normal CMAP. As the affected motor nerve fibers lose their ability to generate and transmit action potentials, the recorded CMAP decreases in size. In general, this decline begins on day 3 or 4 and maximizes around day 6 or 7 when all of the disrupted motor nerve fibers have lost their ability to generate and conduct action potentials. At this point, the recorded motor response reflects only the unaffected (normal) fibers and indirectly reflects the affected (degenerated) ones. With incomplete lesions, the percentage of affected nerve fibers can be estimated by comparing the

recorded negative AUC/amplitude values of the distal motor response to those recorded from the contralateral side (in the setting of a unilateral lesion) or to the normal control values of the laboratory (when the contralateral side cannot be utilized for this purpose). The recorded SNAP shows the same several-day decrement, but it begins later (around day 6 or 7) and reaches its nadir later (around day 10 or 11). Because neuromuscular junction (NMJ) transmission is lost before the distal nerve segments stop transmitting action potentials, the conduction failure is apparent on motor NCS prior to its appearance on sensory NCS because the CMAP reflects the intervening NMJs. Thus, the time elapsed between the onset of the symptoms and the performance of the EDX study must always be considered to avoid misleading conclusions (e.g., the underlying pathophysiology) and mislocalization. For example, if the study were done around day 6, the low motor-normal sensory response pattern would mislocalize the lesion proximally (i.e., intraspinal canal) or distally (i.e., distal to the takeoff site of the sensory branch). On needle EMG, axon disruption produces fibrillation potentials and dropout of MUAPs. Because of the high innervation ratio of most extremity muscles, hundreds of fibrillation potentials are generated per disrupted motor axon. Thus, they can be quite prominent even when the lesion is only minimal in degree. Although this attribute makes the needle EMG the most sensitive portion of the EDX study for identifying motor axon loss, fibrillation potentials do not appear in the early setting (they generally appear around day 21), and they may quickly disappear as reinnervation via collateral sprouting occurs. Although MUAP dropout occurs at the time of lesion onset, it is an insensitive parameter and typically is not apparent unless the lesion is at least moderate in severity (i.e., about half of the motor axons innervating the muscle under study are disrupted).

EDX Severity Assessment

When lesions affect brachial plexus elements that contain both sensory and motor fibers, the least severe lesion manifests as isolated fibrillation potentials (the sensory and motor responses and MUAP recruitment are normal). With more severe lesions, the appropriate sensory responses decrease in size. As the severity increases further, the sensory responses become quite low or absent, at which point, there are motor response decrement and MUAP dropout, although the latter may not yet be appreciable. With even more severe lesions, the CMAP amplitudes decrease further and the MUAP loss becomes more pronounced and obviously neurogenic (decreased number firing with rapid firing rate). Accordingly, the motor responses are extremely helpful in severity assessment and pathophysiology determination. Specifically, the amplitude and negative AUC values can be used to estimate the percentage of affected motor axons and the underlying pathophysiology. To illustrate this point with a hypothetical and mentally friendly set of motor amplitude response values, suppose a patient with a 5-week history of foot drop has bilateral peroneal motor responses (recording tibialis anterior, the primary dorsiflexor of the foot) performed. On the symptomatic side, the value of the motor response amplitude with stimulation below the fibular head is 4 mV; it is 2 mV with stimulation above the fibular head. On the contralateral, asymptomatic side, the response is 8 mV with stimulation below the fibular head. Comparison of the distal motor response amplitude values of the two sides indicates an axon loss process that involves approximately 50 % of the motor fibers of the common peroneal nerve (4 mV versus 8 mV). The distal and proximal response values on the symptomatic side indicate that there is a demyelinating conduction block that affects 50 % of the conducting fibers (4 mV versus 2 mV). Thus, regarding the motor fibers of the common peroneal nerve, 50 % are affected by axon loss, 25 % are affected by demyelinating conduction block, and 25 % are unaffected. By comparing the distal response values of the two sides, the erroneous conclusion – that the common peroneal neuropathy represents a 50 % demyelinating conduction block (4 mV versus 2 mV) – is avoided. It is important to be aware that following reinnervation via collateral sprouting, although the CMAP improves as the muscle fibers are reinnervated, the of degenerated motor fibers is unchanged. Thus, in the more chronic setting, comparison of the distal motor responses between the symptomatic and asymptomatic sides underestimates the severity of the lesion.

Assessment of Brachial Plexopathy

Clinical Assessment

Brachial plexus assessment begins with a detailed history. Documentation of the onset date, the symptoms at onset and subsequently (e.g., severe shoulder pain followed by wasting and weakness 7–10 days later), and the circumstances surrounding the onset (e.g., following backpack usage, median sternotomy, an axillary or scalene block anesthesia, or trauma) are imperative. With trauma, the position of the neck, shoulder, and upper extremity at impact should be ascertained, as it dictates the nerve fibers at greatest risk of injury. Concomitant injuries should be also noted since they may also be contributory (e.g., fractures of the scapula, clavicle, or humerus; glenohumeral dislocation; scapulothoracic dissociation) [30].

With traumatic brachial plexopathies, the general examination must include a visual inspection of the skin and bones for signs of trauma and of the affected shoulder and upper extremity muscles for evidence of atrophy. In addition, the neck, axilla, and the supraclavicular, infraclavicular, and

scapular regions are palpated for evidence of a mass, bony abnormalities, tenderness, and Tinel sign. The neurological examination is important for preliminary lesion localization. The status of the cervical spinal cord, cervical plexus, and the spinal accessory and phrenic nerves is determined. Dysautonomic features (e.g., sudomotor or vasomotor abnormalities) in the head, neck, shoulder, and upper extremity are sought. The presence of Horner syndrome and/or involvement of the dorsal scapular, long thoracic, or phrenic nerve indicates a proximal localization and portends a worse prognosis. The triad of severe pain, an anesthetic limb, and Horner syndrome is strongly associated with avulsion injury (discussed below) [3]. Since the overwhelming majority of these lesions are axon loss in nature, sensory loss and weakness are expected. With supraclavicular plexopathies, the sensorimotor deficits are segmental in distribution and resemble those observed with involvement of one or more root elements, whereas with infraclavicular plexopathies, they are nonsegmental in their distribution and resemble those observed with involvement of one or more terminal nerves. With *upper plexus* involvement, sensory disturbances involve the C5 and C6 dermatomes (the lateral aspects of the arm, forearm, and hand (especially the thumb)). This includes the cutaneous distributions of the superior and inferior lateral brachial cutaneous nerves, lateral antebrachial cutaneous nerve, and the median nerve territory of the thumb. The cutaneous territories of the superficial radial, median to index finger, and median to middle finger are less frequently involved (60, 20, and 10 %, respectively). Upper plexus weakness involves muscles of the C5 and C6 myotomes such as those involved in external humeral rotation, shoulder abduction, forearm flexion and supination, and, to a lesser degree, forearm pronation and extension, as well as muscles innervated by the dorsal scapular and long thoracic nerves. The biceps and brachioradialis muscle stretch reflexes may be reduced or absent. With *middle plexus involvement*, the sensory loss has a C7 distribution, as does the weakness, including forearm extension and pronation, radial wrist extension and flexion, and, to a lesser extent, finger extension. The triceps muscle stretch reflex may be reduced or absent. With *lower plexus involvement*, the sensory loss involves the medial aspects of the arm, forearm, and hand, and the weakness has a C8 and T1 distribution, affecting the C8-radial (e.g., EIP, EPB) and the C8 and T1 median and ulnar nerve-innervated muscles. The finger flexor reflex may be reduced or absent. In addition, Horner syndrome may be noted.

Radiologic Assessment

The circumstances surrounding the lesion, including the suspected etiology, lesion site, urgency, and study availability, dictate the radiologic procedures employed. Plain films of the cervical spine, clavicle, scapula, chest, and humerus are of value in the assessment of concomitant injuries (e.g., elevated hemidiaphragm with phrenic nerve injury, mediastinal widening with vascular trauma, pneumothorax or hemothorax with lung breach) and, with open injuries, foreign body identification [11]. Certain radiologic features are associated with brachial plexus injuries. For example, avulsion injuries are associated with fractures (of the transverse process, the proximal portion of the first rib, or neighboring bones) and with lateral tilt of the cervical spine; inadequately treated midshaft clavicular fractures resulting to nonunion or excessive callus formation may disrupt plexus fibers (e.g., divisions); infraclavicular plexus lesions are associated with humeral fracture or glenohumeral dislocation; neoplastic and radiation damage are associated with bone or lung abnormalities; and true neurogenic thoracic outlet syndrome is associated with rudimentary ribs and elongated C7 transverse processes [31]. Computerized tomography, despite its drawbacks (e.g., monoplanar imaging, poor tissue differentiation, beam-hardening artifacts), is useful for identifying bony abnormalities and blood [32]. CT myelography can be used to image spinal cord edema or atrophy (the width of the dye column in the cervical gutter is narrowed or widened, respectively) and can identify intraspinal canal masses. When nerve root avulsion is suspected, very-thin-slice (2-mm) CT myelography can be used to image the axially oriented preganglionic nerve root elements [33]. A contrast-filled meningeal diverticulum may be observed when the meninges are pulled through the intervertebral foramen. Other features associated with root avulsion include deformed dural pouches, poor root sleeve filling, and cord edema or atrophy [20, 33–35]. Extraforaminal injuries and meningeal tearing without root damage lead to false-positive conclusions, whereas healing and scarring of the dural pouch produce false-negative conclusions [3]. Overall, the reliability of CT myelography is greatest for avulsions involving the C8 and T1 nerve roots [36].

Because of its multiplanar imaging and tissue differentiating abilities, its lack of radiation and degradation by bone, and its noninvasiveness, magnetic resonance (MR) imaging is the radiologic procedure of choice for imaging the more distal components of the brachial plexus. Although it is also useful for proximal brachial plexus element assessment, it is less sensitive than CT myelography for root avulsion [37], and when multiple slices and planes are required, acquisition time can be considerable. Magnetic resonance myelography is a newer, relatively quick technique in which T2-weighted images of the cerebrospinal fluid (CSF) are reconstructed in three dimensions to generate myelogram-like images of the intraspinal canal and intervertebral foramina [31, 38, 39]. Magnetic resonance neurography is a technique that images peripheral nerves using either diffusion neurography (tissue differentiation reflects diffusion differences rather than T1 or T2 differences) or T2-based neurography (intraneural fascicles are imaged using T2 weighting following fat and blood

suppression and voxel shortening) [40]. With diffusion neurography, because the water molecules within a nerve diffuse longitudinally, a perpendicular magnetic field gradient is applied to make them spin at exactly the same rate and in phase with one another, thereby causing the neural tissue to appear brighter than the surrounding tissue. Unfortunately, this technique is very sensitive to patient motion, and in addition, it can be difficult to image the brachial plexus elements because they are not truly perpendicular to the sagittal plane of the applied magnetic field gradient [40, 41]. These techniques, which are best applied following lesion localization by clinical or EDX assessment, may be helpful in identifying nerve discontinuities and ball neuromas (e.g., upper trunk disruption), nerve deflections (e.g., true neurogenic thoracic outlet syndrome), and primary nerve tumors (e.g., schwannomas) [3, 40].

Vascular Assessment

Angiographic studies may be of diagnostic utility in the assessment of brachial plexus injuries because these lesions may follow trauma to the subclavian or axillary vessels (via hematoma, aneurysm, or pseudoaneurysm formation). This is especially when the plexopathy follows a penetrating injury or when the general examination identifies an absent carotid or radial pulse or when a bruit, thrill, or expanding mass is noted near the injury site [20, 31]. In general, when brachial plexus injury is associated with concomitant vascular injury, the prognosis for recovery is less favorable because, in general, the distractive force associated with neural and vascular disruption is greater than that associated with isolated neural disruption [20].

Electrodiagnostic Assessment and Prognostication

Although an extension of the clinical examination, the EDX examination of brachial plexus lesions is valuable for determining lesion localization and severity, both of which contribute to patient management and treatment. Rather frequently, patients diagnosed with brachial plexopathies in the EDX laboratory are referred with a different diagnostic consideration, and the brachial plexopathy becomes apparent during the EDX assessment. If only the diagnostic considerations put forth by the referring physicians were sought, many brachial plexopathies would go unrecognized. To avoid this pitfall, an organized approach is required. All three components of the EDX examination – sensory NCS, motor NCS, and needle EMG – are performed because each yields information not provided by the others. Thus, omission of one component renders the study incomplete and potentially misleading. Due to its large size, a complete assessment of the entire brachial plexus would require the performance of a large number of NCS and an extensive needle EMG, as well as contralateral studies; this is impractical and would be unnecessarily time-consuming and unjustifiably costly. For this reason and, more importantly, because most brachial plexus lesions are focal, a regional approach is useful in its assessment. We prefer to begin with the sensory NCS, which are the most useful studies for brachial plexus lesion localization and the only studies that assess its sensory nerve fibers. As previously discussed, the sensory response amplitudes are the most important measurement in the assessment of an axon loss process. In addition to differentiating pre- and postganglionic lesions, the pattern of sensory response abnormalities has regional localizing value. Although the motor NCS are quite insensitive to motor axon loss (and hence less useful for localizing) and are normalized by reinnervation, they are extremely useful for determining the pathophysiology and severity of the lesion. We perform the needle EMG last to further localize the lesion (especially its proximal extent), to determine its rate of progression (dictated by the relationship between the acute and chronic motor axon loss), and to confirm the information gleaned from the sensory and motor NCS. In addition, it can determine lesion continuity when there is no muscle movement clinically. The conclusions from all three components of the EDX study should be concordant with each other; otherwise an error or misinterpretation has occurred. Similarly, the final EDX impression should be in concordance with the clinical impression; otherwise one of these two impressions is inaccurate (typically the clinical impression).

Because each brachial plexus element is composed of nerve fibers derived from different spinal cord segments, elemental lesions of the brachial plexus have unique (and occasionally pathognomonic) EDX findings, the recognition of which permits localization. The muscles innervated by a given spinal cord segment or nerve root are referred to as a *myotome* to reflect the segmental nature of the spinal cord. As these motor fibers progress distally, this segmental nature is lost and the suffix *-tome* is inappropriate. We prefer to use the term *muscle domain* to refer to the muscles innervated by a given PNS element. Through anatomic reasoning, the muscle domain of any brachial plexus element is easily derived from the standard myotomal charts [42–48]. The muscle domains of the brachial plexus elements are provided in Table 46.1. The CMAP and SNAP domains of each brachial plexus element, which are determined by the motor and sensory fibers contained within that element and whether they are assessable by NCS, are also calculable [3, 26, 48]. The CMAP domains of the brachial plexus elements are provided in Table 46.2. Because the sensory fibers assessed by the different sensory NCS do not derive from the same DRG, the brachial plexus elements assessed by each sensory NCS vary with the particular sensory NCS. The SNAP domains of the brachial plexus elements are provided in Table 46.3. Based

Table 46.1 The muscle domains of the brachial plexus

Upper plexus	Middle plexus	Lower plexus
Supraspinatus	Pronator teres	Abductor pollicis brevis
Infraspinatus	Flexor carpi radialis	Flexor pollicis longus
Biceps	Triceps	Pronator quadratus
Deltoid	Anconeus	Extensor indicis proprius
Teres minor	Extensor carpi radialis	Extensor pollicis brevis
Triceps	Extensor digitorum communis	Extensor carpi ulnaris
Pronator teres	Serratus anterior	First dorsal interosseous
Flexor carpi radialis		Abductor digiti minimi
Brachioradialis		Adductor pollicis
Extensor carpi radialis		Flexor digitorum profundus – 4, 5
Brachialis		Flexor carpi ulnaris
Levator scapulae		
Rhomboids		
Serratus anterior		
Lateral cord	**Posterior cord**	**Medial cord**
Biceps	Latissimus dorsi	Abductor pollicis brevis
Brachialis	Deltoid	Opponens pollicis
Pronator teres	Teres minor	Flexor pollicis longus
Flexor carpi radialis	Triceps	First dorsal interosseous
	Anconeus	Adductor pollicis
	Brachioradialis	Abductor digiti minimi
	Extensor carpi radialis	Flexor carpi ulnaris
	Extensor digitorum communis	Flexor digitorum profundus – 3, 4
	Extensor pollicis brevis	
	Extensor carpi ulnaris	
	Extensor indicis proprius	

Only those muscles easily assessed by needle EMG are shown

The percentages shown in parentheses represent the frequency with which the sensory nerve fibers subserving the listed sensory NCS traverse the different trunk and cord elements

on these SNAP domains, the brachial plexus elements assessed by each sensory NCS, and hence, the pathways traversed through the brachial plexus can be depicted.

Sensory Fiber Pathways

In 1995, a study of focal supraclavicular brachial plexus lesions and their effect on the standard upper extremity sensory NCS defined the DRG from which the sensory fibers for each sensory NCS are derived [26]. This information defined the brachial plexus pathways that these sensory fibers travel when traversing the brachial plexus and, consequently, the brachial plexus elements assessed by each of the sensory NCS (Table 46.4):

- The sensory fibers composing the LABC nerve derive from the C6 DRG [26], and therefore, the PNS elements assessed by the LABC sensory NCS include the LABC nerve, musculocutaneous nerve, lateral cord,

upper trunk, and the C6 APR, spinal nerve, and DRG (Fig. 46.5).

- The median sensory fibers innervating the thumb derive from the C6 DRG [26]. Consequently, the median sensory NCS, recording thumb (Med-thumb), assesses the median nerve, lateral cord, upper trunk, and the C6 APR, spinal nerve, and DRG (Fig. 46.6).
- The median sensory fibers innervating the index finger derive from the C6 and C7 DRG approximately 20 and 80 % of the time, respectively [26]. Thus, the median sensory NCS, recording index finger (Med-index), assesses the median nerve and lateral cord 100 % of the time; the upper trunk and the C6 APR, spinal nerve, and DRG 20 % of the time; and the middle trunk and the C7 APR, spinal nerve, and DRG 80 % of the time (insert Fig. 46.7).
- The median sensory fibers innervating the middle finger derive from the C6, C7, and C8 DRG approximately 10, 70, and 20 %, respectively [26]. Thus, the median sensory NCS, recording middle finger (Med-middle), assesses the median nerve 100 % of the time; the lateral cord and the C6 APR, spinal nerve, and DRG 10 % of the time; the lateral cord and the C7 APR, spinal nerve, and DRG 70 % of the time; and the medial cord and the C8 APR, spinal nerve, and DRG 20 % of the time (Fig. 46.8). Of the sensory NCS performed in the assessment of brachial plexus lesions, because of this wide distribution, this is the least sensitive and specific sensory NCS.
- The sensory fibers composing the superficial radial nerve derive from the C6 and C7 DRG approximately 60 and 40 % of the time, respectively [26]. Thus, the PNS elements assessed by this sensory NCS include the superficial radial nerve, radial nerve, and posterior cord

Table 46.4 The brachial plexus elements assessed by various sensory NCS

LABC: LABC nerve, lateral cord, C6 fibers of upper plexus
Med-thumb: median nerve, lateral cord, C6 fibers of upper plexus
Med-index: median nerve, lateral cord, C6 fibers of upper plexus (20 %), C7 elements of middle plexus (80 %)
Med-middle finger: median nerve, lateral cord, C6 fibers of upper plexus (10 %), C7 elements of upper plexus (70 %), C8 elements of upper plexus (20 %)
Superficial radial: superficial radial nerve, radial nerve, posterior cord, C6 elements of upper plexus (60 %), C7 fibers of middle plexus (40 %)
Ulnar-little finger: ulnar nerve, medial cord, C8 fibers of lower plexus
MABC: MABC nerve, medial cord, T1 fibers of lower plexus

100 % of the time; the upper trunk and the C6 APR, spinal nerve, and DRG 60 % of the time; and the middle trunk and the C7 APR, spinal nerve, and DRG 40 % of the time (Fig. 46.9).

- The sensory fibers composing the ulnar nerve derive from the C8 DRG [26, 49, 50], and consequently, the PNS elements assessed by the ulnar sensory NCS, recording little finger (Ulnar-D5) include the ulnar nerve, medial cord, lower trunk, and the C8 APR, spinal nerve, and DRG (Fig. 46.10).
- The sensory fibers composing the medial antebrachial cutaneous (MABC) nerve derive from the T1 DRG [4, 12, 26, 49–51], and hence, the PNS elements assessed by the MABC sensory NCS include the MABC nerve, medial cord, lower trunk, and the T1 APR, spinal nerve, and DRG (Fig. 46.11).

NCS Assessment of Brachial Plexus Regions

Upper Plexus

The upper plexus contains motor and sensory nerve fibers from C5 and C6. Table 46.5 lists the EDX studies useful in its assessment (Table 46.5). On sensory NCS, the LABC and Med-thumb sensory NCS assess its C6 fibers and, when abnormal, tend to affected to equal degrees [26]. At least one of these studies may need to be performed contralaterally to avoid missing a relative abnormality (i.e., side-to-side differences exceeding 50 %). The superficial radial and Med-index sensory NCS also assess the C6 fibers of the upper plexus but less frequently (60 and 20 %, respectively) [26]. There are no reliable sensory NCS to assess its C5 sensory fibers. On motor NCS, the musculocutaneous study, recording biceps (MC-biceps), and the axillary study, recording deltoid (AX-deltoid), assess all of the upper plexus elements (i.e., upper trunk and C5 and C6 roots). These studies are performed contralaterally whenever the sensory NCS localize the lesion to the upper plexus or whenever the motor response amplitudes are abnormal or near the lower limit of normal. On needle EMG, shoulder girdle and upper extremity muscles belonging to the C5 and C6 myotomes are helpful (see Table 46.1).

Middle Plexus

The middle plexus contains motor and sensory nerve fibers derived from C7. Table 46.5 lists the EDX studies useful in its assessment. On sensory NCS, the Med-index, Med-middle, and radial NCS are useful 80, 70, and 40 % of the time [26]. Again, contralateral studies help identify relative abnormalities. On motor NCS, the radial study, recording extensor digitorum communis (Radial-EDC), which assesses the upper, middle, and lower plexus, is performed bilaterally. Although there is no motor NCS that solely assesses the middle plexus, this motor NCS limitation usually is not a problem because isolated middle plexus lesions are rare [11, 22, 26]. Needle EMG of selected muscles is more specific in the EDX assessment of this element (see Table 46.1).

Lower Plexus

The lower plexus contains motor and sensory nerve fibers from C8 and T1. Table 46.5 lists the EDX studies useful in its assessment. On sensory NCS, the ulnar, recording little finger (Ulnar-little), and MABC studies are available for its assessment. For localization within the lower plexus, both usually are required. Both typically are affected by lower trunk lesions, whereas their involvement is more discordant with lower plexopathies located proximal to the lower trunk

Table 46.5 The electrodiagnostic assessment of the supraclavicular plexus

Radial (extensor indicis proprius)	
Median (abductor pollicis brevis)	

[a]The full muscle domain of each supraclavicular plexus region is not shown; only those muscles considered most helpful by the author are included. Other helpful upper plexus muscles include the serratus anterior, rhomboids, teres minor, brachialis, flexor carpi radialis, and, to a lesser degree, the pectoralis major and levator scapulae muscles. Other helpful middle plexus muscles include the extensor digitorum communis, extensor carpi ulnaris, and extensor carpi radialis. Other helpful lower plexus muscles include the extensor carpi ulnaris, extensor digitorum communis, pronator quadratus, and pectoralis minor

(i.e., those restricted to or predominantly involving the C8 or T1 root). On motor NCS, the ulnar, recording abductor digiti minimi (Ulnar-ADM); the ulnar, recording first dorsal interosseous (Ulnar-FDI); and the median, recording abductor pollicis brevis (Median-APB), assess the lower plexus. The radial nerve study, recording extensor indicis proprius (Radial-EIP), is useful for assessing the C8 fibers of the lower plexus. These four motor NCS assess the pre-trunk fibers of the lower plexus differentially – the Radial-EIP study assesses the C8 root, the Ulnar-ADM and Ulnar-FDI studies assess the C8 root to a greater extent than the T1 root, and the Median-APB study assesses the T1 root to a greater extent than the C8 root [26, 49, 50]. On needle EMG, C8,T1-median, C8,T1-ulnar, and C8-radial muscles are useful.

Lateral Cord

The lateral cord contains motor (C5–C7) and sensory (C6–C7) fibers. Its EDX assessment is provided (Table 46.6). On sensory NCS, it is assessed by the LABC, Med-thumb, Med-index, and Med-middle sensory NCS. Most lateral cord lesions affect the LABC, Med-thumb, and Med-index responses to similar degrees, and 80 % of these lesions also affect the Med-middle sensory response, typically to a lesser degree. This pattern helps to differentiate lateral cord lesions from upper trunk lesions, which only affect all four of these studies 2 % of the time and tend to affect the LABC and Med-thumb uniformly and to a greater extent than the Med-index and Med-middle responses [26]. On motor NCS, the MC-biceps response may be affected, but the AX-deltoid is spared. Any needle EMG abnormalities are restricted to musculocutaneous and C6,7-median nerve-innervated muscles. Unlike with upper plexus lesions, the C5,6-axillary, C5,6-radial, suprascapular, long thoracic, and dorsal scapular nerve-innervated muscles are spared.

Posterior Cord

The posterior cord contains motor (C5–C8) and sensory (C5–C7) fibers. Its EDX assessment is provided (see Table 46.6). On sensory NCS, the superficial radial NCS assesses it. On motor NCS, the AX-deltoid and the radial motor responses (recording EIP and EDC, respectively) are useful in its assessment. On needle EMG, axillary, radial, and thoracodorsal nerve-innervated muscles are helpful. Unlike lesions of the middle plexus, posterior cord lesions do not affect the Med-index or Med-middle sensory responses or C6,7-median nerve-innervated muscles.

Medial Cord

The medial cord contains motor (C8–T1) and sensory (C8–T1) fibers. Its EDX assessment is provided (see Table 46.6). On sensory NCS, it is assessed by the Ulnar-little and MABC NCS. The dorsal ulnar cutaneous (DUC) sensory NCS also assesses this element but usually is not required. On motor NCS, the Ulnar-ADM and Median-APB motor NCS are helpful. On needle EMG, C8,T1-median and ulnar nerve-innervated muscles may be affected, but C8-radial nerve-innervated muscles (EIP, extensor pollicis brevis (EPB)) are spared.

The percentages shown in parentheses represent the frequency with which the sensory nerve fibers subserving the listed sensory NCS traverse the various cord elements

Terminal Nerves

Reliable NCS are available to assess the five terminal nerves of the brachial plexus, and most of the muscles innervated by these nerves are easily assessed by needle EMG. It is not possible by clinical or EDX means to differentiate a terminal nerve lesion of the brachial plexus (distal axilla) from a proximal peripheral nerve lesion.

A Practical Approach

As stated above, because most brachial plexus disorders are regional, a complete EDX assessment of the brachial plexus typically is not required. In general, we begin with the sensory NCS and perform a *general* survey – superficial radial, Med-index, and Ulnar-little sensory NCS – on all patients referred for EDX assessment of the upper extremity. Subsequent studies are dictated by the general survey findings (and the clinical diagnoses under consideration). If the superficial radial or Med-index response is abnormal, we add the LABC and Med-thumb NCS, whereas if the Ulnar-little response is abnormal, we add the MABC NCS. After the screening and added sensory NCS are performed, the lesion usually can be localized. From a clinical perspective and because our general survey does not assess the upper plexus well, we usually add the LABC and Med-thumb studies whenever a patient is referred with sensory or motor dysfunction in a C5 or C6 distribution. Likewise, we often add the MABC whenever a patient is referred with sensory or motor dysfunction in a C8 or T1 distribution.

The motor NCS are then performed to assess the underlying pathophysiology and severity, as well as to confirm the localization indicated by the sensory NCS. The motor NCS survey includes Ulnar-ADM and Median-APB studies. It is expanded based on the sensory and motor NCS findings. The needle EMG follows the NCS and is useful for further characterizing the lesion, including its chronicity and rate of progression, as well as defining its proximal extent and confirming the impression of the NCS. With intraspinal canal lesions, the preganglionic sensory and motor root fibers may be affected. Because the NCS assess the nerve fibers under study from the nerve segments located below the more distal surface recording electrodes to their cell bodies of origin, the motor NCS and needle EMG assess the intraspinal canal portions of the motor fibers, whereas the sensory NCS do not. (An exception to this statement occurs when the DRG are located within the intraspinal canal [52].) Thus, whenever there is motor response involvement with sensory response sparing at the same PNS level, there are three possibilities: (1) the lesion is preganglionic, (2) the lesion lies distal to the sensory branch takeoff site (e.g., disorders involving individual motor branches (e.g., distal neuralgic amyotrophy), terminal motor branches (e.g., early Guillain-Barre syndrome), NMJs (e.g., Lambert-Eaton syndrome, myasthenia gravis), and muscle fibers (myopathies)), and (3) when a mixed lesion is studied after motor fiber degeneration has occurred but before sensory fiber degeneration is apparent (e.g., 6–10 days post-injury).

Prognostication

Like that of all PNS lesions, the prognosis of brachial plexopathies primarily reflects the underlying pathophysiology: demyelinating conduction block or axon loss. With demyelinating conduction block, the prognosis is excellent because remyelination typically occurs within 6 weeks. With axon loss, the prognosis usually is dictated by its potential for reinnervation, which reflects three factors: (1) the grade of the injury, (2) the distance between the site of injury and the

denervated muscle fibers, and (3) the completeness of the lesion. The grade of the injury reflects the disruption incurred by the connective tissue elements of the nerve (endoneurium, perineurium, epineurium). When these structures are spared, there is no impediment to proximodistal reinnervation, and since these lesions tend to be milder, there also is no impediment to reinnervation via collateral sprouting. Conversely, with significant connective tissue involvement, proximodistal reinnervation cannot occur because the nerve fibers of the proximal stump cannot advance distally. In order for successful reinnervation via proximodistal reinnervation to occur, the distance between the lesion and the denervated muscle fibers cannot exceed 20–24 in. because axon advancement occurs at a rate of approximately 1 in. per month and muscle fibers only remain in the denervated state for 20–24 months before degenerating. Thus, distances exceeding this range are not amenable to reinnervation via proximodistal reinnervation but, rather, must be reinnervated via collateral sprouting. In order for successful reinnervation to occur via collateral sprouting, the lesion must be incomplete because with complete lesions there are no unaffected intramuscular motor fibers available from which sprouting can occur.

In summary, the best prognosis for motor recovery following axon disruption occurs when (1) the connective tissue structures are spared, (2) the distance between the lesion and the denervated muscle fibers is short, and (3) the lesion is incomplete. These statements also pertain to the sensory fibers except that there is no distance requirement because the sensory end organs do not degenerate. Repeat clinical and EDX assessments are necessary to determine if the lesion is progressing, static, or improving. Clinically, the motor assessment is more reliable in this regard because the sensory examination can improve without concomitant motor improvement (1) when the adjacent sensory nerve fibers extend into the anesthetic area, thereby diminishing its size, and (2) when sensory nerve fiber regeneration occurs without motor nerve fiber regeneration (rare) [15]. In addition, an advancing Tinel sign may reflect advancing sensory nerve fibers without accompanying motor fiber advancement and should not be used to define motor nerve fiber advancement.

Selected Site-Specific Disorders of the Brachial Plexus

Supraclavicular Plexopathies with Regional Predilection

Upper Plexus

The upper plexus is the most commonly affected region of the brachial plexus. Most of these lesions represent closed-traction injury [2, 31]. Specific brachial plexus disorders that have a predilection for the upper plexus include burner syndrome, rucksack paralysis, and classic postoperative paralysis.

Burner Syndrome (Stinger Syndrome)

An upper plexus traction injury may follow the application of sudden force to the shoulder or head when that force causes the shoulder and head to deviate away from each other. When these injuries, which are more common among males involved in contact sports, are associated with transient (minutes to hours) pain or paresthesias, the term *burner* or *stinger* is applied. Among sports-related injuries, these injuries are the most common ones encountered, accounting for 38 % of 190 injuries in one report [53]. Most sports medicine personnel recognize this syndrome and only refer the patient for evaluation when the symptoms persist or when a more severe process is suspected. Typically, the pain is sharp, burning, and of sudden onset and resolves within a few minutes. The pain and paresthesias extend distally into the upper extremity, often to the thumb. Clinically, mild sensorimotor and reflex dysfunction may be noted in an upper plexus distribution. When EDX assessment identifies abnormalities, they typically indicate an axon loss process of mild severity (i.e., a small number of fibrillation potentials present in an upper plexus distribution without NCS abnormalities). Although this constellation of EDX abnormalities could also be observed with a C6 radiculopathy that spares the paraspinal muscles, most sports medicine physicians localize the lesion to the upper plexus, thereby avoiding the debate as to whether the lesion is preganglionic (i.e., a radiculopathy) or postganglionic [31, 54, 55]. As would be expected from these EDX abnormalities, permanent neurologic injury is rare, and most sports medicine physicians allow the patient to return to the sport once the weakness has completely resolved [15]. One long-term follow-up study reported that these patients often later demonstrate pathologic fatigue following vigorous use of the previously affected limb [56].

Rucksack Paralysis

Rucksack paralysis, which is also referred to as *pack palsy* or *cadet palsy*, represents a rare upper plexus lesion that is related to wearing a rucksack or similar device (e.g., backpack, child carrier). It most likely results from nerve fiber compression related to direct pressure from the pack straps where they pass over the shoulders. Patients with rucksack paralysis typically present with painless, unilateral weakness in an upper plexus distribution that followed or started during rucksack usage. A history of transient weakness following rucksack usage may be elicited [2]. Sensory symptoms (e.g., paresthesias) in the same distribution are common. Risk factors include the weight of the load transported, the duration worn, and the device characteristics

(e.g., presence of a metal frame or waist belt) [14]. Individuals with previous local injury or an underlying abnormality (e.g., cervical rib, vertebral anomaly) may be more susceptible [57]. In approximately two-thirds of patients, the lesions are predominantly demyelinating conduction block [2]. For this reason, the sensory NCS are normal, and the abnormalities are noted on motor NCS and needle EMG, which define its severity and localization. With discontinuance of the precipitating activity, rapid recovery is expected and, therefore, treatment is conservative. In the one-third of patients with predominantly or solely axon loss, the outcome varies from no recovery to full recovery [2]. Recurrences are prevented through patient education such as the application of a waist belt to shift the majority of the weight from the shoulder straps to the hips, widening and padding the straps, and frequent rest periods with backpack removal [58].

Classic Postoperative Paralysis

Classic postoperative paralysis, which was first described by Budinger in 1894, is a traction or pressure injury that presents in the immediate postoperative setting [59]. This disorder is related to multiple variables, including patient positioning, loss of muscle tone (from anesthesia), and unconsciousness (blocks weight-shifting ability). Factors believed to predispose to this disorder include the Trendelenburg position, upper extremity abduction exceeding 90°, contralateral deviation and rotation of the head, and use of an arm board restraint in an abducted, extended, and externally rotated position [60]. Patients present with unilateral, painless weakness, with or without associated paresthesias, and the diagnosis is made based on the history and examination features. It typically is restricted to the upper plexus or, when it involves the entire supraclavicular plexus, disproportionately affects the upper plexus. When involved, the middle and lower plexuses recover quicker, ultimately leaving an isolated upper plexopathy [2, 55]. The underlying pathophysiology is the demyelinating conduction block; axon loss infrequently predominates. On EDX testing, when studied prior to remyelination, the sensory NCS are normal, the motor NCS show demyelinating conduction block lesions located between the two stimulation sites (i.e., the axilla and supraclavicular fossa) along the involved upper plexus nerve fibers (e.g., musculocutaneous, recording biceps; radial, recording brachioradialis). The axillary response, recording deltoid, may be reduced or absent, but because this motor NCS can only be recorded with supraclavicular stimulation (i.e., single-site stimulation), the pathophysiology cannot be determined. The lack of muscle atrophy and the unimpressive number of fibrillation potentials are consistent with a predominantly demyelinating process. Treatment is conservative and patients typically recover rapidly and fully [3].

Middle Plexus

The middle plexus is rarely affected in isolation. In one review of 417 brachial plexus lesions, 53 focal supraclavicular plexopathies were noted; of these, only one (surgically verified fibrosis restricted to the middle plexus) was an isolated middle plexus lesion [26]. Thus, most lesions involving the middle plexus are associated with upper plexus or lower plexus involvement, the majority of which are due to closed traction.

Lower Plexus

Among supraclavicular plexopathies, the incidence of lower plexus involvement is less than that of upper plexus involvement [55]. Although the percentage of lower plexus lesions related to closed traction is lower than that observed among upper or middle plexopathies, traction-induced avulsion injuries are more common at the lower plexus level [31]. This susceptibility reflects the lack of connective tissue tethering of the C8 and T1 spinal nerves to the transverse processes of their respective vertebral bodies following their exit from the intervertebral foramina. Because traction injuries tend to disrupt the stretched nerve fibers at their tether points, these fibers are disrupted at their connection to the spinal cord. Several disorders have a predilection for this region of the brachial plexus, including true neurogenic thoracic outlet syndrome, postmedian sternotomy brachial plexopathy, and Pancoast syndrome.

True Neurogenic Thoracic Outlet Syndrome

The thoracic outlet (actually the thoracic inlet) is defined as the body region extending from the supraclavicular fossa to the axilla and includes the area between the clavicle and the first rib (Fig. 46.1). Both neural (the brachial plexus) and vascular (the subclavian and axillary arteries and veins) elements traverse it. The term *thoracic outlet syndrome* (TOS) refers to a heterogeneous group of disorders, all of which have in common compression of one or more of these neurovascular elements at some point within the thoracic outlet. This group is divided into vascular TOS (arterial and venous), neurogenic TOS (true and nonspecific), and neurovascular TOS (traumatic) [61]. Pertinent to this discussion is *true neurogenic TOS*, also referred to as *classic TOS* and the *cervical rib and band syndrome.* This entity has a lower plexus predilection and is a rare disorder with an incidence of approximately one per million persons [51]. It more commonly affects young to middle-aged individuals, especially women, a gender predisposition that may partially be accounted for by the higher incidence of cervical ribs among females [62]. Overall, however, the presence of a cervical rib does not increase the risk for true neurologic TOS significantly. Based on the reported incidences of cervical ribs and true neurogenic TOS, for every 20,000–80,000 individuals with a cervical rib, only one will have true neurogenic TOS [62].

The pathogenesis of true neurogenic TOS was first reported in 1903 by Thomas and Cushing, who described angulation and stretching of the inferior elements of the supraclavicular brachial plexus by a taut fibrous band extending from the first thoracic rib to a bony anomaly at the C7 level, either a small (rudimentary) cervical rib or an elongated transverse process [63]. The site at which the band affects the brachial plexus usually is along the distal portions of the C8 and T1 APR or, less commonly, at the proximal aspect of the lower trunk [64]. In addition, a single case with clinical manifestations similar to those observed in true neurogenic TOS – but without radiologic evidence of either a cervical rib or an elongated transverse process – was reported in a competitive swimmer in whom the lower trunk was compressed by a fibrous band located within a hypertrophied scalene muscle (this even rarer disorder is referred to as scalenus anticus syndrome) [65]. Anatomically, when the lower plexus fibers are angulated and stretched from below, the T1 fibers, which lie inferior to the C8 fibers, are angulated and stretched more profoundly and, consequently, sustain greater injury [51, 64]. This difference in the severity of involvement of the T1 and C8 APR has profound effects on both the clinical and the electrodiagnostic examinations [26, 62]. With rare exception, the motor abnormalities are more pronounced than the sensory ones, and for this reason, most patients present with a chief complaint of hand muscle atrophy, weakness, or progressive loss of dexterity [51]. On motor examination, upper extremity weakness and wasting in a lower trunk distribution are apparent. Because the thenar eminence muscles are innervated primarily by motor nerve fibers derived from the T1 spinal cord segment, they are more affected than the ulnar nerve-innervated hypothenar muscles, which, in turn, show more involvement than the medial forearm muscles. The sensory examination shows abnormalities in the C8 and T1 distributions (typically patchy) that are either more pronounced in the T1 distribution or equally pronounced in these two distributions. In retrospect, most patients acknowledge a long history of intermittent, mild, upper extremity aching pain and paresthesias along the medial aspects of the arm and forearm and, to a lesser degree, the hand. On EDX examination, this same pattern of T1 involvement exceeding C8 is more easily demonstrated and is essentially pathognomonic [3, 26]. The MABC SNAP (often unelicitable) and median CMAP, recording thenar eminence (usually very low in amplitude), are affected to a greater extent than are the ulnar sensory and motor studies because the former two studies primarily assess the T1 fibers of the lower plexus, whereas the latter two studies primarily assess its C8 fibers [26, 49, 50]. On needle EMG, features of a slowly progressive axon loss process are observed. As expected, the latter have a lower plexus distribution and are most prominent in the more heavily T1-innervated thenar eminence muscles. The chronic changes (e.g., increased duration, neurogenic MUAP firing pattern) involve all of the median and ulnar nerve-innervated hand muscles as well as the flexor pollicis longus, ulnar forearm muscles, and, depending on the degree of C8 APR involvement, the C8-radial nerve-innervated muscles (e.g., EIP, EPB). Because of the slowly progressive nature of this disorder, maximal reinnervation via collateral sprouting has already occurred, and consequently, fibrillation potentials are sparse in number and may be restricted to the thenar eminence muscles. Since the fibrous band compressing the brachial plexus is radiolucent, it cannot be reliably visualized by plain films or CT imaging. MRI may identify brachial plexus distortions, but it does not reliably identify the responsible band [66–68]. Although the bony anomalies associated with this condition are reliably identified by plain films of the neck, special views are occasionally required [68]. When the bilateral cervical ribs are identified, the smaller rib is usually on the symptomatic side [69].

Because maximal reinnervation has already occurred, patients are not treated conservatively. Rather, true neurogenic TOS is electively treated by surgical sectioning of the fibrous band. Because the band affects the supraclavicular portion of the brachial plexus elements, a supraclavicular approach is better than a transaxillary one, which is not only too distal but also provides inadequate anatomic visualization. The distal portion of the bony anomaly may also be removed, but the normal first thoracic rib should be left in place, as should the ipsilateral scalene muscles [31, 62, 64]. Following division of the band, the affected nerve fibers are no longer angulated and stretched, and typically, the aching pain and intermittent paresthesias and dysesthesias resolve and the hand weakness and loss of dexterity stop progressing. Because of the limitations of reinnervation (collateral sprouting has already been maximized and reinnervation via proximal-distal advancement is impossible due to the distance between the lesion and the denervated hand muscle fibers), motor improvement of hand function is unexpected. The more proximally located forearm muscles may show some improvement if the disrupted motor nerve fibers can traverse the lesion site, which depends mostly on the degree of connective tissue formation impeding their advancement.

Postmedian Sternotomy Plexopathy

This condition follows operations that require median sternotomy [70], the most frequent of which is coronary artery bypass surgery [71]. The clinical and EDX manifestations of this lower plexopathy indicate that it involves the C8 APR in isolation or disproportionately [3]. Etiologic proposals implicate a lower plexus traction injury that is related to the first thoracic rib. Either chest wall retraction pushes the clavicle into the retroclavicular space, thereby rotating the first thoracic rib into the C8 APR, or chest wall retraction fractures the first rib (the more likely possibility), which, in turn, damages the lower plexus fibers [70, 72, 73]. Because the C8

APR contains sensory fibers destined solely for the ulnar nerve, patients with C8 APR lesions present with paresthesias in an ulnar nerve distribution and, for this reason, mimic a postoperative ulnar neuropathy at the elbow. When the true nature of this disorder goes unrecognized, it may be misattributed to operative malpositioning and inappropriately blamed on the anesthesiologist. In addition, the patient may undergo unnecessary operative intervention of the ulnar nerve at the elbow segment. Because the motor fibers contained within the C8 APR supply the radial and median nerves, in addition to the ulnar nerve, mislocalization usually is avoidable by thorough clinical assessment of the C8-radial (e.g., extensor indicis proprius, extensor pollicis brevis) and C8-median (e.g., flexor pollicis longus) muscles. An incomplete EDX study may also mislocalize the lesion to the ulnar nerve because, on sensory NCS, an absent or low-amplitude Ulnar-little response is essentially always observed. However, low-amplitude Ulnar-D5 responses are also observed with medial cord, lower plexus, and C8 APR lesions. Thus, the MABC sensory NCS should also be performed. It is spared with ulnar and C8 APR lesions. In the setting of medial cord or lower trunk lesions producing a low-amplitude or absent Ulnar-little response, it usually is affected [26, 49, 50]. On motor NCS, isolated ulnar CMAP response abnormalities are commonly needle EMG, which is the most important portion of the EDX assessment for lesion localization, typically demonstrates involvement of C8-radial nerve-innervated muscles (e.g., extensor indicis proprius, extensor pollicis brevis), thereby excluding an ulnar neuropathy and localizing the lesion to, at, or proximal to the lower trunk. Because the median nerve-innervated thenar eminence muscles are more heavily innervated by T1-derived motor fibers, the C8-median nerve-innervated muscles (e.g., flexor pollicis longus) often are spared or affected to a lesser degree than the affected ulnar nerve-innervated muscles. When the needle EMG study is performed early, in addition to fibrillation potentials, discordance between the CMAP size (e.g., normal to near normal) and the MUAP recruitment pattern (neurogenic) indicates a demyelinating conduction block pathophysiology [47, 55]. Even with predominantly axon loss lesions, because the lesion tends to be incomplete, reinnervation via collateral sprouting readily occurs. Consequently, these lesions do not benefit from surgical interventions (e.g., first rib removal) and typically are treated conservatively (unless significant axon loss involves the dominant limb or causalgic pain develops) [3, 31, 55].

Pancoast Syndrome

The direct extension of cancer from the lung apex to the lower plexus and the clinical features associated with such an extension were reported by Pancoast in 1924 [74, 75]. Apical lung cancer, which constitutes 3 % of all lung cancer, frequently involves the lower plexus because only the pleural lining of the lung separates it from the lower plexus. Although Pancoast syndrome most frequently accompanies bronchogenic carcinoma, accounting for its higher incidence among middle-aged to elderly males with heavy smoking histories, it may occur with any disorder of the thoracic inlet, including other tumors (both benign and malignant), tumor recurrences, and infectious and inflammatory disorders [76]. Unlike most lung cancers, apical lung cancers are slow growing, predominantly extrapulmonary, locally aggressive, and radiosensitive and infrequently metastasize. Typically, the initial and most pronounced clinical feature is severe, unrelenting shoulder pain that is characterized as burning or boring and that is worse at night, typically interfering with sleep. It tends to extend into the axilla and along the medial aspect of the arm to the elbow level (T2); less frequently, it also involves the medial aspects of the forearm (T1) and hand (C8). This shoulder pain may reflect pleural, lower plexus, rib, or spinal column involvement. When the superior mediastinum or posterior primary rami become involved, medial scapular pain may also appear [77]. The pain quickly becomes dysesthetic [78]. As expected, the associated weakness and sensory loss are in a lower plexus distribution. Involvement of the T1 root or the inferior cervical sympathetic ganglion leads to Horner syndrome (miosis, facial anhidrosis, and ptosis). Other reported clinical features include supraclavicular fullness, venous distension, upper extremity edema, and bone destruction of the upper thoracic ribs and, less often, the adjacent vertebral bodies [75, 79]. Diagnosis usually is by tissue procurement following imaging studies that often were ordered following EDX studies that localized the lesion to the lower plexus. Many patients with this syndrome will demonstrate fibrillation potentials in the paraspinal muscles (lesion is at or proximal to the posterior primary ramus takeoff site) and abnormal sensory responses (lesion is ganglionic or postganglionic), indicating a two-level lesion. Therapy is directed toward the underlying cause. Narcotics and radiation therapy may be required when the pain is severe [76, 80]. It is important to be familiar with this syndrome because it often is the first manifestation of an underlying neoplasm and early recognition and treatment are associated with a higher cure rate [81].

Other Supraclavicular Plexopathies

Root Avulsions

Root avulsions, which follow high-energy traction (stretch) injury, represent one of the most devastating types of brachial plexus injury because the disrupted nerve fibers are unable to spontaneously regenerate and are not amenable to surgical repair. For these two reasons, they result in irreversible loss of function. Root element susceptibility to this type of injury reflects lack of a connective tissue covering and a

spinal cord anchorage point. Of the five roots comprising the brachial plexus, the upper two are more susceptible to traction-induced extraforaminal rupture, whereas the lower two are more susceptible to traction-induced avulsion. This reflects differences in their sites of proximal anchorage, their angles of exit from the intervertebral foramina, and their lengths. Anatomically, connective tissue securely anchors the C5 and C6 spinal nerves as they pass through a groove in the transverse process located between the intertransversalis muscles; it variably anchors the C7 spinal nerve and typically does not anchor the C8 and T1 spinal nerves. For this reason, traction injuries, which tend to disrupt nerve fibers at their anchorage sites, have a tendency to disrupt the C5 and C6 nerve roots at their transverse process attachment sites (i.e., extraforaminal disruption) and to disrupt the C8 and T1 nerve roots at the spinal cord (i.e., avulsion). Additionally, the oblique angle of the upper cervical roots also favors extraforaminal disruption over avulsion, whereas the short length of the T1 nerve root favors avulsion [22]. Overall, because they are of lesser caliber, have thinner dural sacs, and are more dispersed along the spinal cord, the ventral roots are more easily avulsed than the dorsal ones [82]. Another important variable is the position of the upper extremity at the moment that the traction force occurred. When the upper extremity is alongside the torso, the C5 and C6 roots are most susceptible, whereas the C8 and T1 roots are most susceptible when it is located above the shoulder; the greatest susceptibility for the C7 root occurs when it is parallel to the ground. Thus, it is important to document the position of the head, neck, and arm at the time of the traction injury, if possible. However, in the setting of strong traction forces, all of the roots may be avulsed regardless of limb position, although limb position still contributes to the order of the avulsions. Approximately 15 % of these lesions involve both preganglionic and postganglionic components (i.e., they are two-level processes), especially when the upper two cervical roots are involved [22]. The suprascapular, musculocutaneous, and axillary nerves may also be disrupted at their anchorage sites (the suprascapular or spinoglenoid notch, the coracobrachialis muscle, and the quadrangular space, respectively). In addition to sensory loss or weakness in the distribution of the disrupted nerve root, severe pain (often involving the hand) is common, the incidence of which increases with the number of involved nerve roots [15]. It typically is described as a relatively constant burning or crushing discomfort with superimposed, episodic, much more pronounced, shock-like pain of short duration. Avulsion pain tends to be lessened by warming and worsened by cooling [2, 20, 21, 57, 83]. Other clinical features associated with avulsion injuries include bony injuries (especially transverse process fractures), long tract signs (associated with more severe trauma), severe burning pain, shooting pain in the anesthetic area, the presence of Horner syndrome, scapular winging, and asymmetrical chest wall excursion (the long thoracic and phrenic nerves are formed at the APR level and indicate a more proximal lesion) [3, 57]. Following avulsion of the spinal root from the spinal cord, spontaneous proximodistal axon regeneration cannot occur. Although some surgeons attempt to reinsert the avulsed root fibers back into the spinal cord, the utility of this approach has not been confirmed [21, 84]. Salvage procedures have been performed utilizing neurotization, a technique in which the avulsed brachial plexus element is reattached proximally, but not to its original source. Instead, it is reattached to the proximal stumps of different plexus elements that remain in continuity with the spinal cord or to extraplexal nerves following their intentional transection (e.g., ipsilateral spinal accessory, phrenic, or intercostal nerves). In this manner, a specific function can be restored, typically forearm flexion. A more recent procedure to restore shoulder or forearm flexion function is contralateral C7 nerve root transfer; however, significant donor site morbidity has been described using this method [85]. Although good outcomes have been reported with bypass coaptation of the C3 and C4 APR (distal to their contribution to the phrenic nerve) to the upper and lower trunk of the brachial plexus, this technique requires further assessment before being routinely employed [86]. The Oberlin procedure involves transfer of a nerve fascicle to the flexor carpi ulnaris muscle from the ulnar nerve to the musculocutaneous nerve with reports of elbow flexion strength obtained in nearly 90 % and should be considered in patients who have suffered nerve root avulsion in the upper plexus distribution [87]. Several reconstructive orthopedic procedures are also available (e.g., tendon transfers, shoulder orthodeses). The feasibility of these approaches varies inversely with the number of brachial plexus roots avulsed. Another major issue is the alleviation of the associated root avulsion pain, which is notoriously difficult to accomplish. Analgesic agents, including neuropathic pain medications, seldom provide substantial or sustained relief. Transcutaneous nerve stimulation, sympathectomy, stellate ganglionectomy, amputation of the flail limb, and anterolateral high cordotomy are ineffective. Epidural-placed spinal cord stimulation is being explored as a potential treatment for this pain as well. When C8 and T1 root avulsions coexist with C5–C7 plexus fiber ruptures, repair of the ruptures may diminish the pain. The DREZ operation, which consists of coagulation of the dorsal root entry zones of the avulsed roots, is the most helpful surgical procedure of all but has enough associated risk that some surgeons are reluctant to perform it [15, 84].

Obstetric Brachial Plexopathy

Obstetric brachial plexopathy, which is the most common cause of arm paralysis in the neonatal period, is another supraclavicular plexopathy that follows traction injury. Shoulder dystocia, which is the most common risk factor for obstetric

brachial plexopathy, is defined as anterior shoulder impaction behind the maternal symphysis pubis that requires obstetric maneuvers to affect vaginal delivery. When lateral traction on the head is used to free the shoulder, obstetric brachial plexopathy may result [88, 89]. Its incidence, which appears to be declining, ranges from 0.4 to 4.0 per 1,000 full-term live births [14, 89, 90]. In addition to shoulder dystocia, other reported risk factors include infantile macrosomia (birth weight greater than 4 kg), short mothers, maternal obesity, multiparity, ethnic background, uncommon fetal presentations (e.g., breech, face), second-stage labor exceeding 1 h, low or midforceps delivery, vacuum extraction, passive head rotation with the shoulders fixed, and delivery of a previous infant with this disorder [3]. Of these, shoulder dystocia and infantile macrosomia are the two major risk factors, and consequently, fetal growth restriction and prematurity are protective [3, 91]. In about 50 % of cases, there is no recognizable risk factor [92]. With breech deliveries, there is an increased risk of bilateral involvement and of avulsion injury (usually the C5 and C6 roots, less commonly the C5–C7 roots) [93]. Importantly, because obstetric brachial plexopathy also follows delivery by cesarean section, this disorder cannot simply be attributed to poorly performed deliveries [3, 94]. An *in utero* onset is further supported by the presence of fibrillation potentials and MUAPs with chronic neurogenic changes on EDX studies performed shortly after delivery. Other disorders must also be considered, including congenital root absence, congenital constriction band syndrome, brachial plexus neoplasms, humeral osteomyelitis, neonatal hemangiomatosis, exostoses of the first thoracic rib, congenital varicella, cerebellar disorders, and cervical osteomyelitis with paracervical abscess with unilateral presentations; amyoplasia congenita and cervical spinal atrophy are considerations with bilateral presentations [15].

Five patterns of nerve fiber involvement have been reported: (1) C5–C6, (2) C5–C7, (3) C5–T1 with some finger flexion sparing, (4) C5–T1 with flail arm and Horner syndrome, and (5) C8–T1 [89]. The C5–C6 pattern (*classic Erb's palsy*) is the most common form, comprising about 50 % of these injuries, and generally has the best prognosis. The C5–C7 pattern (*Erb's-plus palsy*, 25–35 %) results in the waiter's tip position (adduction and internal rotation of the arm, extension and pronation of the forearm, and wrist and finger flexion) and has an intermediate prognosis. The C8–T1 pattern (*Klumpke palsy*) is almost never seen [95]. Concomitant postganglionic lesions are more common with C5–C7 fiber involvement (extraforaminal connective tissue anchoring), whereas avulsion is more common with C8–T1 fiber involvement (spinal cord anchoring) [33].

Obstetric plexopathies are diagnosed by the clinical features. The inability of the infant to cooperate with the EDX study limits its utility in determining the extent, pathophysiology, and severity of the underlying lesion. Among the available neuroimaging studies, MRI is considered the modality of choice, especially when modifications specific to the needs of the infant are available (e.g., phased-array surface coils custom built for infants). Despite their initial description in 1764, the management of these lesions is somewhat controversial [96]. Although, there is a tendency for this type of traction injury to be less severe than that observed among adults, the outcome reflects a number of factors, including the degree of connective tissue disruption, the distance between the lesion site and the denervated muscles, the completeness of the lesion, whether the lesion involves both preganglionic and postganglionic elements (i.e., a two-level process), and the presence of avulsion injury. Because of the higher incidence of avulsion injury and the distance between the lesion site and the denervated muscles, the outcome tends to be the worst for those with C8–T1 fiber involvement [3]. Although many reports suggest that spontaneous recovery occurs in over 90 % of patients with obstetric brachial plexopathy, two Swedish studies of patients not undergoing surgical intervention reported significant impairment in later life among 20–25 %, an outcome that has been corroborated by more recent reports [89, 97–101]. Although remyelination may contribute to early recovery in those individuals with a demyelinating component, spontaneous recovery does not follow avulsion injury. Thus, the primary focus is in determining if operative intervention is required and, if so, at what point it should be performed. Because there are no clinical or EDX assessments capable of distinguishing patients destined to have spontaneous recovery from those who will become significantly impaired, most patients undergo an initial period of watchful waiting with interventions to prevent contractures, pressure ulcers, and further traction injury [102]. If antigravity forearm flexion strength has not returned by 6 weeks of age, surgical referral is indicated because some of these neonates will require microsurgical intervention for avulsion and rupture injuries and these are best performed by 3 and 6 months, respectively [90]. Even with less severe injuries, most groups agree that the observation period should not extend beyond 3–6 months, although some groups operate as late as 9 months [33, 90]. Physical rehabilitation – to maintain range of motion, prevent glenohumeral joint deformity as the child grows, and maximize function – is always indicated and is started within the first 7–10 days of life and continued until the injury has recovered [91].

Infraclavicular Plexopathies with Regional Predilections

The regional proclivity of infraclavicular plexopathies is much lower than that of supraclavicular lesions. At the cord level, axillary lymph node irradiation tends to involve the

infraclavicular plexus, especially the lateral cord, whereas the medial cord is more susceptible to injury in the setting of midshaft clavicular fractures [3]. At the terminal nerve level, medial brachial fascial compartment syndrome has a predilection for the median terminal nerve, crutch palsies more frequently involve the radial terminal nerve, procedures in the vicinity of the coracoid process more frequently affect the musculocutaneous terminal nerve (e.g., operative procedures to correct anterior shoulder dislocations), and proximal humerus fractures and glenohumeral dislocations more frequently affect the axillary terminal nerve [3].

Medial Brachial Fascial Compartment Syndrome

The medial brachial fascial compartment syndrome was first described in 1966 by Staal et al. [103]. This compartment, which extends from the clavicle to the elbow, is formed by the medial intermuscular septum following its division into two fascial extensions, both of which extend to the brachial fascia surrounding the arm. It contains the axillary blood vessels and the five terminal nerves of the brachial plexus. The latter exit this compartment in the following order: musculocutaneous, axillary, radial, ulnar, and median. Intracompartmental vascular disruptions (e.g., penetrating injuries from gunshot or stab wounds, cannula insertion during percutaneous axillary arteriography, axillary artery penetration during local anesthetic injection, spontaneous bleeding in the setting of a blood dyscrasia or anticoagulation) produce mass effect (e.g., hematomas, aneurysms, and pseudoaneurysms) and increase the intracompartmental pressure, thereby impeding the nerve fiber microcirculation without causing overt signs of large-vessel occlusion distally. Of the five nerves contained within this compartment, the median nerve characteristically is the first to be affected, the most severely affected, and the most frequently affected in isolation. The ulnar or radial nerve rarely is affected in isolation [104, 105]. Concomitant involvement of the median and ulnar nerves represents the most common two-nerve combination [105]. The radial, axillary, and musculocutaneous are the least frequently affected nerves. It may be that the nerves nearest the lesion (e.g., the hematoma) are exposed to the greatest pressure and manifest the most impaired microcirculation [106]. For example, with axillary arteriogram-related medial brachial fascial compartment syndrome, because the median and ulnar nerves lie near the axillary artery at its point of cannulation, the local formation of a hematoma may account for the higher incidence of involvement of these two nerves. Another possibility is that because they are the last two nerves to exit the compartment, longer lengths of nerve are affected. Clinically, pain and paresthesias develop in the distribution of the affected nerves, followed by weakness in the same or a more widespread distribution. Without prompt recognition and surgical decompression, the likelihood of recovery is poor. In one study, complete recovery was 8.3 times more likely when surgical intervention occurred within 4 h of symptom onset [107]. Thus, it is imperative to recognize this disorder early. In the setting of obvious trauma, recognition usually is straightforward. However, in the setting of iatrogenic injury, symptom-free intervals of up to 2 weeks have been described, making misdiagnosis or delayed diagnosis much more common [2, 55, 104, 105]. EDX testing has no role in the early diagnosis of these patients.

Selected Site-Nonspecific Disorders of the Brachial Plexus

Neuralgic Amyotrophy (Parsonage-Turner Syndrome)

Among the many titles applied to this disorder, *neuralgic amyotrophy* best conveys its two most important clinical features: severe pain and muscle wasting. Neuralgic amyotrophy is a multifocal, inflammatory disorder of the PNS that most commonly involves the forequarter region of the body and that is believed to be immune-mediated. It affects individuals of any age but is uncommon during the first decade of life and is somewhat more common among males. In one series of 281 patients, the average age was 41.4 years, approximately 70 % of patients were male, and 80 % presented unilaterally (the dominant limb was involved 60 % of the time) [108]. Neuralgic amyotrophy has a predilection for purely or predominantly motor nerves. For this reason, the long thoracic, suprascapular, axillary, and musculocutaneous nerves are most susceptible proximally, whereas, more distally, the anterior and posterior interosseous nerves and motor nerve branches innervating individual muscles (e.g., the motor branch to the pronator teres) are most susceptible [108, 109]. Less commonly, extraplexal motor nerves are involved, including the spinal accessory, phrenic, and recurrent laryngeal nerves, as well as other forequarter nerves composed predominantly of motor nerve fibers. The major upper extremity nerves – radial, median, and ulnar – are involved less frequently due to their mixed (sensory and motor) composition. Pure sensory nerves are rarely involved. Among the latter, the LABC nerve has the highest incidence of involvement [108, 109]. When the LABC nerve is significantly involved (very low amplitude or absent response) without clinical or EDX evidence of motor fiber involvement (normal brachialis and biceps on needle EMG), it is likely involved distal to its takeoff from the musculocutaneous nerve. In our series of 703 individual lesions, only 18 involved a pure sensory nerve: 15 LABC, 1 MABC, 1 superficial radial, and 1 median digital branch [108]. It is most often unilateral in distribution; when bilateral, it may involve the two sides sequentially (more common) or simultaneously and may be symmetric or asymmetric. Although

most affected individuals only have a single bout, patients are infrequently encountered who have had multiple bouts. When it recurs in a previously affected limb, it may involve the same or different nerves [2, 15]. The pathophysiology of these lesions usually is axon loss but, on occasion, patients are encountered who recover so quickly (e.g., several days) that the underlying pathophysiology must have been predominantly demyelinating conduction block. Clinically, most patients present with excruciating, sudden-onset, shoulder pain that commonly has a nocturnal onset and either awakens the patient or is present immediately upon awakening (*neuralgic*). The shoulder pain usually reaches its maximum intensity quickly and most commonly is located laterally. Pain may also be noted over the involved nerve – lateral shoulder pain with axillary nerve involvement, posterior scapular region pain with suprascapular nerve involvement, superolateral thoracic pain with long thoracic nerve involvement, antecubital fossa pain with anterior interosseous nerve involvement, and lateral arm or forearm pain with musculocutaneous nerve involvement. The pain typically resolves within a few weeks or is replaced by dull aching pain. Paresthesias may also be present, but numbness is less common. As the pain abates and the patient is able to move the affected limb, weakness and obvious atrophy become apparent (*amyotrophy*). Approximately 75 % of affected individuals report an antecedent event (trigger), such as a recent flu-like illness, medical illness, invasive medical or dental procedure, unaccustomed exertion, recent trauma, vaccination, and childbirth [110]. In one study of 268 bouts of neuralgic amyotrophy, a trigger preceded 196 (73 %): operative or medical procedure (57), recent illness (48), excessive or unaccustomed activity (34), closed trauma (19), childbirth (13), dental procedure (11), vaccination (10), and open trauma (4) [110]. There typically is a delay between the trigger occurrence and the onset of pain. The time interval ranges from a few hours to 30 days, but most commonly does not exceed 7 days. In one study of 268 bouts of neuralgic amyotrophy, the time interval between the identified trigger and the onset of pain ranged from 1 to 28 days but within over two-thirds of patients occurs within 1 week [110]. There also typically is a delay between the onset of the shoulder pain and the recognition of the atrophic weakness. This time interval likely reflects lack of awareness related to limitations imposed by the pain (most patients splint the upper extremity against the chest). About 50 % of patients have only a single nerve involved (i.e., a *mononeuropathy*) and 50 % have involvement of two or more nerves [108]. When patients present with involvement of only a single nerve, neuralgic amyotrophy may not be considered and the diagnosis missed. When patients present with involvement more than one of the proximal nerves listed above, the lesion may be mislocalized to the upper plexus. Imaging studies frequently are utilized to exclude other possibilities (e.g., rotator cuff test, acromioclavicular joint separation), especially initially when the pain limits accurate examination or in the setting of a mononeuropathy. EDX studies reliably establish the distribution of the muscle involvement, often identifying abnormalities not clinically apparent, including contralateral ones. When more than one nerve is involved, EDX assessments typically identify the lesion as a multiple mononeuropathy rather than a focal brachial plexopathy. In one series of 703 lesions, only four were localized to the brachial plexus [108]. Accurate diagnosis helps protect the patient from unnecessary surgical procedures (e.g., cervical spinal column surgery, rotator cuff repair, nerve release). For example, when a patient with neuralgic amyotrophy presents with severe posterior shoulder pain related to a suprascapular mononeuropathy and the consulting physician, unfamiliar with this presentation of neuralgic amyotrophy, diagnoses the patient with suprascapular nerve entrapment, the patient may undergo an unnecessary release procedure. This scenario may account for the reason that the suprascapular nerve is the most commonly affected nerve overall but is second to the long thoracic nerve when only mononeuropathies are tabulated [108]. In addition, recognition and accurate diagnosis prevent unjustified medical malpractice claims. Unfortunately, a large majority of these claims are filed against physicians who may be unaware of this entity (e.g., anesthesiologists, surgeons).

Treatment consists of analgesics (including narcotics), often with a short course of corticosteroids, for the initial severe pain while awaiting more chronic neuropathic pain medications (e.g., tricyclic and antiepileptic agents) to take effect. Like other PNS lesions associated with significant muscle weakness, strengthening and stretching exercises are indicated. Tsairis et al. reported recovery rates of 36 % by 1 year, 75 % by 2 years, and 89 % by 3 years [111]. However, because of the multifocal nature of this disorder, we have found it more reliable to prognosticate the lesions individually using completeness of the lesion and the distance between the lesion and the denervated muscle fibers as guidelines. Unlike sporadic neuralgic amyotrophy, the hereditary form has a younger onset age, typically recurs, and is associated with dysmorphic features (e.g., hypotelorism, syndactyly, high-arched palate) and septin 9 gene mutations [3, 112–118].

Neoplastic Brachial Plexopathies

Although cancer is a leading cause of death in the USA, neoplastic plexopathies are uncommon, occurring in only 1 % of cancer patients [76]. Of the four primary PNS plexuses, they most commonly involve the brachial plexus and account for 15 % of all brachial plexus lesions [80]. In 1969, Harkin and

Reed pathologically detailed and classified peripheral nerve tumors, and in 2000, the World Health Organization classified peripheral nerve tumors into four groups: (1) neurofibromas, (2) schwannomas, (3) perineuriomas, and (4) malignant neural sheath tumors (NSTs); the latter are also referred to as neurogenic sarcomas [119, 120]. Neurofibromas are further divided into discrete and plexiform (involvement of multiple nerve fascicles) types. Another approach divides these tumors into four groups based on their cell of origin and malignancy status: (1) benign NSTs, (2) malignant NSTs, (3) benign non-NSTs, and (4) malignant non-NSTs (i.e., all malignant tumors of extraplexal origin that invade the plexus by either direct extension or metastasis). Perhaps the simplest approach, and the one used in this chapter, divides these tumors based on whether they originate from the plexus itself (primary) or from outside of it (secondary invasion via metastasis or direct extension) and on their malignancy status (benign versus malignant), resulting in four categories: primary and secondary neoplastic plexopathies that are then further divided into benign and malignant categories. Because the clinical management of patients with sporadic neurofibromas differs from those with neurofibromatosis type 1 (NF1), these two types must be considered separately. Neoplastic processes may also affect plexus fibers indirectly, such as by compression, infection (e.g., related to immunosuppression), or ischemia (e.g., leukemic infiltration) [80]. Accurate diagnosis is important because when neoplastic plexopathies are misattributed to orthopedic or other neuromuscular disorders, diagnostic delays result that adversely affect outcome and quality of life. Because of the wide diversity of neoplastic plexopathies, treatment plans must be individualized based on etiology, location, tumor aggressivity, sensitivity to radiation therapy and chemotherapy, degree of involvement of adjacent structures, and general health and wishes of the patient, as well as the treatment goals (e.g., cure, restoration of function, symptom relief, palliation, cosmetic improvement). In general, most nonmetastatic lesions are treated surgically. With benign lesions, intralesional incisions (visible tumor remains) or marginal excisions (includes surrounding capsule or reactive zone) are usually applied, whereas malignant lesions usually require wide resection with a cuff of normal tissue or radical resection (removal of entire anatomical compartment). Chemotherapy and radiation therapy serve adjunctive roles.

Primary Neoplastic Brachial Plexopathies

Most primary neoplastic plexopathies derive from the nerve sheath (nerve sheath tumors, NSTs), with benign lesions outnumbering malignant ones [121–123]. Most benign NSTs are solitary paraneural schwannomas or intraneural neurofibromas that involve the proximal aspects of the upper or middle plexus. Solitary schwannomas are slow-growing, encapsulated tumors that have a peak incidence in the fourth and fifth decades and that more commonly involve the upper plexus. Although schwannomas are more frequent among women, when they involve the brachial plexus, their sex distribution is more uniform [20, 121, 123, 124]. When they grow through the neural foramen and expand at both ends, they are dumbbell-shaped [119]. Rarely, schwannomas are multiple, undergo malignant transformation, or occur in NF1 patients [125]. Among non-NF1 patients, neurofibromas usually are sporadic, solitary, nonencapsulated tumors that originate from the neural sheath, are more common on the right, are more common among females, have a low risk of malignant degeneration, and involve the supraclavicular plexus nearly twice as often as the infraclavicular one (most frequently the upper and middle plexuses) [20, 121–123]. The incidence of neurofibromas is higher among the NF1 population because defective neurofibromin (a protein product with a role in tumor suppression) predisposes to neurofibroma formation [126, 127]. Among NF1 patients, neurofibromas more frequently are multiple and plexiform, do not have a regional plexus predilection, have a higher risk of malignant degeneration (5–10 %), and more frequently recur following excision [31, 33]. Only 10 % of patients presenting with solitary neurofibromas have NF1 [128]. Benign non-NSTs include desmoids tumors, lipomas, hamartomas, ganglioneuromas, myoblastomas, lymphangiomas, myositis ossificans, osteochondromas, and vascular tumors (e.g., venous angiomas, hemangiopericytomas, glomus tumors, hemangioblastomas) [76]. Most patients with benign NSTs present with painless palpable masses that overlie the course of a nerve, often with associated paresthesias, that occur spontaneously or are precipitated by movement or percussion (i.e., Tinel sign). Their mobility tends to be greater laterally than longitudinally. Associated sensorimotor deficits are more common with neurofibromas (intraneural) than with schwannomas (paraneural). Unlike non-NF1 patients, the neurofibromas associated with NF1 are larger, are more frequently multiple, do not show a gender bias, are noted roughly two decades earlier, involve the brachial plexus more diffusely, have a much higher rate of malignant degeneration (15 %), and are more frequently plexiform [20, 122, 123]. Plexiform neurofibromas, which may produce overlying soft tissue hypertrophy or skin hyperpigmentation, are virtually pathognomonic for NF1, are seen in up to 44 % of NF1 patients, and are locally invasive because they lack a capsule and thus are able to grow along tissue planes [80]. NF1 patients may also demonstrate café au lait spots, axillary or inguinal freckling, or Lisch nodules (iris hamartomas) on general examination. Bony dysplasia and optic gliomas are other features associated with NF1. The evaluation of patients with plexus region masses is discussed below. The treatment of benign NSTs usually is conservative when there is no associated neurological dysfunction, pain, disfigurement, or suspicion of malignancy. Surgical excision generally is

employed in the presence of one of these features. Schwannomas typically are excised without neurologic deficit or recurrence because they are well encapsulated and do not arise from the fascicle. With neurofibromas, intraoperative EDX studies are useful to identify the nonfunctioning fascicles so that they can be excised with the parent fascicle (always nonfunctioning) and tumor. Although neurologic deficits are uncommon following excision, the risk is greater for NF1 patients than for non-NF1 patients [121, 122]. The likelihood of incomplete resection and postoperative deficits is increased with plexiform fibromas because of their poor delineation, increased vascularity, and infiltrative nature [122, 129, 130]. Nerve grafting may be required when nerve function cannot be preserved. When symptoms of sarcomatous transformation (new deficits, localized swelling, intractable pain) develop in patients with long-standing or plexiform neurofibromas, immediate MRI is required to look for evidence of malignant transformation (e.g., inhomogeneous intratumoral enhancement) [127]. Palliative treatment is indicated for regionalized neurofibromatosis (a condition in which hundreds of smaller neurofibromas are present above and below the parent tumor and, occasionally, along other nerves of the limb) [129]. With benign non-NSTs growing extrinsic to their parent fascicles without epineurial adherence (e.g., intraneural lipomas), epineurotomy and excision usually can be performed without further neurologic deficit [131]. Malignant NSTs, which account for 10 % of sarcomas, are rare (incidence of 0.001 %, approaches 5 % among NF1 patients), do not demonstrate a gender bias, and originate from Schwann cells (especially at the myelination transition zone where oligodendrocytes and Schwann cells abut) or from pluripotent neural crest cells [132–134]. Most arise de novo or through the malignant transformation of a plexiform neurofibroma, less commonly from an intraneural neurofibroma, and rarely from a schwannoma [119, 135, 136]. They spread via direct extension or blood-borne metastasis [76]. Because half of these tumors occur among NF1 patients, NF1 is the greatest risk factor for their development. Overall, NF1 patients have a 2–10 % cumulative lifetime risk. Moreover, NF1 patients tend to present one to two decades earlier and have a 10–15-year life expectancy reduction [135, 137, 138]. The second greatest risk factor for malignant NST occurrence is previous radiation therapy (about 11 % of cases), which demonstrates a latency period of 4–41 years (average, 15 years) [139, 140]. Malignant NSTs are much more aggressive, and patients usually present with painful, rapidly growing masses and progressive neurologic deficits. Early and aggressive treatment with wide tumor margins or amputation yields improved disease-free survival [141]. Resectability is primarily a function of location and ranges from around 20 % (for paraspinal tumors) to about 95 % (for extremity tumors). Neural sacrifice usually is unavoidable, and unfortunately, nerve grafting usually cannot be performed due to the length of nerve resected and the adverse effects of radiation therapy on graft tissue [142]. Tumor diameter below 5 cm, gross total tumor resection, and younger age are favorable prognosticators [134]. More proximally located tumors are more likely to infiltrate the spinal cord or brainstem.

Secondary Neoplastic Brachial Plexopathies

Secondary plexopathies, which far outnumber primary ones, are due to plexus invasion from an extraplexal source, such as a metastatic lesion, an adjacent primary cancer (e.g., apical lung cancer), or contiguous lymph node metastases (e.g., breast or cervical cancer). Neoplastic plexopathies also follow invasion from hematogenous (e.g., hematologic malignancies), CSF (e.g., melanoma, breast and lung cancer, hematologic malignancies), or lymphatic dissemination. Much rarer causes include intraneural metastases (reported with carcinoid and hematologic malignancies), direct perineural spread, or via a paraneoplastic phenomenon [76, 143]. The actual incidence of metastatic plexopathies is likely an underestimate because (1) neoplastic plexus involvement may go unrecognized and (2) plexus assessments may not be performed when the results would not affect clinical management, when the patient is too ill, or when the patient refuses further evaluation. Breast and lung cancer, lymphoma, and melanoma account for most metastatic plexopathies [144]. Other sources include sarcoma, thyroid, testicular, bladder, gastrointestinal, and head and neck cancer [121, 145, 146]. Of these, breast carcinoma is the most common and typically invades the plexus from adjacent lymph node metastases [121, 129]. For this reason, most metastatic plexopathies involve middle-aged to elderly females. Unlike primary neoplastic plexopathies, there is no regional predisposition with metastatic involvement [144]. Exceptions to this statement include head and neck cancer, especially squamous and basal cell carcinoma, which tends to infiltrate the upper plexus from above; breast cancer, which favors the infraclavicular plexus when it metastasizes to the lateral group of axillary lymph nodes; and apical lung cancer, which tends to infiltrate the lower plexus [80]. Apical lung cancer, through direct invasion, is the most common nonmetastatic malignancy to involve the brachial plexus [147]. Other common sources include esophageal, gastrointestinal, thyroid, testicular, bladder, pancreatic, sarcoma, rhabdomyosarcoma, and head and neck cancer [121, 123, 145]. In addition to metastatic plexopathy, other considerations include radiation plexopathy (in those who received radiation therapy), neoplastic advancement (e.g., neoplastic meningitis, epidural extension), iatrogenic trauma (e.g., from surgical intervention or anesthetic administration), orthopedic conditions (e.g., rotator cuff tear), and conditions related to treatment (e.g., subclavian artery occlusion, effects of chemotherapy) [76]. Among patients with metastatic

plexopathies, pain usually overshadows the other clinical features. Typically, it is progressively severe and unrelenting, involves the shoulder and axillary regions, interferes with sleep, and radiates along the medial aspects of the ipsilateral upper extremity. Neurologic deficits are frequent, involve the sensory and motor distributions of the plexus elements affected, and progress as the cancer spreads through the plexus [145]. With the possible exceptions of head and neck cancer, lymphoma, and neurotropic skin cancer, most patients with metastatic plexopathies have widely metastatic disease. Typically, they are already known to harbor a malignancy and have already been treated for that malignancy, although in one series, 35 % of patients with metastatic plexopathies presented without a history of known malignancy [148]. Because most metastatic plexopathies are incurable (due to their advanced stage and resistance to chemotherapy and radiation therapy), treatment is palliative. Subtotal resection may be useful for pain relief [129, 149]. External neurolysis and removal of as much tumor as possible may be performed in the setting of metastatic breast carcinoma because it may not invade the nerve beyond the epineurium, whereas with lymphoma and melanoma, tumor removal from epineurial attachments followed by local radiation therapy may be beneficial [129].

Evaluation of Neoplastic Plexopathies

Accurate diagnosis requires coupling of the pertinent clinical features (e.g., personal or family history of NF1 or cancer; constitutional symptoms; NF1 stigmata; pain or tenderness; characteristics of the mass (size, location, and mobility; presence of other masses in the neck, supraclavicular fossa, shoulder, or axilla); neurologic dysfunction; Tinel sign; previous cancer treatments) with ancillary studies. On clinical examination, features of Horner syndrome are sought because of its association with epidural metastasis (risk of spinal cord compression). Sympathetic involvement may also cause the upper extremity to become warm and dry. Imaging studies are the most helpful ancillary studies for assessing these patients. Plain films of the chest, cervical spine, clavicle, scapula, and humerus help in the identification of lung lesions (e.g., superior sulcus tumors), neoplastic bony changes (e.g., intervertebral foraminal enlargement, vertebral erosion), radiation changes, and spinal column instability. Isotope bone scans identify bone metastases. The multiplanar imaging ability, lack of bony degradation, excellent soft tissue contrast, noninvasiveness, and lack of radiation exposure make MRI the imaging modality of choice for defining the location and margins of the lesion, the relationship to adjacent structures, and the presence of lymphadenopathy, all of which are helpful in staging, planning surgical and radiation therapy, and monitoring treatment response. Features of mass effect (e.g., anterior displacement of the anterior scalene muscles) may also identify a supraclavicular mass lesion not otherwise observable. MRI can determine the proximity of the lesion to the epidural space and spinal cord and may directly (enhancement) or indirectly (obliteration of apical lung fat) identify the mass [150, 151]. MRI may not identify malignant cells infiltrating and tracking along the connective tissue sheaths of plexus elements. NSTs, neoplastic invasion, and some metastatic lesions require gadolinium for visualization. On MRI, NSTs appear as fusiform or spherical enlargements that are isointense to muscle on T1 and hyperintense on T2. Schwannomas brightly enhance and often demonstrate exiting, entering, or displaced fascicles, whereas neurofibromas rarely show displaced fascicles [152]. Frequently, the capsule and the nerve of origin are visible. NF1 is suggested by multiple neurofibromas or the multifocal nature of a plexiform tumor. These studies do not differentiate neurofibromas from schwannomas or benign lesions from malignant ones because benign and malignant lesions both display heterogeneous signal and bone erosion and because irregular infiltrative borders are also observed with benign plexiform neurofibromas [80, 151]. MRI is also useful for screening presymptomatic NF1 patients. Other useful imaging techniques include fluorodeoxyglucose positron emission tomography (to identify malignant changes within the plexus, to differentiate benign and malignant plexiform neurofibromas), magnetic resonance neurography (to differentiate intraneural and paraneural masses), and angiography (to define tumor vascularity and neighboring vessels for preoperative planning) [135, 146, 153, 154]. CSF assessment is necessary when neoplastic meningitis is a consideration. Although often downplayed as an extension of the neurological examination, EDX testing provides information critical to patient management and, in addition, has several advantages over clinical assessment, including (1) evaluation of muscles not easily assessed clinically (e.g., brachialis); (2) identification of subclinical muscle involvement; (3) better definition of the extent of the lesion (EDX studies frequently identify involvement beyond the distribution identified clinically or radiographically); (4) determination of severity, chronicity, and rate of progression; and (5) the ability to redirect the evaluation toward non-neurologic entities (e.g., orthopedic disorders) when, for example, the EDX study of a patient with "weakness" is normal. In addition, it also identifies the EDX features of radiation fibrosis syndrome (although this does not exclude tumor recurrence) and, through serial studies, can assess tumor progression and treatment response. Unfortunately, EDX studies often are normal until persistent sensorimotor deficits are present [122]. Overall, the most accurate histologic information follows tissue procurement from the tumor or involved lymph nodes. When benign plexus tumors are mistaken for nonneural lesions and improperly biopsied or excised, severe, permanent, and unnecessary neurologic deficits and pain may result. Not only is patient outcome and quality of life

adversely affected, but subsequent excisions are impeded. Thus, consultation with a neurosurgeon experienced in the evaluation and treatment of such lesions is mandatory [121–123, 145]. When a malignant NST is suspected, definitive diagnosis is made by biopsy and, if confirmed, is followed by a metastatic evaluation, including chest films, bone scan, chest and abdominal CT scans, and MRI of the surrounding structures [129]. When a malignant plexopathy is suspected and the MRI is normal, additional studies to look for extraplexal involvement (e.g., bone, liver, and brain imaging) may be necessary, as may surgical exploration; if these results are negative, repeat studies and reexploration 3–6 months later may be necessary [144].

Radiation-Induced Brachial Plexopathy

Although the PNS is relatively radioresistant, radiation therapy may have toxic effects on its nerve fibers and vasa nervorum, resulting in extensive demyelination (with later conversion to axon loss), blood vessel destruction, and marked tissue fibrosis, a condition termed *radiation fibrosis syndrome* [76, 155]. When this syndrome involves the brachial plexus, the term *radiation plexopathy* is applied, the earliest cases of which were reported in 1964 [156]. Unless midline radiation is given, brachial plexus involvement typically is unilateral and may follow radiation therapy to the neck, upper thorax, or axilla. Because it most commonly follows axillary lymph node irradiation for breast cancer, it usually involves middle-aged to elderly females [15]. Following awareness that the incidence of radiation damage increased with higher total dose, larger fraction size, shorter application time, use of the three-field technique, and concomitant chemotherapy, technical modifications and dosing adjustments (lower doses administered over longer periods) were introduced and the incidence declined [157–162]. Symptoms of radiation plexopathy usually appear within 12–20 months of course completion, but onset times range from a few weeks to over 30 years [163, 164]. Radiation plexopathy most commonly affects females with breast cancer who received axillary lymph node chain radiation therapy months to decades earlier [165]. Most patients present with painless paresthesias in the median nerve-innervated regions of one or more of the lateral three digits (i.e., lateral cord distribution). Pathophysiologically, these symptoms reflect demyelinating conduction block. Over time, the paresthesias become more intense and their distribution expands [2, 55]. Unlike most demyelinating conduction block lesions, which typically recover over several weeks to months (remyelination), these lesions persist and, typically, over a several-year period or greater, convert to axon loss. As this conversion takes place, numbness, sensory ataxia, weakness, and muscle atrophy appear. With continued progression, the extremity may become atrophic, insensate, edematous, and essentially useless [166, 167]. Extremity edema may also be noted. Pain may develop, but its incidence is unclear. It has been reported to occur infrequently by some and in up to two-thirds of patients by others [144, 166]. Initially, the distribution of the paresthesias may result in an erroneous clinical diagnosis of carpal tunnel syndrome or a C6 or C7 radiculopathy and an unnecessary surgical procedure. Tumor recurrence is another consideration, especially in the setting of pain (discussed below). MRI is the imaging study of choice and typically demonstrates diffuse thickening and enhancement [168]. EDX studies may initially be normal, but once the symptomatic digits show continuous paresthesias or numbness, low-amplitude sensory responses with normal latencies typically are recorded. The low-amplitude sensory responses exclude cervical radiculopathy, and the normal latencies exclude carpal tunnel syndrome, thereby sparing the patient from unnecessary surgical procedures. With more advanced lesions, the sensory responses are unelicitable, the motor responses are low in amplitude, and focal demyelinating conduction blocks are apparent with supraclavicular fossa stimulation. The needle EMG shows fibrillation potentials, a neurogenic MUAP firing pattern, chronic neurogenic MUAP changes, and widespread fasciculation potentials as well as myokymic potentials [3, 15, 144, 166, 167, 169, 170]. When these features are encountered on EDX examination, one can reliably diagnose radiation-induced plexopathy. However, radiation plexopathy does not exclude tumor recurrence because both may be present simultaneously. There is no effective treatment for radiation plexopathy and treatment is therefore symptomatic. Physical therapy is used to prevent contractures, capsulitis, muscle atrophy, and lymphedema formation. Pain is treated in a similar manner to neoplastic plexopathy. External neurolysis can break up perineural adhesions and scar tissue and may lessen severe, unresponsive pain but may result in greater clinical deficits [121]. Surgical procedures to restore plexus circulation and impede fibrosis (e.g., neurolysis with omental transfer) have not been shown to be of long-term benefit, and the role of anticoagulation remains unclear [167, 171]. Thus, with inexorable progression and lack of treatment options, the prognosis for this condition is poor, with most patients ultimately developing a functionally useless extremity [80]. Even with incomplete lesions, the associated sensory ataxia often renders the limb functionally useless [31]. Rarely, radiation therapy produces transient sensory symptoms, typically paresthesias, that resolve over a 6–12-month period [160, 164]. Other radiation-induced neurologic complications include ischemic brachial plexus injury from subclavian artery thrombosis, dropped head syndrome and atrophy of neck muscles from cervical AHC damage, and the induction of NSTs (mostly malignant ones).

Radiation Versus Neoplastic Plexopathies

When patients with neoplastic plexopathies and a history of radiation therapy develop recurrent or new upper extremity symptoms, it can be challenging to differentiate tumor recurrence from radiation plexopathy. Features predictive of tumor recurrence include severe shoulder pain, rapid progression, lower plexus involvement, metastatic disease in other body regions, and paraspinal muscle fibrillation potentials. Features predictive of radiation plexopathy include painless paresthesias (often in a lateral cord distribution), slow progression, and certain EDX features (i.e., demyelinating conduction block, fasciculations, grouped repetitive discharges, and myokymic discharges) [80, 144, 148, 163, 166]. The presence of Horner syndrome and the time elapsed since radiation therapy are not helpful differentiating features [121]. The presence of nodular enhancement or a mass on MRI strongly suggests tumor recurrence, whereas homogenous enhancement or signal abnormalities involving the ipsilateral scalene muscles or other neighboring structures without nodularity support radiation plexopathy [80]. Surgical exploration with biopsy may be necessary but can be nondiagnostic. A negative biopsy does not exclude tumor recurrence [144]. The identification of radiation plexopathy never excludes tumor recurrence because these two conditions may exist simultaneously.

Traumatic Brachial Plexopathies

Most traumatic brachial plexopathies follow closed traction and reflect the susceptibility of the brachial plexus to stretch injury. The brachial plexus fibers elongate with movements of the neck, shoulder, and arm. Because these fibers are anchored both proximally (i.e., the spinal cord and transverse processes) and distally (e.g., within the axilla), excessive elongation produces traction injury. Most closed-traction injuries to the brachial plexus involve the supraclavicular plexus and are related to motor vehicle accidents (especially those involving motorcycles), sports, and particular occupations (e.g., industrial accidents) and, consequently, are more frequent among young adult males [2, 3, 11, 20, 21, 23]. Some of these entities have already been discussed (e.g., avulsion injuries, classic postoperative paralysis, obstetric brachial plexopathy, postmedian sternotomy plexopathy) because they are region specific or involve particular brachial plexus elements (e.g., roots). Among supraclavicular plexopathies related to closed traction, most involve the upper plexus and follow forceful separation of the head and shoulder. When more severe, the middle and lower plexuses, in that order, are involved. Traction injuries to the lower plexus are less common, usually follow forceful separation of the upper extremity from the torso, more commonly are associated with bone and blood vessel injuries, and frequently also involve the middle plexus [172]. Again, severe lower plexus traction injury is followed by middle plexus and then upper plexus involvement. Traction lesions restricted to the middle plexus are rare; they usually are accompanied by upper or lower plexus involvement [26]. Theoretically, application of traction to the upper extremity while it is abducted and parallel to the ground favors middle plexus involvement. Open traction injuries, which usually follow gunshot or chainsaw accidents, are much less common than closed-traction injuries [15, 20]. The majority of penetrating injuries affect the infraclavicular plexus. Most low-velocity insults (knife blade, low-velocity round) produce direct plexus damage resulting in conduction failure from axon loss, whereas high-velocity rounds, in addition to directly disrupting the plexus fibers, can indirectly damage them as well – the pressure waves and cavitation created by passage of the bullet produce contusive and traction forces proportional to the cube of its velocity [20, 173, 174]. The pathophysiology associated with high-energy injuries ranges from demyelinating conduction block to axon loss related to plexus fiber disruption. Among 90 civilian patients with gunshot wounds to the brachial plexus, only 6 % showed disruption [172], whereas among military personnel, 24 % had complete loss of continuity [175]. Although indirect forces usually are not disruptive, they can be quite lengthy [20]. When blood vessel disruption occurs, the plexus fibers may be injured secondarily through hematoma or pseudoaneurysm formation. The cords and the median nerve are adherent to the axillary artery and are particularly susceptible. In this setting, the plexus injury may present in a delayed manner, characteristically with painful paresthesias and subsequent weakness in the distribution of the affected fibers. With traumatic neurovascular injuries, the cord elements are most often involved, whereas with iatrogenic insults, the terminal nerves are more frequently involved. The rate of the progression depends on the rapidity of expansion of the responsible hematoma or pseudoaneurysm, and the likelihood of recovery depends almost entirely on the amount of time required to make the diagnosis. When only ischemic conduction block has occurred, all of the symptoms are reversible. Later, after axon disruption has occurred, the potential for recovery is essentially zero. Transection injuries may be either sharp (knife blade, glass) or blunt (animal bites, chainsaw, metal fragments, fan or motor blades). It is important to document the site of injury, the injurious object, and the onset of symptoms in relation to the initial trauma. Symptoms recognized immediately after the injury most likely represent direct plexus damage, whereas those developing subsequently may reflect an expanding hematoma or neuralgic amyotrophy. Because most compression injuries occur between the clavicle and first thoracic rib, the distal trunk, division, and proximal cord elements are most frequently affected. While the plexus fibers are compressed, contralateral head movements

produce traction forces on the supraclavicular elements, whereas downward or lateral upper extremity movement produces traction forces on the cords. Fractures and dislocations (more commonly anterior) of the humeral head or neck may produce infraclavicular plexus damage. These lesions most commonly involve the axillary terminal nerve, less frequently the suprascapular nerve (often in combination with the axillary nerve), and least frequently the musculocutaneous nerve [15]. They are more common among elderly males, almost always are unilateral, and are more frequently right-sided due to the tendency of a falling individual to use the dominant limb to break the fall [2, 176, 177]. With severe lesions, most of the cords or terminal nerves may be involved. The clinical features reflect the particular infraclavicular elements disrupted, and the likelihood for recovery reflects the underlying pathophysiology. Because imaging studies are more helpful in the assessment of intraspinal canal lesions, they typically are uninformative in the setting of closed-traction injury. CT and MRI studies are useful when traumatic plexopathies are associated with hematoma formation, although when the hematomas are induced by iatrogenic injury, they may be too small for visualization and may require axillary arteriography for recognition [104]. Plain films identify humeral fractures and dislocations. Supplemental imaging studies for the latter include ultrasound, CT arthrography, and MRI. In the acute setting, EDX studies are not indicated because the EDX abnormalities associated with axon loss require time to manifest (discussed above). If there is a concern about lesion continuity, the needle EMG may be used acutely to establish continuity. Later, however, EDX studies are used to fully characterize the lesion. These determinations can be challenging, however, in the setting of a concomitant extraplexal lesion (e.g., midshaft humeral fracture-induced radial neuropathy) or a two-level intraplexal process that involves both preganglionic and postganglionic fibers. The treatment of traumatic brachial plexopathies – surgical or conservative – reflects a number of features, including the injury type, location, severity, and chronicity and, consequently, must be individualized. With injured plexus elements, the goal of surgical intervention is to permit proximodistal axonal regeneration to occur. This can be accomplished through a number of techniques. To successfully restore motor function, surgical intervention is best performed within the first 3 months (or at most, the first 6 months) by surgeons with expertise in peripheral nerve disorders.

Most closed-traction injuries produce lesions in continuity and initially are treated conservatively (physical therapy with serial clinical and EDX assessments) because, at this point, it is not possible to determine the likelihood of recovery or the type of surgical intervention required [33]. Initially, the presence of demyelinating conduction block causes the severity of the lesion to be overestimated. At day 7, motor NCS can usually differentiate the percentage of nonconducting fibers due to demyelinating conduction block from the percentage related to axon loss. If no signs of recovery appear after 2–3 months (4–5 months for more pronounced injuries), surgical exploration is considered [33]. Shorter observation periods (3 weeks to 3 months) may be considered with high-energy injuries or those associated with total or near-total paralysis [178]. The ability of the damaged segment to transmit action potentials can be determined through intraoperative nerve conduction studies. In general, when the damaged segment transmits nerve action potentials, only external neurolysis is required [20]. When the damaged segment does not transmit action potentials (because connective tissue proliferation impedes axonal advancement), it is removed and the ends are reattached, either directly (less commonly) or via a cable graft (more commonly). Injuries related to high-velocity rounds are initially (2–4 months) managed conservatively because affected brachial plexus elements are infrequently disrupted. When evidence of recovery is not observed, surgical intervention usually is required (typically resection with graft placement) [20]. In the setting of a transection, the ends of the transected element can be reattached or the damaged portions of each end can be removed and a cable graft placed. Sharp transections usually are repaired within 72 h by primary end-to-end neurorrhaphy because they are easier to assess prior to scarring and easier to repair prior to retraction [20, 33, 178]. Early intervention is also indicated with worsening pain or neurologic dysfunction, hematoma formation, concomitant bone or vascular injuries, and compartment syndrome [33]. With blunt transections, repair is delayed until the full proximal and distal extents of the neuroma can be appreciated [20, 33]. Unless a severe lesion in continuity or a rupture is suspected, most infraclavicular plexus lesions following humerus fracture or glenohumeral dislocation (mostly axillary neuropathies) are initially treated conservatively [31].

Iatrogenic Brachial Plexopathies

Iatrogenic injuries represent 7–10 % of brachial plexopathies, most of which reflect blunt injuries in continuity [3]. Most follow operations or other medical procedures and reflect a number of factors, including patient positioning and the particular procedure performed. In addition to direct injuries (e.g., suture or hardware misplacement, injection injury, transection), indirect injuries (pseudoaneurysm or hematoma formation) also occur. With the latter, the presentation may be delayed, such as when previously placed hardware subsequently detaches and damages an adjacent blood vessel [60, 179, 180]. Treatment is individualized and reflects the type of injury and its location, severity, and chronicity. Injuries related to malpositioning

typically are treated conservatively, as are plexopathies following procedures requiring median sternotomy. With misplaced sutures or hardware, removal and repair are employed. With blunt transections, treatment usually is delayed until enough time has elapsed for neuroma formation to have occurred (e.g., several weeks). With sharp transections, acute end-to-end repair usually is performed within the first 72 h [20].

Lumbosacral Plexopathies

47

Seward B. Rutkove and Tracy W. Sax

Introduction

The accurate evaluation, diagnosis, and treatment of a lumbosacral (LS) plexopathy often presents a challenge to the clinician. In addition to being relatively uncommon, LS plexopathies can have very varied presentations, due to the fact that any nerve fibers derived from the L1 through S4 levels may be involved. Moreover, it is common to mistake an LS plexopathy for an LS radiculopathy, especially given the high prevalence of structural lumbar spine disease. One final difficulty is that in patients with nonstructural plexopathies, such as idiopathic LS plexitis or diabetic amyotrophy, the diagnosis may be one of exclusion. This can make both patient and physician uneasy, especially if more aggressive treatment options, such as immunosuppression, are under consideration.

Despite these issues, a careful history and examination in conjunction with electrodiagnostic, radiologic, and serologic testing can usually lead to a correct diagnosis and causation (Table 47.1). In addition to avoiding unnecessary LS spine surgery, the patient can receive appropriate therapy directed toward the relief of pain and restoration of function.

Anatomy

The LS plexus consists of two distinct regions: the lumbar plexus and the sacral plexus. The lumbar plexus (Fig. 47.1) is formed from the anterior rami of lumbar roots 1–4 and lies within the posterior portion of the psoas muscle. The anterior rami of roots L2–4 divide into anterior and posterior divisions. The anterior division forms the obturator (L2–4), the genitofemoral (L1, 2), iliohypogastric, and ilioinguinal (L1) nerves. The posterior division of L2–4 forms the femoral and the lateral femoral cutaneous nerves.

The lumbar plexus communicates with the sacral plexus via the anterior division of L4. The sacral plexus is formed from the anterior rami of spinal nerves L4–S3. The anterior division forms the tibial portion of the sciatic nerve, and the posterior division contributes to the peroneal portion of the sciatic nerve. The superior (L4–S1) and inferior gluteal (L5–S2) arise from the posterior division of the sacral plexus. The posterior cutaneous nerve of the thigh arises from the anterior divisions of S1–3.

Clinical Presentation of Lumbosacral Plexopathy

Lumbar plexus disorders cause symptoms in the territories of the iliohypogastric, genitofemoral, ilioinguinal, femoral, and obturator nerves. This results in weakness of hip flexion, knee extension, and thigh adduction with sensory loss in the

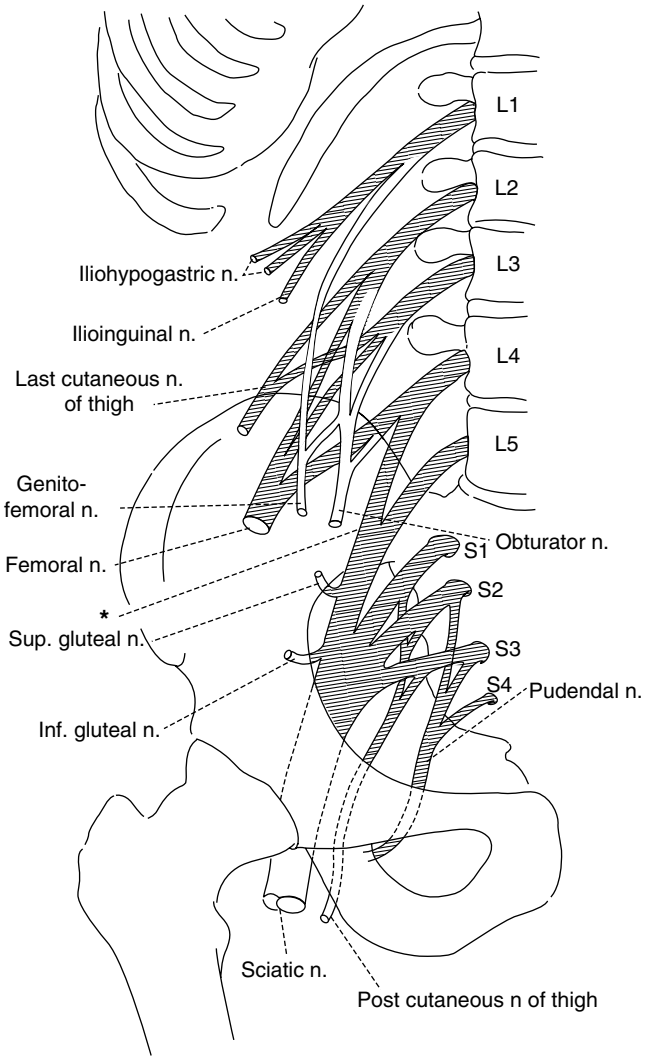

Fig. 47.1 The lumbosacral plexus is divided anatomically into an upper, lumbar plexus and a lower sacral plexus. The iliohypogastric, ilioinguinal, lateral cutaneous nerve of the thigh, genitofemoral, femoral, and obturator are the major nerves derived from the lumbar plexus. The sciatic, superior gluteal, inferior gluteal, posterior cutaneous nerve of the thigh, and pudendal nerves are derived from the lower lumbosacral plexus. The lumbosacral trunk (*) is formed primarily by the L5 root with a contributing branch from the L4 root. It travels a relatively long distance in close contact with the ala of the sacrum adjacent to the sacroiliac joint (Adapted from Hollinshead [1])

lower abdomen, inguinal region, and over the entire medial, lateral, and anterior surface of the thigh and the medial lower leg. The patellar reflex is decreased or absent.

A lesion of the sacral plexus produces dysfunction within the territories of the gluteal, sciatic, tibial, and peroneal nerves, producing weakness in the hip extensors, hip abductors, knee flexors, and foot plantar flexor and dorsiflexors. Diminished sensation may be found over the posterior aspect of the thigh, anterolateral and posterior aspect of the leg below the knee, and almost the entire foot. The ankle jerk may be diminished or absent. A combination of weakness in the glutei and sciatic nerve-innervated muscles helps localize the lesion to the sacral plexus.

Pain in LS plexopathy is very common and, given its intensity, may be one of its most disabling features. Depending on the nature of the plexopathy, pain is often localized to the region of the hip, buttock, and proximal thigh, with prominent radiation down the leg. On examination, certain movements may elicit pain. For example, in sacral plexopathies, the straight leg test may enhance pain, whereas in lumbar plexopathies, hyperextension of the leg at the hip (femoral stretch, reversed straight leg test) may have the same effect. Unlike radicular lesions, however, coughing or straining will usually not produce much change in symptoms. Back pain, although sometimes present, is usually relatively minor.

Electrodiagnostic Studies

As with the clinical presentation of LS plexopathy, the electrodiagnostic findings can be quite variable and complex. Multiple nerve conduction studies, often with comparisons to the opposite limb, and extensive needle electromyography (EMG) are often necessary to accurately characterize an LS plexopathy [2].

Peroneal and tibial motor conduction studies reveal often low compound muscle action potential (CMAP) amplitudes when involvement of the lower lumbar and sacral nerve fibers is present. Femoral motor conduction studies will reveal reduced CMAP amplitude if a lumbar plexus lesion is present.

Sensory conduction studies are usually very helpful in identifying LS plexopathy. Concurrent reductions in the amplitude of superficial peroneal, sural, and saphenous responses demonstrate that the process is at or distal to the dorsal root ganglion. Unfortunately, some of the sensory nerves that would be very helpful to evaluate are, for technical reasons, not possible to study, such as the iliohypogastric and ilioinguinal nerves. The lateral femoral cutaneous sensory response may be difficult to obtain in healthy subjects.

It is important to distinguish LS trunk lesions from peroneal nerve compression or an L5 radiculopathy, because all may present with foot drop. Many patients with peroneal neuropathy across the fibular head have conduction block. In addition, detecting weakness or denervation, or both, in ankle inversion (tibialis posterior), toe flexion (flexor digitorum longus), or hip abduction (gluteus medius or tensor fascia lata) eliminates a peroneal neuropathy. It is more difficult to separate an LS trunk lesion from L5 radiculopathy, because the weakness involves the L5 myotomes exclusively in both conditions. However, in L5 radiculopathy, the superficial peroneal sensory response is normal and paraspinal fibrillation potentials may be present.

Proximal stimulation studies, at the level of the spinal root, are rarely needed but can be helpful to identify mild injury across the plexus by demonstrating slowing of conduction velocity. Some normal latency values have been established for evaluating both the lumbar and sacral plexi, recording from vastus medialis and gastrocnemius [2].

On needle EMG, multiple muscles need to be sampled, including, importantly, those derived from the inferior and superior gluteal nerves (in the case of a low-lumbar/sacral plexopathy) to distinguish this disorder from a sciatic neuropathy. In lumbar plexopathy, evaluation of iliopsoas, hip adductors, and quadriceps is important to distinguish LS plexopathy from a femoral or obturator mononeuropathy. Because the dorsal rami are not part of the plexi, LS plexopathies should spare the paraspinal muscles. Certain disorders, such as diabetic amyotrophy, also may involve the roots, complicating the electrodiagnostic picture.

General Recommendations

Evaluation

Although electrodiagnostic testing may help confirm a diagnosis of LS plexopathy, abnormalities may take a number of days to several weeks to become fully established. Hence, in a patient with an acute onset of possible LS plexopathy, imaging studies are important to obtain early in order to exclude a potentially treatable structural disorder such as tumor. In fact, an imaging study is usually a necessity in any patient with an LS plexopathy of uncertain cause. Although computerized tomography (CT) and magnetic resonance imaging (MRI) both give excellent visualization of the pelvis and can effectively exclude a mass lesion, MRI provides better visualization of the plexus itself and is useful in assessing for inflammation or neoplastic infiltration of the plexus [3, 4].

As part of the initial work-up, serologic tests have relatively limited value although a serum erythrocyte sedimentation rate (ESR), glucose, hemoglobin A1C, Epstein-Barr virus (EBV) titers, and Lyme titers may be useful in assessing for some of the more common inflammatory and infectious causes of LS plexopathy.

Treatment

Regardless of cause, pain is often a prominent complaint in patients with LS plexopathy. Treatment with some of the common neuropathic pain medications including tricyclic antidepressants, gabapentin, or pregabalin may be helpful. However, the addition of opioid medications may also be necessary, as pain may be excruciating in many of these disorders, including diabetic amyotrophy, idiopathic LS plexitis, and in infiltrative neoplastic disease. Once the pain is under improved control, efforts toward treating the underlying illness can be pursued (see below). Physical therapy, assistive devices, and orthoses are important adjunctive treatments, helping to maintain mobility during recovery.

Compressive Disorders

Hemorrhage

Hemorrhage within the retroperitoneum is a well recognized, though sometimes overlooked, cause for LS plexopathy. In most instances, hemorrhage is associated with therapeutic anticoagulation or an underlying clotting disorder, although trauma is another common cause. Several various iatrogenic causes have also been described including secondary to failed lumbosacral plexus anesthetic block and due to femoral vein dialysis [5, 6]. In a review of 26 cases of LS plexopathy due to anticoagulation, two distinct clinical syndromes have been described [7]. If the hemorrhage was located within the iliacus muscle, an essentially pure femoral neuropathy resulted. If the hemorrhage was within the psoas muscle, more widespread injury occurred, causing a complete lumbar plexopathy. The volume of hemorrhage within the psoas can be considerably larger, possibly due to the distensibility of the psoas sheath compared to the iliacus fascia [8].

Initially, patients complain of severe pain in the lower abdomen and groin, followed by motor deficits and sensory loss. In some patients, a palpable mass may be found within the groin. A characteristic posture may be observed in which the patient attempts to decrease the pain by flexing and externally rotating the hip. In a poorly responsive ICU patient, an abrupt reduction in the hematocrit may be the only sign of retroperitoneal hemorrhage. Imaging of the pelvis and abdomen usually reveals the abnormality. Later, EMG may be useful in identifying the extent and severity of the injury.

Conservative treatment, with correction of any hemostatic abnormality, is usually the preferred management approach. Most patients will demonstrate a partial recovery, with only a third to one-half of patients experiencing a full recovery [8]. Surgical decompression has met with only varied success and is generally not recommended. One report, however, suggests that percutaneous drainage might be an effective alternative [9].

Neoplastic Plexopathy

LS plexopathy may occur by direct invasion of the plexus or from external compression by the tumor [10]. Neoplastic plexopathy is relatively uncommon, occurring in less than 1 % of patients with a known neoplasm. The most common

tumors associated with LS plexopathy include colorectal, pelvic, genitourinary, breast, and lymphoma, with direct extension in 73 % of patients and by metastasis from extra-abdominal sites in 27 %. In 15 % of cases, LS plexopathy represents the initial presentation of the neoplasm [11].

On presentation, patients generally complain of severe pain followed by sensory loss and weakness. Unilateral lower extremity edema may also be present. The lumbar plexus alone is affected in about one third of patients, the sacral plexus alone (L5–S3) is involved in about one-half, with the rest demonstrating abnormalities in both areas. Although unilateral plexopathy occurs in most patients, bilateral plexopathy may occur in up to 25 %.

CT and MRI are invaluable in making the diagnosis of neoplastic LS plexopathy. CT, however, is less sensitive, producing equivocal results in some patients in which MRI is suggestive of neoplasm [3]. Positron emission tomography (PET) scanning in conjunction with CT can also be performed and can help identify localized malignant neoplasm [12] but is not routinely performed. In addition to localizing the problem to the plexus initially, electrodiagnostic studies can also be helpful in evaluating a patient with a history of pelvic neoplasm who subsequently develops new weakness and sensory loss in the leg. In this situation, the presence of myokymic discharges supports the diagnosis of radiation-induced plexitis over tumor recurrence (see "Radiation Plexopathy" below).

Radiotherapy and chemotherapy, possibly in combination with surgery, may result in improved strength or stabilization of neurologic deficits. Supportive therapy is also clearly important, to help reduce concomitant lymphedema, superimposed compressive neuropathies, and ulcerations [10]. The majority of patients, however, eventually succumb to the underlying neoplasm, with a median survival of less than 2 years.

Pregnancy and Labor

Direct pressure from the fetus on the LS plexus can develop during pregnancy by 32–34 weeks gestation [13]. Women most susceptible are primigravida mothers of short stature (usually less than 5 ft tall) carrying large infants. The earliest symptoms in most patients, however, do not begin until the onset of active labor, at which point pain, usually in a sciatic distribution, radiates down the leg [14]. Some patients may complain of paresthesias over the lateral aspect of the calf and dorsum of the foot as labor progresses. However, it is usually only when the new mother attempts to walk after delivery that weakness in the leg is generally first appreciated. A foot drop usually is the main problem, occurring on the same side as the infant's brow during labor. Occasionally, bilateral weakness may occur. Injury most results from direct pressure of the fetal head against the plexus as it descends into the pelvis during the second stage of labor [15]. Specifically, the LS trunk, the large bundle made up of L5–S1 fibers which directly overlies the pelvic brim, is predominantly involved. In many cases, labor is arrested and delivery needs to be completed by Caesarean section.

Electrodiagnostic studies typically reveal predominant involvement of L5 fibers with some compression of S1 fibers. This results in reduced superficial peroneal sensory response amplitude and rarely reduced sural amplitude as well. On motor studies, a normal or slightly reduced deep peroneal motor response amplitude recording extensor digitorum brevis and tibialis anterior with prolonged or absent peroneal F responses may be present. The tibial motor study is normal. Tibial H reflex may be prolonged or absent if the S1 fibers are involved. Needle examination discloses denervation predominantly involving the L5 myotomal muscles. Prognosis is very good with complete recovery in most cases within 3 months, consistent with a demyelinating process [15].

Traumatic and Postoperative Plexopathy

Unlike the brachial plexus, traumatic injury to the LS plexus is relatively uncommon, with most cases due to falls or motor vehicle accidents, with fractures involving the pelvic ring or sacrum [16], with the incidence and severity of plexopathy increasing with the number of fractures present and fracture instability [17]. In addition to direct crush injury from bone and bone fragments, hemorrhage and avulsion of the nerve roots may also occur [18]. Although isolated involvement of the sacral plexus occurs commonly, most patients develop simultaneous injury to both lumbar and sacral nerve fibers. Weakness predominantly affects muscles derived from the common peroneal and gluteal nerves with more mild problems in the distribution of tibial and femoral nerves. Prominent sensory loss throughout the leg, most commonly in sciatic and posterior femoral cutaneous nerve distributions, occurs. Electrodiagnostic studies provide helpful prognostic information in addition to localizing the lesion; normal or only mildly reduced motor response amplitudes in affected muscles generally imply a good prognosis, due to primarily demyelinating physiology. Conservative treatment is recommended, unless ongoing compression of nerve fibers can be identified and corrected surgically.

Postoperative lesions of the LS plexus can occur after hip replacement, treatment of a fracture of the femur and acetabulum [16], radical pelvic surgery [13], and aortic vascular surgery [19]. However, even the simple placement of a pacemaker via the femoral vein has been described to cause LS plexopathy [20]. Isolated lesions affect either the lumbar or sacral plexus alone, although simultaneous involvement is again more common. Distinguishing a mononeuropathy from an LS plexus injury can also be difficult as patients with

high sciatic lesions (e.g., secondary to hip replacement) or femoral nerve lesions (e.g., secondary to abdominal or pelvic surgery) may present similarly. Postoperative LS plexus lesions are best treated conservatively, with mild ones improving significantly over time.

Aneurysms and Large Vessel Disease

Expansion of iliac or hypogastric artery aneurysms may cause direct compression on the LS plexus with radiation of pain in the distribution of the sciatic nerve [21, 22]. Likewise, slow leakage of an abdominal aortic aneurysm may lead to a very large retroperitoneal hematoma, producing an LS plexopathy [23]. Unexplained back and leg pain in conjunction with a pulsatile mass on palpation of the abdomen or during rectal exam should alert the clinician to the possibility of aneurysm. CT scans of the abdomen and pelvis usually confirm its presence. Early recognition of an aneurysm is crucial, as the likelihood of survival after aneurysmal rupture is much lower than if treated beforehand. Imminent occlusion of the abdominal aorta due to severe atherosclerotic disease may also affect the LS plexus, likely on an ischemic basis [24].

Abscess

Bacterial abscesses arising from the psoas or paraspinal regions resulting in plexopathy are rare. Psoas abscess was common when tuberculosis was more prevalent [25]. Perirectal abscess may cause bilateral sacral plexopathy and should be considered in immunocompromised patients or in those with a prior history of rectal surgery [26]. Patients present with fever and, depending on the location of the abscess, abdominal, groin, or back pain that radiates down the leg. Associated sensory loss and weakness in the leg may also be present. As with any mass, imaging of the pelvis is extremely important in making a rapid, accurate diagnosis. Electrodiagnostic studies may be useful later when assessing the severity and extent of the lesion. Surgical drainage of the abscess and appropriate antimicrobial therapy are usually effective.

Gluteal Compartment Syndrome

Gluteal compartment syndrome has been described as causing a lumbosacral plexopathy or lumbosacral plexus-like syndrome. This rare syndrome is usually caused by trauma, such as a fall or from prolonged positioning due to drug overdose [27] or as a rare postsurgical complication [28]. Early recognition of the syndrome with aggressive surgical debridement and fasciotomy is critical to ensuring prevention of long-term neurological injury.

Noncompressive Disorders

Diabetic Amyotrophy

Diabetic amyotrophy is a poorly understood disorder that affects the LS plexus that is discussed in detail in Chap. 31. It is probably most easily considered a radiculoplexus neuropathy in that involvement of nerve roots, plexus, and individual nerves probably occurs simultaneously [29]. A number of other names have been used to describe this disorder, each with its own bias toward mechanism and site of injury (Table 47.2). For the purposes of this discussion, we will employ the term diabetic amyotrophy, as it is commonly used and understood.

Diabetic amyotrophy is a relatively infrequent complication of diabetes with a prevalence of about 0.8 % among patients with both types I and II diabetes mellitus [30]. In some cases, diabetic amyotrophy may herald the onset of diabetes mellitus. In the classic form of diabetic amyotrophy, patients present with subacute onset of weakness and atrophy of the pelvic and femoral muscles with considerable pain in the hip and thigh. Although unilateral onset is common, some patients present with bilateral symptoms, while others first develop symptoms affecting one lower extremity and weeks or months later develop a similar syndrome affecting the opposite side. Rarely, the proximal upper extremities may also be affected. In most patients, definite sensory loss involving the proximal leg is usually not described; however,

distal sensory loss due to a preexisting symmetric polyneuropathy is usually present. An associated weight loss of 10–30 lb often occurs as well.

On examination, weakness is usually found predominantly in iliopsoas, quadriceps, hip abductors, hip adductors, quadriceps, and hamstrings. Mild distal weakness may be identified in foot dorsiflexors and plantar flexors. The patellar reflex is unobtainable. Distal sensory loss and reduced or absent ankle jerks are usually present bilaterally, likely due to the underlying polyneuropathy.

Electrodiagnostic studies are often complex, although a consistent picture generally emerges [31]. First, signs of a predominantly distal symmetric axonal polyneuropathy are often present. Specifically, bilateral peroneal and tibial motor responses are often mildly reduced in amplitude and conduction velocity with corresponding prolongation in F responses. Likewise bilateral distal sensory responses, such as the sural, are usually reduced in amplitude or simply unobtainable [2]. Femoral motor conduction studies reveal a reduction in motor response amplitude on the affected side relative to the unaffected side. Although it might be helpful to obtain a saphenous sensory response in this situation, these responses are usually also unobtainable bilaterally. Needle EMG shows fibrillation potentials and positive sharp waves with decreased recruitment of motor unit action potentials in the weak proximal muscles as well as in the lumbar paraspinal muscles, supporting involvement of the nerve roots.

In evaluating patients with this syndrome, imaging of the pelvis with MRI or CT is reasonable in order to exclude a structural lesion. Imaging of the LS spine may also be obtained, which, unfortunately, may lead to an incorrect diagnosis of structural spine disease. One case, however, has been reported of showing evidence of enhancement on MRI T1 imaging of the LS nerve roots [32]. Although spinal fluid studies may show elevated protein (50–147 mg/dl) [33], lumbar puncture is usually not necessary in a patient with a typical presentation of this disorder. The ESR may also be mildly elevated. In those patients in whom diabetic amyotrophy coincides with the onset diabetes mellitus, a fasting glucose, hemoglobin A1C, and in some patients, glucose tolerance testing may help validate the diagnosis.

The pathophysiology of this disorder remains uncertain. An inflammatory component with a microvasculitis and secondary ischemia is likely [29], given the presence of inflammatory cells on sural nerve and intermediate cutaneous nerve of the thigh biopsies [34, 35]. In its most common form, patients with diabetic amyotrophy experience a gradual but definite recovery in strength on the affected side over a period of 6 months. Eventually strength may normalize, although some quadriceps atrophy and mild weakness may persist. The proximal pain, which can be quite severe initially, usually decreases and resolves entirely often after 2–4 months. In a minority of patients, improvement in strength is more limited.

Given the disorder's relatively good prognosis in most patients, good glycemic control and relief of pain are usually the two initial priorities. Although there is no clear proof that improved glycemic control will hasten recovery, most physicians encourage tight control. Standard pain therapies, including tricyclic antidepressants, gabapentin, and, if necessary, narcotics, are most effective. Directed treatment for this disorder, however, has remained controversial. Some authors have advocated the use of immune-modulating treatments, such as intravenous immune globulin (IVIG), pulsed methylprednisolone, cyclophosphamide, and azathioprine [33–37]. Even a single localized spinal steroid injection has been utilized [32]. However, the evidence argues against any specific treatment. Indeed, in a consensus statement, there was an agreement that there was no convincing evidence to support the use of IVIG in this disorder [38]. Similarly, a Cochrane review supported the absence of any evidence for an effective treatment of this condition [39]. However, this clearly remains a disorder that requires further study and investigation.

Radiation Plexopathy

LS radiation plexopathy usually presents with slowly progressive weakness and sensory loss often years after exposure to radiation in the treatment of cancer. Lymphoma, testicular, ovarian, uterine, and cervical cancers are most commonly associated with radiation plexopathy. With the exception of lymphoma, this group is different from cancers that invade the plexus directly, which usually include prostate, sarcoma, and colon/rectal [11]. Although the median onset of symptoms occurs approximately 5 years after treatment, the effects of radiation can be highly variable with some individuals developing symptoms two to three decades later. There is also no clear relationship between the duration of the latent period and the amount of radiation used, although plexopathy occurs rarely in people receiving less than 4,000 rad. Weakness usually affects distal L5–S1 muscles predominantly; symptoms may be unilateral, but are often bilateral and symmetric. Associated sensory loss is common. Pain is usually more minor, although in some individuals, pain is the initial and most prominent symptom. Approximately 50 % of all patients with the disorder complain of significant pain, which usually has an aching, burning, or lancinating character.

Examination discloses weakness with associated atrophy, reduced or unobtainable patellar and ankle reflexes, and abnormal sensation in the affected extremity. On electrodiagnostic testing, nerve conduction studies demonstrate reduced motor and sensory amplitudes and mild slowing of

conduction velocity, consistent with a predominantly axonal lesion. In addition to demonstrating prominent chronic reinnervation of motor unit action potentials and mild ongoing denervation, the needle EMG of the affected muscles reveals myokymic discharges in 60 % of subjects. Although not sensitive, their presence is highly suggestive of radiation-induced injury, as they are not commonly found in neoplastic disease. Myokymic discharges may not be prominent, occurring in only one or two locations in the entire extremity. Additional testing is often obtained including MRI to exclude the recurrence of neoplasm. Lumbar puncture may reveal an elevated spinal fluid protein but is otherwise generally unhelpful in confirming a diagnosis of radiation plexopathy. Differentiating tumor recurrence from radiation plexopathy is usually reasonably straightforward. In addition to distinct findings on MRI and EMG, tumor recurrence proceeds at a rapid rate (over weeks to months) with pain as a predominant symptom, whereas radiation plexopathy has a slow, often insidious onset (over months to years) with only mild pain.

The course of the disorder is variable, with some patients developing mild weakness, while others have a slowly progressive course leading to prominent weakness, sensory loss, and pain in the affected extremity. Most patients note no further progression in their neurologic dysfunction 1–5 years after diagnosis. Although a diagnosis of radiation plexopathy is preferable to that of recurrent neoplasm, in some individuals the disorder can render the affected limb(s) almost useless.

There is no evidence-based treatment for radiation plexopathy. The use of anticoagulants has been suggested on the basis of maintaining blood flow in vessels with radiation-induced endothelial damage. In one study, warfarin was utilized, keeping prothrombin time more than 1.5 the control values for a period of 3–6 months [40]. Both patients with LS plexopathy experienced mildly improved leg function and reduced pain. Although surgical neurolysis with omental transfer has been utilized with some success in radiation injuries affecting the brachial plexus [41], such treatments have not been described for the LS plexus. Tendon transfers may restore limited function in some individuals. In addition to treatment of any underlying pain, physical therapy and appropriate bracing often become the most important therapeutic modalities.

Idiopathic Lumbosacral Plexitis

In 1981, Sander and Sharp [42] and later Evans and co-workers [43] described a syndrome of acute idiopathic LS plexitis analogous to brachial neuritis (neuralgic amyotrophy, Parsonage-Turner syndrome). In 1984, Bradley and colleagues described a syndrome that had a similar onset, but was more prolonged with persistent or recurrent bouts of pain [44]. They also noted that the patients had an elevated ESR and perivasculitis on sural nerve biopsy. Several of their patients improved with prednisone. Most clinicians, however, now consider these two entities as a single disease with variable course [45]. Some patients appear to have a monophasic illness that requires only treatment of pain, whereas others have a recurrent, sometimes debilitating course. This disorder also has a variable age of onset, affecting children as well as adults. Cases from age 2.5 to 81 years have been reported with a peak incidence occurring before age 20 and then again between 40 and 60 years [46].

Patients generally present with the acute onset of severe pain that starts in the buttock, groin, or thigh and radiates distally down the leg, often in a sciatic or femoral nerve distribution. Like brachial neuritis, mild antecedent trauma or a viral illness often precedes this disorder. An association with EBV has also been suggested. The pain is usually described as burning, jabbing, or sharp and may be so severe as to dominate the entire clinical picture [47]. Weakness usually ensues several days to weeks after the onset of pain and may affect predominantly fibers of either the lumbar or sacral plexus. Sensory symptoms are less prominent and include paresthesias in the affected territory with or without objective sensory loss on exam. In a subset of patients, symptoms may also eventually affect the opposite extremity, although usually to a lesser degree.

On nerve conduction studies, the sural, superficial peroneal, and/or saphenous sensory responses may be normal or only mildly reduced. Motor conduction studies are also usually normal. EMG reveals denervation in assorted limb muscles with normal paraspinal muscles. Notably, the disorder can be quite patchy (again similar to brachial neuritis) or predominantly affecting only one nerve, such as the peroneal. Although laboratory investigations may reveal an elevated ESR, additional serologic testing is negative, including tests for diabetes mellitus (e.g., fasting blood glucose, hemoglobin A1C, and glucose tolerance test). Although imaging is often unremarkable, MRIs of the plexus may reveal inflammation [4]. In one study, biopsy of the sural nerve revealed perivascular collections of inflammatory cells in some patients, although this is not always present [44]. In the end, the diagnosis of idiopathic LS plexitis is simply one of the exclusions: the clinical and electrophysiologic characteristics appear most consistent with plexopathy, and yet no cause can be identified.

The course of the disorder is variable. Children are more likely to have a monophasic illness as compared to adults who are more likely to have a prolonged, recurrent course. Initially pain management is the primary concern. In addition to tricyclics and gabapentin, narcotics may be necessary. In patients with recurrent or persistent disease, a number of immune-modulating treatments have been attempted to reduce pain and improve weakness; these treatments have been met with varying success. In Bradley's initial report, the authors used prednisone at a dose of 60 mg/day alone or in

combination with cyclophosphamide [44]. More recently, the use of IVIG at a dose of 400 mg/kg/day for 5 days has been advocated with or without the concomitant use of prednisone [48]. We initially treat patients with high-dose steroids (either prednisone 60 mg oral daily for 6 weeks or 1,000 mg methylprednisolone IV daily for 5 days). If no improvement occurs, we utilize a 5-day course of IVIG, reserving cytotoxic therapy only as a last resort.

Vasculitis

Rarely, LS plexopathy may occur as an initial sign or as a consequence of an already diagnosed necrotizing vasculitis [48]. Patients present with severe pain, weakness, and fixed sensory loss affecting one or more regions of a leg. Electrodiagnostic studies demonstrate an axon-loss physiology with prominent denervation in affected limb muscles. If a diagnosis of vasculitis has not already been previously established, a variety of laboratory studies including ESR, antinuclear antibody, rheumatoid factor, complement levels, antineutrophil cytoplasmic antibodies, and eosinophil count may be helpful as well as potentially biopsy. Since the plexus itself cannot be readily biopsied, biopsy of the sural nerve may be performed, which would reveal transmural inflammation and vessel wall necrosis, in addition to axonal loss [49]. Aggressive immunosuppression, including the use of cyclophosphamide and prednisone, alone or in combination, may be necessary to control the inflammation, allowing neuronal recovery.

Infectious/Parainfectious Disorders

In addition to abscesses, infections directly or indirectly, through autoimmune mechanisms, may produce LS plexopathy. As noted above, an association between EBV infection and LS plexitis may occur in some individuals. In one study, five patients developed severe gluteal/thigh pain followed by weakness in the leg shortly after clinical and serologic EBV infection [50]. Weakness and sensory loss were predominant with diminished knee and ankle jerks on the affected side. Laboratory studies were normal with the exception of EBV antibody titers. Cerebrospinal fluid studies showed increased lymphocytes (8–9 mm^{-3}) and elevated protein of 57–78 mg/dl. Two of the patients in the study were given prednisone 60 mg/day for 10 weeks although spontaneous resolution within 6 months occurred in those not treated.

Lyme infection may also cause plexopathy. In one report, a patient experienced severe buttock pain followed by weakness 2 weeks later [51]. ESR was elevated and electrophysiologic studies showed abnormalities consistent with plexopathy. Serum and cerebrospinal fluid were positive for antibody against *B. burgdorferi*. The patient was treated with IV penicillin 24 million units daily for 14 days with significant improvement in symptoms.

West Nile and herpes zoster viruses have also been described to cause brachial plexopathy-like syndromes [52, 53], but no such disorder has been reported impacting the lumbosacral plexus.

Heroin

The primary toxin linked to LS and brachial plexopathy is heroin [54–56]. Onset of symptoms may occur several to 36 h following the last injection of heroin. Patients usually complain of intense pain with only mild weakness and sensory loss. Resolution of the pain occurs over a several week period with a more protracted course for recovery of motor function. The mechanism of injury is unknown, although a direct toxic effect of the molecule or adulterants has been suggested [56].

Part VI

Neuromuscular Disorders: Neuromuscular Junction Disorders

Myasthenia Gravis

48

Henry J. Kaminski

Introduction

In 1895, Friedrich Jolly used the Greek terms for muscle and weakness forming "myasthenia" and the Latin "gravis" for "severe" to describe patients with fatiguing strength that often leads to death [1]. Although Jolly named the disorder, earlier accounts by Wilks, Erb, and Goldflam clearly describe patients with manifestations consistent with myasthenia gravis (MG), and for years the disorder was known as the Erb-Goldflam symptom complex [2]. Earlier descriptions of individuals possibly with MG exist. Some consider the account by Thomas Willis in *De Anima Brutorum* as the first identification of patients with MG [2]. In particular, he reports a woman who "for some time can speak freely and readily enough, but after she has spoke long, or hastily, or eagerly, she is not able to speak a word, but becomes as mute as a Fish, nor can she recover the use of her voice under an hour or two." Willis's account clearly emphasizes the cardinal feature of fatigable weakness, which involves the limbs and bulbar muscles. He further warned physicians not to mistake these patients for hysterics, a warning, which often goes unheeded today.

Effective treatment for MG began in the 1930s. Walker, as a house officer, appreciated the similarity of MG to curare poisoning, and she treated a patient with MG with physostigmine, the treatment for curare poisoning, leading to prompt improvement in the patient's ptosis [3]. At the turn of the last century, reports began to appear which associated the presence of thymic tumors and MG [4]. Blalock removed a thymic cyst from a 19-year-old woman who had suffered for years with worsening relapsing and remitting weakness [5]. After the surgery, the patient improved significantly. Later, Blalock reported the observations from six patients with MG; all improved postoperatively [6]. With these reports thymectomy became an established treatment although its efficacy is poorly supported by evidence-based review [7] and is the subject of an ongoing randomized clinical trial [8].

A mainstay of treatment, corticosteroids, which became available in the 1950s, was not quickly accepted as therapy. Initial results of adrenocorticotropic hormone (ACTH) were not impressive, and widespread use of prednisone waited until the 1970s (for review, see Rowland [9]). Established clearly through the work of Patrick and Lindstrom [10], the autoimmune basis of MG has led to the application of various immunotherapies to treatment.

Etiology and Pathogenesis

Physiologic Defect

MG is characterized by a reduction of the endplate potential necessary for action potential generation secondary to the reduction of skeletal muscle acetylcholine receptors (AChR) [11]. The reduction of AChR is caused by antibodies directed at the receptor directly or through compromise of signaling that clusters AChR at the junction. Antibodies to the muscle-specific kinase (MuSK) [12] were discovered among patients with MG in 2000 and in 2011 to LRP-4 [13, 14]. MuSK and LRP-4 are involved in the concentration of AChR to the neuromuscular junction. With repetitive stimulation or repeated activity, the amount of acetylcholine released is insufficient to activate the remaining AChR of the damaged neuromuscular junctions to achieve an endplate potential above the threshold for action potential generation.

The safety factor for neuromuscular transmission is defined as the difference between the membrane potential and the threshold potential for initiating an action potential. Quantal release, AChR conduction and density, postsynaptic architecture and sodium channel density, and acetylcholinesterase (ChE) activity all contribute to the endplate

potential and influence the safety factor [15]. AChR are normally activated only once in response to acetylcholine (ACh) released by a nerve terminal action potential. Inactivation of ChE prolongs the duration of action of ACh and slows the decay of the endplate current. Postsynaptic folds form a high-resistance pathway that focuses endplate current flow on voltage-gated sodium channels concentrated in the depths of the folds. Both these factors reduce the action potential threshold at the endplate and serve to increase the safety factor. Human junctions are smaller and have more extensive folding than other mammals, suggesting an evolutionary pressure towards postsynaptic modifications to enhance safety factor. The destruction of the postsynaptic membrane also disrupts the architecture of the secondary synaptic folds and reduces sodium channel density, which contributes to the compromise of the safety factor. Decreased temperature or inhibition of ChE produces an increase in endplate potential, which may be adequate to achieve threshold. In the diagnosis of MG, this property is exploited for the ice pack and edrophonium tests (see below).

Immunopathogenesis

MG is one of the few disorders that fulfills strict criteria for an autoimmune disease [16]. (1) The antigen can be administered to an animal and induce a disorder analogous to MG. (2) Passively transferred antibodies to animals produce the clinical manifestations and electrophysiological abnormalities observed in MG patients. (3) Immunoglobulin is bound to the neuromuscular junction of the myasthenic, and AChR isolated from myasthenic muscle has antibody bound. (4) AChR antibody can be detected in up to 90 % of MG patients. Some seronegative patients may synthesize AChR antibody, which is not detected by the assays commonly used, or antibody to muscle antigens other than the AChR. (5) Treatments that reduce the serum concentration of AChR antibody improve myasthenic weakness.

AChR antibodies produce the neuromuscular transmission defect in MG by three mechanisms (Fig. 48.1) [17, 18]. The most important is complement-mediated destruction of the neuromuscular junction. Complement is associated with degraded membranous material, and the abundance of complement correlates with the degree of junctional fold destruction. Antibody also cross-links AChR and increases their degradation rate, and the ability of AChR antibody to increase degradation correlates with clinical manifestations to some degree. Monoclonal antibodies that bind to the ACh-binding site produce experimentally acquired MG in animals within hours of injection by a direct blockade of ACh-induced opening of the ion channel. Antibodies directly modify AChR channel function although such antibodies appear to be only a small fraction of the total serum AChR antibodies in a given MG patient. Therefore, modification of AChR channel function is not a major mechanism in compromising neuromuscular transmission, but dramatic exceptions do exist. MG patients have small amounts of anti-AChR antibodies that recognize the cholinergic binding site. Such antibodies cause acute, severe weakness in animals, which suggests that antibodies may cause a functional block of the AChR and produce profound weakness at low concentrations.

AChR antibodies are polyclonal IgG subclasses which bind to many different sites on the AChR [18]. Investigators using monoclonal antibodies towards the AChR have defined immunogenic regions on the α-subunit of the AChR. The majority of myasthenic antibodies bind to the so-called main immunogenic region (MIR), which is located on the extracellular loop of α-subunit of the AChR. The reasons for the domination of the MIR over AChR antibody distribution are not known. In other autoimmune disorders, a few epitopes dominate the immune response to a protein antigen, and the MIR may be a particular focus of the antibody response in MG. Cross-reactivity of the MIR with epitopes on microbial or autologous antigens could facilitate the antibody response to the MIR by molecular mimicry. Although AChR antibodies characterize MG, the correlation between their serum concentration in individual patients and clinical severity is poor. Some AChR antibodies bind without causing damage, serving only as a marker of the disease, and explaining why some patients in remission continue to have high levels of serum antibodies [19].

Autoantibody production in MG is a T-cell-dependent process, and a breakdown in tolerance towards self-antigens appears to be the primary abnormality in MG. The thymus plays a key role in tolerance induction to self-antigens and in responsiveness of lymphocytes to foreign antigens. The immature T cells pass through the thymic cortex, and those which recognize self-major histocompatibility complex (MHC) antigens pass through the medulla. During this stage in thymic cortex, T cells, which would react towards self-antigens, are removed; however, the mechanisms by which this occurs are not known. Sequestration of antigens from the immune system may also be important in preventing autoimmune attack. Once in the medulla, the T cells differentiate into helper and suppressor cells and eventually are released to the periphery.

The development of a T-cell-dependent autoimmune disease is caused by a loss of self-tolerance [20]. How a loss of tolerance develops in MG is not understood, but several pieces of data indicate that thymic abnormalities are important [21]. First, pathological changes of the thymus occur in 90 % of myasthenics, lymphoid follicular hyperplasia occurs in 80 %, and neoplasia in the remainder. Some patients have a normal or atrophic gland. Compston et al. [22] found that differences in thymic histology correlated with certain

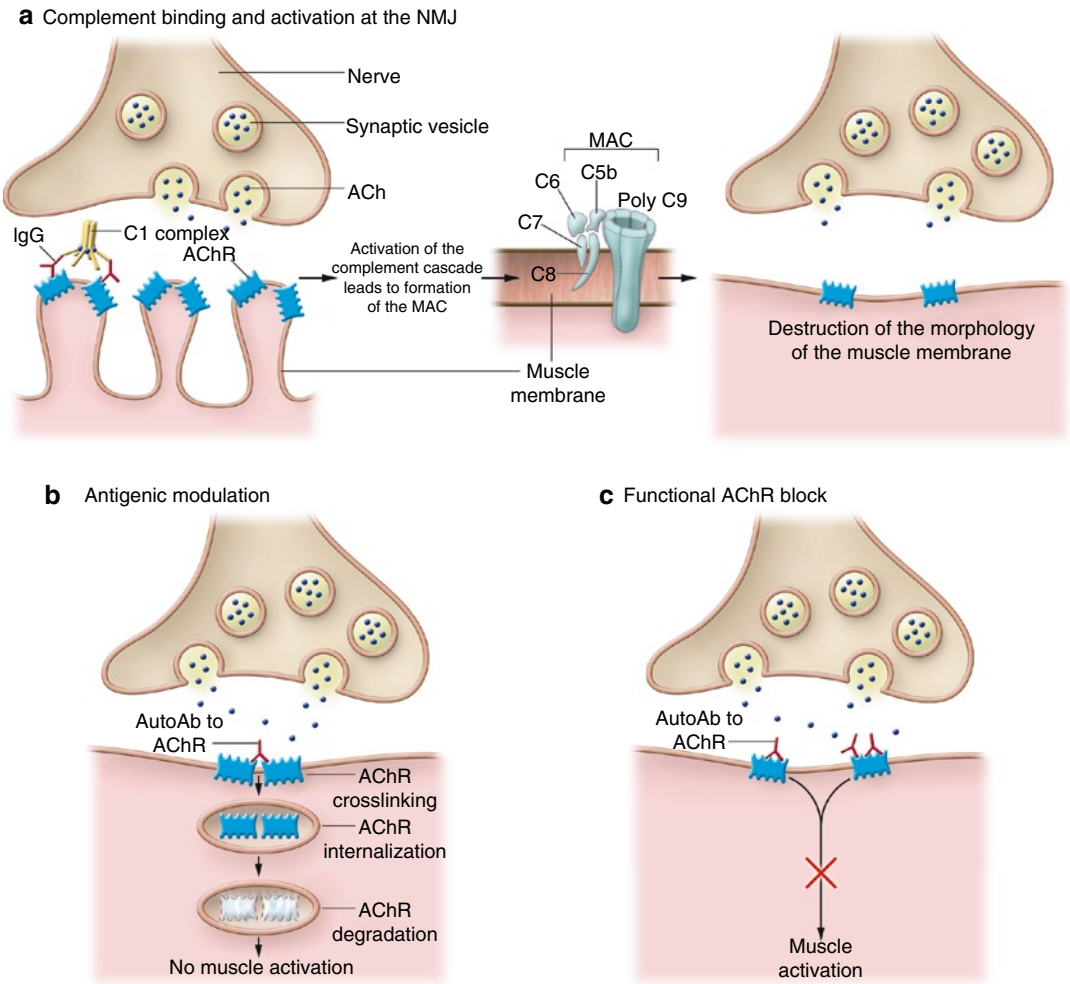

Fig. 48.1 Mechanisms of AChR antibodies that compromise neuromuscular transmission. (**a**) Antibody binds to the AChR, activates the complement cascade, and leads to formation of membrane attack complex (MAC) and localized destruction of the postsynaptic NMJ membrane. This ultimately leads to a simplified morphology of the postsynaptic membrane, which lacks the normal deep folds and has a relatively flat surface. (**b**) Antibodies may cross-link AChR molecules on the postsynaptic membrane, causing endocytosis of the cross-linked AChR molecules and their degradation (antigenic modulation). This ultimately leads to a reduced number of AChR molecules on the postsynaptic membrane. (**c**) Antibodies may bind to the ACh-binding sites of the AChR causing functional block of the AChR by interfering with binding of ACh and failure of neuromuscular transmission (From Conti-Fine et al. [16], with permission)

clinical features. Patients with thymoma had no sex or HLA associations, high titers of AChR antibody, high titers of striated muscle antibodies, and a low frequency of associated autoimmune diseases. Second, thymectomy may improve the clinical course of MG [7]. Third, AChR antibody-producing cells may be isolated from thymus, bone marrow, and peripheral blood, but a greater proportion of antibody is spontaneously produced by thymic cells [23]. These observations may explain the therapeutic benefits of thymectomy and that thymectomy does not lead to complete resolution of the disorder. Finally, the thymus contains proteins which are antigenically similar, or identical, to the AChR. Myoid cells, which express muscle proteins and form muscle fibers in tissue culture, are present in normal and hyperplastic thymus of MG patients. Cultured myoid and thymus cells of MG patients express transcripts of AChR subunits, and some AChR antibodies and α-bungarotoxin will bind to myoid cells. Epithelial cells from thymomas bind AChR antibodies and express transcripts of the α-subunit, but functional AChR are not expressed. The expression of antigenically similar proteins to the AChR in the thymus would provide a source of antigen for autosensitization of T cells towards the skeletal muscle AChR [23].

With increasing disease duration, $CD4^+$ sensitization spreads to larger parts of the AChR. The epitope repertoire of anti-AChR $CD4^+$ cells in MG patients is complex and characteristic of an individual patient. The $CD4^+$ cells recognize epitopes formed by a number of sequence regions on each AChR subunit. A few sequence regions are recognized in most or all MG patients and by large numbers of $CD4^+$ cells.

They form $CD4^+$ epitopes that are both universal and immunodominant. These universal epitopes sensitize pathogenic $CD4^+$ cells and drive the synthesis of AChR antibodies. Thus far, studies of the T-cell receptors of the AChR $CD4^+$ cells in MG patients do not allow the distinction between an initial pathogenic mechanism that entails molecular mimicry and the intervention of a superantigen. Superantigens, found on viruses or bacteria, stimulate particularly powerful proliferative responses, which could stimulate anergic T cells directed towards self-antigens like the AChR [24].

Patients with MG demonstrate a broad and variable spectrum of muscle group involvement. The basis for this differential involvement must be due to a combination of inherent differences in physiological properties of the muscles, a given muscle's ability to adapt to disease-induced damage, and the specific nature of the antibody-mediated damage. With the exceptions of extraocular muscle (EOM), however, the reasons for the differential involvement of a given muscle group are poorly defined (for review, see Ref. [25]).

Clinical Presentation

The manifestations of MG are remarkably varied, and for any patient with weakness and fatigue, MG is a diagnostic consideration [26, 27]. Of course, intermittent symptoms, in particular, those that appear with repetitive activity, are strong indicators of a neuromuscular transmission disorder. However, nearly all patients with diseases of the nervous system complain of excessive tiredness, and a clear deterioration in muscle strength should be determined.

Nearly half of the patients present with EOM weakness, manifested roughly equally between ptosis and diplopia. Most importantly, almost all patients at some point during the course of their illness develop ocular manifestations. Hence, the diagnosis of MG may need to be questioned, if ocular manifestations do not develop. Within 6 months of presentation, slightly more than half of the patients develop generalized disease, and three-quarters of the patients will have bulbar or extremity weakness within the first year. After 3 years of onset, only 6 % of ocular myasthenics develop generalized disease, but rarely a patient with ocular myasthenia develops generalized disease decades after initial presentation. In up to 15 % of MG patients, clinical involvement is restricted to the EOM. On examination, ptosis usually develops within 2 min of constant upgaze. Patients often have different degrees of ptosis of each lid and may have marked unilateral lid weakness and hyper-retraction of the contralateral lid. With elevation of the ptotic lid, the other lid will droop, a sign specific for MG [28, 29].

About 20 % of patients with MG present with prominent manifestations of dysarthria and dysphagia. Because of palatal muscle weakness, speech becomes nasal, and regurgitation of liquids through the nose occurs. Jaw muscles may be prominently affected with a "jaw drop" leading patients to hold their jaw closed. Facial muscle weakness produces a smooth face and the smile becomes straight. The pattern of prominent weakness of cranial-innervated muscles leads some classifications of MG to place such "bulbar" patients into a set category, and such a grouping was supported by the Myasthenia Gravis Foundation of America (Table 48.1) [30, 31]. The justification is that these patients may differ somehow in their underlying disease pathogenesis and, perhaps, response to therapy.

Table 48.1 Myasthenia Gravis Foundation of America clinical classification

Class I	Any ocular muscle weakness
	May have weakness of eye closure
	All other muscle strength is normal
Class II	Mild weakness affecting other than ocular muscles
	May also have ocular muscle weakness of any severity
IIa	Predominantly affecting limb, axial muscles, or both
	May also have lesser involvement of oropharyngeal muscles
IIb	Predominantly affecting oropharyngeal, respiratory muscles, or both
	May also have lesser involvement of limb, axial muscles, or both
Class III	Moderate weakness affecting other than ocular muscles
	May also have ocular muscle weakness of any severity
IIIa	Predominantly affecting limb, axial muscles, or both
	May also have lesser involvement of oropharyngeal muscles
IIIb	Predominantly affecting oropharyngeal, respiratory muscles, or both
	May also have lesser involvement of limb, axial muscles, or both
Class IV	Severe weakness affecting other than ocular muscles
	May also have ocular muscle weakness of any severity
IVa	Predominantly affecting limb, axial muscles, or both
	May also have lesser involvement of oropharyngeal muscles
IVb	Predominantly affecting oropharyngeal, respiratory muscles, or both
	May also have lesser involvement of limb, axial muscles, or both
Class V	Defined by intubation, with or without mechanical ventilation, except when employed during routine postoperative management. The use of a feeding tube without intubation places the patient in class IVb

The breadth of clinical presentations is remarkably varied, and the clinician must be vigilant to this fact. Despite the hallmarks of fatigue and ocular muscle involvement, such manifestations may at times be overwhelmed by severe weakness where fatigue is not readily appreciated, or severe involvement of non-ocular muscle groups. A few examples emphasize this point. Respiratory muscle weakness or upper airway obstruction may occur as an isolated manifestation [32, 33]. Such patients commonly take rapid shallow breaths,

and their condition may be confused with psychogenic hyperventilation. This presentation is particularly dangerous because of the risk of acute respiratory arrest. Rarely, MG may be manifested postoperatively among patients who are unexpectedly difficult to wean from the ventilator. Acute onset of isolated limb weakness or dysarthria may lead to confusion with stroke, especially among the elderly [34, 35]. Weakness of neck extensors or distal limb muscles may occur in isolation [27, 36].

One of the reasons that the diagnosis of MG is often not appreciated by non-neurologists is its relative rarity. The prevalence rate of MG is estimated at about 400 per million with incidence estimates of less than 6 per million [37, 38], but marked variation in rates exists likely related to demographic characteristics and perhaps environmental factors. The incidence and prevalence of MG appears to be higher among African-Americans than Caucasians [39]. The peak incidence of MG in Japanese and Chinese populations occurs before age 20, and ocular myasthenia appears to be more common than in Caucasians [40, 41]. The common characterization of MG as a disease of young women and old men continues to be true. Similar to nearly all autoimmune disorders, women between the ages of 20 and 45 have a peak incidence and prevalence. The overall frequency of MG then rises with age with some studies showing that men and women have equal frequencies of the disease.

Differential Diagnosis

The differential diagnosis of ocular MG is relatively limited (Table 48.2) [29, 42]. Ocular myasthenia may mimic cranial neuropathies or intrinsic brainstem dysfunction, but several features aid in distinguishing these disorders. Since MG never involves the pupil, isolated ptosis is easily differentiated from Horner's syndrome and third cranial nerve dysfunction. Unilateral ptosis may be a sign of a third cranial nerve abnormality, but painless ptosis developing over several days is most consistent with MG. Alternating or recurrent ptosis is usually caused by MG. Isolated abduction weakness caused by MG may mimic sixth nerve palsy but can be differentiated by fatigability or involvement of other muscles. MG may produce isolated medial rectus weakness causing a "pseudo-internuclear ophthalmoplegia." Patients with a true internuclear ophthalmoplegia usually have spared convergence and have other signs of brainstem disease. Graves' ophthalmopathy produces a limitation of ocular movement but can be differentiated from MG by the absence of ptosis and presence of proptosis. Forced ductions confirm the restrictive nature of EOM, and radiologic imaging demonstrates enlargement of EOM. However, one must bear in mind that MG and Graves may coexist. Chronic progressive external ophthalmoplegia, a mitochondrial disorder, leads to progressive symmetric ophthalmoparesis with ptosis that may be confused with ocular myasthenia, but the lack of fluctuating weakness, evidence of systemic disease, and slow saccades in the mitochondrial disorder should differentiate the disorders clinically.

Table 48.2 Clinical presentations and diagnostic considerations in myasthenia gravis

Site of predominant weakness	Other diagnostic considerations
Ocular	Brainstem and motor cranial nerve pathology including Horner's syndrome, oculopharyngeal muscular dystrophy, Kearns-Sayre syndrome, Graves' disease, congenital myasthenia
Bulbar	Brainstem and multiple cranial nerve pathology, motor neuron disease, obstructive lesion of the nasal and oropharynx
Lateralized limb weakness	Stroke, peripheral nerve or root lesion
Distal extremity	
Arm	Distal myopathies
Leg	Peroneal neuropathy or L5 radiculopathy
Isolated respiratory	Acid maltase deficiency, myotonic dystrophy, polymyositis, motor neuron disease, Lambert-Eaton myasthenic syndrome,
Isolated neck	Motor neuron disease, inflammatory myopathy, paraspinous myopathy

Confusion of generalized MG with other neuromuscular disorders must be guarded against (Table 48.2) [42]. Polymyositis, inclusion body myositis, and late-onset muscular dystrophies can be distinguished from MG by the presence of elevated serum creatine kinase, abnormal needle electromyography, and characteristic muscle pathology. Endocrine disorders, such as hyper- and hypothyroidism, glucocorticoid excess, and adrenal insufficiency, produce generalized extremity weakness but usually are differentiated by associated clinical findings and characteristic laboratory abnormalities. Autoimmune thyroid diseases may coexist with MG and complicate the diagnosis of both conditions. Motor neuron disease and MG may mimic each other; however, electromyography should distinguish the disorders. The bulbar form of amyotrophic lateral sclerosis may mimic bulbar MG, but the pyramidal findings associated with motor neuron disease (including brisk jaw jerk and gag reflexes) distinguish the disorders. LEMS and MG may be difficult to differentiate clinically [43], and rarely, LEMS presents with pure ocular manifestations or oculobulbar weakness, more typical of MG [44, 45]. Autonomic manifestations, especially dry mouth, as well as proximal muscle ache point to LEMS. Typical electrodiagnostic findings and detection of serum antibodies against neuronal calcium channels should identify LEMS.

Congenital myasthenic syndromes may be confused with MG, in particular in patients without detectable AChR antibodies. However, these patients usually have a much longer history, often dating to birth, with gradual deterioration in function. Unfortunately, patients with congenital myasthenia may have been treated with immunosuppressive therapies, and a lack of response may also suggest this diagnosis. Certain specific electrodiagnostic findings, such as identification of repetitive compound muscle action potentials to a single stimulation, may suggest the slow channel syndrome or acetylcholinesterase deficiency. A lack of a family history does not eliminate this diagnosis as many of the congenital myasthenic syndromes are autosomal recessive or spontaneous mutations.

Just as the fatigable weakness of MG should not be confused with psychiatric disease, vague symptoms of "tiredness," which represent underlying depression, should not be considered evidence of MG. In my practice I have encountered patients with somatization disorders who were mislabeled with the diagnosis of MG. The incorrect diagnosis of MG may have devastating consequences. Depression may occur among patients with MG, which may complicate diagnostic assessment, and patients with MG often are mistakenly identified as having psychiatric disorders.

Evaluation and Diagnosis

Once MG is suspected based on clinical findings, the physician should attempt to confirm the diagnosis based on objective criteria. Diagnostic tests include the clinical tests, electrodiagnosis, and serology for AChR antibodies. Each has its pitfalls, which the clinician must be aware.

Improvement in strength after intravenous injection of edrophonium is the hallmark of a postsynaptic neuromuscular transmission disorder. Opinions as to the exact manner in which edrophonium should be administered vary, but in general for adults, a 1–2 mg test dose is given intravenously, and if no improvement occurs within 45 s, an additional 3 mg is given [46]. If improvement occurs in a single weakened muscle, the test is considered positive. If no clear increase in strength is appreciated, a total of 10 mg of edrophonium is given. A response is expected within 5 min. It is unnecessary to administer a larger dose, if the test has proven positive. This only increases adverse affects. The test is most useful if improvement in ptosis or the strength of an EOM is demonstrable because of the objective nature of this response. Difficulties arise in interpretation of the test when attempting to evaluate improvement in limb strength or bulbar function. Patients with bulbar muscle weakness may actually complain of worsened swallowing because of excess secretions produced by edrophonium. Additional, adverse affects include tearing, sweating, and gastrointestinal cramps. Rarely, diarrhea may occur as well as bradycardia with hypotension. Atropine should be immediately available to counteract significant bradycardia. Patients with asthma should be tested with caution. Injection of saline and edrophonium in a double-blind fashion is not useful given the obvious muscarinic side effects, which make blinding impossible for examiner and patient. False-positive edrophonium tests are described with motor neuron disease, LEMS, and intracranial mass lesions [47]. Physicians should not "talk themselves into" a positive response and should set clear standards for positive results. False-negative tests are relatively common, and repeated tests are of value. Within the proper clinical context, a single positive edrophonium test is strong support for the diagnosis of MG. Unfortunately, because of rare, severe adverse effects, edrophonium testing has become less popular in the United States leading to greater use of the rest and ice pack tests.

The ice pack test is performed by having a patient with ptosis. An ice pack is placed over the eyes for 5 min. Improvement in ptosis is appreciated and at times improvement in eye movement [48, 49]. Some patients may have difficulty tolerating the ice pack. For the rest test patients are asked to lie for 30 min with eyes closed and ptosis evaluated before and after [50]. The test is inconvenient for the busy outpatient practice, although clearly without risk. Both these tests lack the widespread clinical experience of the edrophonium test [51].

There are three AChR antibody tests and they should be performed in a selective manner. There is no need to perform all the varieties of AChR antibody tests or striational muscle antibody tests. When screening a patient for MG, the AChR binding antibody is the most sensitive test and, in my opinion, the only one that should be performed. The blocking antibody does not add significantly to the diagnostic yield, and the modulating antibody evaluation has a greater potential for false positives. About 85 % of patients with generalized MG will have elevated binding antibodies, while at best 50 % of ocular myasthenics will be positive [52, 53]. Repeat testing is useful in patients with recent symptom onset since the frequency for seropositivity increases with time. About three percent of patients with generalized MG and a very small number of ocular myasthenics will have antibodies against MuSK [54, 55]. I test for MuSK antibodies only in patients who are negative for AChR antibodies. The MuSK antibody test is about five times as expensive as the AChR binding evaluation. Serological testing is a useful adjunct to the diagnosis of MG; however, a large minority of patients will be seronegative, and confirmation of the diagnosis will rely on other diagnostic testing. Also, the clinician must be mindful that on rare occasions, AChR antibodies are detected in other conditions when there is no clinical or electrophysiological evidence of MG.

Striational antibodies are only present in patients with MG who are also positive for AChR antibodies [56] and, therefore, have no diagnostic value. Antistriational antibodies may

also be detected in LEMS, other autoimmune and paraneoplastic diseases, thymoma patients without MG, and the normal elderly. Therefore, there is the risk of confusing diagnosis by their identification in patients without MG. Antistriational muscle antibodies are a marker for thymoma. Elevation of antistriational antibodies among patients between the age of 20 and 50 increases the diagnostic likelihood of thymoma [57]. However, the gold standard for diagnosis of thymoma is imaging, and therefore, assessment of antistriational antibodies is of limited use even in thymoma assessment.

Patients seronegative for both AChR and MuSK antibodies and MG may represent a special subset of acquired autoimmune MG. Some of these patients likely harbor other autoantibodies. In 2011, antibodies were detected to LRP-4 in sera of "double-negative" patients; however, commercial testing for these autoantibodies as yet is not available, and evaluation of the pathogenic nature of LRP-4 antibodies is ongoing [13, 14]. Determination of autoantibody status is clinically important, not only for diagnosis but also guidance of treatment decision. MuSK-positive patients do appear to respond poorly to cholinesterase therapy and better to plasma exchange compared to the AChR-positive patients. It is likely that a portion of seronegative patients have high-affinity antibodies to neuromuscular junction proteins that are at such low levels in the serum that they cannot be identified by conventional assays [52].

Electrodiagnostic studies (Figs. 48.2 and 48.3) are critical in the evaluation of the patient with possible MG, and their performance is detailed elsewhere in this text. A decremental response of the compound muscle action potential with slow 2–3 Hz repetitive stimulation is identified in at least three-quarters of patients with MG [53]. Ocular myasthenics despite lack of generalized manifestations may also demonstrate a decremental response but in a lower percentage than generalized myasthenics [59]. As with serological testing, a decremental response with slow repetitive stimulation is observed in LEMS congenital myasthenias, botulism, and motor neuron disease. Therefore, electrodiagnostic testing needs interpretation in the context of clinical presentation. Single-fiber EMG is the most sensitive test for detecting abnormalities consistent with MG (Fig. 48.4) [61]. However, its usefulness is compromised by its time-intensiveness and requirement for specialized equipment and training. Therefore, it should be used only by experienced electromyographers in the definitive diagnosis of suspected MG patients, whose other diagnostic tests are normal and who do not harbor other neuromuscular diseases.

The evaluations above often confirm or refute the clinical impression of MG; however, there are a small minority of patients that prove difficult to diagnose. Some patients do not have clear fatigue or fluctuation in severity of weakness making recognition difficult. Serological testing and slow repetitive stimulation studies have a poor sensitivity further complicating diagnosis (Fig. 48.4).

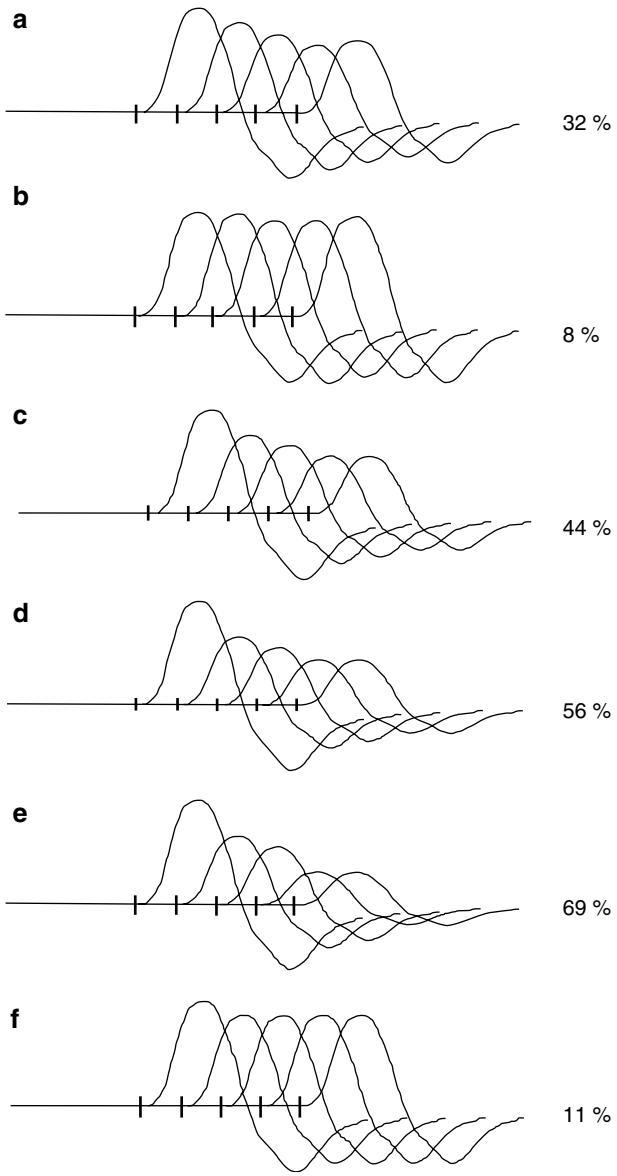

Fig. 48.2 Three Hz repetitive nerve stimulation in a patient with myasthenia gravis. (**a**) Decrement of compound muscle action potential (CMAP) amplitude at rest. (**b**) Postexercise facilitation: decrement of CMAP immediately following 10 s of maximal voluntary exercise. Decrement has repaired towards normal. (**c**, **d**, **e**) Postexercise exhaustion: decrements of CMAP 1, 2, and 3 min after 1 min of maximal voluntary exercise. Decrement becomes progressively more marked over the baseline decrement. (**f**) Postexercise facilitation after a decrement: immediately following another 10 s of maximal voluntary exercise, the decrement, which has worsened as a result of postexercise exhaustion, repairs towards normal (From Preston and Shapiro [58], with permission)

In addition to diagnostic testing, every MG requires evaluation of commonly associated diseases. Thyroid dysfunction is a frequent accompaniment of MG and may aggravate myasthenic weakness. Rheumatoid arthritis and systemic lupus erythematosus also occur more frequently among

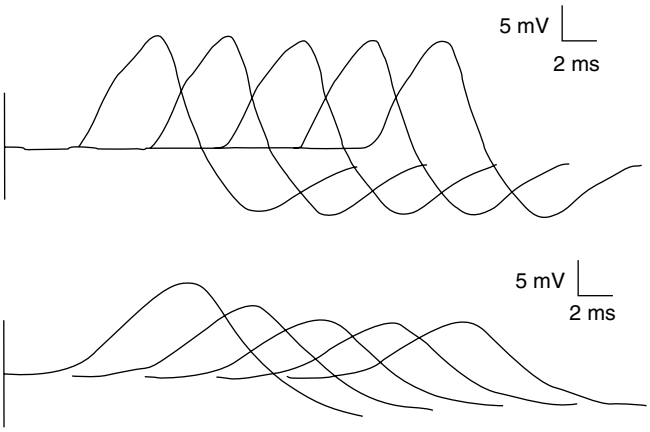

Fig. 48.3 Three Hz repetitive nerve stimulation of proximal and distal nerves in patient with myasthenia gravis. (*Top trace*) Normal decrement (4%) in the ulnar nerve. (*Bottom trace*) Markedly abnormal decrement (42%) in the spinal accessory nerve. In myasthenia gravis, the yield of an abnormal decrement is greater with proximal nerves (From Preston and Shapiro [58], with permission)

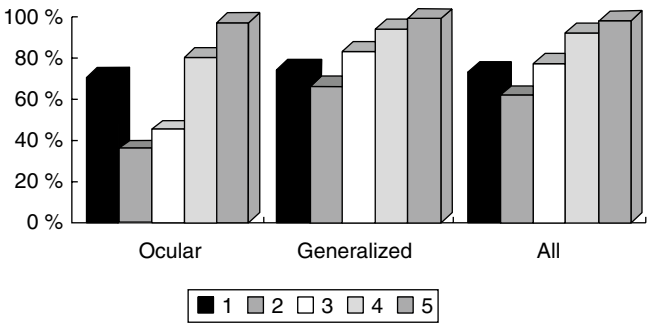

Fig. 48.4 Comparison of diagnostic techniques in myasthenia gravis. *1* AChR antibody positive, *2* Slow repetitive nerve stimulation (RNS) recording hand muscle, *3* Slow RNS recording shoulder muscle, *4* Single fiber EMG of forearm muscle, *5* Single fiber of EMG of facial muscle (Adapted from Oh et al. [53] and from Howard et al. [60])

patients with MG, and if clinically indicated patients, patients may require further evaluation for these disorders. Computed tomography or magnetic resonance imagining of the chest is needed to evaluate for thymoma. In patients with respiratory or bulbar manifestations, pulmonary function tests and barium swallowing studies are helpful in gauging the severity of the disorder. In anticipation of prednisone use, evaluation for tuberculosis and bone density measures are indicated. Screening for IgA deficiency is appropriate for those patients likely to receive intravenous immunoglobulin therapy.

Treatment

Care of the newly diagnosed myasthenic begins with a thorough discussion with the patient, family, and caregivers of the natural history, treatment options, and pathogenesis of the disease. Patients may be directed to the website of the MG Foundation of America or other international organizations, which provide excellent resources on various aspects of the disease. Support group services provided by these organizations are of particular benefit for many patients. Patients should receive a list of medications, which may exacerbate myasthenic manifestations and that such medications need to be used with caution. Because of the patient's special needs and unfamiliarity of primary care physicians with MG, the patient may wish to be provided by their primary care physician with information about MG. The patient should be educated on adverse effects of treatment and approaches to minimize severe side effects of treatment. Often a discussion of the costs of medication is necessary (Table 48.3). Psychological adjustment is difficult to a chronic illness in which definite predictions of outcome cannot be made and patients fear the development of incapacitating weakness. These fears may limit an individual's functional improvement despite significant resolution of myasthenic weakness. The neurologist should attempt to strike a balance between the difficulties in treating MG and the hope of complete remission.

Treatment choices must be individualized based on the severity of the disease, patient's lifestyle and career, associated medical conditions, and the patient's assessment of risk and benefit of various therapies. For example, an older individual with a sedentary lifestyle and mild general weakness may do well with cholinesterase inhibitors, while a young woman with an active career may require immunosuppressive treatment. Of course, the complications of immunosuppressive treatment need thorough explanation, and the patient and physician must work together to optimize the care plan.

Cholinesterase Inhibitors. ChE inhibitors, which retard the hydrolysis of ACh at the neuromuscular junction, are the initial treatment of MG. Pyridostigmine bromide is the only oral ChE inhibitor easily available in the United States. Initial therapy begins at doses of 30–60 mg with individual doses of greater than 120 mg rarely being affective. Dosing intervals of pyridostigmine are set at 3–6 h depending on symptoms. Timed-release forms are available but tend to have erratic absorption; however, they may be useful in some patients. Gastrointestinal complaints of nausea, diarrhea, and abdominal cramps are most common but may be controlled with administration of atropine and glycopyrrolate. Muscle twitches, fasciculations, and cramps are less common but may be particularly bothersome to patients. Rarely, patients may develop confusion from ChE inhibitor therapy. Respiratory secretions may be increased, which complicates treatment of patients with reactive airway diseases and may actually worsen breathing. Patients with dysphagia may have a worsening of symptoms from excess and thick saliva, especially when concomitant treatment with antimuscarinic medications is used. Such apparent paradoxical responses should

Table 48.3 Mechanism of action, cost comparison, and time of onset of clinical benefit for pharmacological agents used in myasthenia gravis

Drug	Mechanism of action	Cost in the USA[a]
Pyridostigmine 60 mg tablets	Reversibly binds to and inactivates acetylcholinesterase	$88 (120 tabs)
Pyridostigmine 180 mg controlled release (time span)		$126 (30 tabs)
Prednisone 20 mg tablet	Anti-inflammatory effects related to the following: (a) redistribution of lymphocytes and reduction of production and differentiation; (b) alterations of function of TNF, IL-1, and IL-2; (c) inhibition of antigen processing and presentation by macrophage	$12 (30 tabs)
Azathioprine 50 mg tablet	Inhibits T- and B-cell proliferation by reducing nucleic acid (purine) synthesis	$ 84 (120 tabs)
Mycophenolate mofetil 500 mg	Inhibits T- and B-cell proliferation by inhibition of guanosine nucleotide synthesis. Additional mechanisms include (a) apoptosis of activated T-lymphocytes, (b) decrease in cell adhesion molecules thus reducing lymphocyte recruitment, and (c) reduction of inducible NOS activity	$130 (100 tabs)
Tacrolimus 1 mg capsule	Calcineurin-mediated pathway inhibition of T-cell and IL-2 production. Modulates the activity of T-cells, increases their apoptosis, and may enhance T regulatory cells	$ 423(100 tabs)

[a]From Epocrates® online searched in July 2012

be appreciated, and a reduction of ChE inhibitor dose may improve symptoms. Patients frequently appreciated that effectiveness of pyridostigmine diminishes over time and this may be explained by expression of a soluble splice variant of the ChE gene, which is not effectively inhibited by pyridostigmine [62].

ChE inhibitor-induced weakness ("cholinergic crisis") is frequently discussed but is rarely encountered now that effective immunosuppressive treatment is available. The use of intravenous edrophonium to determine if muscle weakness is secondary to MG or ChE treatment is unreliable. Therefore, if cholinergic weakness is seriously considered, then ChE therapy should be temporarily discontinued and the patient monitored for improvement. In patients with myasthenic crisis, discontinuation of cholinesterase inhibitors is recommended to limit secretions while on artificial ventilation [63].

Glucocorticoids. Corticosteroids are usually recommended for patients with ocular and generalized or bulbar weakness which does not improve significantly with ChE inhibitor treatment. There is no consensus on the dose and manner of initiation of corticosteroid therapy [64–67]. Some advocate high-dose prednisone (80–100 mg) treatment until clinical improvement occurs followed by alternate-day steroid treatment with gradual tapering as tolerated [68]. Some patients may develop worsening of strength usually within the first few days, of treatment, which has lead to the recommendation for gradual initiation of corticosteroids [69]. For patient on a ventilator, there is no benefit delaying high-dose therapy, especially, if acute treatments, such as IV IG or plasma exchange, are being performed. Eighty percent of patients may expect significant improvement or resolution of weakness on such a regimen during the first months of therapy. However, prior to the widespread use of immunosuppressives used as "steroid-sparing" agents, few patients were able to stop corticosteroid treatments [68].

The clinical situation dictates the optimal treatment regimen. The patient in myasthenic crisis or hospitalized with severe general weakness or dysphagia requires acute treatment with IVIg or plasma exchange. Here, high-dose steroids should be started immediately since these other treatments, in my experience, limit the degree of steroid-induced exacerbation and the time of treatment response hastened. In contrast, patients with mild to moderate weakness may have corticosteroids initiated on a gradually escalating dosage regimen as outpatients [65, 70]. The potential complications of corticosteroids, as described elsewhere in this text, are legion and the patient must be made aware of them.

Azathioprine (Imuran®). Azathioprine is a purine analogue, which inhibits synthesis of nucleic acids. The primary effect on the immune system is interference with T- and B-cell proliferation. Azathioprine is used for treatment of patients with moderate to severe myasthenia alone or in combination with corticosteroids [71, 72]. It is critical to appreciate that azathioprine has a long onset to initial clinical response of at least 12 months. The efficacy of azathioprine in reducing the daily dose of corticosteroid and clinical outcome was demonstrated in a randomized trial. A steroid-sparing effect was only identified at 18 months of treatment. It is critical for the patient to receive a dose based on weight (1–3 mg/kg/day). Underdosing may lead to the false impression of a lack of efficacy. An increase of mean corpuscular

volume and decrease in lymphocyte counts are indicators of a biological effect of azathioprine [73].

About 10 % of patients upon initiation of therapy develop fever and flu-like symptoms necessitating discontinuation of the medication. Adverse reactions appear to be related to the activity of the thiopurine *S*-methyltransferase enzyme which metabolizes azathioprine [74]. Increased rates of lymphoma occur in patients treated with azathioprine, and this risk needs explanation to the patient. Monitoring of liver function tests and complete blood counts is necessary throughout the treatment course. Improvement tends to correlate with elevations of mean red blood cell volume.

Mycophenolate mofetil (CellCept®). Mycophenolate mofetil effects primarily T- and B-cell proliferation through inhibition of guanosine nucleotide synthesis. Initial evaluation of mycophenolate with brief follow-up indicated that it was effective in reducing corticosteroid dose and reduced AChR antibody levels leading to its common use [75]. Two randomized, controlled trials failed to demonstrate efficacy of mycophenolate for generalized MG [66, 76]; however, the trials have been criticized for several reasons, primarily their short duration [77, 78]. Mycophenolate mofetil is given at standard dose of 1 g twice daily, but I have increased the dose in patients with poor response and who are over 90 kg. Mycophenolate is generally well tolerated, except for initial minor gastrointestinal intolerance. Rarely, bone marrow depression may occur with anemia, thrombocytopenia, and leucopenia. Mycophenolate may increase the risk of malignancy, and occasional cases of progressive multifocal leukoencephalopathy have been reported, although not as yet in patients with MG.

Cyclosporine. Cyclosporine is derived from a fungus and is a cyclic undecapeptide with actions directed exclusively on T cells. Cyclosporine blocks T-helper-cell synthesis of cytokines, in particular interleukin (IL)-2 and IL-2 surface receptors. The agent also interferes with transcription of genes critical in T-cell function. Cyclosporine suppresses T-helper-cell-dependent function, maintains tolerance in transplant patients, and prevents experimental autoimmune MG. Cyclosporine has been used to treat myasthenics previously treated with thymectomy and corticosteroids with benefit [79, 80]. In the initial studies of treatment-resistant patients, doses of 5 mg/kg/day were used. Corticosteroids were discontinued or decreased in nearly all patients in clinical trials of the agent; however, 5 % of patients could not tolerate the drug. In general practice, adverse effects of hypertension and renal insufficiency limit its use, and in the last 10 years, use of the agent appears to have decreased among experts in the field.

Tacrolimus (Prograf®). Tacrolimus is a macrolide antibiotic, which inhibits calcineurin, as does cyclosporine. The agent may produce nephrotoxicity and hypertension as well as tremor and nausea. Tacrolimus has been evaluated in a randomized trial and large retrospective studies [81–83]. Taken together, the reports indicate efficacy and a safety profile superior to cyclosporine. The agent is provided in two divided doses of 0.075–0.1 mg/kg with an intention to achieve a trough level of 7–10 ng/ml.

Thymectomy. Since the popularization of thymectomy in 1940s and 1950s, the surgery has become a generally accepted treatment for patients with generalized MG. Rates of stable remission after thymectomy vary widely ranging from 15 to 90 % [7]. Comparison among studies is difficult because of variations in surgical approach (transcervical vs transsternal vs robotic vs videoscopic), time of follow-up, and population characteristics; however, the general consensus among experts is that thymectomy is an effective therapy [30, 84, 85], but a clinical trial is ongoing comparing patients randomized to thymectomy and prednisone versus prednisone alone [8]. No clear relationship among age, sex, thymic pathology, or severity of disease and clinical response to thymectomy is observed. With improvements in surgical technique, anesthesia, and respiratory care, operative morbidity and mortality approaches zero in recent reviews. Thymectomy is best performed within the first few years of diagnosis and usually recommended for patients without a significant contraindication to surgery and under age 65. The surgical method used to remove the thymus remains a point of controversy, but the greater the extent of thymic tissue removal, the better [86, 87].

Plasma Exchange. Although never subjected to a randomized control trial [88], plasma exchange is well established as treatment for severe exacerbations of MG and myasthenic crisis [89]. Typically exchanges are done to remove one to two plasma volumes three times per week up to six exchanges. In my experience, more than six exchanges are not beneficial. Patients may show improvement within 48 h while others may take up to 2 weeks [90, 91]. Treatment reduces immunoglobulin levels rapidly; however, rebound may occur in weeks, leading to clinical worsening, if concomitant immunosuppressive treatment has not begun. Its general usefulness is limited by its restriction to major medical centers and the frequent need for large-bore intravenous catheters, which leads to infectious complications. In rare patients, plasma exchange may be used as chronic therapy, but its use has not been studied.

Intravenous Immunoglobulin. Intravenous immunoglobulin IgG (IVIg) is used in similar clinical situations as plasma exchange. The primary mechanism of action is through anti-idiotype networks [92]. Treatment regimens range from 400 mg/kg/day dose for 5 days to 2 g/kg/day dose for 2 days. I prefer the latter. Treatment response may be rapid (days) but formal studies suggest 3 weeks as the expected time for a significant therapeutic benefit [93]. IVIg therapy may serve as an alternative to plasma exchange in individuals with poor vascular access or contraindications to plasma exchange [94]. IVIg may overall be a less-expensive treatment for hospitalized patients than plasma exchange [95]. IVIg is generally well tolerated with common adverse effects of headache

and nausea. However, the agent has been associated with life-threatening adverse effects of myocardial infarction, stroke, and pulmonary embolism. To date, no clear risk factors have been identified in patients for these complications. Among patients with congestive heart failure or renal insufficiency, IVIg may induce worsening of the underlying conditions. IVIg is used as chronic therapy in patients resistant to standard immunosuppressives to reduce the need for corticosteroids; however, such a practice has never undergone formal evaluation.

Other Treatments. Rituximab has been used for treatment of MG despite the lack of a significant database to warrant its use for AChR antibody-positive MG [96, 97]. In my opinion, it should only be used in treatment of patients who have failed several other immunosuppressive treatments. Cyclophosphamide is used to treat MG resistant to corticosteroids, and one study found half of the patients were asymptomatic after 1 year [98]. Some centers have utilized high-dose cyclophosphamide coupled with bone marrow reconstitution in an attempt to induce tolerance to the AChR, but in the few patients treated thus far, there have been patients that suffer recurrence of MG [99]. Methotrexate inhibits purine metabolism and thereby inhibits T-cell function. The agent has not been widely evaluated for therapy of MG. A blinded, controlled study, which was stopped prior to target recruitment, suggested the agent may have similar efficacy to azathioprine [100]. At the time of this writing, methotrexate is under study in a randomized controlled trial in the United States.

Prognosis

Generalized MG is no longer the grave disease it once was with life spans of patients being normal [101]. The natural history of MG moderates in severity after 5 years, but there is a subgroup of patients with chronic, moderate to severe disease. Improved outcome has occurred from the combination of modern critical care and immunosuppressive therapy. However, patients with severe weakness need to be identified and rapidly treated as mortality of patients hospitalized with MG exacerbations remains high [102]. Estimates vary but remission of weakness may occur in upwards of 80 % of patients. However, quality of life remains compromised [103], in large part due to immunosuppressive therapies with poor side effect profiles. Novel approaches are being taken to specifically target autoimmune pathology with some close to clinical trial evaluation [17, 104].

Special Situations

Treatment of Ocular Myasthenia. Care of patients with ocular myasthenia has its own special requirements [105–107]. The physician should appreciate that purely ocular manifestations, although not life-threatening, are often disabling, but that disability needs to be weighed against the complications of therapy. Some patients respond well to nonmedical therapy, such as ptosis crutches or tape although these are uncomfortable. Alternating eye patching will alleviate diplopia. Attempts may be made to treat ocular manifestations with ChE inhibitors which may improve symptoms adequately in some patients [107]. When diplopia or bilateral ptosis is disabling, corticosteroid treatment must be considered. Regimens for treatment of ocular myasthenia vary but, typically, involve starting at a dose of 10–20 mg with gradual increase every few days until symptoms are controlled. Half of the patients have a recurrence of manifestations with tapering of steroids. About 80 % of ocular myasthenics will develop generalized disease. There is a suggestion from a retrospective trial that corticosteroid treatment may reduce the risk of generalization, but a prospective trial is required to confirm this observation.

Myasthenia and Pregnancy. MG is not a contraindication to pregnancy [108, 109]. Women have highly variable course and the severity of MG may vary among pregnancies in the same individual [110]. The potential effect of MG treatments on the fetus is a concern. Mestinon and prednisone are safe, but all the immunosuppressives are potential teratogens and consideration needs to be given to the risk of harm to the fetus from the drug versus harm caused by significant myasthenic exacerbation. Despite the obvious concern of the parents, assessment of azathioprine use during pregnancy suggests that risk of birth defects is not increased [111]. There are no large studies of the effect of plasma exchange or IVIg in pregnant women but both appear to be safe. There is no reason to perform a thymectomy during pregnancy.

Approximately a third of infants of MG patients have neonatal myasthenia [112–114]. This is a transient disorder manifested by general weakness, difficulty feeding, and respiratory insufficiency in some. Such infants require supportive care and cholinesterase treatment. Weakness resolves over weeks without any residue or risk of development of MG later in life. Development of neonatal MG is independent of the clinical status of the mother and the mother may be asymptomatic. AChR antibody levels of the mother also do not predict occurrence of MG. An increased ratio of antibodies against the fetal AChR compared to the antibodies directed only against the adult AChR isoform correlates with the development of neonatal myasthenia. Commercial tests for this ratio are not available. Case reports exist in infants with arthrogryposis multiplex that were due to passage of antibodies against the fetal AChR, which severely compromised fetal muscle development [115, 116].

Treatment of the Myasthenia Gravis Patient with Thymoma. Ten percent of patients with MG have a thymoma. Usually, the thymoma is identified because of the manifestation of MG, but thymoma detection may predate and postdate the onset of MG by years. Such patients are more often men in the age range of 40–60 and are seropositive for AChR

and striational antibodies. Some studies suggest that thymoma-associated MG has a more severe clinical picture. Once a thymoma is detected, it should be removed, although the patient should be aware that the surgery is not to cure MG. If the tumor has broken through its capsule to involve adjacent tissue, local irradiation is necessary. Thymomas generally have good prognosis with surgical resection being curative. However, some thymomas are aggressive and produce widespread metastases. In the elderly patient with a contraindication to surgery, consideration may be given following the tumor radiologically, since many tumors are very slow growing [117–119].

Juvenile Myasthenia Gravis. The pathophysiology of children presenting with MG younger than 18 years is no different than the adult disorder. The incidence of juvenile MG is one per million with girls being more frequently affected with a ratio of 3:1. The disorder may be more common among the Chinese, Japanese, and African-American populations compared to Caucasians. Differential diagnosis and diagnostic methods are identical to adults; however, treatment considerations are more difficult. Prepubertal patients appear to have higher rates of spontaneous remission, and therefore, thymectomy has been recommended to be delayed by some. As in adults, treatment must be individualized and the parents educated regarding the complications of therapy. Care of the child with MG is more complex because of the complications of corticosteroids on growth and cosmetic changes. The risk of long-term immunosuppression is even a greater issue for the young compared to the elderly [120, 121].

Lambert-Eaton Myasthenic Syndrome

49

Jan J.G.M. Verschuuren, Maarten J. Titulaer,
and Paul Maddison

Introduction

Lambert-Eaton myasthenic syndrome (LEMS) is a neuromuscular transmission disorder, which was first recognized as a myasthenic-type illness in association with oat cell (small-cell) lung cancer in a 47-year-old man, who presented with fatiguable proximal leg weakness with absent tendon reflexes, swallowing difficulty, and arm fatigue [1]. Prolonged apnea followed succinylcholine administration during general anesthesia, and electrodiagnostic examination revealed a neuromuscular block. Manifestations of neuromuscular blockade reversed with intravenous injection of edrophonium.

After the introduction of more advanced, neurophysiological methods, Lambert, Eaton, and Rooke [2] (and reported fully by Eaton and Lambert [3]) distinguished six patients with lung cancer and myasthenic manifestations from patients with typical findings of myasthenia gravis. They described the classical electrophysiological abnormalities that are still used to determine the diagnosis of LEMS and identified the disorder as a "myasthenic syndrome." Two of their patients had small-cell lung cancer, and a further two had lesions identified on chest X-rays. Soon after the original reports, the clinical details of 30 patients were published from the same department [4, 5]. These papers highlighted the range of clinical and electrophysiological features of the syndrome. Included in these data were the first accounts of patients with "myasthenic syndrome" who had no signs of lung cancer, even after extended follow-up. Some patients with small-cell lung cancer had a marked improvement in myasthenic symptoms after successful treatment of cancer.

Etiology and Pathogenesis

The pathophysiology underlying the myasthenic syndrome was first described by Elmqvist and Lambert, [6] who later confirmed their findings in a larger series of patients [7]. Microelectrode recordings from intercostal muscle biopsies of patients with myasthenic syndrome revealed the nature of the neuromuscular transmission defect. Intracellular recordings from the end plate region of single muscle fibers showed that the miniature end plate potentials, produced by spontaneously released packets or "quanta" of acetylcholine, were normal in frequency and amplitude. However, the end plate potential amplitudes and the quantal content were reduced, increasing to normal with high-frequency nerve stimulation or increased calcium concentrations in the bathing solution. The defect in neuromuscular transmission was therefore discovered to be presynaptic, resulting in a reduction in the number of acetylcholine quanta released from the nerve terminal in response to a stimulus. The drug guanidine, capable of increasing the release of acetylcholine with each nerve impulse, improved neuromuscular transmission and symptoms of fatigue.

The suggestion of an autoimmune etiology in LEMS arose partly from the association between noncarcinomatous LEMS and other autoimmune disorders such as thyroid disease and pernicious anemia; [8] this link was also later established in a large series of LEMS patients in whom organ-specific autoantibodies were found in 24 % with

small-cell lung cancer (SCLC) and 44 % with no detectable lung cancer [9]. Evidence of an autoimmune basis came additionally from the observations that (1) passive transfer by intraperitoneal injection of LEMS IgG into mice resulted in neuromuscular electrophysiological abnormalities identical to those seen in intercostal muscle in vitro studies on LEMS patients, [10–12] (2) passive transfer of LEMS from mother to child has been described, and (3) significant clinical and electromyographic improvement in LEMS patients without SCLC occurred after plasma exchange [10] and sustained benefit with immunosuppressive treatment [13]. Furthermore, LEMS is strongly associated with HLA-B8 and the Ig heavy chain marker Glm(2) [14, 15].

Subsequent studies suggested that the antibodies responsible for the characteristic electrophysiological abnormalities seen in LEMS patients were directed against voltage-gated calcium channels (VGCCs) at the motor nerve terminal. First, Lambert and Elmqvist had commented that in their electrophysiological recordings from intercostal muscle biopsy specimens from LEMS patients, the increase in end plate potential quantal content during repetitive nerve stimulation was similar to the low Ca^{2+} concentration effect at the neuromuscular junction [7]. Second, reduced evoked transmitter release at various extracellular calcium concentrations and smaller calcium currents were recorded in ex vivo nerve-muscle preparations from mice injected with LEMS IgG [16, 17]. Third, freeze-fracture electron microscopy of motor nerve terminals in LEMS patients [18] and in mice injected with LEMS IgG [18] showed the same quantitative loss of active zone particles, believed to be the morphological representation of VGCCs. Reduction in VGCC density appears to depend on the cross-linking of adjacent active zone particles by the divalent IgG. Loss of active zone particles was only seen in animal studies when divalent LEMS IgG or F(ab')2 aggregated and depleted the active zone particles, whereas monovalent Fab had no effect [19]. Later studies confirmed the presence of N-type anti-VGCC antibodies, detected by immunoprecipitation of radiolabelled Ca^{2+} channels, in about 90 % of patients with LEMS in one series [20] but only 44–52 % of patients in another [21]. Subsequently, antibodies to P/Q-type VGCCs were discovered in a greater proportion of LEMS patients (see below).

Neuronal VGCCs are multimeric proteins consisting of five subunits, α_1, β, α_2, δ, and γ [22]. The α_1-subunit, which consists of four homologous repeats, each having 6 transmembrane regions, forms the central ion pore. It is associated with the disulfide-linked α_2- and δ-subunits and a cytoplasmic β-subunit that modifies the channel's current amplitude, voltage dependence, and activation properties. Different subunit isoforms give rise to distinct channel subtypes.

Each VGCC subtype is identified by its specific pharmacological and electrophysiological properties, and the gene encoding the α_1-subunit differs for each VGCC subtype. Therefore, differences in functional properties between each VGCC subtype are in part due to differences in α_1-subunit structure [23, 24]. Both N- and P/Q-type VGCCs are located primarily on neurons, whereas L-type VGCCs are expressed not only in neural tissue but also on cardiac and endocrine cells [25]. The use of VGCC-blocking agents, such as dihydropyridine, nitrendipine, or the neurotoxins ω-agatoxin IVA and ω-conotoxin GV1A, demonstrates that neurotransmitter release at the mammalian neuromuscular junction is mediated principally by P/Q-type, rather than N- or L-type, VGCCs [26, 27]. Immunocytochemical experiments show that immunoreactivity to α_{1A}, the gene thought to encode for the pore-forming α_1-subunit in P/Q-type VGCCs, is localized presynaptically in areas thought to be motor nerve terminals, thereby providing further evidence of P/Q-type VGCCs at human neuromuscular junctions [28].

The antigenic target on the VGCC itself is not fully established. In addition, antibodies to other synapse-associated proteins can be found in the serum of LEMS patients. Antibodies to synaptotagmin, a synaptic vesicle protein, are found in LEMS patients [29], and immunization of rats with a synthetic peptide analogous to synaptotagmin induces physiological changes characteristic of LEMS [30]. The significance of these findings is not clear. Also, antibodies to the intracellular portion of the β-subunit of the VGCC were found in 55 % of patients with LEMS [31]. Probably, these determinants are not the primary target of the immune response, and these antibodies might arise because their antigens are released and presented due to immune-mediated attack on the VGCCs.

Two-thirds of LEMS patients with SCLC, and 43 % of SCLC patients without LEMS, have antibodies to one of the SOX or Hu proteins in their serum [32, 33]. SOX proteins are transcription factors that have critical roles in the regulation of developmental processes. Hu proteins are expressed in neurons and play an important role in the development and maintenance of the nervous system. Both proteins are also expressed in SCLC cells. Most likely, the immune response elicited by the SCLC is directed not only against VGCC but also to other tumor-related proteins like SOX and Hu proteins.

SOX antibodies had a sensitivity of 67 % and a specificity of 95 % to discriminate between LEMS with SCLC and nontumor LEMS. No difference in survival was observed between SOX positive- and SOX-negative SCLC patients [32, 34].

The functional effect of LEMS anti-VGCC antibodies on specific VGCC antigenic targets has been studied by recording calcium influx in human embryonic kidney cells transfected with different cloned α_1-subunits. LEMS serum most effectively blocked those cells expressing the α_{1A}-subunit type, as found in P/Q-type VGCCs, indicating that the α_{1A}-subunit of P/Q-type VGCCs may be a functionally important immunogen in LEMS [35]. Further studies found antibodies to recombinant peptides corresponding to the pore-forming S5-6 extracellular region of the 4 domains that form the α_{1A}-subunit of the P/Q-type VGCC in up to 30 % of patients with

LEMS [36]. Electrophysiological studies of rats immunized with the S5-6 peptide showed changes similar to previous studies of animal models of LEMS.

The presence of SCLC in over half of LEMS patients led to the hypothesis that this tumor, of presumed neuroectodermal origin [37], which express L-, N- and P-type VGCCs [38, 39], was capable of triggering a primary autoimmune response, where antibodies to tumor VGCCs cross-react with those at the motor nerve terminal, resulting in LEMS. Initial support for this theory came from Roberts et al. [40] who showed that LEMS IgG is capable of inhibiting K^+-stimulated Ca^{2+} flux in cultured human SCLC cell lines. Subsequent studies showed that LEMS IgG can block Ca^{2+} flux in SCLC cell lines by blocking more than one type of VGCC subtype [38, 41]. The clinical improvement, or even remission of LEMS, that can occur following successful antitumor therapy supports the theory that in SCLC-LEMS, the tumor is capable of triggering the autoimmune response. Immunocytochemical studies of SCLC tumors from patients with LEMS, compared to those without, show that tumor macrophage infiltration and MHC class I expression are less in the tumors of patients with LEMS [42]. This could imply that SCLC antigenic determinants trigger the autoimmune response resulting in immune-mediated tumor cell destruction in LEMS.

The autonomic dysfunction that occurs in LEMS also appears to be caused by anti-VGCC antibodies. To assess the effect of anti-VGCC antibodies on postganglionic autonomic neurons, mice were injected with IgG from LEMS patients or controls. The release of transmitter from parasympathetic and sympathetic neurons was recorded using muscle contraction amplitude in bladder strips and vas deferens [43]. LEMS IgG-treated mice showed impaired transmitter release principally through P/Q-type VGCCs.

Although VGCCs are important in stimulus-secretion coupling in endocrine tissues, pituitary hormone release or pancreatic β-cell function was not impaired in ten LEMS patients [44]. This result may be due to upregulation of non-P/Q-type VGCCs in pancreatic and pituitary cells or to antigenic differences between isoforms of P/Q-type VGCCs expressed in neurons and endocrine cells.

Pathology

Muscle biopsy is usually unhelpful in the diagnosis of LEMS, since a variety of mild, nonspecific changes occur, or normal muscle fibers are usually found. However, distinctive changes were reported in a muscle biopsy from one LEMS patient, which led to the diagnosis of LEMS in another patient with similar muscle biopsy findings [45]. Serial muscle biopsies showed progressive atrophy and type 1 muscle fiber loss, resulting in marked type 2 fiber predominance. The mechanism behind the alteration in fiber-type distribution is not known. Type 2 fiber predominance in LEMS was also reported by others [46, 47].

Clinical Presentation

The clinical features of LEMS, as first described in detail by Rooke and colleagues [4], were further defined as a syndrome in a large study by O'Neill et al. [9] and recently reviewed by Titulaer et al. [48].

Extremity Weakness

Leg weakness is universal and the presenting complaint in over three-quarters of LEMS patients [49]. The weakness is classically proximal, and patients have difficulty climbing stairs or walking uphill [4]. Pain in the weak muscles occurs much less frequently [9]. Classically, progressive augmentation of muscle strength is seen during the first few seconds of maximal voluntary contraction. Continued, prolonged voluntary effort, however, does lead to fatigue, as in myasthenia gravis. Muscle wasting is rare even after prolonged disease duration. Limb weakness can be worse in hot weather and improve in the cold [9]. Although less common than leg weakness, arm weakness occurs in over three-quarters of LEMS patients.

Oculomotor or Bulbar Weakness

During progression of the disease, weakness spreads proximally to distally and from caudal to cranial. Thus, in general, oculomotor and bulbar weakness appears later and only in more severely affected patients. This is in contrast to myasthenia gravis, where weakness most often starts in oculomotor or bulbar muscles and then descends. Isolated weakness of extraocular muscles in LEMS is rare [50].

Tendon Reflexes

Unlike myasthenia gravis, deep tendon reflexes are typically depressed or absent. LEMS patients can display posttetanic potentiation of reflexes, in that initially absent or depressed tendon reflexes can appear if tested directly after a brief voluntary contraction of the tested muscle. This is a unique and very useful clinical feature for diagnosing LEMS, although not very sensitive [51, 52].

Autonomic Manifestations

Although described in the original clinical descriptions of LEMS [4], dry mouth, impotence, blurred vision, and

constipation were first considered to be a specific cholinergic dysautonomia by Rubenstein et al. [53]. Of all autonomic disturbances seen in LEMS, by far the most common is dry mouth, present in about 75 % of patients, followed by erectile dysfunction and constipation [9, 48]. Patients may also have orthostatic hypotension, micturition difficulties, impaired sweating, dry eyes, and blurred vision [48].

Respiratory Insufficiency

LEMS may present with respiratory failure requiring assisted ventilation [54]. Occasionally, muscle relaxants, such as curare, during general anesthesia can produce prolonged apnea due to neuromuscular blockade [9].

Tumor Association

LEMS can occur at almost any age and has been reported in a 9-year-old child [55]. The mean age of onset of neurological manifestations for LEMS patients is about 50 years, but those with associated lung cancer tend to develop symptoms later (onset at about 58 years) [9, 48]. Over half of patients develop small-cell lung cancer (SCLC) [48] most commonly after the onset of LEMS, usually within 2 years. Some decades ago, a few cases were described with a latency of 5 or 6 years. Most likely this was due to less sensitive radiographical techniques for tumor screening. In recent series, screening with CT thorax or PET scans detected SCLC in 91 % of the patients within 3 months and in 96 % within 1 year after the diagnosis of LEMS. Using only chest X-ray is inadequate for the detection of an SCLC [56].

Patients with SCLC and LEMS have similar clinical features as those without lung cancer, but LEMS patients with an SCLC have a more progressive course of disease [49]. Based on this observation, a simple and sensitive clinical score was developed that predicts the presence of an SCLC. With this DELTA-P score, the probability for an SCLC can be calculated at the time of diagnosis of LEMS by solely using clinical criteria (Fig. 49.1) (Table 49.1) [57].

The overall prevalence of LEMS among SCLC patients is estimated to be about 1–3 % [58]. With such a prevalence of LEMS among a rather common cancer, many patients likely are not diagnosed, with muscle weakness probably being attributed to the underlying tumor or chemotherapy treatment. LEMS is reported with tumors other than SCLC (Table 49.2); however, some of these reports date to before VGCC antibody testing was available.

We feel that most of these tumors have co-occurred due to chance. However, it cannot be excluded that some of these tumors, like thymomas, prostate cancer, and lymphoproliferative disorders, may have a causal relationship with LEMS. Proof for this relationship can be obtained from histological studies, showing that the tumor has neuroendocrine characteristics [67].

Differential Diagnosis

LEMS patients are often initially given an inappropriate diagnosis. Over half of patients in one study were misdiagnosed, with the most common alternative diagnosis (in 20 %) being myasthenia gravis [9, 48]. Other diagnoses included primary myopathy, cervical myelopathy, polymyositis, and polymyalgia rheumatica. LEMS differs clinically from

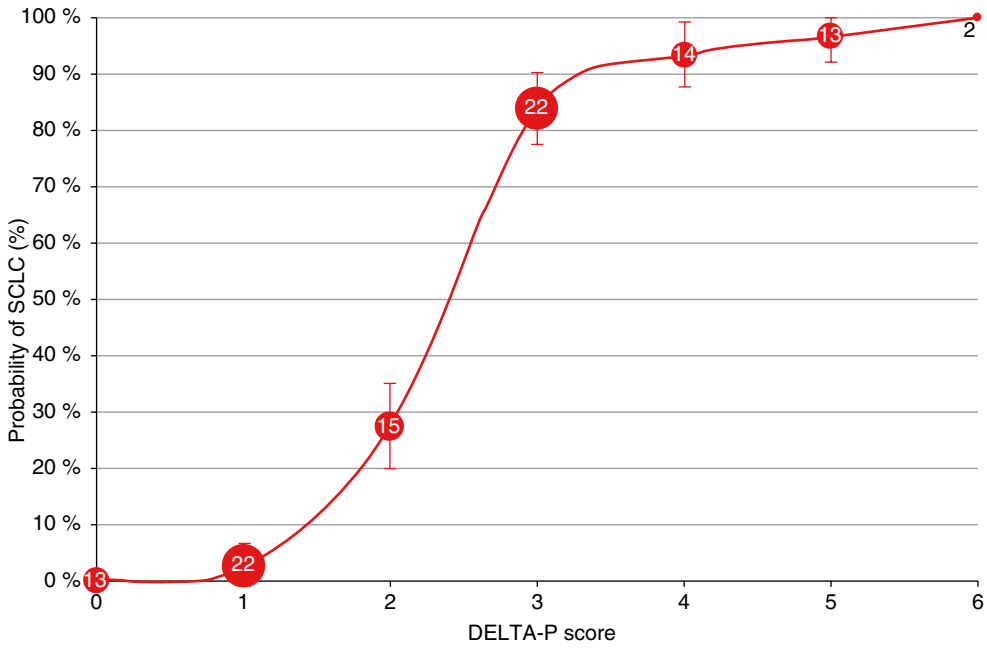

Fig. 49.1 DELTA-P score. Predicted percentage of SCLC in patients with LEMS, based on the Dutch-English LEMS Tumor Association Prediction (DELTA-P) score. Point sizes proportionate to the number of patients with a specific score also represented by the percentage inside the circle. Vertical bars indicate SEM(57) (Reprinted with permission from Titulaer et al. [57])

Table 49.1 Items of the DELTA-P score

	Categories		Score
D	**D**ysarthria, dysphagia, neck weakness: bulbar weakness	Absent	0
		Present	1
E	**E**rectile dysfunction	Female	0
		Male: absent	0
		Male: present	1
L	**L**oss of weight	Absent or < 5 %	0
		≥ 5 %	1
T	**T**obacco use at onset	Absent	0
		Present	1
A	**A**ge of onset	< 50 years	0
–		≥ 50 years	1
P	Karnofsky **p**erformance score	70–100	0
		0–60	1
	DELTA-P score		0–6

DELTA-P score. This score helps to estimate the chance for the presence of an SCLC in patients presenting with clinical signs and symptoms of LEMS (see also Fig. 51.1) [57]

Table 49.2 Malignancies other than SCLC reported to be associated with LEMS

Intrathoracic malignancies
Thymoma [59–62]
Carcinoid tumor [63]
Non-Hodgkin lymphoma [64]
Leukemia [65, 66]
Prostate cancer [67–69]
Breast cancer [9]
Cervical cancer [70]
Malignant bone tumor [71]
Transitional cell cancer of the bladder [72]

myasthenia gravis in that ocular manifestations are much less common at initial diagnosis and during the course of the disease, and the weakness ascends from the legs upward, while in myasthenia it develops in the opposite way [50]. Proximal leg weakness characteristically occurs in LEMS, where muscle power can be augmented after a brief voluntary contraction, a finding not displayed in myasthenia gravis. Also, most LEMS patients have absent or depressed reflexes and symptoms of dysautonomia. Thymectomy is not beneficial in LEMS, unlike myasthenia gravis [73], and the thymus is usually atrophic [9]. The different pattern of autoantibodies found and the incremental muscle responses following voluntary contraction on electromyography (EMG) should distinguish LEMS from myasthenia gravis. Rarely, LEMS and myasthenia gravis coexist in the same patient.

Predominant proximal weakness suggests a diagnosis of myopathy, and when associated with SCLC, the possibility of carcinomatous myopathy or polymyositis in association with cancer may be considered. Further confusion may arise when needle EMG demonstrates brief, small polyphasic units consistent with a myopathy; however, with sustained contraction, the interference pattern normalizes with increased motor unit action potential amplitudes. Type 1 muscle fiber atrophy on muscle biopsy also suggests the diagnosis of myopathy.

Incidentally, LEMS patients are misdiagnosed with neuropathy. Diminished compound muscle action potentials observed by nerve conduction studies may be inappropriately ascribed to a neuropathy, especially if the patient has received chemotherapy for treatment of cancer or thought to have a "carcinomatous neuropathy" [74]. The lack of sensory symptoms and the distribution of weakness to proximal muscles should alert the clinician.

Finally, the clinician must not confuse patients with LEMS and chronic fatigue syndrome. Such patients may demonstrate greater weakness by examination than expected by their level of function. Needle EMG may show a reduced or variable recruitment pattern, which may superficially resemble LEMS, but nerve conductions reveal normal compound muscle action potentials.

Diagnosis

The diagnosis of LEMS can often be made from the distinctive clinical features. The laboratory diagnosis of LEMS depends primarily on detection of specific antivoltage-gated calcium channel autoantibodies or characteristic electrodiagnostic findings.

Anti-Voltage-Gated Calcium Channel Antibodies

Using a standard radioimmunoassay, the detection of antibodies against ^{125}I-ω-CmTx MVIIC-labeled (P/Q-type) VGCCs in significant titers in 85–90 % of LEMS patients is possible [75]. About 33 % of these sera are also positive for ^{125}I-ω-CgTx GVIA-labeled (N-type) VGCC antibodies [75]. In the original study, anti-VGCC antibody titers were not significantly raised in healthy or disease control patients. In subsequent work, anti-P/Q-type VGCC antibodies were detectable in 1–4 % of patients with SCLC and no neurological symptoms [32, 76]. Also, 24 % of patients with SCLC and paraneoplastic cerebellar degeneration had anti-P/Q-type VGCC antibodies, half of whom had no manifestations of LEMS [77].

Electrodiagnostic Features

Eaton and Lambert first defined the classical electrophysiological characteristics of LEMS [3]. They demonstrated, unlike myasthenia gravis, the amplitude of the resting compound muscle action potential (CMAP) obtained by supramaximal nerve stimulation was reduced. Remarkably, transient further decrement was seen with slow repetitive

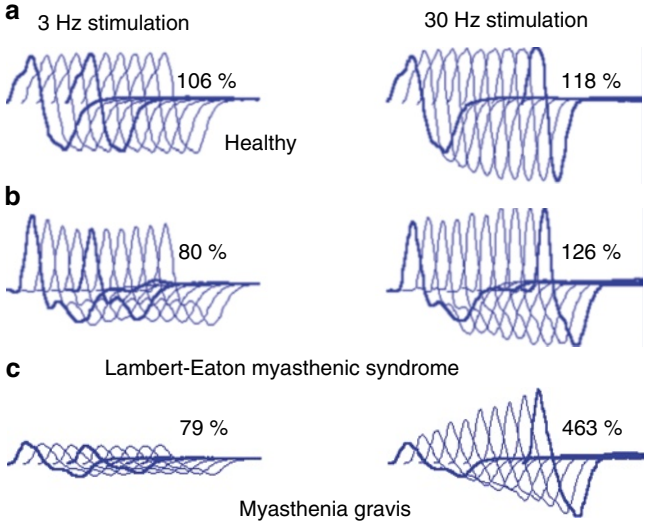

Fig. 49.2 Electrodiagnostic repetitive nerve stimulation studies. Electrodiagnostic repetitive nerve stimulation studies of the adductor digiti minimi muscle in a healthy person (**a**), in a patient with MG with acetylcholine receptor antibodies (**b**), or in a patient with LEMS (**c**). The *left-hand column* shows the results after low-frequency 3 Hz nerve stimulation. The *right-hand side* shows the recordings obtained directly after 20 s of maximal voluntary muscle contraction. Both patients with MG and LEMS show decrement at low-frequency stimulation (**b**, **c**). Only the patient with LEMS shows increment more than 60 % after maximal voluntary contraction (C) (Courtesy to prof. Gert van Dijk for providing these figures)

maximal nerve stimulation (RMNS) at rates less than 10 per second. However, following high-rate repetitive nerve stimulation (>10 Hz) or 10 s of maximal voluntary contraction, there was an increase in CMAP amplitude, typically over 100 % (see Fig. 49.2) [5].

These results suggested that the neuromuscular transmission disorder was presynaptic. The combination of a first lowered CMAP, decrement on low-rate RMNS, and increment after high-rate RMNS in a patient with acquired proximal muscle weakness is pathognomonic for LEMS.

RMNS may be abnormal in other neuromuscular disorders. Standard nerve conduction studies and needle EMG must be considered to exclude other muscle and anterior horn cell diseases. Needle EMG demonstrates increased low-amplitude, short-duration motor unit potentials. Amplitudes may enlarge with sustained contraction.

In one study of electrophysiological abnormalities of LEMS, the muscle most likely to detect the classical changes was the abductor digiti minimi (ADM). Although weakness predominates in proximal muscles, stimulating the ulnar nerve at the wrist with recording from the ADM is very sensitive in detecting typical electrophysiological abnormalities in LEMS [78]. All patients in this study had a reduced resting CMAP amplitude in at least one distal arm muscle. In another study, incremental responses of 60 % rather than 100 % were sufficient to diagnose LEMS with the same specificity over healthy control patients [52]. Overall, almost all LEMS patients are likely to have abnormal incremental CMAP responses over 100 % in ADM, abductor pollicis brevis, or anconeus after 10 s of voluntary contraction [78, 79]. One must appreciate that the increment of the CMAP is in fact a normalization of the previous low CMAP amplitude. For example, 300 % increment implies that the original CMAP was maximally 25 % of normal reference values. The higher the first original CMAP is, the less the increment that can be obtained.

In clinical practice, the differential diagnosis is often whether a patient has LEMS or MG, rather than having to distinguish between a patient with LEMS and a healthy subject. The postsynaptic disorder of myasthenia gravis characteristically shows a decremental response in CMAP amplitude. In myasthenia gravis, no significant incremental pattern is found, because the original CMAP is not or only marginally decreased. This is in keeping with the results from 18 myasthenia gravis patients [80], who showed that the incremental response in ADM seen after maximal voluntary contraction was under 40 % in 17 patients with only one outlier registering an increment of about 70 %. A 60 % increment was observed in only 4 of 538 patients with myasthenia gravis by high-rate stimulation testing and in none by postexercise electromyographic testing. The use of a 60 % increment showed a sensitivity of 97 % for the diagnosis of LEMS and a specificity of 99 % in excluding myasthenia gravis [52].

Single-fiber EMG, which detects defects of neuromuscular transmission with high sensitivity, has been used to diagnose LEMS. Abnormal jitter and blocking, typical of defective neuromuscular transmission, are seen in all LEMS patients [9, 81]. While this technique is highly sensitive, it lacks specificity. The degree of jitter and blocking seen in LEMS is usually less when high-frequency nerve stimulation is used, a finding more specific to LEMS [81, 82].

Treatment

The weakness of LEMS responds well to treatment with 3,4-diaminopyridine (3,4-DAP) [83, 84], which in animals has been demonstrated to block voltage-sensitive potassium channels, thereby increasing evoked transmitter release by prolonging the action potential duration [85, 86] and increasing calcium influx at the nerve terminal [87]. Most patients commence 3,4-DAP treatment at 10 mg four times daily, increasing up to a 100 mg maximum per day. Symptomatic improvement usually occurs within an hour of ingestion. A prospective, placebo-controlled, double-blind trial of 3,4-DAP in 12 LEMS patients (with and without associated SCLC) showed its effectiveness in increasing muscle strength and improving autonomic symptoms at doses up to 100 mg/day [83]. A Cochrane review described the results of four

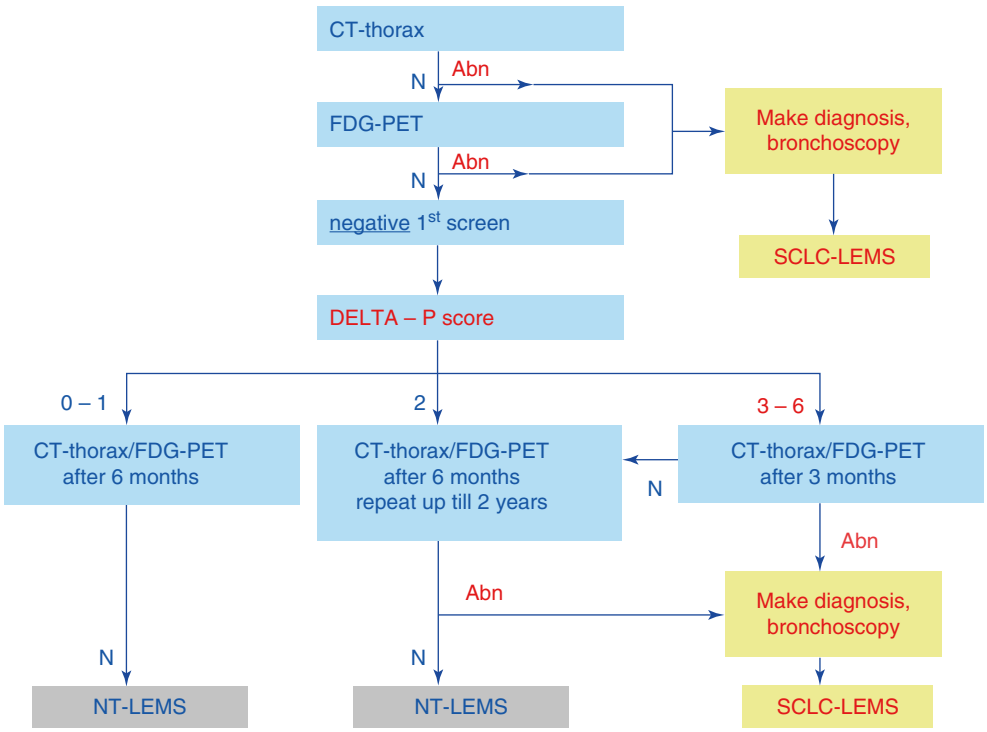

Fig. 49.3 Screening for SCLC. Scheme for screening for SCLC [56] (Reprinted with permission from Titulaer et al.[48]). To screen for SCLC, the DELTA-P score can help to estimate the chance that an SCLC might be present (see Fig. 49.1)

randomized trials in 54 patients with LEMS [88]. A significant improvement in muscle strength score, myometric limb measurement, or CMAP amplitude after treatment was reported. Common associated symptoms are perioral and distal paresthesias or less frequently gastrointestinal symptoms. In rare cases, an overdosage has caused epileptic attacks. At a dose around 100 mg a day, seizures have been described [89, 90].

Pyridostigmine, although not as effective as in myasthenia gravis, benefits some patients with LEMS [83, 91]. Guanidine has been used as an alternative symptomatic treatment of LEMS, although serious side effects such as bone marrow suppression and renal failure can occur [92]. Guanidine at doses of less than 1,000 mg/day in combination with pyridostigmine may be particularly useful with limited severity of side effects.

LEMS associated with SCLC should not modify treatment of the underlying cancer. Anticancer chemotherapy also has immunosuppressive effects which may contribute to the improvement of the neurological disorder. Following specific tumor therapy (chemotherapy, radiotherapy, or lung resection), seven of 11 LEMS patients who survived for more than 2 months had substantial and progressive neurological improvement [93]. One patient remained free of tumor recurrence and symptoms of LEMS over 12 years since lobectomy and radiotherapy for SCLC [94].

For all LEMS patients, thorough screening for SCLC is mandatory. CT of the thorax or 18 F-fluorodeoxyglucose (FGD)-PET or even an integrated FDG-PET/CT is these days available to screen for SCLC. Every patient with LEMS should be screened at least twice. A chest radiograph has insufficient sensitivity for diagnosis and should not be used for screening. After an initial negative screening, the DELTA-P score can be used to estimate the risk for an SCLC and help to decide how frequent further screening is necessary (Fig. 49.3) [57].

Although most patients benefit from symptomatic treatment (even after successful treatment of SCLC), often the response is incomplete, or limited, and other disease-modifying treatments are required (see treatment algorithm, Fig. 49.4).

For patients with severe symptoms requiring prompt treatment, a plasmapheresis course of five exchanges produces short-term clinical improvement [95]. Repeated exchanges result in similar improvement. This treatment is particularly useful in LEMS patients with initial respiratory depression [54]. In general, LEMS has a more indolent course of disease, and in contrast to autoimmune myasthenia gravis, the need for ventilatory support is rare.

Intravenous immunoglobulin (IVIg) was first reported to benefit an LEMS patient with clinical and electrophysiological improvement evident 2 weeks after treatment, which lasted for 10 weeks before relapse [96]. In a randomized, double-blind, placebo-controlled crossover trial of IVIg in nine LEMS patients, significant improvement occurred in strength that peaked at 2–4 weeks and lasted up to 8 weeks following 1 g/kg of IVIg given on two consecutive days [97]. There was also a significant reduction in mean P/Q-type VGCC antibody titers. This effect was not thought to be due to an anti-idiotypic neutralizing action as there was no

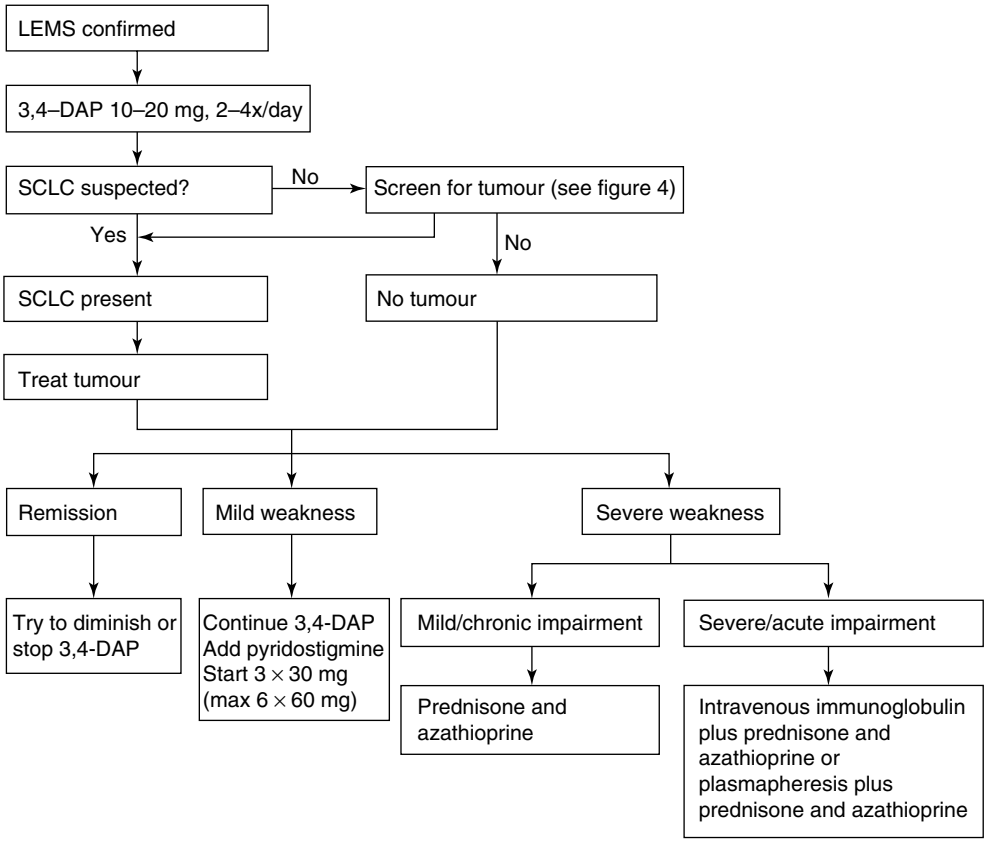

Fig. 49.4 Treatment of LEMS. A treatment algorithm to provide a guide to therapy in LEMS ((Ref. Lancet Neur); reprinted with permission from Titulaer et al.[48])

evidence of in vitro direct neutralization of VGCC antibodies by radioimmunoassay. From our experience, ongoing use of regular IVIg has been disappointing, with gradual reduction in clinical effectiveness occurring.

When disease remission does not occur after symptomatic or antitumor therapy, or after passive treatment such as plasma exchange, immunotherapy with prednisolone should commence. Alternate day prednisolone can result in full clinical remission in some patients, although the response is usually slow [95]. The initial prednisolone dose is up to 1–1.5 mg/kg on alternate days. For patients without detectable SCLC, concomitant daily azathioprine at doses up to 2.5 mg/kg can result in sustained remission, even allowing for reduction in the prednisolone dose [95]. Therefore, when clinical remission is achieved in LEMS patients taking both prednisolone and azathioprine, the prednisolone dose should be tapered to the minimum required to maintain remission. In patients intolerant of azathioprine, oral cyclosporine in doses up to 3 mg/kg body weight should be considered.

Prognosis

A longitudinal clinical, electrophysiological, and immunological study of 62 LEMS patients with and without SCLC during extended follow-up was matched for sex, age at diagnosis of SCLC, tumor extent (limited or extensive), and treatment (chemotherapy or radiotherapy). Survival data from 15 patients with SCLC and LEMS was compared with 81 patients with SCLC alone [98]. Median survival time from SCLC diagnosis was significantly longer in patients with SCLC and LEMS (17 months) compared with patients with SCLC alone (10 months), thus suggesting that the immunological response targeting tumor VGCCs in LEMS may retard SCLC growth. This prolonged survival was confirmed in a second study, comparing 138 SCLC patients to 53 patients with SCLC-LEMS (Fig. 49.5).

Further supportive evidence for this hypothesis arises from data [99] on cultured SCLC cells in vitro, which suggest that VGCC-blocking agents reduce tumor cell proliferation. However, this favorable prognosis may be related to lead-time bias, in that once LEMS is diagnosed, the vigilance for associated lung cancer may be increased.

In the 47 LEMS patients without SCLC, sustained clinical remission was achieved by 20 (43 %), almost all of whom still required significant doses of steroids and azathioprine (mean alternate day dose of prednisolone after 5 years' treatment and follow-up was 25 mg) [100]. Among clinical scores of muscle strength, anti-P/Q-type VGCC antibody titers, CMAP amplitudes and postexercise increments, and disease duration at first presentation, the only predictor of sustained clinical remission was muscle strength score, i.e., the stronger

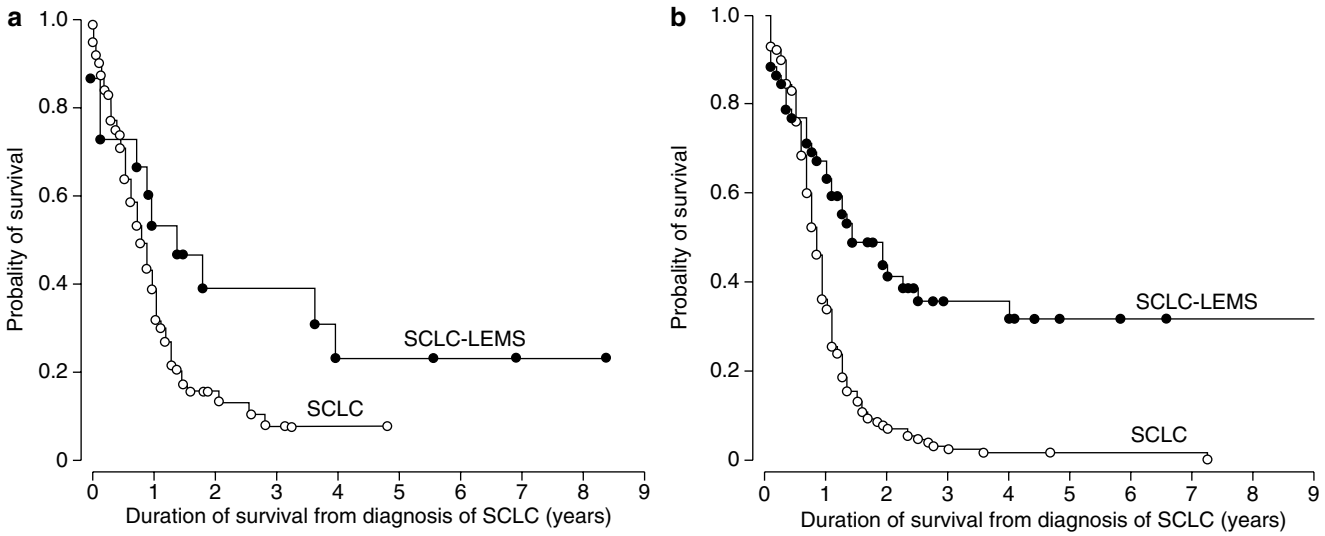

Fig. 49.5 Survival of LEMS patients with SCLC. Kaplan-Meier survival curves of small-cell lung cancer patients with (SCLC-LEMS) and without (SCLC) Lambert-Eaton myasthenic syndrome. Patients with LEMS and SCLC have a significantly longer median survival from the time of diagnosis of the lung tumor. At the *left side*, an English cohort ($p = 0.048$; reprinted with permission from Maddison et al., The Lancet [98]) and on the *right side*, a Dutch cohort of patients ($p < 0.0001$; reprinted with permission from Titulaer and Verschuuren, Ann N Y Acad Sci, 2008 [101])

the patient at initial presentation, the more likely the achievement of clinical remission. Conversely, ten patients (22 %) with markedly weak arms and legs required a wheelchair after a median 7 years' follow-up. Immunological and electrophysiological measurements are useful objective parameters for following disease progression and response to immunosuppression in individual patients but are not significant predictors of disease outcome in LEMS.

Botulism

50

Mark Keezer, Ruba Benini, and Colin Chalk

Introduction

Although botulism was not formally described until the nineteenth century, evidence exists that as early as the tenth century, the disease was recognized when Emperor Leo IV of Byzantium outlawed the manufacture of blood sausage [1]. He did so after observing an outbreak of blood sausage-associated food poisoning which had proven fatal. In the early nineteenth century, the German physician and Romantic poet Justinus Kerner systemically described 76 patients with "lethal poisoning occurring… through the consumption of smoked sausages" [2]. As a result of his clinical and experimental observations, Kerner correctly proposed that this "sausage poisoning" occurred after the consumption of a biological toxin, which he referred to as a "fatty acid," a toxin which required an anaerobic environment to cultivate, that acted on both the motor and autonomic systems and that was lethal in even very small doses. Initially called Kerner's disease [2], the syndrome later became known as botulism (derived from *botulus,* the Latin word for sausage) due to its original gastronomic association [3]. Several decades later, in 1897, the microbiologist Emile Pierre-Marie van Ermengem isolated the responsible organism after an outbreak of botulism in the small Belgian village of Ellezelles [4].

Etiology and Pathogenesis

Botulism is an acute paralytic illness caused by a neurotoxin produced by the bacterium *Clostridium botulinum*, a sporulating, obligate anaerobic, gram-positive bacillus [5]. The bacterium and its spores are found ubiquitously in soil and aquatic sediment as well as in the gastrointestinal tracts of grazing livestock and animal wildlife [6]. Although *C. botulinum* is generally innocuous, it does produce regular outbreaks of disease in wildlife. Avian botulism generally leads to the death of 50,000, and on occasion as many as 1,000,000, wetland birds per year in North America during local epidemics [7].

There are seven types of *C. botulinum*, differentiated by the antigenicity of the neurotoxin produced (types A through G). Types A, B, and E are most often the cause of human botulism [8] although there are occasional cases of type F [9]. Types C and D are associated with disease in animals and birds, while type G has never been clearly implicated in either human or animal disease [10]. Rare cases of botulism due to toxigenic *Clostridium butyricum* and *Clostridium baratii* have occurred [11–14].

Botulinum neurotoxin (BoNT) is among the most potent known toxins. Estimates suggest that as little as 1 g of aerosolized BoNT could lead to the death of over 1.5 million people [15]. The potency of the toxin is enhanced by the resilience of *C. botulinum* spores. Temperatures of 120 °C are required to kill the spores [16]. *C. botulinum* spores can survive 30 years in a fluid medium, likely even longer in a dry medium [17], and have even been shown to survive 10 months in a simulated Martian environment [18].

Much of the detailed molecular pathophysiology of BoNT's actions is now understood (Fig. 50.1). BoNT is a 150 kDa protein which compromises the release of synaptic vesicles from presynaptic cholinergic nerve terminals into the synaptic cleft [20]. BoNT possesses a heavy and a light chain bound by a disulfide bond. The 100 kDa heavy chain is responsible for binding to an unknown receptor on the presynaptic cell membrane. Endocytosis ensues and dissociation of the heavy and light chains allows the 50 kDa light chain to cross the vesicular membrane and enter the neuronal cytoplasm. Having arrived in the axon terminal, the BoNT light chain, as a zinc-dependent endoprotease, interrupts neurotransmitter exocytosis into the synaptic cleft through

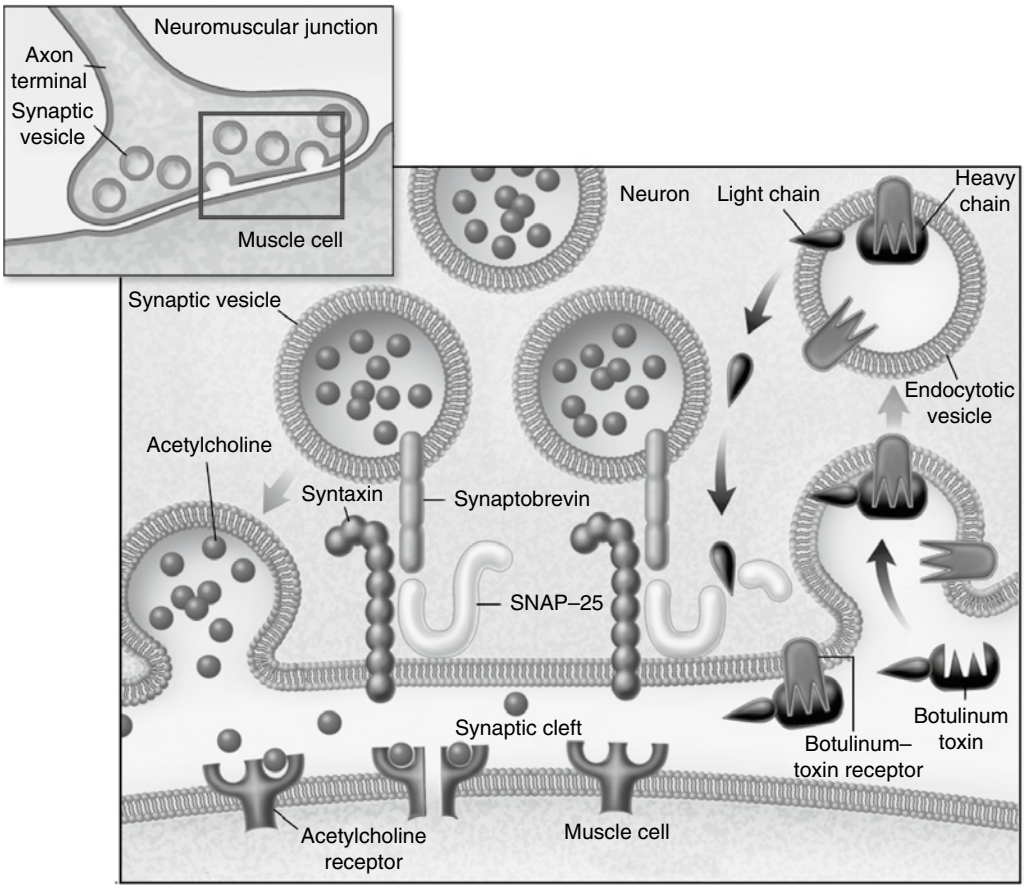

Fig. 50.1 Diagrammatic depiction of the neuromuscular junction and the action of *C. botulinum* neurotoxin (BoNT). BoNT, composed of a heavy and light chain, binds to an unknown receptor on the presynaptic cell membrane and is endocytosed; after which the BoNT light chain, a zinc-dependent endoprotease, interrupts neurotransmitter egress into the synaptic cleft through the cleavage of a number of different components of the synaptic vesicle docking and fusion complex. These targets include synaptosomal-associated protein (SNAP-25), synaptobrevin/vesicle-associated membrane protein (VAMP), and syntaxin (Reproduced with permission from Hallet [19])

the cleavage of a number of different components of the molecular complex responsible for the docking and fusion of synaptic vesicles with the axon terminal plasma membrane. Three targets have been described: synaptosomal-associated protein (SNAP-25) which is cleaved by BoNT A, C, and E; synaptobrevin/vesicle-associated membrane protein (VAMP) which is cleaved by BoNT B, D, F, and G; and syntaxin which is cleaved by BoNT C [21]. Failure of transmission at the level of peripheral cholinergic nerve terminals follows, resulting in both skeletal muscle paralysis and dysautonomia.

There are four major forms of human botulism: food-borne or "classical" botulism, infant botulism, wound botulism, and adult intestinal toxemia or "hidden" botulism. To these may also be added inhalational botulism and iatrogenic botulism, following the cosmetic or therapeutic injection of BoNT, but these remain exceedingly rare [22].

The pathogenesis of botulism differs among the various forms of the disease. Both infant and adult enteric toxemia botulism occur after the ingestion of *C. botulinum* spores which germinate in the host's gastrointestinal tract and subsequently produce BoNT in vivo [23]. Wound botulism occurs after the direct introduction of spores into devitalized flesh, classically after crush injuries to an extremity but increasingly among injection drug users [24]. Food-borne botulism differs from other types of botulism in that it occurs after the ingestion of preformed BoNT and does not involve an actual *C. botulinum* infection [22].

Clinical Presentations

Food-Borne Botulism (Classic Botulism)

More than 12,000 cases of food-borne botulism have been reported worldwide since 1951 [20]. Approximately 24 cases are reported annually to the Centers for Disease Control and Prevention (CDC) in the United States [25]. Although only 62 cases were reported in the United Kingdom between 1922 and 2005 [26], occasional outbreaks continue to occur. In 2006, four Americans and two Canadians suffered from food-borne botulism after consuming a commercially prepared carrot juice [27]. In the same year, 209 people in northern Thailand contracted botulism after having consumed the same home-canned bamboo shoots [28].

Food-borne botulism occurs with the ingestion of foods such as home-canned comestibles and salted, smoked, or fermented meats where *C. botulinum* spores have suitable anaerobic and alkaline environments to germinate and then

Fish or seafood
Fermented or salted fish products
Whale or seal products
Relish or salsa
Chili peppers
Baked potatoes in aluminum foil
Garlic in oil
Sautéed onions kept under butter sauce
Cheese sauce

[a]Adapted from Shapiro et al. [25] and McClauchlin et al. [26]

produce BoNT (Table 50.1) [25, 26]. The median incubation period among humans after intoxication is between 1 and 2 days but may be as long as 8 days [28, 29].

The clinical course of food-borne botulism may be heralded by the onset of abdominal cramps, nausea, and vomiting, the exact mechanism of which is unclear. Cranial nerve symptoms and signs are consistently the initial neurological manifestation, presenting as blurred vision and photophobia, diplopia, ptosis, dysarthria, dysphonia, and dysphagia [28, 30]. These initial deficits are often followed by varying degrees of descending and symmetrical muscle paralysis, beginning with neck muscles and progressing to respiratory and limb muscles. In the 2009 outbreak of food-borne botulism in northern Thailand, from which BoNT type A was eventually isolated, 9 % of hospitalized patients were found to have weakness of the extremities, and 30 % required mechanical ventilation [31].

Autonomic dysfunction is often present, from involvement of both the parasympathetic and sympathetic nervous systems. The dysautonomia may be more severe and more persistent than the neuromuscular dysfunction [32, 33] and is typically characterized by orthostatic hypotension, xerostomia, ileus, and urinary retention. Mydriasis is less frequent, occurring in 1–44 % of patients [16, 28, 30]. Decreased heart rate variation and impaired sudomotor skin responses may also be demonstrable [32, 33].

> A 62-year-old Inuit man from northern Quebec, Canada, developed abdominal pain, vomiting, and abdominal distension 12 h after eating fermented beluga whale fat and oil, a local delicacy. He was initially suspected to have a small bowel obstruction, and he was flown to the Montreal General Hospital. In retrospect, the patient had already developed diplopia and dry mouth at this point. Over the next 48 h, the patient's blood pressure became increasingly labile, albeit without associated tachycardia. He became progressively obtunded and required intubation and ventilation for hypercapnic ventilatory failure. Neurological examination, limited by intubation and a language barrier, showed nonreactive, mid-position pupils and normal eye movements. There was mild tetraparesis and diffusely hypoactive tendon reflexes. Sensory examination was normal. Nerve conduction studies showed low-amplitude compound muscle action potentials in all four limbs, normal motor conduction velocities, and normal sensory nerve conduction studies. Two Hz repetitive stimulation of the left ulnar nerve showed a 12–14 % decrement; 50 Hz repetitive stimulation produced an increment of 22 %. Concentric needle examination of the left deltoid, first dorsal interosseous, and vastus lateralis was normal.
>
> A diagnosis of probable food-borne botulism was made, and equine-derived trivalent *C. botulinum* antitoxin was administered on the fourth day after the onset of his symptoms. Stool cultures were later positive for *C. botulinum* type E. The patient improved and he was extubated 11 days after symptom onset. He was discharged home 5 days later without apparent sequelae.

The rapidity of disease onset as well as disease severity likely vary depending on the inoculated dose of the neurotoxin [34]. Furthermore, the various types of BoNT appear to have different pathogenicity. Poisoning with BoNT type A results in a more severe clinical syndrome than poisoning with BoNT type B or E [29, 30]. BoNT type E appears to have a significantly shorter incubation period [29].

The differential diagnosis of food-borne botulism is generally limited to other disorders of the neuromuscular junction as well as acute peripheral neuropathies, in particular Guillain-Barré syndrome (GBS) and, its variant, Miller-Fisher syndrome (MFS). Prominent gastrointestinal symptoms accompanying acute flaccid paralysis might suggest arsenic or thallium poisoning as well as botulism. The descending pattern of weakness, beginning with the cranial nerves and only later involving the upper and then lower extremities, along with the frequent preservation of deep tendon reflexes, helps to distinguish botulism from most peripheral neuropathies. Likewise, in tick paralysis, weakness begins in the legs and ascends before cranial nerves are involved. Ophthalmoplegia and bulbar weakness may suggest myasthenia gravis, although onset of severe deficits in only a few days would be unusual, and pupillary paralysis does not occur in myasthenia. In an occasional patient with acute flaccid weakness, hypokalemia proves to be the cause, although cranial nerves are usually not affected. Diphtheria presents with prominent cranial neuropathies, but these develop over 1–4 weeks and are preceded by acute pharyngitis symptoms.

Electrophysiological studies are the most useful investigation to distinguish botulism from its mimics, although the electromyographer must be alerted to the possibility of botulism. Serological studies may also be helpful, although results may not be available sufficiently quickly in the acute setting. Up to 90 % of patients with myasthenia gravis are either acetylcholine receptor or muscle-specific tyrosine kinase (MuSK) antibody positive [35, 36]. In 95 % of Lambert-Eaton myasthenic syndrome (LEMS) patients, voltage-gated calcium channel antibodies can be found on serological testing [37] and 92 % of patients with

ophthalmoplegia in GBS or MFS are GQ1b antibody positive [38]. A dramatic response to intravenous anticholinesterase inhibitors such as edrophonium chloride favors myasthenia gravis, but some patients with mild botulism may also show a response [30, 39, 40].

Death from untreated botulism generally occurs because of respiratory arrest in the context of airway obstruction secondary to pharyngeal muscle paralysis as well as respiratory muscle and diaphragmatic failure [22]. Untreated, the mortality of food-borne botulism may be up to 60 % [25]. On the other hand, with the advent of mechanical ventilation, the mortality has dramatically decreased, with various authors reporting rates of zero to 18 % [28, 30, 41].

Up to 30 % of patients with botulism require mechanical ventilation, lasting days to weeks [41]. Once clinically stabilized, recuperation is usually complete, albeit prolonged. There is some evidence that recovery of autonomic function may be more prolonged than that of neuromuscular transmission [42].

Infant Botulism

Since its initial description in 1976 [43, 44], infant botulism is now recognized worldwide to be the most common form of botulism, surpassing both its food-borne and wound counterparts [25]. Perhaps due to increased physician awareness, the majority of cases have been diagnosed in the United States, where the incidence is estimated at 2.1 cases per 100,000 live births [45, 46].

Typically, affected infants are between the age of 2 weeks and 1 year (median age 10 weeks), with about 90 % of cases occurring before the age of 6 months [47, 48]. Although rare before the age of 2 weeks, cases of infant botulism within the first few days of life have been reported [49, 50], suggesting that the previously estimated incubation period for *Clostridium botulinum* of 3–30 days in infants [51] may need to be revisited.

Infants typically present with constipation, weak cry, lethargy, difficulty in feeding, poor sucking, and progressive weakness of limb and bulbar muscles developing over hours to several days [22, 44, 52–54]. Constipation and other signs of dysautonomia are present in up to 65 % of cases and may precede weakness by several weeks [53–55]. Weakness is a principal feature of infant botulism in up to 90 % of cases, beginning with poor head control and progressively evolving into a picture of descending flaccid paralysis with generalized hypotonia and hyporeflexia [53]. The severity of the clinical spectrum of infant botulism may range from mild hypotonia to flaccid paralysis to sudden unexpected death [56–58]. Respiratory distress, which can be exacerbated with the use of aminoglycosides, is often a late manifestation, with up to 70 % of infants requiring ventilatory support [53, 59, 60]. The mortality rate is reported to be as high as 5 % [47, 61]. Despite this, with timely and adequate supportive care, most infants with botulism have an excellent prognosis with complete recovery within weeks to months [45]. Relapse of symptoms is possible and usually occurs within 2 weeks.

> A 7-day-old baby boy presented to the emergency department (ED) with a 1-day history of decreased respiratory effort and cyanosis. He was the product of a spontaneous vaginal delivery at 37 weeks of gestation to a healthy mother. The pregnancy and delivery were unremarkable. Apgars were 5 and 10 at 1 and 5 min, respectively. He was initially fed with concentrated liquid formula and was waking up every 2–4 h to feed. Stools were normal and regular. At 4 days, he was switched to powdered infant formula, and the following day, he was noted to be constipated, with no stools since the switch in formula. He also became progressively sleepy and needed to be woken up for feeds. Feeding became difficult, with progressively weaker suck. He was found to be more floppy. On day 7, cyanosis and decreased respiratory effort were evident. He was brought to the ED, where he was found to be poorly responsive and hypopneic with an oxygen saturation (SpO2) of 43 %. He was afebrile and hemodynamically stable. A capillary blood gas revealed a pH of 7.2 and pCO2 of 60. He was promptly intubated and admitted to the intensive care unit (ICU).
>
> Initial investigations to rule out an infectious or metabolic etiology, including lumbar puncture, were unrevealing. Shortly after admission, the patient was noted to have fixed and dilated pupils (4 mm), with preserved corneal and gag reflexes. Suck was poor. Spontaneous movements were decreased, with marked axial and appendicular hypotonia. Moro reflex was absent. Deep tendon reflexes were diminished, but were bilaterally symmetrical with upgoing plantar responses. No tongue fasciculation was noted. The general examination was unremarkable. Brain MRI, cardiac and abdominal ultrasound, and ophthalmological assessment were unremarkable.
>
> During the second day in the ICU, the patient began to exhibit hemodynamic instability, with a labile BP requiring dopamine support for 48 h. At this point, infantile botulism was suspected and stool cultures were sent. Nerve conduction studies performed 5 days after onset of symptoms showed decreased ulnar, median, and tibial compound muscle action potential amplitudes, with normal motor conduction velocities and sensory nerve conduction studies. 2-Hz and 50-Hz repetitive stimulation of the median nerve showed neither increment nor decrement. Concentric needle examination of the deltoid, tibialis anterior, and vastus lateralis was normal.
>
> The patient received human-derived botulinum immunoglobulin (BIG) 8 days after admission. The following day, he began to trigger the ventilator, and 24 h later, he was extubated. Spontaneous movements increased and he began passing stool. Eleven days after symptom onset, he was feeding well. He was discharged home after 14 days. Stool culture and toxin assay demonstrated *C. botulinum* type F spores and toxin.

Due to the turnaround time of toxin assays (usually days), the clinical presentation and physical examination remain pivotal in making the diagnosis of infant botulism and in initiating treatment [22]. Importantly, other etiologies that commonly cause hypotonia in the infant need to be considered and appropriately ruled out including infectious, toxic,

metabolic, or other neuromuscular pathologies such as myopathies, spinal muscle atrophy, myasthenia gravis, Guillain-Barré syndrome, and poliomyelitis [54]. Electrodiagnostic tests can play a complementary role to the clinical presentation and allow for early diagnosis of botulism [62]. Notably, however, the characteristic electrodiagnostic findings of botulism (see below) are not reliably present in infants, and their absence does not rule out the diagnosis.

Although up to 85 % of cases of infant botulism have an unidentified source, epidemiologic studies have acknowledged a number of intrinsic and environmental factors that may predispose the infant to botulism [47, 63]. The absence of both protective bacterial flora as well as *Clostridium*-inhibiting bile acids renders the infant's gut particularly susceptible to colonization by the toxin-producing bacteria. Environmental exposure to *C. botulinum* spores, which are commonly found in soil and dust, may occur through inhalation of microscopic dust, particularly in infants who live in rural areas or through exposure to a parent who works with soil [58, 63]. Honey is a well-established source of *Clostridium botulinum* spores and has been implicated as a significant risk factor for infant botulism [64, 65]. As a result, avoidance of honey in infants younger than 1 year is recommended, and this practice has probably contributed to decreasing the incidence of honey-associated botulism to less than 5 % in the USA [46]. Breastfeeding as a risk factor remains controversial, with contradictory evidence for both an increased risk as well as a conferred protection [66, 67]. Nevertheless, botulism has been described in both breastfed and formula-fed infants.

Wound Botulism

Wound botulism was thought to be rare, reported in patients with traumatic and surgical wounds. More recently, however, it has become increasingly important since being recognized in illicit drug abusers [68]. In 1995 alone, 19 laboratory-confirmed cases of wound botulism among intravenous heroin users were reported to the California Department of Health Services [69].

It is generally held that wound botulism occurs with the introduction of *C. botulinum* spores at a site of injury followed by the in vivo formation of BoNT [70]. The major risk factor for wound botulism appears to be the frequent subcutaneous or intramuscular injection of illicit drugs [71] although cases have been reported after the inhalation of cocaine as well [72].

The neurologic features of wound botulism are largely similar to those in food-borne botulism although early abdominal cramps, nausea, and vomiting are conspicuously absent [22]. The clinical outcome is also similar between the two forms of botulism. There appears to be a relationship between wound botulism severity and the number of cutaneous abscesses [70].

Adult Intestinal Toxemia Botulism (Hidden Botulism)

In the majority of adults, *C. botulinum* cannot germinate in the generally acidic environment of the human gastrointestinal tract. It is likely thanks to this fortuitous circumstance, as well as to competitive inhibition from endogenous intestinal flora, that botulism is not more common in humans in spite of the fact that its spores are found ubiquitously in our environment.

Adult intestinal toxemia botulism occurs when *C. botulinum* spores successfully germinate in, and subsequently colonize, the gastrointestinal tracts of certain adults which then results in the in vivo production of BoNT. Not surprisingly, it is the comorbid abnormalities of the gastrointestinal tract that appear to predispose individuals to the condition including achlorhydria, whether due to medications or truncal vagotomy, Crohn's disease, as well as various abnormalities in small and large bowel anatomy, both spontaneous and iatrogenic [73–75]. Recent antibiotic therapy has also been associated with adult intestinal toxemia botulism, likely due to its effect on endogenous intestinal flora [73]. The clinical characteristics of this most rare form of botulism are again identical to those in food-borne botulism.

Iatrogenic and Inhalational Botulism

Since the first description in 1997, there have been a number of case reports and small case series of botulism that have occurred after the therapeutic and cosmetic injection of BoNT [76]. The majority of cases have occurred during the course of treating blepharospasm, dystonia, and spasticity where the average dose is up to 75 times larger than cosmetic applications [77–79]. There has been only one outbreak of iatrogenic botulism after the cosmetic use of BoNT [80]. On the other hand, it should be noted that in the aforementioned outbreak, the medical staff involved used an unlicensed form of BoNT type A and performed a dilution error which led to the inadvertent injection of more than 2,500 times the estimated human lethal dose into each of the four affected patients.

In addition to cases of frank botulism, patients who receive therapeutic injections of BoNT may have prolonged jitter and increased blocking on single-fiber electromyography of muscles distant to the site of injection, even in the absence of weakness [81]. Pathologic studies have also

demonstrated muscle fiber atrophy distant to the site of injection without any clear clinical significance [82].

A report in 1962 described three cases of inhalational botulism in a group of German laboratory technicians who had been participating in animal experiments that involved aerosolized BoNT [83]. Although there have been no further reports of inhalational botulism since then, it remains a concern among health agencies and governments alike due to its frightening potential as a biological weapon. It is thought that a number of countries have attempted to exploit botulism as a weapon over the last century, some expending considerable energy and resources on the endeavor [84]. There have also been fears that paramilitary groups might resort to biological weapons. In fact, there were a number of attempts by the religious group *Aum Shinrikyo,* later responsible for the 1995 sarin gas attack in Tokyo, to carry out assaults on civilian and American military targets in Japan during the early 1990s using aerosolized BoNT, all of which fortunately failed [85].

Evaluation and Diagnosis

Laboratory Findings

Laboratory confirmation of botulism may be established via a number of methods. The primary approach is to test the preformed BoNT in either gastric, serum, or stool samples using a bioassay [8]. This bioassay is available through a small number of laboratories and involves the intraperitoneal injection of various preparations of patient samples and BoNT type-specific antitoxins into a panel of mice. These mice are then observed for the development of botulism-specific manifestations, both to confirm the diagnosis of botulism as well as to establish the type of BoNT. Samples of the suspected food, if available, should be tested.

The sensitivity of bioassays for BoNT in food-borne botulism appears to be between 30 and 50 % although in one series it was as low as 18 % of stool samples [29, 86]. Samples collected within 2 days of symptom onset appear to be of greater sensitivity, reportedly as high as 60–70 % [29]. Interestingly, in these same studies involving what were ostensibly cases of food-borne botulism, up to 60 % of gastric and stool cultures were positive for *C. botulinum*. Such findings impress upon the clinician, the utility of investigating for both preformed toxin and *C. botulinum*. In addition, they suggest that our understanding of the pathogenesis of food-borne botulism is incomplete or that perhaps adult intestinal toxemia botulism is more frequent than currently appreciated. In cases of suspected infant botulism, stool samples for BoNT assay and bacterial culture are preferred [86]. In cases of suspected wound botulism, bacterial cultures of the wound may be helpful, with yields as high as 57 % [87]. Routine serologic examinations and cerebrospinal fluid analysis are normal in the majority of patients with botulism [25].

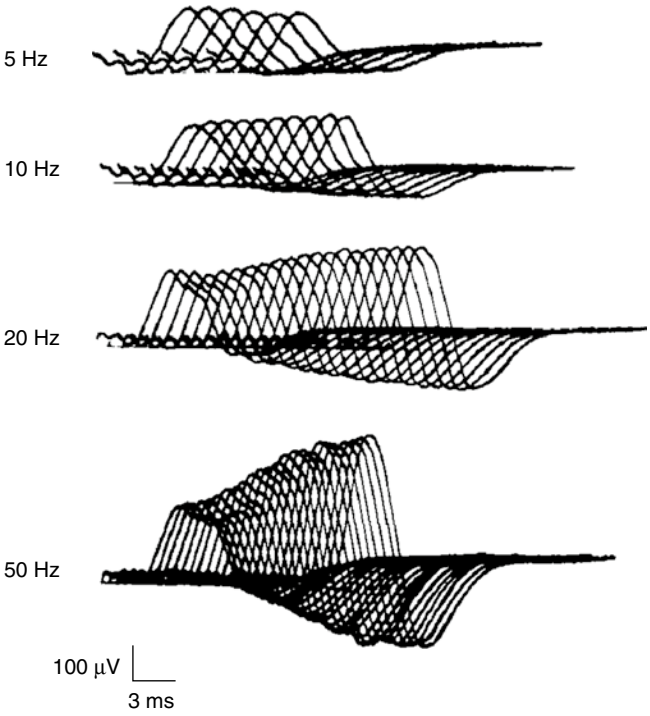

Fig. 50.2 Repetitive nerve stimulation in the left abductor pollicis brevis of a patient with infant botulism. The frequency of nerve stimulation is listed along the vertical axis. At 5 Hz, an 8 % decrement was seen. At higher frequencies, an increment was seen: 25 % at 10 Hz, 38 % at 20 Hz, and 94 % at 50 Hz (Reproduced with permission from Cornblath et al. [90])

Electrodiagnostic Findings

Due to the low sensitivity of laboratory testing as well as the time required to obtain their results, electrodiagnostic studies remain the cornerstone of botulism diagnosis.

Nerve conduction studies in botulism are characterized by decreased compound muscle action potential (CMAP) amplitudes in 85–92 % of patients, while conduction velocities and distal latencies remain relatively normal [88, 89]. Compound sensory nerve action potential amplitudes, conduction velocities, and latencies are normal. A decremental response to low-frequency (2–5 Hz) repetitive nerve stimulation (RNS) has been described in 56 % of patients with infant botulism [90]. Finally, an incremental response may be seen as a result of posttetanic facilitation (PTF), after either high-frequency (30–50 Hz) RNS or 10 s of isometric exercise.

In a study of 63 patients with food-borne botulism and 60 controls, an increment of only 25 % was shown to have both a sensitivity and specificity greater than 95 % [89]. This same study also reported a median increment of 97 % among patients with botulism. The increment is most evident at higher rates of RNS (50 Hz vs. 20 Hz) [90], and isometric exercise may be superior to RNS at eliciting this response [91]. A representative tracing of the RNS findings in botulism is shown in Fig. 50.2.

Conventional electromyography (EMG) studies occasionally reveal low-amplitude and polyphasic motor unit

potentials (MUP) and fibrillation potentials [92]. Such findings are described in up to 54 % of patients with infant botulism [90]. Increased jitter and blocking with single-fiber EMG are reported in a large proportion of patients [92–94]. Some argue that single-fiber EMG may be more sensitive for identification of botulism than RNS although clear evidence is lacking [94].

Findings in botulism are similar to those in Lambert-Eaton myasthenic syndrome (LEMS), since they are both presynaptic disorders of the neuromuscular junction. However, differences exist. Electrophysiological findings in botulism tend to be more variable among muscle groups and to change considerably over periods of days, whereas in LEMS they are more uniform from muscle to muscle and stable over months or longer [92]. It is also suggested that PTF in botulism is rather prolonged, lasting up to 20 min, while PTF in LEMS generally lasts only 30–60 s [95, 96].

Treatment

The most important advance in the treatment of botulism over the last century was the advent of modern intensive care, in particular mechanical ventilation. Vigilant surveillance and aggressive management of respiratory failure have dramatically decreased the mortality rate of botulism. Notably, there were no deaths in the 2006 outbreak that affected 209 individuals in Thailand [28].

A number of medical therapies have been developed over the last decades for botulism, although rigorous evidence supporting their efficacy is lacking. A Cochrane review examining medical therapy in botulism identified only one randomized controlled trial (RCT) [97]. The study involved 129 patients with infant botulism, of whom 65 were given a single infusion of human-derived botulism immune globulin (BIG) and 64 received a similar infusion of intravenous immune globulin (Gammagard or Gammagard S/D), both within 72 h of hospitalization [98]. Patients treated with BIG had significant decreases in the duration of hospitalization (3.3 weeks less), mechanical ventilation (2.6 weeks), and tube or parenteral feeding (6.4 weeks). There were no deaths in either group and no significant differences in adverse effects. An open-label extension of this study including 382 patients produced similar results and also suggested that administration of BIG within 3 days of hospitalization as opposed to 7 days conferred greater benefit [98]. There have not been any studies examining the efficacy of BIG in other forms of botulism.

Equine-derived botulinum antitoxin is widely considered to be the "standard of care" in the treatment of food-borne botulism, although the efficacy of antitoxin has not been demonstrated in an RCT. The best evidence supporting the use of antitoxin is derived from a retrospective observational cohort study that included 132 patients with laboratory-confirmed food-borne botulism [99]. One hundred fifteen patients (87 %) received trivalent (types A, B, and E) equine-derived botulinum antitoxin. Compared to untreated patients, those administered antitoxin had a 31–36 % decrease in mortality, depending on whether antitoxin was given within the first 24 h of symptom onset or later. There was also a 15–46-day decrease in the duration of hospitalization as well as a 7–28-day decrease in the duration of mechanical ventilation, again depending on the timing of antitoxin administration. Whether these findings were statistically significant was not reported and potential adverse effects of antitoxin were not addressed. In another small retrospective cohort study of 18 patients with food-borne botulism, administration of the antitoxin on day 4 as opposed to day 6 after exposure to BoNT resulted in a significant decrease in the duration of mechanical ventilation [100]. Equine-derived botulinum antitoxin has also been used in wound botulism, although the evidence of its efficacy is limited to small case series [101].

It must be emphasized that both acute and delayed hypersensitivity reactions frequently occur after the administration of equine-derived botulinum antitoxin. In a review of 268 patients reported to the CDC over a 10-year period, 24 (9 %) suffered from a hypersensitivity reaction, 5 (1.9 %) of which were anaphylaxis and 10 (3.7 %) of which were serum sickness [102]. These risks have been somewhat mitigated by the use of a horse serum skin test prior to the administration of the antitoxin although a negative skin test does not entirely rule out the possibility of anaphylaxis [103].

Other reported treatments for botulism have included guanidine and 3,4-diaminopyridine, both of which promote the presynaptic release of acetylcholine at the neuromuscular junction [104, 105]. Robust evidence of their efficacy in botulism is lacking, although the efficacy of 3,4-diaminopyridine in Lambert-Eaton syndrome was demonstrated in an RCT [106]. There are isolated reports describing the use of plasmapheresis in botulism [107].

In the case of wound botulism, debridement of any abscesses and removal of devascularized tissue is recommended to limit the further germination of spores and production of BoNT [5, 22, 108]. Treatment with antibiotics is also recommended, although this has not been formally studied [5, 22].

Congenital Myasthenic Syndromes

51

Andrew G. Engel

Introduction

Congenital myasthenic syndromes (CMS) are inherited disorders of neuromuscular transmission in which the safety margin of neuromuscular transmission is compromised by one or more specific mechanisms. An understanding of the concept of the safety margin and of the mechanisms that can compromise it requires a brief overview of the anatomic and physiologic aspects of neuromuscular transmission [1].

At the motor endplate (EP), the nerve terminal is separated from the postsynaptic region of clefts and folds by primary and secondary synaptic clefts. The nerve terminal contains numerous synaptic vesicles that store quantal packets (5–10,000 molecules) of acetylcholine (ACh). Readily releasable vesicles abut on the active zones of the presynaptic membrane (Fig. 51.1). The acetylcholine receptor (AChR) is strategically deployed on the terminal expansions of the postsynaptic junctional folds at a density of about 10,000 molecules per μm^2. The EP species of acetylcholinesterase (ACHE) is concentrated in the synaptic space where it is anchored to the basal lamina. Exocytotic release of single quanta occurs spontaneously in the resting state. Depolarization of the nerve terminal by nerve impulse opens voltage-gated Ca^{2+} channels positioned in the active zones of the presynaptic membrane. The entry of Ca^{2+} ions triggers the release of multiple quanta. The number of released quanta (m) is a function of the probability of release (p), which depends mostly on the prevailing Ca^{2+} concentration near the intraterminal release sites, and the number of readily releasable quanta (n), so that $m = np$.

ACh released into the synaptic space diffuses toward the postsynaptic membrane. About 20 % of the released ACh is hydrolyzed by ACHE before it binds to AChR. Binding of ACh to AChR causes the cation-selective AChR channel to open for a period distributed exponentially from a fraction of a millisecond to several milliseconds, allowing Na^+, and, to a lesser extent Ca^{2+}, to enter the muscle fiber. After ACh dissociates from AChR, ACHE hydrolyzes it rapidly and completely to choline and acetate. Choline is taken up by the nerve terminal by Na^+-dependent active transport. ACh is resynthesized in the nerve terminal from choline and acetyl coenzyme A in a reaction catalyzed by choline acetyltransferase. The newly synthesized ACh is concentrated in synaptic vesicles by a proton-pump-dependent ACh transporter.

The postsynaptic depolarization and the concomitant current flow induced by a single quantum give rise to a miniature endplate potential (MEPP) and a miniature endplate current (MEPC), respectively. The amplitude of the MEPP depends on the number of ACh molecules per quantum; the EP geometry; the number of activatable AChRs, which is a function of postsynaptic AChR density; the depolarization per channel opening; and the input resistance of the muscle fiber. The duration of the MEPP depends on the mean open time of the AChR channel, the functional state of ACHE, and the cable properties of the sarcolemma. The amplitude and duration of the MEPC are independent of the cable properties of the sarcolemma but are otherwise determined by the same factors that determine the amplitude and duration of the MEPP.

Multiquantal release by nerve impulse generates an endplate potential (EPP). The EPP amplitude is a function of m and of the MEPP amplitude. When the EPP exceeds the threshold for activating perijunctional voltage-gated Na^+ channels, it triggers a muscle fiber action potential. *The safety margin of neuromuscular transmission is the difference between the actual EPP amplitude and the EPP amplitude required to trigger a muscle fiber action potential*. From the above discussion, it follows that the safety margin will be compromised by defects that affect the (1) number of ACh molecules per quantum, (2) quantal release mechanisms, and (3) quantal efficiency. Quantal efficiency depends on EP geometry, the functional state of ACHE in the synaptic space, and the density and kinetic properties of AChR.

The nerve terminal contains mitochondria, synaptic vesicles, and a few giant synaptic vesicles. *Arrows* indicate presynaptic active zones in register with the secondary synaptic clefts. The nerve terminal is covered by a Schwann cell process and faces the primary synaptic cleft (reduced from × 24,800)

Classification of the Congenital Myasthenic Syndromes

The CMS can be classified according to inheritance, the EP-specific protein that is altered, or the site of the defect (presynaptic, synaptic, or postsynaptic). A classification by inheritance is simple: the slow-channel syndromes are caused by autosomal dominant gain-of-function mutations; all other CMS recognized to date are caused by autosomal recessive loss-of-function mutations. Table 51.1 shows a classification of the CMS in 321 kinships investigated at the Mayo Clinic according to the site of the defect and according to mechanisms governing endplate (EP) development and maintenance. The classification is still tentative because additional CMS might yet be discovered or because, for some presynaptic CMS, the disease protein or gene is not yet known.

Table 51.1 indicates that the purely presynaptic CMS are least frequent, accounting for only 6 % of all cases. Of note, however, a defect in presynaptic quantal release is also present in EP ACHE deficiency [2], Dok-7 myasthenia [3, 4], β2-laminin deficiency [5], and in the CMS associated with centronuclear myopathy [6]. The purely postsynaptic CMS account for most patients in this group, and mutations in AChR subunits account for more than one-half of all cases.

Diagnosis of a Congenital Myasthenic Syndrome

Many CMS patients remain undiagnosed or are diagnosed incorrectly. A generic diagnosis of a CMS can be made from the features listed in Table 51.2. Also, in some CMS, there are

Table 51.1 Classification of the congenital myasthenic syndromes based on 321 kinships investigated at the Mayo Clinic[a]

Defect site	Index cases	Relative frequency (%)
Presynaptic (5.9 %)		
Choline acetyltransferase	17	5.3
Paucity of synaptic vesicles[b]	1	0.3
Congenital Lambert-Eaton-like syndrome[b]	1	0.3
Synaptic basal lamina (13.7 %)		
Endplate ACHE deficiency	43	13.4
β2-laminin deficiency	1	0.3
Postsynaptic (68 %)		
Primary AChR deficiency with/without kinetic abnormality	109	34
Primary kinetic abnormality with/without AChR deficiency	58	18.1
Rapsyn deficiency	48	15
Plectin deficiency	2	0.6
Na channel myasthenia	1	0.3
Defects in mechanisms governing endplate development and maintenance (12.5 %)		
Dok-7 myasthenia	31	9.7
Glutamine-fructose-6-phosphate transaminase deficiency (GFPT1)	8	2.5
Myasthenic syndrome associated with centronuclear myopathy[b]	1	0.3
Total	321	100

[a]Mutations in MuSK [107, 109, 110] and agrin [113] have been identified in few kinships at other medical centers
[b]No gene defect identified

Table 51.2 Generic diagnosis of a congenital myasthenic syndrome

Fatigable weakness involving ocular, bulbar, and limb muscles since infancy or early childhood
Similarly affected relative
Decremental EMG response at 2–3 Hz stimulation or abnormal jitter and blocking on single-fiber EMG[a]
Negative tests for anti-AChR antibodies
Exceptions and caveats
In some CMS, the onset is delayed
There may be no similarly affected relatives
EMG abnormalities may not be present in all muscles or are present only intermittently
Weakness can be restricted to selected muscle

[a]Single-fiber EMG has high sensitivity but can also be abnormal in myopathies and some neuropathies

Table 51.3 Clinical clues pointing to a specific diagnosis[a]

Endplate choline acetyltransferase deficiency
Recurrent apneic episodes, spontaneous or with fever, vomiting, or excitement
No or variable myasthenic symptoms between acute episodes
Stimulation at 10 Hz for 5 min causes marked decrease of CMAP followed by slow recovery over 10 min
EMG decrement at 2 Hz can be absent at rest but appears after stimulation at 10 Hz for 5 min and then disappears *slowly* over 10 min
EP ACHE deficiency
Repetitive CMAP
Refractoriness to cholinesterase inhibitors
Delayed pupillary light reflexes in some cases
Absence of cholinesterase reactivity from EPs in muscle specimens
Slow-channel CMS
Repetitive CMAP
Selectively severe involvement of cervical and wrist and finger extensor muscles in most cases
Dominant inheritance
Rapsyn deficiency
Multiple congenital joint contractures or dysmorphic features in ~30 %
Increased weakness and respiratory insufficiency precipitated by intercurrent infections
Ophthalmoparesis in ~25 %; strabismus relatively common
Dok-7 myasthenia
Predominantly limb-girdle and axial distribution of weakness, mild facial weakness, and ptosis are common; normal ocular ductions in most patients
Significant bulbar muscles involvement in some patients
Often worsened by pyridostigmine; responds to ephedrine and albuterol
Can present with stridor and vocal cord paralysis in neonates and infants
GFPT1 (GFAT) myasthenia
Tubular aggregates in muscle in most patients[b]
Predominantly limb-girdle and axial distribution of weakness
Responds to pyridostigmine
Laminin-β2 myasthenia
Nephrotic syndrome, ocular abnormalities (Pierson syndrome)
Refractoriness to cholinesterase inhibitors

Abbreviations: *ACHE* acetylcholinesterase, *CMAP* compound muscle fiber action potential, *CMS* congenital myasthenic syndrome, *EP* endplate, *GFPT1* glutamine-fructose-6-phosphate transaminase 1

[a]There are no specific clues to the diagnosis of the fast-channel congenital myasthenic syndrome, primary endplate AChR deficiency, and many cases of rapsyn deficiency

[b]Not all CMS patients with tubular aggregates have GFPT1 myasthenia

strong phenotypic clues pointing to a specific diagnosis, and these are listed in Table 51.3. In other CMS, the phenotypic features do not suggest a specific diagnosis or site of defect. In these patients, molecular genetic studies alone, or sometimes in combination with specialized morphologic and electrophysiologic investigations, are required to determine the etiology. Table 51.4 lists the differential diagnosis of the CMS.

Genetic Analysis

This is greatly facilitated when clinical, physiologic, or morphologic studies point to a candidate protein or gene. For example, a kinetic abnormality of AChR detected at the single-channel level [7] or severe EP AChR deficiency revealed by α-bungarotoxin binding studies [8] predicts mutations in

Table 51.4 The differential diagnosis of congenital myasthenic syndromes

Neonatal period, infancy, childhood
Spinal muscular atrophy
Morphologically distinct congenital myopathies (central core disease, nemaline myopathy, myotubular myopathy, fiber-type disproportion-related syndromes)
Congenital muscular dystrophies
Infantile myotonic dystrophy
Mitochondrial myopathy
Brain stem anomaly
Möbius syndrome
Infantile botulism
Seropositive and seronegative autoimmune myasthenia gravis[a]
Older patients
Motor neuron disease
Radial nerve palsy[b]
Peripheral neuropathy[b]
Limb-girdle or facioscapulohumeral dystrophy
Mitochondrial myopathy
Chronic fatigue syndrome
Seropositive and seronegative autoimmune myasthenia gravis

[a]Not reported in the first year of life
[b]This diagnosis has been made in some cases of the slow-channel CMS

an AChR subunit gene. However, only few highly specialized laboratories can perform these studies.

Genetic testing for CMS is now commercially available and facilitates diagnosis and management by neuromuscular specialists. It is also best used in a targeted manner based on specific clinical features, as listed in Table 51.3, or beginning with the most frequently mutated genes, as shown in Table 51.1. However, this approach has a number of drawbacks: (1) it is expensive, especially if used in a shotgun manner; (2) it does not establish that recessive mutations are heteroallelic unless they are homozygous; therefore, DNA from both parents also must be analyzed; (3) it will miss intronic mutations not close to exons; (4) evaluation of pathogenicity is based on software programs whose reliability is still debated; (5) it does not inform on kinetic consequences of mutations in AChR or ChAT or on pathogenicity of mutations that render the disease protein structurally unstable; and (6) negative results do not exclude the diagnosis of a CMS because only previously identified disease genes are sequenced.

Another approach is linkage analysis if a sufficient number of informative relatives are available. If successful, it will point to a candidate chromosomal locus. If the physical map of the locus shows an attractive candidate gene, then mutation analysis by direct sequencing becomes feasible. This approach seldom works for CMS because large informative CMS kinships are seldom available; however, it has been successful in inbred populations with multiple consanguineous families [9].

A direct and efficient approach is the use of microarrays specifically designed for screening multiple candidate disease loci in known CMS genes. One publication finds that this approach has a 73.3 % overall sensitivity and a 95.5 % sensitivity for missense mutation, but it is not recommended for detecting insertion or deletion mutations [10]. Also, this approach will miss mutations in novel CMS disease genes.

A novel approach to mutation discovery is whole-exome sequencing that searches for mutations in exons. This technique is still evolving. A discussion of its use and limitations is beyond the scope of this chapter.

Endplate Choline Acetyltransferase (ChAT) Deficiency

The disease is characterized by sudden episodes of apnea precipitated by infections, fever, excitement, or no apparent cause [11–13]. In some patients, the disease presents at birth with hypotonia and severe bulbar and respiratory weakness requiring ventilatory support. In some children, an acute attack is followed by respiratory insufficiency that lasts for weeks [14]. Few patients are apneic, respirator dependent, and paralyzed since birth, and some develop cerebral atrophy after episodes of hypoxemia [13]. The symptoms gradually improve, but are followed by recurrent apneic attacks associated with bulbar paralysis in later life. Other patients are normal at birth and experience their first apneic attack during infancy or early childhood. Variable ptosis and fatigable weakness may persist between the attacks. After the first decade, the apneic crises become less frequent. The external ocular muscles are frequently spared. The clinical diagnosis is established by the clues listed in Table 51.3.

Endplate studies reveal no AChR deficiency and the postsynaptic regions show no structural abnormality. The amplitude of the evoked compound muscle action potential (CMAP), the EPP, and the MEPP is normal in rested muscle, but decreases abnormally during 10 Hz stimulation for 5 min and then returns to the baseline slowly over the next 10–15 min. Quantal release by nerve impulse is not depressed after 10 Hz stimulation for 5 min [15]. These findings point to a defect in the resynthesis or vesicular packaging of ACh.

The muscle weakness, when present, responds well to small or modest doses of anticholinesterase drugs. Some patients are asymptomatic or have only minimal weakness, except during exacerbations. These patients require anticholinesterase drugs only on an emergency basis. Patients with frequent apneic attacks are best treated prophylactically with anticholinesterase medications. Parents of affected children must be taught to anticipate sudden worsening of the weakness and possible apnea with febrile illnesses, excitement, or overexertion. Parents must also be familiar with the use of a hand-assisted ventilatory device and should be able to administer appropriate doses of prostigmine intramuscularly during

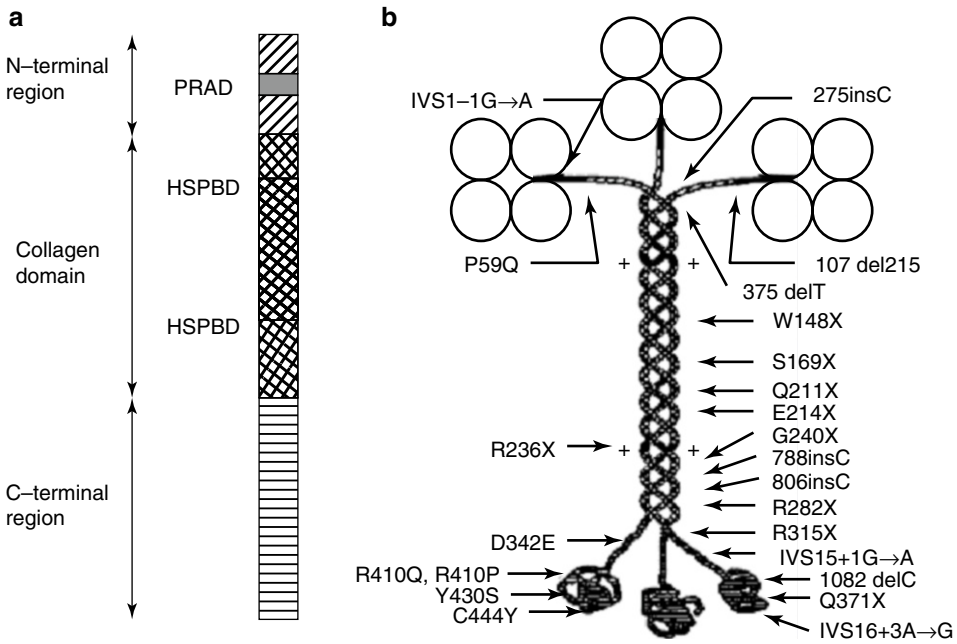

Fig. 51.2 (**a**) Schematic diagram showing domains of a COLQ strand with identified COLQ mutations and (**b**) components of the A_{12} species of asymmetric ACHE. The N-terminal region of each COLQ strand contains a proline-rich attachment domain (PRAD) that binds a homotetramer of the catalytic $ACHE_T$ subunit. The triple helical collagenic domain contains two positively charged heparan sulfate proteoglycan binding regions (HSPBD) that participate in anchoring the tail subunit in the synaptic basal lamina. The C-terminal region of COLQ is essential for the assembly of the triple helix of the collagen domain in a C- to N-terminal direction and also participates in anchoring the tail subunit

such crises. Patients with a febrile illness and a previous history of crisis should be hospitalized for close observation and for ventilatory support as needed.

Paucity of Synaptic Vesicles and Reduced Quantal Release

The clinical features of this syndrome closely mimic those of autoimmune MG, but EP studies reveal no AChR deficiency. A presynaptic defect is indicated by a severe decrease (to ~20 % of normal) in the number of ACh quanta (*m*) released by nerve impulse. The decrease in *m* is due to a decrease in the number of readily releasable quanta (*n*), and this decrease is associated with a comparable decrease (to ~20 % of normal) in the numerical density of synaptic vesicles. The putative defect resides in the synthesis or axonal transport of vesicle precursors from the anterior horn cell to the nerve terminal or, less likely, is related to impaired recycling of the synaptic vesicles [16]. A generic diagnosis of a CMS is easy to establish (see Table 51.2), but a specific diagnosis requires in vitro studies of neuromuscular transmission and quantitative electron microscopy examination of the EP. The disorder responds partially to anticholinesterase medications.

CMS Resembling the Lambert-Eaton Myasthenic Syndrome

In this CMS, repetitive nerve stimulation shows marked facilitation of the compound muscle action potential (CMAP) at physiologic rates of stimulation [17]. In a single patient investigated by the author, the number of quanta released by nerve impulse was decreased due to a decreased probability of quantal release. EP ultrastructure was normal [18]. The patient failed to respond to 3,4-diaminopyridine (3,4-DAP), which enhances quantal release in the acquired forms of the Lambert-Eaton syndrome.

Endplate Acetylcholinesterase Deficiency

The EP species of ACHE is an asymmetric enzyme composed of catalytic subunits encoded by $ACHE_T$ and a collagenic structural subunit encoded by *COLQ*. No spontaneous mutations have been observed in $ACHE_T$. The COLQ protein anchoring the complex in the synaptic basal lamina is composed of three identical strands. The N-terminal residues of each strand bind a catalytic homotetramer. Mutations in the N-terminal region of COLQ prevent its association with the catalytic subunits; frameshift or nonsense mutations in collagenic midsection of COLQ produce an insertion incompetent single-stranded enzyme. Mutations of critical residues in the globular C-terminal region of COLQ prevent COLQ insertion into the synaptic basal lamina or hinder the triple helical assembly of the COLQ strands [19, 20] (Fig. 51.2).

This CMS is caused by absence or marked reduction of ACHE from the synaptic space [2]. Absence of ACHE from the EP prolongs the lifetime of ACh in the synaptic cleft because each ACh binds multiple AChRs before leaving the synaptic space by diffusion. This prolongs the duration of the MEPP and EPP, and when the EPP outlasts the absolute refractory period of the muscle fiber, it generates a second (or repetitive) muscle action potential, reflected by a repetitive compound muscle action potential (CMAP) that is not affected by edrophonium.

Cholinergic overactivity at the EP results in cationic overloading of the postsynaptic region and causes degeneration of the junctional folds with loss of AChR. The nerve terminals are abnormally small and often encased by Schwann cells, which reduces the number of releasable quanta. The safety margin of neuromuscular transmission is compromised by decreased quantal release, loss of AChR from degenerating junctional folds, altered endplate geometry, and desensitization of AChR from overexposure to ACh [2, 21].

The clinical course is variable [19, 20, 22]. Most patients present in early infancy and are severely disabled. These patients typically harbor mutations in the N-terminal or rod domain of COLQ which abolish the expression of ACHE in the synaptic space. Patients with the C-terminal missense mutations that do not abolish the triple helical assembly or the insertion of the COLQ into synaptic basal lamina present later in childhood and have a milder course.

Therapy is still unsatisfactory, but ephedrine has had a significant beneficial effect in some patients [23–25]. More recently, albuterol was found to be as or more effective than ephedrine [26].

CMS Associated with β2-Laminin Deficiency

β2-laminin, encoded by *LAMB2*, is a component of the basal lamina of different tissues and is highly expressed in kidney, eye, and the neuromuscular junction. Synaptic β2-laminin governs the appropriate alignment of the axon terminal with the postsynaptic region and, hence, pre- and postsynaptic trophic interactions. Defects in β2-laminin result in Pierson syndrome with renal and ocular malformations. A patient carrying heteroallelic missense and frameshift mutations in *LAMB2* had Pierson syndrome with severe ocular, respiratory, and proximal limb muscle weakness [5]. The renal defect was corrected by renal transplant at age 15 months. In vitro microelectrode studies revealed decreased quantal release by nerve impulse and a reduced MEPP amplitude. Electron microscopy showed that the nerve terminals were abnormally small and often encased by Schwann cells, accounting for the decreased quantal release. The synaptic space was widened and the junctional folds were simplified, accounting for the decreased MEPP amplitude.

Mutations in the AChR

Because more than one-half of all CMS are caused by mutations in AChR and because understanding the consequences of the mutations requires grasp of the structural features of the receptor, we will first focus on this topic. The AChR is a ligand-gated ion channel with a pentameric structure consisting of four homologous subunits with a stoichiometry of $\alpha_2\beta\delta\gamma$ in the fetal and $\alpha_2\beta\delta\varepsilon$ in the adult receptor. Each subunit is composed of two extracellular domains at its N- and C-terminal ends, an intracellular domain, and four transmembrane (M) domains connected by intra- and extracellular linkers [27]. Two agonist-binding pockets of AChR are present at the α/δ and α/ε subunit interfaces (Fig. 51.3a, b). The principal face of each binding site is formed by the α-subunit [28]. In each binding pocket, the cationic agonist ACh is stabilized by interaction with conserved aromatic residues. The transmembrane domains are connected by an extracellular M2/M3 linker and by intracellular M1/M2 and M3/M4 linkers. The M3/M4 linker forms a long cytoplasmic loop that likely serves as an attachment site for cytoskeletal elements (Fig. 51.3b). Cryoelectron microscopy studies in 2005 provided a structural model of the *Torpedo* AChR at 4 Å resolution at near physiological conditions [29] (Fig. 51.3d–f). Additional information came from multiple studies: solution at 2.7 Å of the structure of snail AChR-binding protein that corresponds to the extracellular domain of vertebrate nicotinic (n) AChRs [30], homology modeling based on the structure of the human nAChR-binding domain [31], resolution of the crystal structure of the nAChR α1 subunit bound to α-bungarotoxin at 1.94 Å resolution [32], and the recent report of the X-ray crystal structure of the ligand-binding domain of the eukaryotic α7 nAChR bound to epibatidine at 2.8 Å [33]. These studies pave the way to deciphering the molecular events triggered by agonist binding and the subsequent coupling of agonist binding to channel opening.

Primary AChR Deficiency with or Without Minor Kinetic Abnormalities

CMS with severe EP AChR deficiency result from different types of homozygous, or more frequently heterozygous, recessive mutations in AChR subunit genes. The clinical symptoms range from mild to very severe and resemble those of autoimmune MG. A generic diagnosis of a CMS is readily made from the criteria listed in Table 51.2**,** but muscle biopsy studies are needed to demonstrate the EP AChR deficiency for mutations that do not alter the open reading frame, and in vitro microelectrode studies are required to prove or disprove an associated significant kinetic abnormality of AChR [7, 34].

Mutations causing severe EP AChR deficiency are concentrated in the ε subunit. The main reason for this is that expression of the fetal-type γ- subunit, although at a low level, partially compensates for absence of the ε- subunit [35–37], whereas patients harboring null mutations in subunits other than ε might not survive for lack of a substituting subunit (Fig. 51.4). Different types of recessive mutations causing severe EP AChR deficiency have been identified. These mutations are frameshifting [8, 36, 38–40], occur at a

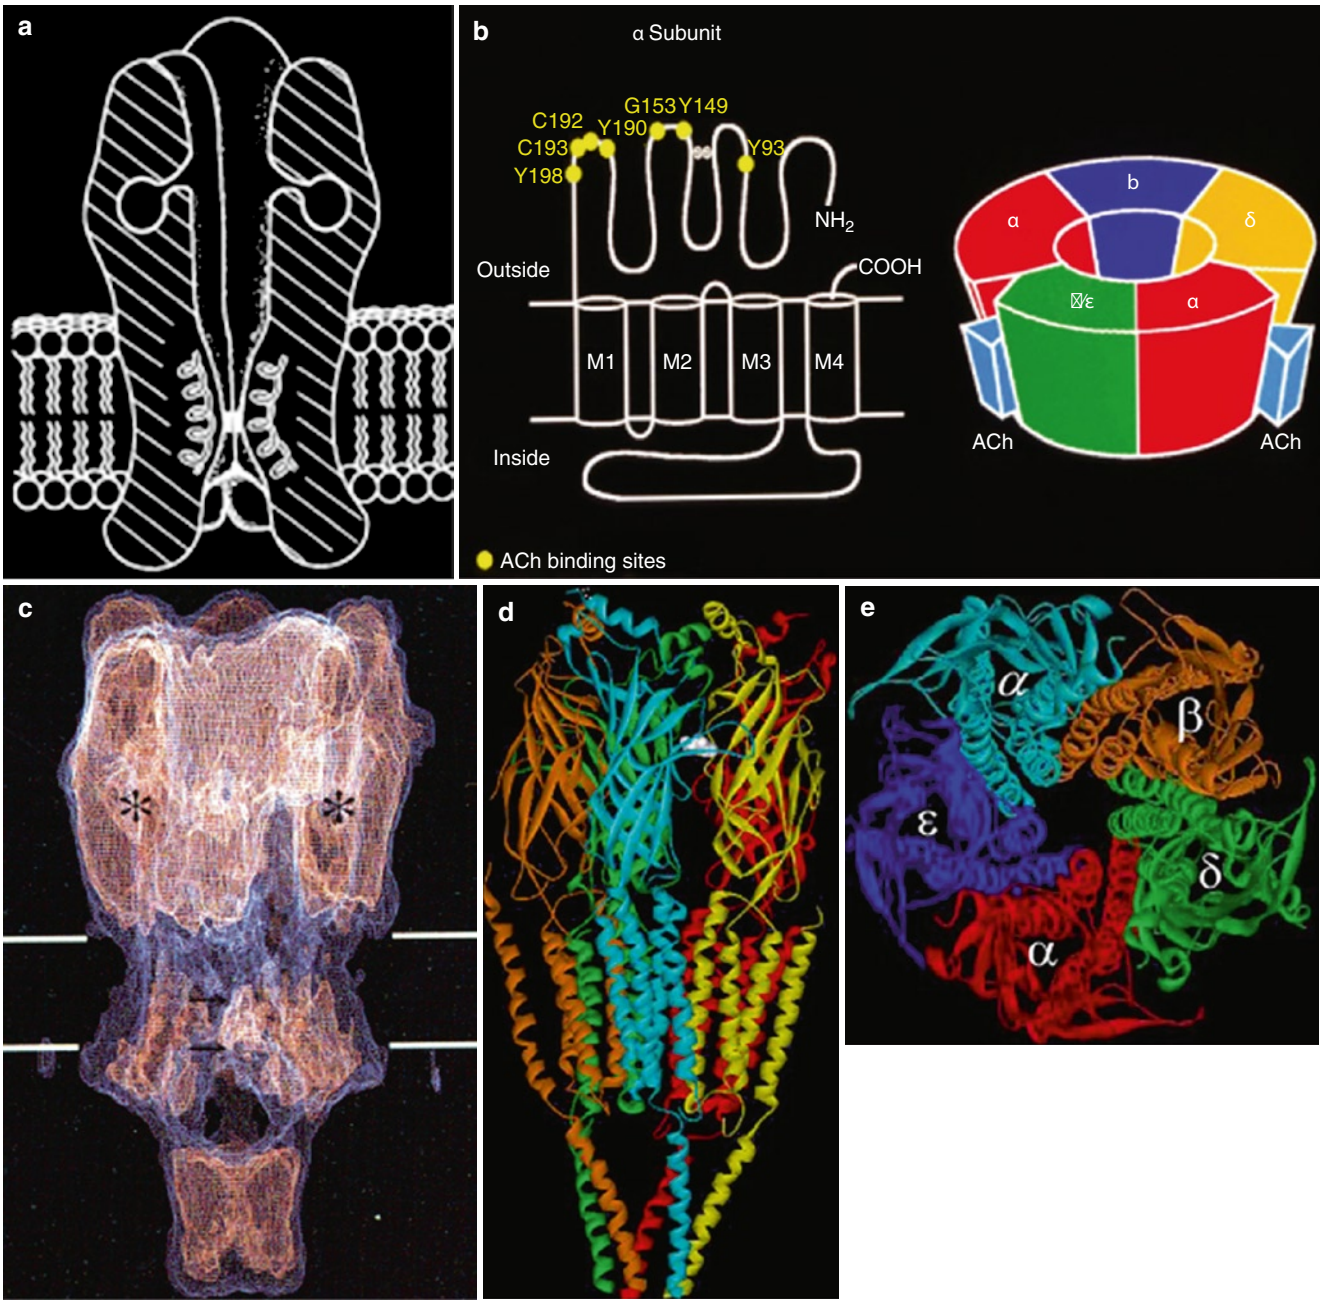

Fig. 51.3 Schematic diagrams: (**a**) AChR in lipid bilayer showing putative ACh-binding pocket and the central pore of the channel. (**b**) Folding pattern of the of α subunit; residues indicated on 3 peptide loops are implicated in governing affinity for ACh. (**c**) Cross section of AChR at the level of the ACh-binding pocket. Note that the circular arrangement of AChR subunits and that the ACh-binding pockets appear at the interfaces between α and ε/γ subunits, and between the α and δ subunits. (**d** and **e**). Structure of the *Torpedo* AChR as determined at 4 Å resolution (PDB2BG9) showing side view (**d** and **e**) and top view (**d**) of the receptor. For each subunit, the extracellular domain contains predominantly β-sheets, the transmembrane domains contain four α helices, and the cytoplasmic domain contains an α-helix and unresolved structure

splice site [8, 39], produce a stop codon directly [36], or arise from a chromosomal microdeletion [41]. An important mutation in this group is ε1369delG because it results in loss of a C-terminal Cys470 residue crucial to maturation and surface expression of the adult receptor [42]. Thus, any mutation that truncates the ε subunit upstream of Cys470 abrogates expression of the ε- subunit. Some missense mutations affect both AChR expression and kinetics. For example, εR311W in the long cytoplasmic loop between M3 and M4 decreases, whereas εP245L in the M1 domain increases the open duration of channel events [36]. In the case of εR311W and εP245L, the kinetic consequences are modest and are overshadowed by the reduced expression of the mutant gene.

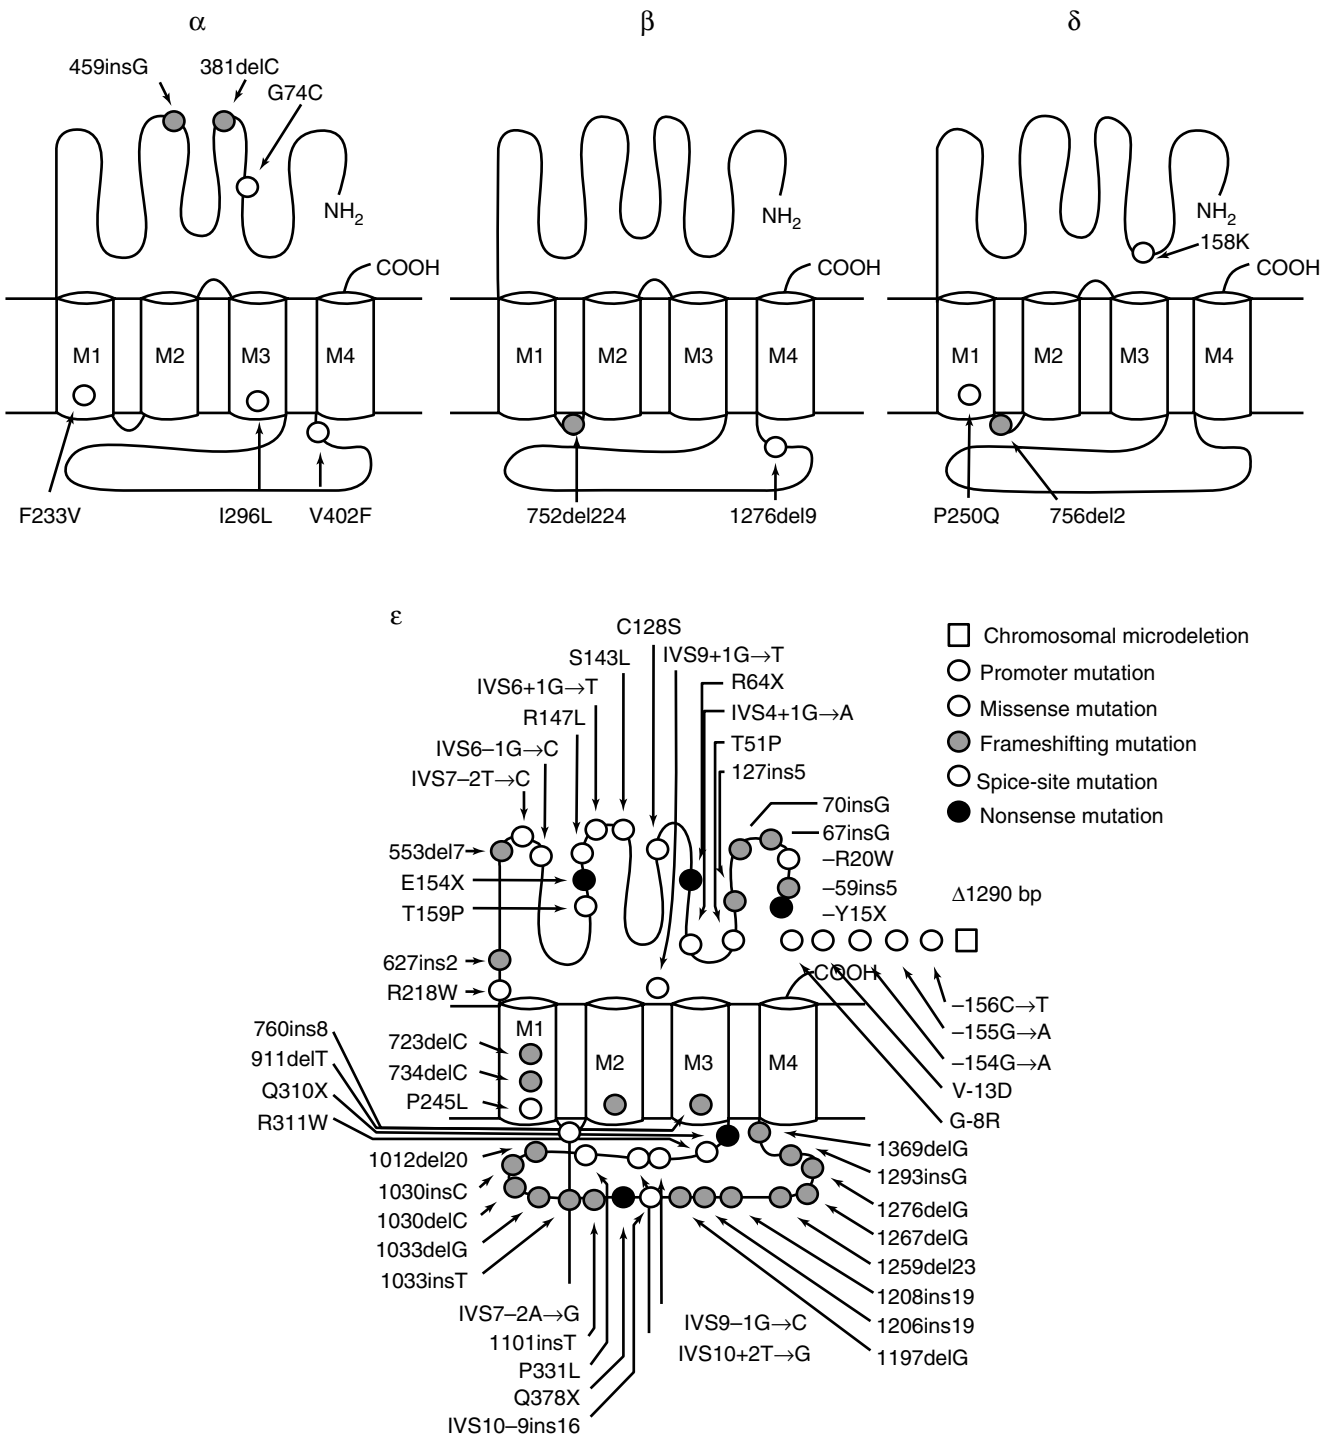

Fig. 51.4 Mutations in AChR subunits. Most mutations occur in the ε subunit of the receptor, but only few appear in the α, β, or δ subunits

Morphologic studies show an increased number of EP regions distributed over an increased span of the muscle fiber. The integrity of the junctional folds is preserved, but AChR expression on the folds is patchy and faint. Compared to normal, some EP regions are simplified and small, and some display a reduced number of secondary synaptic clefts (Fig. 51.5). The MEPP and MEPC amplitudes are small, but quantal release by nerve impulse is often higher than normal.

Most patients respond favorably but incompletely to ACHE inhibitors. The additional use of 3,4-DAP results in further improvement, but the limited ocular ductions, pronounced in most patients with AChR deficiency, are typically refractory to any therapy. Recently, albuterol was found

Fig. 51.5 Ultrastructural localization of AChR with peroxidase-labeled α-bungarotoxin at an endplate (EP) from a patient harboring two heteroallelic low-expressor mutations in the AChR ε- subunit (ε127ins5 and P245L). The postsynaptic region is simplified and lacks connections between the primary and secondary clefts in the plane of sectioning. The reaction for AChR is attenuated and the length of the postsynaptic membrane reacting for AChR is markedly is reduced × 25,900

Table 51.5 Kinetic abnormalities of the AChR

	Slow-channel syndromes	Fast-channel syndromes
Endplate currents	Slow decay	Fast decay
Channel opening events	Prolonged	Brief
Open states	Stabilized	Destabilized
Closed states	Destabilized	Stabilized
Mechanisms[a]	Increased affinity	Decreased affinity
	Increased β	Decreased β
	Decreased α	Increased α
		Mode-switching kinetics

β = channel opening rate; α = channel closing rate
[a]Different combinations of mechanisms operate in the individual slow- and fast-channel syndromes

to be effective in two patients responding poorly to pyridostigmine and 3,4-DAP [43].

Kinetic Abnormalities of the AChR

These result from missense mutations that may or may not reduce AChR expression. Two major and physiologically opposite syndromes are recognized. We refer to them as the slow-channel and fast-channel syndromes. Table 51.5 compares the two syndromes.

The Slow-Channel Syndromes

The clinical phenotypes vary. Some slow-channel CMS present in early life and cause severe disability by the end of the first decade; others present later in life and progress slowly, resulting in little disability even in the sixth or seventh decade [7, 44, 45]. Most patients show selectively severe involvement of cervical and wrist and finger extensor muscles. The clinical diagnosis of a slow-channel syndrome is based on the clues listed in Table 51.3. It can be confirmed by excluding EP ACHE deficiency which also causes repetitive CMAPs by histochemical demonstration of AChE activity at the patient endplates.

The phenotypic consequences stem from prolonged opening episodes of the AChR channel on exposure to ACh (see Fig. 51.6, panels b and c). Moreover, choline, present in serum at ~10 μM/L, also opens the mutant channels and renders them leaky in the resting state [46]. These factors cause cationic overloading of the junctional sarcoplasm and an EP myopathy. The EP myopathy comprises degeneration of the junctional folds with loss of AChR, widening of the synaptic space, and subsynaptic alterations consisting of degeneration of organelles, apoptosis of nuclei, and vacuolar change [7, 44, 45] (Fig. 51.7). The prolonged channel activation episodes prolong the EP potential, so that a single nerve stimulus elicits one or more repetitive CMAPs. During physiologic activity, the markedly prolonged EP potentials undergo staircase summation producing a depolarization block.

The slow-channel mutations occur in different AChR subunits and in different functional domains of the subunits [7, 45, 47–56] (Fig. 51.6a). Each is dominant, causing a pathologic gain of function. Patch-clamp studies at the EP, mutation analysis, and expression studies in human embryonic kidney (HEK) cells indicate that mutations near extracellular ACh-binding sites [48, 51] and in the N-terminal part of M1 [49] act mainly by enhancing affinity for ACh, which promotes channel reopenings, and mutations in M2, which lines the channel pore, promote the open state by affecting gating and may or may not enhance affinity [7, 45, 47] .

Therapy depends on the use of long-lived open-channel blockers of AChR, such as quinidine [57–59] or fluoxetine [60]. While these agents have a beneficial effect in the slow-channel syndrome, they are liable to worsen all other CMS. Therefore, they must not be used in a CMS unless the diagnosis of a slow-channel syndrome is firmly established.

The Fast-Channel Syndromes

The fast-channel syndromes are caused by recessive loss-of-function mutations that decrease affinity for ACh, or reduce gating efficiency, or destabilize channel kinetics, or act by a combination of these mechanisms. Each of these derangements

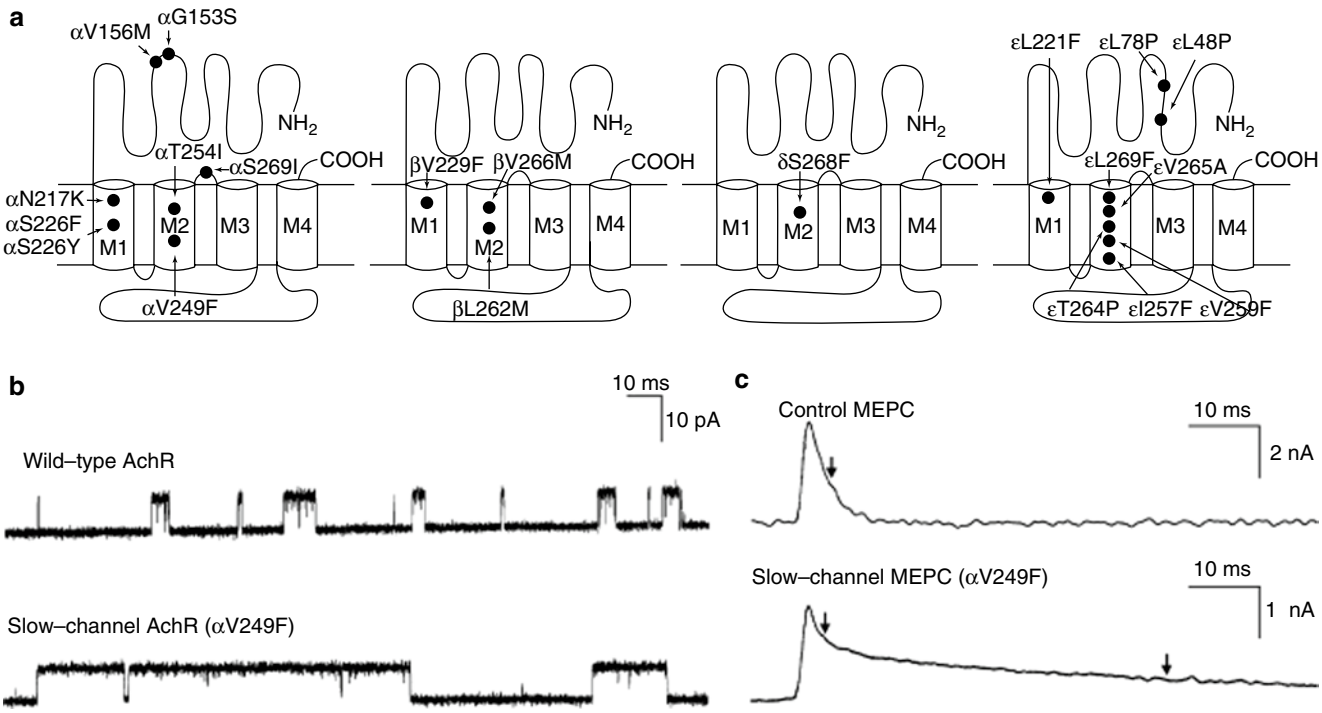

Fig. 51.6 Slow-channel syndromes. (**a**) Schematic diagram of AChR subunits with slow-channel mutations. (**b**) Single-channel currents from wild-type and slow-channel (αV249F) AChRs expressed in HEK cells. (**c**) MEPCs recorded from endplates of a control subject and a patient harboring the αV249F mutation. The slow-channel MEPC decays exponentially due to expression of both wild-type and mutant AChRs at the endplate (Reproduced from Engel and Franzini-Armstrong [1]. By permission)

Fig. 51.7 Severe endplate myopathy in a patient harboring the εL269F slow-channel mutation. All junctional folds facing the nerve terminal have degenerated, and the synaptic space here contains only globular debris (*asterisk*). The junctional sarcoplasm harbors dilated vesicles and a myeloid structure (*m*). The nearby myofibrils are disorganized and their Z-disks (*z*) are disintegrating. Compare with normal endplate imaged in Fig. 51.1 × 21,500

results in abnormally brief channel opening events that are reflected by an abnormally fast decay of the synaptic response (Fig. 51.8a, b). A fast-channel mutation dominates the clinical phenotype when the second allele harbors a null mutation or if occurs at homozygosity. Some fast-channel mutations also reduce the expression of the mutant receptor [37, 61, 62].

The fast-channel mutations occur in different domains of different subunits (Fig. 51.8c). The mutated residues affecting affinity or gating efficiency are positioned near or at the agonist-binding site [34, 63], or are involved in isomerization of the receptor in the transient interval between the closed and open states [64, 65], or appear in a gating domain [62]. Still other mutated residues appear in the long cytoplasmic loop between the third and fourth transmembrane domains and are required to stabilize channel kinetics [37, 66].

The symptoms resemble those of autoimmune myasthenia gravis. They can be mild when the main effect is on gating efficiency [62, 64], moderately severe when channel kinetics are unstable [37, 66], and severe when affinity for ACh, or both affinity and gating efficiency, is impaired [34, 67–69] . In each syndrome, a generic diagnosis of a myasthenic disorder can be made on the basis of the criteria listed in Table 51.2, but there are no clinical or EMG clues that can point to the specific diagnosis of a fast-channel syndrome.

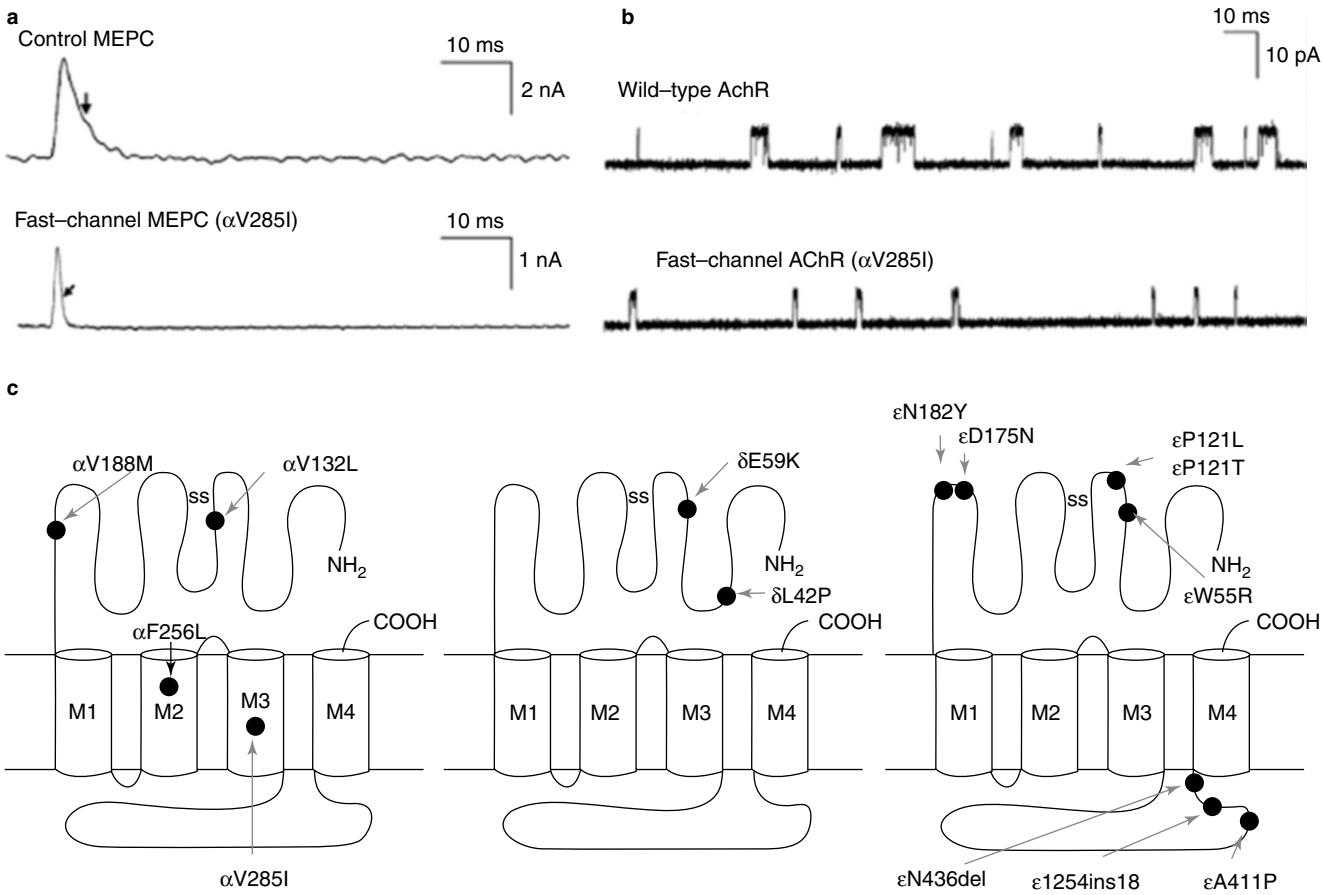

Fig. 51.8 (**a**) Fast-channel mutations result in endplate currents that decay abnormally fast due to abnormally brief channel opening events. *Arrows* point to the MEPC decay time constants. (**b**) Schematic diagram of fast-channel mutations identified in our patients. The mutations appear in different subunits of AChR and in different functional domains of the subunits (Reproduced from Engel and Franzini-Armstrong [1]. By permission)

A definitive diagnosis requires in vitro microelectrode studies to analyze the decay time constant of the miniature EP currents at voltage-clamped EPs, or patch-clamp analysis of the kinetic properties of AChRs expressed at patient EPs, or patch-clamp analysis of AChRs harboring identified mutations engineered into fibroblasts.

Treatment consists of pyridostigmine in doses similar to those used in autoimmune MG and 3,4-DAP, 1 mg/kg/day given in divided doses. 3,4-DAP increases the number of quanta released by nerve impulse, and pyridostigmine increases the number of AChRs activated by each quantum.

CMS Caused by Defects in Rapsyn

Rapsyn, under the influence of agrin, LRP4, MuSK, and Dok-7, concentrates AChR in the postsynaptic membrane and links it to the subsynaptic cytoskeleton through α-dystroglycan [70–74]. Nearly all Indo-Europeans harbor a common N88K mutation in *RAPSN* [75], but one patient carried 2 heteroallelic non-N88K mutations [76]. Expression studies in different cell lines reveal that different rapsyn mutations hinder rapsyn colocalization with AChR, prevent formation of agrin-induced AChR clusters, impede rapsyn self-association, or reduce rapsyn expression [77, 78]. Despite these differences, there are no consistent genotype-phenotype correlations except in Near Eastern Jewish patients with homozygous E-box mutation (−38A>G) who have prominent masticatory and facial muscle weakness, ptosis, prognathism, and hypernasal speech with sparing of the cervical, axial, and limb muscles [79].

In most patient, myasthenic symptoms present at birth or infancy with only few presenting after the age of 10 years [80]. Arthrogryposis at birth and other congenital malformations occur in nearly one-third [77, 80, 81] but are not associated with specific mutations. Respiratory infections or other febrile illnesses precipitate increased weakness and respiratory crises and can cause an anoxic encephalopathy [77, 80, 82, 83].

The distribution of weakness resembles that in autoimmune myasthenia gravis except ophthalmoparesis is less common [80]; in the Mayo Clinic series, 9 of 39 patients had constant or episodic involvement of the extraocular muscles [81]. Out-of-proportion weakness of the foot dorsiflexors was reported to be a feature of the late-onset phenotype [80].

The morphologic features of the EP and the factors that impair the safety margin of neuromuscular transmission are the same as in primary AChR deficiency, but the EP AChR deficiency is relatively mild in most patients. In some patients, single-fiber EMG is required to demonstrate a defect in neuromuscular transmission.

Most patients respond well to ACHE inhibitors; some derive additional benefit from the use of 3,4-DAP [82], and some patients observed by the author benefited from the added use of ephedrine or albuterol.

CMS Associated with Plectin Deficiency

Plectin, encoded by *PLEC*, is a highly conserved and ubiquitously expressed intermediate filament-linking protein. Owing to tissue- and organelle-specific transcript isoforms, plectin is a versatile linker of cytoskeletal components to target organelles in cells of different tissues [84–86]. It is concentrated at sites of mechanical stress, such as the postsynaptic membrane lining junctional folds, the sarcolemma, Z-disks in skeletal muscle, hemidesmosomes in skin, and intercalated disks in cardiac muscle. In skeletal muscle, multiple alternatively spliced transcripts of the exon preceding a common exon 2 link cytoskeletal intermediate filaments to specific targets: the outer nuclear membrane (isoform 1), the outer mitochondrial membrane (isoform 1b), Z-disks (isoform 1d), and the sarcolemmal costameres (isoform 1f) [86]. Pathogenic mutations in plectin result in epidermolysis bullosa simplex (EBS), a progressive muscular dystrophy in many patients, and a myasthenic syndrome in some patients (reviewed in Refs. [87, 88]). Heteroallelic nonsense, frameshift, or splice-site mutations in *PLEC* were recently reported in four unrelated patients with documented defects in neuromuscular transmission [88–90]. In two patients investigated by the author, microelectrode studies of intercostal muscle EPs showed low-amplitude MEPPs. Morphologic studies revealed dislocated and degenerating muscle fiber organelles, plasma membrane defects resulting in Ca^{2+} overloading of the muscle fibers as in Duchenne dystrophy, and extensive degeneration of the junctional folds, all attributable to lack of cytoskeletal support [88]. One patient harbored homozygous frameshift mutations in both *PLEC* and in *CHRNE* [90]. Interestingly, a recent study identified a homozygous deletion mutation in isoform 1f that caused limb-girdle muscular dystrophy but neither EBS nor myasthenia [91].

Na Channel Myasthenia

Only a single patient has been reported to date [92]. She had abrupt attacks of respiratory and bulbar paralysis since birth lasting 3–30 min similar to those caused by ChAT deficiency. Detailed electrophysiology analysis of patient EPs revealed that suprathreshold EPPs failed to generate muscle action potentials pointing to Nav1.4, encoded by *SCN4A*, as the culprit. EP structure and Nav1.4 expression at the EPs were normal, but *SCN4A* harbored 2 mutations (S246L in the S4/S5 linker in domain I and V1442E in S4/S5 linker in domain IV). Recombinant V1442E-sodium channels expressed in HEK cells showed marked enhancement of fast inactivation close to the resting potential and enhanced use-dependent inactivation on high-frequency stimulation; S246L had only minor kinetic effects and is likely a benign mutation. The safety margin in this congenital myasthenic syndrome is impaired because a large fraction of the Nav1.4 channels are inexcitable in the resting state.

Dok-7 Myasthenia

After the discovery in 2006 of Dok-7 as a muscle-intrinsic activator of MuSK [73], numerous CMS-related mutations were indentified in *DOK7* [3, 4, 93–95], and Dok-7 myasthenia is now recognized as a common cause of CMS. Dok-7 is strongly expressed at the postsynaptic region of the skeletal muscle and in the heart. It harbors an N-terminal pleckstrin homology domain (PH) important for membrane association, a phosphotyrosine-binding (PTB) domain, and C-terminal sites for phosphorylation. The PTB and PH domains are required for association with and phosphorylation of MuSK. Phosphorylation of two of the C-terminal residues is a requisite for Dok-7 activation by Crk and Crk-L [96]. A recent review lists all Dok-7 mutations reported since 2006 [95].

Nearly all patients carry a common 1124_1127dupTGCC mutation in exon 7. This and other mutations upstream of the C-terminal phosphorylation sites abrogate the ability of Dok-7 to associate with Crk1/Crk1L and hence its activation [96, 97]. Other mutations disrupt or eliminate the PH and PTB domains of Dok-7 or cause exon skipping due to intronic mutations.

The weakness in Dok-7 myasthenia typically has a limb-girdle distribution, but mild ptosis and facial weakness are not infrequent [4, 93–95, 98–100]. Severe bulbar symptoms are uncommon except for laryngeal stridor in infants [101] but were present in a patient who carries a readthrough mutation in the last codon of *DOK7* [4]. In 16 patients investigated by us, the age at onset ranged from birth to 5 years (mean, 1.6 years; median, 1 year) [4]. The clinical course varied from mild static weakness limited to the limb-girdle

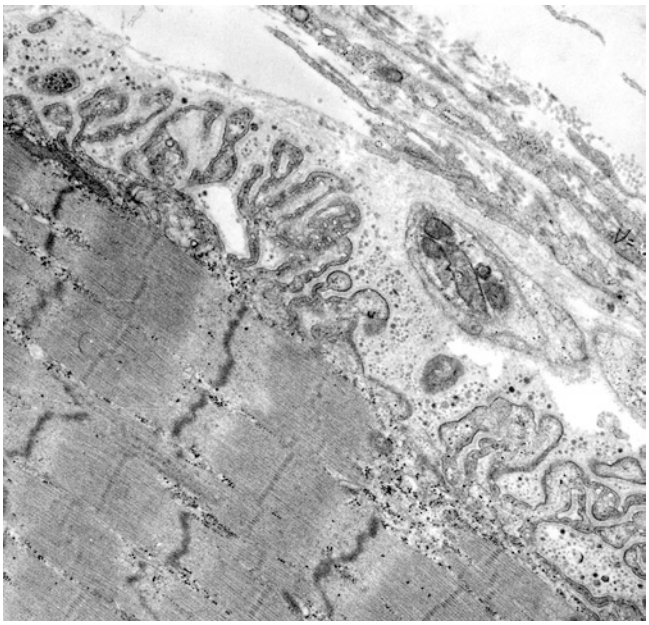

Fig. 51.9 Abnormal endplate region in Dok-7 myasthenia. There is extensive destruction of the junctional fold causing accumulation of globular remnants of the folds in the synaptic space. The junctional folds on the left are denuded of nerve terminal. A small nerve terminal on the right is enveloped by Schwann cell processes (× 10,000)

muscles to severe generalized progressive disease with conspicuous muscle atrophy. All had short-term fatigability on exertion. Ten patients experienced intermittent worsenings lasting from days to weeks, as also observed by others [93, 99]. Seven patients had significant respiratory embarrassment. The overall course was progressive in 12 of the 16 patients.

Morphologic studies often show type 1 fiber preponderance, type 2 fiber atrophy, and frequently minor myopathic features. The synaptic contacts are small relative to fiber size and are single or multiple on a given fiber. Most EPs lack the normal pretzel shape indicating impaired differentiation of the postsynaptic region [4, 98]. Electron microscopy shows ongoing destruction of existing endplates (Fig. 51.9) and attempts to form new endplates, indicating that Dok-7 is essential not only for the development but also for maintaining the structural integrity of the neuromuscular junction throughout life [4]. In vitro microelectrode studies indicate impaired quantal release or impaired postsynaptic response to the released quanta or both.

Most studies found that pyridostigmine worsened the disease either immediately or gradually [4, 93, 95, 99]. In contrast, treatment with ephedrine is beneficial in Dok-7 myasthenia [4, 98, 100, 102, 103]. Because ephedrine is no longer available in the USA, we use albuterol sulfate instead with good and sometimes strikingly beneficial results in doses of up to 4 mg three times daily in adults and appropriate pediatric dosages in children [26].

CMS Caused by Defects in MuSK

MuSK (muscle-specific receptor tyrosine kinase), under the influence of agrin mediated by LRP4 and in concert with Dok-7, plays a role in maturation and maintenance of the EP and in directing rapsyn to concentrate AChR in the postsynaptic membrane [104–106]. Only three reports describe myasthenic syndromes caused by defects in MuSK. One kinship harbored c.220insC and V790M mutations. The missense mutations did not affect the catalytic kinase activity of MuSK but decreased its expression and stability [107]. Expression studies in mice revealed reduced synaptic AChR expression and aberrant axonal outgrowths as observed in the patient [108]. The safety margin in this patient is likely compromised by the AChR deficiency.

A second report describes heteroallelic M605I and A727V mutations in MuSK in a patient with severe myasthenic symptoms since early life that improved after puberty but worsened after menstrual periods. The MEPP and MEPC amplitudes in anconeus muscle were reduced to about 30 % of normal and the EPP quantal content was half normal. Synaptic contacts were small and the postsynaptic regions had poorly differentiated secondary clefts. The patient failed to respond to pyridostigmine, ephedrine, or 3,4-DAP but responded partially to albuterol [109].

A third kinship harbored a homozygous P344R missense mutation in the cysteine-rich extracellular domain of MuSK. The clinical course was progressive. Low doses of pyridostigmine and 3,4-DAP led to gradual improvement; ephedrine or higher doses of pyridostigmine were not tolerated [110].

CMS Caused by Defect in Agrin

Agrin, encoded by *AGRN*, is a multidomain proteoglycan secreted into the synaptic basal lamina by the nerve terminal. The muscle isoform of agrin harbors A and B regions near its C-terminal. Agrin phosphorylates and thereby activates MuSK by way of its receptor LRP4 [111, 112]. Two siblings with eyelid ptosis but normal ocular ductions and only mild weakness of the facial and hip-girdle muscles carried a homozygous missense mutation in *AGRN* at codon 1709 (G1709R). The mutation is in the laminin G-like 2 domain, upstream of the *y* and *z* inserts of neural agrin required for MuSK activation and EP formation. AChR and agrin expression at the EP were normal. Structural studies showed EPs with misshaped synaptic gutters partially filled by nerve endings and formation of new EP regions. The postsynaptic regions were preserved. Expression studies revealed that the mutation did not affect activation of MuSK by agrin or agrin binding to α-dystroglycan. Forced expression of a mutant mini-agrin gene in mouse soleus muscle showed changes similar to those at patient EPs suggesting that the observed

mutation perturbs the maintenance of the EP without altering the canonical function of agrin to induce the development of the postsynaptic compartment. The index patient failed to respond to a cholinesterase inhibitor and 3,4-DAP but responded partially to ephedrine [113].

Myasthenic Syndrome Associated with Centronuclear Myopathy

Centronuclear myopathies (CNM) are clinically and genetically heterogenous congenital myopathies in which the predominant pathologic alteration is centralization of the muscle fiber nuclei. The implicated disease proteins/genes are myotubularin (*MTM1*), dynamin 2 (*DNM2*), amphiphysin 2 (*BIN1*), and the ryanodine receptor (*RYR1*) [114]. Features suggesting a myasthenic disorder, ptosis, ophthalmoparesis, abnormal fatigability, decremental EMG response [115], or abnormally increased jitter [116] have been observed in clinically and genetically different CNM patients.

A recently investigated 39-year-old man with CNM and a myasthenic syndrome [117] had a 19–35 % EMG decrement and responded partially to pyridostigmine. Serologic tests for AChR and MuSK antibodies were negative. No mutations were detected in *MTM1*, *DNM2*, *BIN1*, and *RYR1*. Intercostal muscle EP studies revealed simplified postsynaptic regions and mild AChR deficiency. The safety margin of neuromuscular transmission was compromised by reduction of the MEPP amplitude to 60 % and of quantal release to 40 % of normal [117]. Four other CNM patients with myasthenic features responding to pyridostigmine with no known mutation were also reported, but EP structure and parameters of neuromuscular transmission were not evaluated [118].

CMS Caused by Mutations in *GFPT1*

GFPT1 encodes glutamine-fructose-6-phosphate transaminase-1. GFPT1 controls the flux of glucose into the hexosamine pathway and thus the formation of hexosamine products and the availability of precursors for *N*- and O-linked glycosylation of proteins. The disease gene was discovered by linkage and homozygosity analysis studies of multiplex kinships with a limb-girdle CMS associated with tubular aggregates in skeletal muscle [9]. The affected patients harbored no mutations in Dok-7 and, unlike patients with Dok-7 myasthenia, responded favorably to ACHE inhibitors. Among the 13 reported patients, most presented in the first decade, about one-fourth had elevated serum CK levels, some had distal as well as proximal weakness, but very few had ptosis or respiratory muscle involvement. Immunoblots of muscle of affected patients revealed decreased expression of O-*N*-acetylglucosamine residues on numerous muscle proteins. One patient was shown to have a decreased number of EP AChRs. The effects of the different mutations on EP fine structure and the extent to which they alter parameters of neuromuscular transmission have not yet been determined [9].

Toxic Neuromuscular Transmission Disorders

52

James F. Howard Jr.

Introduction

The neuromuscular junction (NMJ) is uniquely sensitive to the effects of neurotoxins. While the blood–brain barrier protects the brain and spinal cord and the blood-nerve barrier protects peripheral nerve, there are no barriers to protect the NMJ from the deleterious effects of these agents. Several forms of neurotoxins are directed against the NMJ. Many occur as natural substances of plants or animals, others result from the actions of widely prescribed pharmaceutical compounds, and still others are environmental hazards. In nearly all instances of NMJ neurotoxicity, there is a reduction in the safety factor of neuromuscular transmission by one of several mechanisms. These neurotoxins may affect either the presynaptic or the postsynaptic elements of the NMJ. The clinical features of these neurotoxins are quite varied as many have associated toxicity of other parts of the central, peripheral, or autonomic nervous systems. Many will have other systemic effects as well. While feared as the purveyor of morbidity and mortality, many of these neurotoxins have led to significant advances in our understanding of the molecular mechanisms of pharmacology and physiology and their associated diseases. For example, was it not for the recognition that α-bungarotoxin binds to the acetylcholine receptor (AChR), and omega-conotoxin binds to the voltage-dependent calcium channel (VDCC) our advances in the diagnosis and treatment of myasthenia gravis (MG) and the Lambert-Eaton syndrome (LES) would have been delayed [1, 2]. Worldwide, the most common neurotoxicity of the neuromuscular junction results from envenomation. More concern to the clinical neurologist are those situations that result from the direct effects of various pharmacologic agents routinely used in the practice of medicine that produce significant aberrations of neuromuscular transmission in susceptible individuals. The potential for environmental intoxication has been limited by the stringent regulation of federal and international regulatory agencies.

All forms of NMJ neurotoxicity are characterized by progressive, typically symmetrical, muscle weakness. Muscles of eye movement or the eyelid are most often involved as well as the muscles of neck flexion and the pectoral and pelvic girdles. There may be involvement of bulbar and respiratory musculature depending upon the toxin involved, the dose acquired, and the duration of toxin exposure. Cognition and sensation are spared, unless other elements of the central nervous system are simultaneously involved. Muscle stretch reflexes are often preserved or only minimally diminished particularly during the early phases of the illness but may be lost if the weakness is severe.

Pharmacological Neurotoxicity

The adverse reaction of drugs on synaptic transmission may be classified either as acting *presynaptically*, with a reduction in acetylcholine (ACh) release secondary to local anesthetic-like activity on the nerve terminal, alteration or impairment of calcium flux into the nerve terminal, or a hemicholinium effect; *postsynaptically*, with antibody blockade of ACh receptors, curare-like effects, or potentiation of depolarizing or nondepolarizing neuromuscular blocking agents; or, in varying degrees, *both*. Each of these pharmacological interactions may result in any of the clinical situations described above. Since the publication of the summaries of Barrons, Howard, and Kaeser, describing disorders of neuromuscular transmission occurring as the result of adverse drug reactions, many more reports have surfaced adding to the list of potentially dangerous drugs [3–7]. An up-to-date list of these potential drug-disorder interactions is maintained on the web site of the Myasthenia Gravis Foundation of

America (http://www.myasthenia.org/portals/0/draft_medications_and_myasthenia_gravis_for_MGFA_website_8%). Unfortunately, much of the literature is anecdotal and there are only a few comprehensive in vitro studies of drug effects on neuromuscular transmission in animal or human nerve-muscle preparations. The potential adverse effects of these medications must be taken into consideration when deciding which drugs to use in treating patients who have disorders of synaptic transmission.

With the exception of telithromycin and the possible exceptions of D-penicillamine, α-interferon, and botulinum toxin, there are no drugs that are absolutely contraindicated in patients with MG and Lambert-Eaton syndrome (LES). There are, however, numerous drugs that interfere with neuromuscular transmission and will make the weakness of these patients worse or prolong the duration of neuromuscular block in patients receiving muscle relaxants. Drug-induced disturbances of synaptic transmission resemble MG with varying degrees of ptosis, ocular, facial, bulbar, respiratory, and generalized muscle weakness. Treatment includes discontinuation of the offending drug and when necessary reversing the neuromuscular block with intravenous infusions of calcium, potassium, or cholinesterase inhibitors. In rare instances, these drugs may induce an autoimmune form of MG (D-penicillamine and interferon alpha). In these situations, the treating physician must utilize therapies that are typically used for other forms of autoimmune MG.

While it is most desirable to avoid drugs that may adversely affect neuromuscular transmission, in certain instances, they must be used for the management of another illness. In such situations, a thorough knowledge of the deleterious side effects can minimize their potential danger. If at all possible, it is wise to use the drug within a class of drugs that has been shown to have the least effect on neuromuscular transmission. Unfortunately, studies, which allow such comparisons, are quite few.

The most frequently encountered problems are the effects of antibiotics (macrolides, fluoroquinolones, and aminoglycosides) and β-adrenergic blocking agents acutely worsening the strength of patients with MG. Less commonly encountered are prolonged muscle weakness and respiratory embarrassment postoperatively in patients with disorders of neuromuscular transmission.

Antibiotics

Two classes of antibiotics carry the FDA Black Box Warning designation. The ketolide, telithromycin, and the fluoroquinolone class of antibiotics received this designation due to repeated reports of myasthenic exacerbation and death following their use [8, 9]. The aminoglycoside antibiotics may produce neuromuscular weakness irrespective of their route of administration [10]. The weakness is related to serum levels of the drug and is reversible in part by cholinesterase inhibitors, calcium infusion, and the aminopyridines [11]. These drugs have pre- and postsynaptic actions; many have elements of both. Neuromuscular toxicity data exist for several of the antibiotics including amikacin, gentamicin, kanamycin, neomycin, netilmicin, streptomycin, and tobramycin [12]. Of the group, neomycin is the most toxic, tobramycin the least. Clinically, gentamicin, kanamycin, neomycin, tobramycin, and streptomycin have been implicated in producing muscle weakness in non-myasthenic patients [5]. Neuromuscular blockade is not limited to the aminoglycoside antibiotics. Myasthenic patients given the macrolides, erythromycin, or azithromycin will often report a mild to moderate exacerbation of their weakness [13, 14]. Myasthenic crisis has also been reported [15]. The newly recognized ketolide, telithromycin, has produced abrupt and severe worsening in MG or unmasked previously undiagnosed MG [Howard JF, 2003, personal observation] [16–19]. The polypeptide and monobasic amino-acid antibiotics, penicillins, sulfonamides, tetracyclines, and fluoroquinolones, cause transient worsening of myasthenic weakness, potentiate the weakness of neuromuscular blocking agents, or have theoretical reasons for blocking synaptic transmission [20]. Lincomycin and clindamycin can cause neuromuscular blocking which is not readily reversible with cholinesterase inhibitors [21, 22]. Polymyxin B, colistimethate, and colistin are also reported to produce neuromuscular weakness particularly in patients with renal disease or when used in combination with other antibiotics or neuromuscular blocking agents [10, 23]. These drugs, ampicillin, the tetracycline analogs, oxytetracycline and rolitetracycline, and, more recently, ciprofloxacin [24], exacerbate MG, although the mechanisms for each medication are not fully understood [25, 26].

Cardiovascular Drugs

Many cardiovascular drugs are implicated in adversely affecting the strength of patients with MG and LES, and they (along with the antibiotics) account for the majority of adverse drug reactions in patients with neuromuscular disorders. Beta-adrenergic blockers may cause exacerbation of MG, or their use may coincide with the onset of myasthenic manifestations [4, 27]. Even those drugs instilled topically on the cornea are capable of producing such weakness [28, 29]. Atenolol, labetalol, metoprolol, nadolol, propranolol, and timolol cause a dose-dependent reduction in the efficacy of neuromuscular transmission in normal rat skeletal muscle and human myasthenic intercostal muscle biopsies [27]. Different ß-blockers have reproducibly different pre- and postsynaptic effects on neuromuscular transmission. Of the group, propranolol is most effective in blocking

neuromuscular transmission and atenolol the least. The effects of calcium channel blockers on skeletal muscle are not understood fully, and studies have provided conflicting information. Some demonstrated neuromuscular blockade with postsynaptic curare-like effects, presynaptic inhibition of ACh release, and both pre- and postsynaptic effects [30–32]. The oral administration of calcium channel blockers to cardiac patients without neuromuscular disease does not produce altered neuromuscular transmission by single-fiber electromyography (SF-EMG) measures [33]. Acute respiratory failure was temporally associated with administration of oral dose of verapamil in a patient with LES and small-cell carcinoma of the lung [34]. One patient with moderately severe, generalized MG developed acute respiratory failure following verapamil initiation (author's observations). Low doses of verapamil and its timed-release preparation have been used successfully for the treatment of hypertension in patients with MG receiving cyclosporine (author's observations).

Procainamide may produce acute worsening of strength in patients with MG [35]. The rapid onset of neuromuscular block and the rapid resolution of symptoms following discontinuation of the drug suggest the drug has a direct toxic effect on synaptic transmission rather than the induction of an autoimmune response against the neuromuscular junction. The postulated mechanism of action is primarily at the presynaptic membrane with impaired formation of ACh or its release, although it is known to have postsynaptic blocking effects as well. Two case reports suggest that the antiarrhythmic P-glycoprotein inhibitor, propafenone, may cause acute exacerbations of myasthenic weakness [36, 37]. Like the effects of procainamide, the rapid onset of worsening and resolution following the discontinuation of the drug implicates a direct toxic effect on neuromuscular transmission.

The earliest report of quinidine (the stereoisomer of quinine) administration aggravating MG was by Weisman [38]. There are several reports of the unmasking of previously unrecognized MG following treatment with quinidine [39, 40]. The neuromuscular block is both presynaptic, impairing either the formation or release of ACh, and, in larger doses, postsynaptic with a curare-like action [41]. It has been claimed the ingestion of small amounts of quinine, for example, in a gin and tonic, may acutely worsen weakness in a myasthenic patient, although this cannot be substantiated with objective reports.

Cholesterol-Lowering Agents

Several published works suggest that the statin cholesterol-lowering agents may be causal in the exacerbation of myasthenic weakness [42–48] The mechanism(s) for this worsening is not clear, but several postulates have been proposed. It is well recognized that HMG-CoA reductase therapy may produce a myopathy [49–52]. Is it possible the myasthenic worsening could be due to a coexisting disorder of the muscle membrane? Statins have immunomodulatory properties, with the ability to induce production of the Th2 cytokines interleukin (IL)-4, IL-5, and IL-10 [53]. Animal and human studies suggest that these Th2 cytokines play a role in the development of MG [54]. Therefore, it is possible that upregulation of Th2 cytokine production could lead to worsening MG. Statins have been postulated to cause mitochondrial dysfunction by depleting endogenous coenzyme Q10 [55]. Statin-induced mitochondrial failure in the nerve terminal has been proposed as a mechanism to impair neuromuscular transmission given the high content of mitochondria in the nerve terminal [44]. There is no evidence to suggest that HMG-CoA reductase is known to directly interfere with neuromuscular transmission [56].

Magnesium

Hypermagnesemia is an uncommon clinical complication from the use of magnesium-containing drugs [57]. Renal failure predisposes to hypermagnesemia and is the reason to avoid magnesium-containing antacids and laxatives [58, 59]. Excessive use of enemas containing Mg^{++} may produce hypermagnesemia, but this is usually in patients with underlying gastrointestinal (GI) tract disease [60, 61]. Hypermagnesemia commonly results from administration of high doses of parenteral $MgSO_4$ for treatment of eclampsia, at times resulting in serious side effects to the mother or the newborn [62–64]. The clinical manifestations of hypermagnesemia correlate with serum Mg^{++} levels [61, 65, 66]. Muscle stretch reflexes become reduced when the serum Mg^{++} level exceeds 5 mEq/L; levels of 9–10 mEq/L are associated with absent reflexes and muscle weakness. During treatment of preeclampsia, muscle stretch reflexes are monitored and Mg^{++} administration is discontinued if the reflexes disappear [64]. Fatal respiratory failure can occur at levels greater than 10 mEq/L [62, 64]. Serum levels greater than 14 mEq/L can induce acute cardiac arrhythmia, including heart block and arrest. Symptoms of autonomic dysfunction in hypermagnesemia include dry mouth, dilated pupils, urinary retention, hypotension, and flushing and are thought to result from presynaptic blockade at autonomic ganglia [67]. The muscles of ocular motility tend to be spared and the clinical findings of hypermagnesemia resemble those of LES rather than MG [68]. Magnesium inhibits release of ACh by competitively blocking calcium entry at the motor nerve terminal [69]. There may also be a milder postsynaptic affect. Magnesium also potentiates the action of neuromuscular blocking agents, and this must be considered in women undergoing cesarean section after receiving Mg^{++} for preeclampsia [70, 71]. Patients with underlying junctional disorders are more sensitive to Mg^{++}-induced weakness. Patients

with MG and LES may become weaker after receiving Mg^{++} even when serum Mg^{++} levels are normal or only slightly elevated [72–75]. Reports exist of the uncovering of previously unrecognized MG following treatment of preeclampsia with magnesium salts (Howard JF, unpublished observation) [76]. Increased MG symptoms most often occur when Mg^{++} is administered parenterally but on occasion is seen with oral use [75]. Therefore, parenteral Mg^{++} administration should be avoided and oral Mg^{++} preparations should be used with caution in patients with known disorders of synaptic transmission, such as MG, LES, and botulism. Patients with MG or LES respond poorly to calcium and may respond better to cholinesterase inhibitors [72].

Recreational Drugs

Several cases of MG exacerbation following recreational use of cocaine have been reported [77–80]. These attacks frequently include respiratory insufficiency requiring ventilatory support [79, 80] and improve with therapeutic apheresis [80] (D.B. Sanders – unpublished observations) or high-dose intravenous immunoglobulin [80]. Myasthenic exacerbations have been associated with elevated serum creatine kinase in some patients [79]. Cocaine reduces the skeletal muscle response to repetitive nerve stimulation in mice by decreasing the muscle and nerve excitability but without apparent effect on NMT [80]. Cocaine inhibits nicotinic AChR in cultured muscle cells [81].

Rheumatologic Drugs

D-penicillamine (D-P) is used in the treatment of rheumatoid arthritis (RA), Wilson's disease, and cystinuria. A number of autoimmune diseases occur in patients receiving D-P of which MG is most frequent [82–84]. The MG induced by D-P is usually mild and may be restricted to the ocular muscles. In many patients, the symptoms are not recognized, and it may be difficult to demonstrate mild weakness of the limbs in the presence of severe arthritis. It is unlikely that D-P has a direct effect on neuromuscular transmission as MG begins after prolonged D-P therapy in most patients and has a relatively low incidence in patients receiving D-P for Wilson's disease compared with those receiving it for RA [85]. It is more likely that D-P induces MG by stimulating or enhancing an immunological reaction against the neuromuscular junction. When MG begins while the patient is receiving D-P, it remits in 70 % of patients within 1 year after the discontinuation of the drug [86]. In a few patients, the MG persists after D-P is discontinued, implying that a subclinical myasthenic state existed prior to the initiation of the D-P (author's observations).

Chloroquine is used primarily as an antimalarial drug, but in higher doses, it is also used in the treatment of several collagen vascular disorders including RA, discoid lupus erythematosus, and porphyria cutanea. It may produce a number of neurological side effects among which are disorders of neuromuscular transmission. Reported mechanisms of action for this have been both pre- and postsynaptic, but chloroquine may also alter immune regulation producing a clinical syndrome of MG similar to that reported with D-P. One patient with RA and another with systemic lupus erythematosus developed the typical clinical, physiological, and pharmacological picture of MG following prolonged treatment with chloroquine. Antibodies to the AChR were identified and subsequently slowly disappeared, as did the clinical and electrophysiological abnormalities, with discontinuation of the drug [46, 48]. A patient is described with a transient postsynaptic disorder of neuromuscular transmission following 1 week of chloroquine therapy that was thought to be due to a direct toxic effect on the neuromuscular junction rather than a derangement of immune function [87].

Others

Interferon Alpha

Generalized MG may occur after starting interferon alpha therapy for leukemia, during interferon alpha-2b treatment for malignancy, and during treatment for chronic active hepatitis C [88–91]. Myasthenic crisis may even develop with interferon alpha therapy [92]. The mechanism of interferon-induced MG is not known. Expression of interferon gamma at motor endplates of transgenic mice results in generalized weakness and abnormal NMJ function, which improves with cholinesterase inhibitors. Immunoprecipitation studies identified an 87-kD target antigen recognized by sera from these transgenic mice and from human MG patients. Such studies suggest that the expression of interferon gamma at the motor endplates provoked an autoimmune humoral response, similar to that which occurs in human MG [93].

Botulinum Neurotoxin

Botulinum neurotoxin, when used therapeutically for focal dystonia, has unmasked subclinical LES and MG [94, 95]. Worsening of weakness or crisis has also been reported in MG following injections of botulinum toxin [96–99]. A known defect of NMT is considered to be a relative contraindication to the use of botulinum toxin, although others have reported its successful use in patients with MG [100].

Numerous other drugs may interfere with neuromuscular transmission. Many local anesthetics, certain anticonvulsants, magnesium, iodinated contrast dyes, and, of course, the neuromuscular blocking agents used by anesthesiology during surgery are included in this list. Newly reported

adverse drug-disorder interactions are reported frequently. It is beyond the scope of this chapter to discuss them all in detail, and the reader is referred to a more comprehensive review of the topic [4] or to the web address of the Myasthenia Gravis Foundation of America.

Biological Neurotoxins

Botulism

Botulism is caused by a clostridial neurotoxin that blocks the release of ACh from the motor nerve terminal[1] [101]. The result is a long-lasting, severe muscle paralysis. Botulism may be classified clinically according to presentation as noted in Table 52.1. Of eight different types of botulinum toxins, types A and B cause most cases of botulism in the United States. Type E is transmitted in seafood and type A is thought to produce the most severe manifestations. The classic form of the disease usually follows ingestion of foods that were contaminated by inadequate sterilization. Not all persons ingesting contaminated food become symptomatic. Nausea and vomiting are the first symptoms and the neuromuscular features begin 12–36 h after exposure. The clinical findings are stereotypical. Ptosis, blurred vision, dysphagia, and dysarthria are the presenting features. The pupils may be dilated and poorly reactive to light. Descending weakness progresses for 4–5 days and then plateaus. Respiratory paralysis may occur rapidly. Most patients have autonomic dysfunction, such as dry mouth, constipation, urinary retention, and cardiovascular instability.

Infantile botulism is caused by the chronic absorption of toxin from *Clostridium botulinum* growing in the infant gastrointestinal tract [102]. Honey is a common source of contamination. The onset of symptoms, constipation, lethargy, and poor suck, usually occurs between 1 week and 12 months of age, most commonly between 2 and 8 months of age. The majority of reported cases occur with type A or B toxin. A descending pattern of weakness occurs and may produce widespread cranial nerve and limb muscle involvement. The pupils are poorly reactive and the tendon reflexes are hypoactive. Most babies will require ventilatory support.

Wound botulism occurs due to the contamination of a wound with *Clostridium botulinum*. Its rarity may be related to the difficulty of spore germination in a wound environment. The clinical presentation of wound botulism is similar to the classical form of the disease as noted above. It may occur as a complication of intranasal and parenteral use of cocaine [103].

Hidden botulism refers to those cases in which no source of botulism can be identified and in whom no apparent source or exposure is known [104, 105]. Some argue that these cases represent adult forms of infantile botulism [106]. This is suggested by the high prevalence of colonic diverting procedures, achlorhydria, Crohn's disease, or recent antibiotic treatment among these patients [107].

Response to antitoxin treatment is generally poor probably because once toxin binds to the nerve terminal, it is no longer accessible to the antitoxin. Antibiotic therapy is not effective unless the botulism is the infantile or hidden form of the disease. Otherwise, treatment is supportive with respiratory assistance when necessary. Cholinesterase inhibitors are not usually beneficial; guanidine or 3,4-diaminopyridine (3,4-DAP) may improve strength but not respiratory function. Recovery takes many months but is usually complete.

EMG abnormalities evolve as the disease progresses and may not be present at onset of symptoms. CMAP amplitude is decreased in affected muscles, but motor and sensory nerve conduction is normal. Some patients demonstrate a decremental pattern, and most have post-tetanic facilitation in some muscles of 30–100 % at some time to low-frequency stimulation. These findings are similar to LES but have a more restricted distribution. SF-EMG shows markedly increased jitter and blocking. The organism can be recovered from the stool of infected infants or in the hidden form of the disease.

Envenomation

Most biological toxins of animal origin affect the cholinergic system and either facilitate the release of neurotransmitter from the presynaptic nerve terminal or block the AChR. In general, bites from snakes, scorpions, and ticks are more common during summer months when they are inadvertently encountered. In contrast, exposure to marine toxins may occur at any time as they are acquired through ingestion and less rarely by injection or penetration. Specific geographic

[1]While tetanus toxin also binds to the neuromuscular junction, its mechanism of action is distinctly different. This toxin is translocated into the nerve terminal and then moves in a retro-axonal fashion to the synaptic space between the alpha motoneuron and inhibitory neurons. There it inhibits exocytosis resulting in paresis. Because it does not directly involve the motor nerve terminal, it will not be discussed further.

Table 52.2 Mechanisms of arthropod blockade of synaptic transmission

Facilitation of ACh release with subsequent exhaustion of neurotransmitter
Facilitation of ACh release without subsequent exhaustion of neurotransmitter
Depletion of ACh release with subsequent exhaustion of neurotransmitter

loci can be demonstrated for each of these vectors. For example, tic envenomation predominates in States west of the Rocky Mountains, the western provinces of Canada, and in Australia. The geography of snake envenomation is species specific. The cobras are found in Asia and Africa, the kraits in Southeast Asia, the mambas in Africa, the coral snake in North America, and the sea snakes in the waters of the Pacific near Australia and New Guinea.

Arthropods

The venoms of the phylum Arthropod are used to incapacitate prey for feeding or as a defense against predators [108]. An observation made in antiquity. Few of the arthropods, however, produce toxicity at the NMJ, but when produced, it is by three mechanisms (Table 52.2). In the first, there is an initial augmentation of ACh release followed by presynaptic depletion of neurotransmitter. The second leads to a facilitation of ACh release without a subsequent presynaptic depletion of neurotransmitter. The third mechanism causes a depletion of ACh release without a subsequent presynaptic depletion of neurotransmitter.

Spider Bites

Only a few spider venoms affect the neuromuscular junction. The funnel web spider and the redback spider of Australia are the most dangerous spiders in this group. In North America, only the bite of the black widow spider is of concern. The usual victim of a black widow spider bite is a small boy, perhaps the result of their inquisitiveness of nooks and crannies.

Latrotoxins found in the venoms from the spider genus *Latrodectus* (black widow spider) cause systemic latrodectism. These toxins produce a marked facilitation in neurotransmitter release by depolarization of the presynaptic nerve terminal and increasing Ca^{++} influx into the nerve terminal at all neurosecretory synapses including the neuromuscular junction [109–111]. There is a subsequent depletion of neurotransmitter from the nerve terminal resulting in a blockade of synaptic transmission. This toxin exerts its effects on the presynaptic nerve terminal by several mechanisms. The toxin binds to neurexin and thereby activates the presynaptic protein complex of neurexin, syntaxin, synaptotagmin, and the N-type calcium channel to massively facilitate ACh release [112]. Neurotransmitter release in nerve-muscle preparations, as measured by MEPP frequency, increases several hundredfold within a few minutes [113]. There is a subsequent depletion of synaptic vesicles, disruption of the highly organized active zone region of the presynaptic nerve terminal, thus inhibiting the docking of synaptic vesicles to the terminal membrane and effective recycling of vesicular membrane [114–119].

Signs of a black widow spider bite begin within minutes of the bite and reflect the massive release of neurotransmitter from peripheral, autonomic, and central synapses [120]. Severe muscle rigidity and cramps precedes generalized muscle weakness due to the depolarizing neuromuscular blockade. The black widow spider bite is rarely fatal but cardiovascular collapse may occur in the elderly or in young children. Treatment is primarily supportive. The administration of calcium gluconate may be helpful in alleviating muscle cramps and rigidity [121]. Magnesium salts may be beneficial by reducing neurotransmitter release [120]. The administration of horse-serum antivenom is effective and rapidly reverses the neurotoxic effects [122].

Tick Paralysis

Tick paralysis, a worldwide disorder, was first described at the turn of the twentieth century in North America and Australia although there is vague reference to an earlier case in the early 1800s [123–126]. It is one of several kinds of neuromuscular disorders that result from tick venom exposure [127]. Tick paralysis results from the introduction of a neurotoxin from one of more than 60 tick species [128, 129]. In North America, the *Dermacentor andersoni, D. variabilis, D. occidentalis, Amblyomma americanum, and A. maculatum* species are toxic. The vectors in Europe and the Pacific are *Ixodes ricinus* and *I. cornuatus* and in Australia, it is *I. holocyclus.* Geographically, tick paralysis is more common in States west of the Rocky Mountains and in British Columbia and Alberta [130].

The symptoms are stereotypical. Within 5–6 days of attachment, there is a prodrome of paresthesia, headache, malaise, nausea, and vomiting. The prodromal period parallels the feeding pattern of the tick. Over the next 24–48 h, an ascending paralysis occurs. It begins symmetrically in the lower extremities and progresses to involve the trunk and arms. In most instances when a tick is found, it is fully engorged. In contrast to the vectors found most commonly in North America (*Dermacentor* and *Amblyomma species),* the weakness of the Australian tick is more severe and much slower to resolve. In these patients, there is often a worsening of clinical signs 24–48 h following the removal of the tick [131]. Sensation is preserved but muscle stretch reflexes are often diminished or not present suggesting the Landry-Guillain-Barré syndrome (Table 52.3), a common

Table 52.3 Comparative features of ascending paralysis

Clinical and laboratory features	Tick paralysis	Landry-Guillain-Barré syndrome
Rate of progression	Hours to days	Days to 1–2 weeks
Sensory loss	Absent	Mild
Muscle stretch reflexes	Diminished or absent	Diminished or absent
Time to recovery	<24 h after tick removal	Weeks to months
CSF WBC count	<10 per mm^2	<10 per mm^2
CSF protein	Normal	Elevated

CSF cerebrospinal fluid, mm^2 per square millimeter, < less than

misdiagnosis [132]. There is no demonstrable response to cholinesterase inhibitors [133, 134]. There is some indication of an association between the proximity of the site of attachment to the brain and the severity of the disease. Antitoxin may be of benefit in some situations, but the high frequency of acute allergic reactions makes its widespread use less useful [135]. Resolution of manifestations is dependent in part on how quickly the tick is removed, suggesting that the amount of muscle weakness is a dose-dependent process. Often, improvement begins within hours of removing the tick. Paralyses due to the *Dermacentor* species may continue over several days. However, prolonged weakness is reported [136]. Death may occur due to respiratory failure from severe bulbar and respiratory muscle weakness, and the clinical picture may be clouded by the presences of central nervous system manifestations [130, 137].

Where once, these envenomations carried a 12–25 % mortality; the improvement in critical care over the latter half of the twentieth century makes these intoxications rarely fatal [123, 138]. Children are more prone to the disorder than adults. This may be due in part to their play habits and their lower body mass relative to the amount of toxin acquired. The head and neck are the most common sites for tick attachment, although any part of the body may be bitten. Some studies suggest that girls are more often affected because they have, on average, longer hair than boys that allows the tick to remain hidden for longer periods and therefore allows prolonged feeding [132, 139]. The identification of a tick bite is often delayed resulting in misdiagnosis. Tic paralysis may be confused with Landry-Guillain-Barré syndrome, myasthenia gravis, spinal cord disease, periodic paralysis, diphtheria, heavy-metal intoxication, insecticide poisoning, porphyria, and hysteria [132, 140]. In many instances, the tick is located by the nurse, the house officer, the mortician, or autopsy personnel [132, 138, 141]. Careful, systematic inspection of the scalp, neck, and perineum, often with a fine-toothed comb, is necessary to locate the tick.

The mechanisms of paralysis following tick envenomation remain controversial. The most potent toxin is from the Australian tick, *Ixodes holocyclus*. Holocyclotoxin, isolated from the salivary glands of female ticks causes a temperature-dependent blockade of neuronally evoked release of ACh [142]. Others have suggested a postsynaptic block of neuromuscular transmission [143]. The tick paralysis of the *Dermacentor* species is understood less clearly, and no direct abnormality of synaptic transmission may occur. Rather, the abnormality may be due to impaired depolarization of the nerve terminal with the consequence of decreased ACh release [144, 145]. Prolonged distal motor latencies, slowed nerve conduction velocities, and reduced compound muscle action potential (CMAP) amplitudes are described [128, 133, 146–148].

Scorpion Bites

The peptides contained in scorpion neurotoxins may cause a variety of neurological effects, the most significant of which are those that modulate Na^+ and K^+ channel function. Some, however, affect the neuromuscular junction and produce an enhanced presynaptic depolarization resulting in neurotransmitter release [149]. Increased excretion of catecholamines is demonstrated after scorpion sting and may relate to the primary effect of the venom or to a secondary sympathetic adrenergic surge. Treatment is nonspecific and focuses on maintaining respiratory, cardiac, and coagulation function. Antivenom appears not to be efficacious [150, 151].

Snakebites

Envenomation by snakebite occurs from four major groups: *Viperidae* (true vipers), *Crotalidae* (rattlesnakes and pit vipers), *Elapidae* (American coral snake, cobras, kraits, mambas), and *Hydrophiidae* (sea snakes). Neuromuscular blockade occurs primarily from the *Elapidae* and *Hydrophiidae* species [152–154]. One *Crotalidae* species, *Crotalus durissus terrificus*, a South American rattlesnake, has a very potent neuromuscular blocking venom. Other rattlesnakes and pit vipers act through hematological and cardiovascular mechanisms. Venom is produced and stored in salivary glands, and inoculation occurs through fangs or modified premaxillary teeth [152].

Snake toxins may act by presynaptic or postsynaptic mechanisms. Presynaptic toxins, β-neurotoxins (β-bungarotoxin, notexin, and taipoxin), act to inhibit the normal release of acetylcholine from the presynaptic cell of the neuromuscular junction. Often, there is an initial augmentation of acetylcholine release followed by presynaptic depletion of neurotransmitter. They tend to be more potent than postsynaptic toxins. Postsynaptic neurotoxins, α-neurotoxins, produce a curare-mimetic, nondepolarizing neuromuscular block and vary in the degree of the reversibility of the block in experimental preparations.

Most venoms are a mixture of the two types of neurotoxin, although one type may predominate in a given venom. For example, the venom of the Thai cobra is composed

primarily of a single postsynaptic neurotoxin [155]. In contrast, the venom of *Bungarus multicinctus* contains β-bungarotoxin, four other presynaptic toxins, α-bungarotoxin, and two other postsynaptic toxins [156]. The venom of *Hydrophiidae* species is more toxic than land snakes although the amount of toxin injected by sea snakes is smaller than that of land-based snakes [157, 158]. The α-neurotoxins (postsynaptic), like curare, bind to the muscle nicotinic AChR. They have a slower onset of action and a longer duration of effect and are 15–40 times more potent than d-tubocurarine [159, 160]. There are numerous subforms of β-neurotoxins (presynaptic). Most have a phospholipase component that is essential for the presynaptic effects of the toxin. All suppress the release of ACh from the nerve terminal although there is some variability in the precise mechanism by which this occurs. In experimental preparations, toxins from different species potentiate each other suggesting different binding sites at the neuromuscular junction [161]. Taipoxin from the Australian and Papua New Guinean taipan snake is unique. In addition to its potent presynaptic blockade of synaptic transmission, it also has a direct myotoxic component. This produces rapid muscle necrosis and degeneration. There is species variation in the susceptibility to toxin exposure. The venom of the Australian mulga snake is fatal in man, produces ptosis in monkeys, and does not produce a neuromuscular block in the rabbit [162, 163].

The clinical course of snake envenomation follows a specific pattern. After the bite of a pit viper or cobra, there is local pain, which is often absent following the bite of other *Elapidae* (mambas, kraits, coral snakes) and *Hydrophiidae*. Swelling typically follows within an hour of the bites from *Viperidae, Crotalidae*, or the cobra but is not seen following bites from other *Elapidae* and *Hydrophiidae.* A preparalytic stage develops with headache, vomiting, loss of consciousness, paresthesias, hematuria, or hemoptysis [164]. These manifestations are not common after envenomation by cobras or mambas. The time between snakebite and paralysis may vary from 0.5–19 h [165]. The first signs of neuromuscular toxicity are usually ptosis and ophthalmoparesis though these are absent following the bite of the South American rattlesnake. Facial and bulbar weakness develops over hours following the ocular signs [166]. For 2–3 days, limb, diaphragmatic, and intercostal weakness follows and may continue to evolve [152, 167], and without appropriate treatment, cardiovascular collapse, seizures, and coma ensue. There is no sensory abnormality other than that from the bite itself. Other systemic effects of neurologic importance relate to coagulation deficits. Cerebral and subarachnoid hemorrhage may occur after bites from many species and is the leading cause of death following viper bites in several regions of the world [168, 169].

Treatment consists of antivenom which is most effective in bites that do not contain significant amounts of phospholipase, a component of presynaptic neurotoxins [166, 170–172]. If the type of snake is known, a high-titer monovalent type is administered, but more often, snake variety is not known necessitating the use of polyvalent antivenom. The goal of antivenom is to shorten the duration of weakness, and frequently, the addition of respiratory, cardiovascular, and hematological support is required. Supportive measures are the mainstay of care for most victims of coral snakebite. Intensive care treatment and airway maintenance is similar to patients with myasthenia gravis. Some authors recommend treatment with cholinesterase inhibitors in cases that are predominantly caused by a postsynaptic abnormality and suggest that electrodiagnostic testing may be useful in determining their effectiveness [173, 174].

Marine Toxins

The rapid rise in marine pollution has spurred a renewed interest in marine toxins. Previously they were only of interest to the physiologist and pharmacologist who use them in the investigation of biological systems. Examples of marine neurotoxicology are scattered throughout the literature dating to biblical times (Exodus 7:20–21). The reader is referred to Southcott's paper for an excellent review of the subject [175]. Marine neurotoxins affecting the neuromuscular junction are rare and occur primarily from poisonous fish, a few mollusks, and perhaps dinoflagellates. Unlike the poisoning from arthropods and snakes, the majority of marine intoxications occur as the result of ingestion. Unique to some marine toxins is that the increase in concentration of toxin through successive predatory transvection up the food chain.

Dinoflagellates are single-celled, biflagellated, algae-like organisms. Diatoms, similar to dinoflagellates, are not flagellated and are encased by a silica shell. The toxins produced by these organisms cause a variety of systemic and neurological effects, but neuromuscular junction effects are rare and indirect. Paralytic shellfish poisoning results from neurotoxins produced by less than 1 % of the 2,000–3,000 species of known dinoflagellates and diatoms [176]. These toxins are rapidly absorbed through the gastrointestinal tract, and symptoms begin within 30 min of ingestion. Characteristically, there is an initial burning or paresthesia of the face and mouth, spreading quickly to involve the neck and limbs. These sensations slowly abate and are replaced with numbness, some ataxia, and, in severe cases, progressive generalized weakness and respiratory failure. Overall, the mortality approaches 10 %. Most neurotoxins from dinoflagellates and diatoms are sodium channel blockers (e.g., saxitoxin and tetrodotoxin). Brevetoxin, a milder neurotoxin that causes the nonlethal neurotoxic shellfish poisoning, depolarizes cholinergic systems, by opening sodium channels and resulting in neuromuscular transmission

alterations indirectly [177, 178]. The cyclic imine group of toxins, gymnodimine and spirolides, are potent antagonists of both cholinergic and muscarinic nicotinic acetylcholine receptors [179]. Recently isolated from New Zealand shellfish, these toxins are rapid in onset and lethal. Ciguatoxin, from *Gambierdiscus toxicus*, is commonly found in the Caribbean, Australia, and South Pacific Island Countries and Territories. The incidence is rapidly increasing and is now considered a major health hazard [180, 181]. This heat-stable lipid enhances the release of ACh from the neuromuscular junction by prolonged sodium channel opening. Onset of symptoms is within hours of ingestion, and respiratory muscle paralysis may occur quickly. Recovery usually occurs within a few weeks.

Conotoxins are a diverse group of toxins from predatory cone snails that inject their venom through a small harpoon-like dart [182]. It is only the fish predatory species (*Conus geographus*, *C. textile*, *C. marmoreus*, *and C. omaria*) of this mollusk that appear dangerous to humans [183–185]. The effects of these toxins are variable among species and within a single species, and several have direct effects on the neuromuscular junction. α-Conotoxins block the binding of ACh to the ligand binding site [186–188]. These venoms function similarly to the snake α-neurotoxins described earlier. The ω-conotoxins block the voltage-gated calcium channel of the presynaptic nerve terminal [189]. The latter toxin has played an important role in understanding of the LES and serves as the basis for the currently used antibody assay [2, 190]. Following the injection of toxin, there is intense local pain quickly followed by malaise, headache, and, within 30 min, progressive generalized weakness. Respiratory failure often occurs within 1–2 h. Most cone shell bites are preventable. These shells should be handled carefully with forceps and thick gloves. The proboscis protrudes from the small end of the shell, but it is flexible and long enough to sting the holder at the other end. The live shells should never be placed in a pocket as the dart may penetrate cloth [175]. Treatment is directed toward respiratory and cardiovascular support. There is no available antivenom. There is no literature discussing the potential efficacy of cholinesterase inhibitors. More than 60 % of stings are fatal [185, 191].

The most venomous fish is the stonefish, *Synanceia horrida, S. trachynis, and S. verrucosa*, found in the Indo-Pacific oceans and Red Sea as well as the genus *Inimicus* found off the coast of Japan [192]. The toxin, stonustoxin, is inflicted by injection through the 13 dorsal spines when the victim steps on the small fish that is buried in the sand [193]. Neuromuscular blockade results from induced neurotransmitter release with depletion of ACh stores, similar to that of other presynaptic toxins [194, 195]. Envenomation results in immediate, excruciating pain that may last for 1–2 days. Severe edema occurs due to the actions of hyaluronidase that promotes the rapid spread of venom through the tissue, and tissue necrosis may occur [175]. In addition to gastrointestinal, autonomic, and cognitive effects, the victim may experience generalized muscle weakness due to the mechanism noted above. Death occurs from cardiotoxicity. Treatment is supportive and in some patients, a specific antitoxin may be administered.

Plant Toxins

Rarely, plant neurotoxins affect the human NMJ, but more toxic effects are observed in animals. Neurotoxicity is dependent upon the potency, concentration, and interaction with other toxins or substrates in the victim. Many are alkaloids. Coniine, the neurotoxin from the herb, *Conium maculatum* (poison hemlock), produces a rapidly ascending paralysis often resulting in death. Sensory abnormalities are common and prominent [196]. The death of Socrates is attributed to hemlock [197]. The mechanisms of action of this piperidine alkaloid neurotoxin are not completely understood. There is evidence that the toxin acts as a curare-mimetic [198]. Many of these alkaloid neurotoxins are teratogenic to the fetus and by desensitizing nicotinic acetylcholine receptors produce arthrogryposis, scoliosis, kyphosis, and lordosis [199].

Occupational Neurotoxins

Heavy Metals

Numerous polyvalent cations affect neuromuscular transmission and are often used to study basic mechanisms of synaptic transmission. These include barium, erbium, cadmium, cobalt, gadolinium, lanthanum, manganese, nickel, praseodymium, triethyltin, and zinc [200–212]. Nearly all of these intoxicants have multiple effects on synaptic transmission, but they predominantly block the release of ACh as well as facilitating spontaneous quantal release of neurotransmitter. They exert their effects by the block of the flux of Ca^{++} through voltage-gated calcium channels and disrupt intracellular stores of Ca^{++} [213].

Heavy-metal intoxication is a rare cause of clinical NMJ toxicity. Interest in this topic arose from the 1971 contamination of grain in Iraq with a methylmercury fungicide. Despite appropriate warnings, the grain was fed to animals, ground for flour, and used for making bread [214]. Symptoms began within one month of consumption ultimately affecting more than 6,500 people and killing nearly 8 % [215]. Patients experienced ataxia, fatigue, generalized muscle weakness, and occasionally optic atrophy. While one of the expected abnormalities following mercurial poisoning is a peripheral neuropathy (based on the Minamata experience), extensive electrodiagnostic examinations of the affected population

Table 52.4 Neuromuscular syndromes of organophosphate poisoning

Acute cholinergic crisis
Intermediate syndrome
Myopathy
Delayed toxin-induced neuropathy

did not demonstrate this [216, 217]. Repetitive nerve stimulation studies demonstrated a decremental response that was partially reversible with cholinesterase inhibitors [218]. Similar abnormalities were demonstrated in experimental animals [219].

Organophosphate and Carbamate Poisoning

The earliest use of a cholinesterase inhibitor as a neurotoxin is attributed to tribesman in Africa who used the Calabar bean as a right of passage or an "ordeal poison" [220, 221]. Organophosphates (OP) are a class of more than 20,000 compounds that irreversibly inhibit cholinesterases including acetylcholinesterase (AChE) [222]. They are widely used in the agricultural, manufacturing, and pharmaceutical industries as well as a weapon of mass destruction [223, 224]. Exposure to OP compounds occurs in the workplace, in food, drinking water, and in the environment. OP intoxication is infrequent in the United States because OP-containing insecticides are not readily available. However, these are used commonly in many other countries, where intoxication most commonly results from attempted suicide by ingestion of insecticides, indiscriminate handling, and storage by poorly informed workers [225–229].

The physiochemical properties of these compounds vary. They may be solid, liquid or gaseous, and soluble in various media. Some are highly corrosive, others are not; some highly volatile, others not. Dermal contact, respiratory inhalation, and gastrointestinal absorption may lead to OP absorption. These various physiochemical properties lend themselves to the wide range of applications noted above as well as to the inherent danger of their use [230].

Four neuromuscular toxicological syndromes occur from OP poisoning: an acute cholinergic crisis (types 1 and 2), an intermediate syndrome, a myopathy, and a delayed induced neuropathy (Table 52.4) [231]. Only the type 2 cholinergic crisis and the intermediate syndrome are the result of NMJ toxicity. OP compounds exert their NMJ toxicity by the irreversible inhibition of AChE. This results in the excessive accumulation of ACh at the NMJ as well as other cholinergic synapses of the central, peripheral, and autonomic nervous systems [232]. The excessive accumulation of ACh produces a depolarizing neuromuscular block at the NMJ that is followed by desensitization of the AChR [233–236]. Electrodiagnostic studies demonstrate normal nerve conduction studies, reduced CMAP amplitudes, a decremental response to repetitive nerve stimulation, and CMAP afterdischarges to a single nerve stimulus [227, 237].

Carbamate salts and esters, which are primarily used as pesticides, are synthetic analogs of the alkaloid physostigmine (eserine). They may directly or indirectly affect the NMJ. Like the OP compounds, carbamates also inhibit the action of AChE at cholinergic synapses. They are easily absorbed into the central nervous system because of their lipid solubility characteristics. Unlike OP compounds, the effects of carbamate agents are reversible. However, the manifestations of carbamate poisoning are indistinguishable from OP poisoning. Neurotoxicity occurs rapidly following significant exposure to both classes of compounds. Mortality rates are high with death usually occurring from respiratory paralysis, which develops in 40 % of poison victims [238].

Pesticides

OP chemistry had its origin around 1820 when Lassainge synthesized triethyl phosphate, but not until the turn of the century did they become commonly used for their insecticidal properties. The OP insecticides are all derivatives of phosphoric acid. There are many subclasses within this group of compounds, and their various moieties (e.g., sulfur, amides) confer variation in overall toxicity. Despite recognition of their toxicity, their use continues to rise, particularly in developing countries where demand was predicted to more than double in the 1990s [239]. Most fatal intoxications result from suicidal ingestion [225–228, 240–243]. Reports of carbamate NMJ toxicity are few [244]. The largest episode of carbamate poisoning occurred in 1985 when aldicarb was illegally used as an insecticide on watermelons [245]. Seventy-seven percent of 1,376 exposed individuals were poisoned, each exhibiting a dose-related spectrum of nicotinic and muscarinic cholinergic receptor toxicity. Fatalities are rare and only occur at high exposure levels [246–249]. Symptoms appear rapidly, often within an hour, peaking in 2–3 h with full recovery within 72 h [250].

Agents of War and Terrorism

The highly dangerous toxicity of OP compounds was recognized in 1932 leading to the development of a series of G-agents (G = German). These compounds, GA (Ethyl N,N-dimethylphosphoramidocyanidate; tabun) in 1936, GB (O-Isopropyl methylphosphonofluoridate; sarin) in 1938, GD (O-Pinacolyl methylphosphonofluoridate; soman) in 1944, and CF (Cyclohexyl methylphosphonofluoridate; cyclosarin), were developed specifically as agents of war [251]. The V-series (V=venomous) followed and include 4 compounds: VE (S-(Diethylamino)ethyl O-ethyl ethylphosphonothioate), VG (O,O-Diethyl-S-[2-(diethylamino)ethyl] phosphorothioate; also called Amiton or Tetram), VM (Phosphonothioic

Table 52.5 Comparative human LCt_{50} and LD_{50} to nerve agents

Nerve agent	Aerosolized (LCt_{50})	Percutaneous (LD_{50})
VX vapor	10 mg·min/m^3	6–10 mg
Soman vapor	50 mg·min/m^3	350 mg
Sarin vapor	100 mg·min/m^3	1,700 mg
Tabun vapor	400 mg·min/m^3	1,000 mg

Abbreviations: LCt_{50} – the dose of vapor necessary to cause death in 50 % of the exposed population where *C* is concentration and *t* is time; LD_{50} – the dose of cutaneous exposure necessary to cause death in 50 % of the exposed population; mg – milligram; min/m^3 – minutes per meter squared

acid, methyl-, S-(2-(diethylamino)ethyl) O-ethyl ester), and VX (O-ethyl-S-[2(diisopropylamino)ethyl] methylphosphonothioate; venom X) in 1952. Little is known about a Russian agent, coded VR-55 [252]. Great Britain ceased nerve gas weapons research in 1959, and the USA transiently discontinued their efforts between 1969 and 1981 [253]. Other countries continue to develop their weapons programs. It is speculated that GA was used in the 1980s during the Iraq-Iran conflict causing innumerable deaths [252]. G-agents share a number of similar characteristic properties. They are highly volatile in room air. As a result, their toxicity may be from either inhalation or by contact. These compounds are soluble in fat and water. This allows ready absorption through the skin eyes and mucous membranes. Vapor agents are absorbed initially through the eyes producing local irritation and then through the respiratory tree. Liquid agents penetrate through the skin at the point of contact and are able to produce more severe and generalized symptoms.

The V-series toxins are the most highly toxic chemical warfare agents. These agents of war are termed persistent agents as they remain active on skin, clothes, and other surfaces for prolonged periods of time. VX was synthesized by the British in 1957. Other agents in the series (Ve, Vg, Vm, and V-gas) are less well-known as information about them is very limited.

Local effects (sweating, mucosal irritation) occur within seconds and paralysis, and apnea may occur as quickly as 1–2 min of exposure. Comparative inhalation toxicities are summarized in Table 52.5. Absorption may be through inhalation, ingestion, or cutaneous contact. VX is the most potent and GA the least. Terrorist attacks in Japan resulted in the exposure of civilians to GB and VX [254–258].

Pathophysiology

The G- and V-series nerve agents inhibit the hydrolysis of acetylcholine by acetylcholinesterase by binding to and phosphorylating the active site of AChE [259]. The resulting depolarizing neuromuscular block leads to rapid and profound muscle weakness. Death occurs by respiratory failure. The inhibition of AChE by these agents becomes irreversible, a phenomenon known as "aging." The aging half-time is variable, as short as 2 min for GD and as long as 48 h for VX [260]. Aging is an irreversible phenomenon. Prior to this reaction, the enzyme can be reactivated with the use of oximes which remove the neurotoxin from the AChE molecule. Oximes dissociate the toxic phosphate moiety from the esteratic site on AChE, thus reactivating esterase and restoring normal NMT [261, 262]. Following attachment of the nerve agent to AChE, a portion of the nerve agent, called the leaving group, is cleaved from the bound molecule. This is followed by a second reaction during which an alkyl group leaves the nerve agent. This results in an aged complex for which oximes have no effect [263].

Treatment

Treatment is directed toward the prevention of chemical exposure by appropriate clothing and the decontamination of exposed victims [264, 265]. Aggressive cardiopulmonary support is necessary. Atropine is an effective antidote to block excessive cholinergic activity at muscarinic receptors in both organophosphate and carbamate intoxications. AChE reactivators (oximes, e.g., 2-PAM) and anticholinergics are often helpful for acute OP intoxications but appear to have little effect to reverse weakness caused by the intermediate syndrome. Oximes dissociate the toxic phosphate moiety from the esteratic site on AChE, thus reactivating esterase and restoring normal neuromuscular transmission [261]. Soman is the least responsive of the nerve agents to oxime therapy because the agent-enzyme complex rapidly undergoes "aging." This refers to the compound undergoing a time-dependent conformational change that is no longer responsive to reactivators [266]. In contrast to OP intoxications, oxime reactivators are contraindicated in carbamate poisoning as these compounds enhance the effects of the carbamate and promote further junctional toxicity [267]. In cases where the offending compound is not known, it is possible to assay the reactivation of AChE activity in vivo and possibly differentiate between OP and carbamate poisoning [268]. Neuromuscular blockade with curariform drugs blocks repetitive discharges although it is not clear whether there is any clinical benefit to their use [269]. The carbamate pyridostigmine was used as a "pretreatment" for organophosphorous poisoning during the Gulf War, but their use is controversial. While studies showed that a 40 % inhibition in AChE activity by physostigmine protected experimental animals from acute cholinergic toxicity following exposure to soman, such findings have not been conclusively demonstrated for pyridostigmine [270].

Neuromuscular Disorders: Muscle Ion Channel Disorders

Disorders of Skeletal Muscle Membrane Excitability: Myotonia Congenita, Paramyotonia Congenita, Periodic Paralysis, and Related Syndromes

53

Robert L. Ruff and Barbara E. Shapiro

Introduction

The disorders of skeletal muscle membrane excitability comprise a group of diseases characterized by muscle stiffness, pain, and sometimes weakness, which may be intermittent or fixed. Myotonia occurs in several of these disorders. Patients with myotonia may describe an inability to relax their muscles after contraction, such as during handgrip. In addition, patients may experience the myotonia as muscle stiffness. Traditionally, the myotonic muscle disorders have been classified into those with dystrophic changes on muscle biopsy, such as the myotonic dystrophies, resulting in weakness, and those without dystrophic changes, such as myotonia congenita and paramyotonia congenita, where progressive weakness is generally not a feature. Furthermore, the dystrophic disorders also manifest extramuscular abnormalities, including cataracts, cardiac defects, and pulmonary or endocrine dysfunction [1]. The dystrophic myotonic muscle disorders are covered elsewhere in this book (see Chap. 59). *Neuromyotonia*, a rare phenomenon associated with peripheral nerve as opposed to muscle disorders, may also result in a delay in muscle relaxation. However, this is distinguished from myotonia by its association with disorders of peripheral nerve origin (see Chap. 70).

Physiology

To understand disorders of skeletal muscle membrane excitability, it is necessary to review the following: (1) factors that alter membrane excitability, (2) the contributions of different ion conductances to the resting membrane potential, (3) ion conductances during an action potential, and (4) the need for skeletal muscle fibers to have high chloride conductances to counteract the destabilizing effect of the transverse tubular system on membrane excitability. There are many types of ion channels. We will consider four classes of ionic channels: (1) voltage-gated sodium channels; (2) two forms of potassium channels, inward rectifier (also called anomalous rectifier) and voltage-gated delayed rectifier potassium channels; (3) skeletal muscle chloride channels; and (4) a subset of voltage-gated calcium channels called L-type or dihydropyridine (DHP)-sensitive calcium channels. Several important features of sodium channel gating are also considered.

Factors Contributing to Skeletal Muscle Membrane Excitability

Directions of Ion Movements and Equilibrium Potentials

Two factors determine the net flow of ions across an open ionic channel: (1) the membrane potential and (2) the differences in ion concentrations between the intracellular and extracellular spaces. Since cells have negative intracellular potentials, the electrical force will tend to direct positively charged ions (cations such as sodium, potassium, and calcium) to flow into a cell. Hence, electrical forces will direct an inward flow of sodium, potassium, and calcium ions and an outward flow of chloride ions. The direction of ion movement produced by the "concentration force" depends on the concentration differences for the ion between the intracellular and extracellular compartments. Sodium, calcium, and chloride ions have higher extracellular concentrations

Table 53.1 Equilibrium potentials for ions in skeletal muscle

Sodium	+65 mV
Potassium	−105 mV
Calcium	>+100 mV
Chloride	−95 mV (resting potential)
Resting potential	−95 mV

compared with intracellular concentrations. The intracellular concentration of potassium is greater than the extracellular concentration. "Concentration forces" direct an inward flow of sodium, calcium, and chloride ions and an outward flow of potassium ions. The membrane potential at which the electrical and "concentration" forces are balanced for a given ion is called the *equilibrium or Nernst potential* for a given ion. At the equilibrium potential, inward and outward current movements are balanced for a specific ion due to balancing of the electrical and "concentration" forces. For a given cation, at membrane potentials that are negative compared with the equilibrium potential, ions flow into the cell. At membrane potentials that are more positive than the equilibrium potential, current carried by the specific ion will flow out of the cell. *The direction of current movement for a specific ion always tends to bring the membrane potential back to the equilibrium potential for that specific ion.* Examples of approximate equilibrium potentials for ions in skeletal muscle are shown in Table 53.1.

The Contributions of Different Ion Conductances to the Resting Membrane Potential

The membrane potential represents a balance among the equilibrium potentials of the ions that the membrane is permeable to. The greater the conductance of an ion, the more that ion will influence the membrane potential of the cell. The principal conductances responsible for establishing the resting membrane potential are chloride conductance, potassium conductance, and sodium conductance.

Chloride conductance is mediated by skeletal muscle chloride channels. *Chloride is the dominant membrane conductance, accounting for about 80 % of the resting membrane conductance*. Chloride channels in skeletal muscle are unusual in that they are gated by the presence of ions at the intracellular and extracellular orifices, rather than by the membrane potential. Thus, the channel is likely to open when a chloride ion presents itself at either the intra- or extracellular opening of the chloride channel. The unique gating properties of chloride channels result in the chloride ions being distributed across the membrane in accord with the membrane potential. Consequently, chloride conductance does not set the membrane potential. Instead, chloride conductance acts as a brake or damper that makes it harder for the membrane potential to change. Therefore, chloride conductance provides an important stabilizing influence on the membrane potential. Another important feature of skeletal muscle chloride channels is that they gate (open and close) slowly. Consequently, chloride channels do not respond to transient changes in membrane potential, such as that occurring during an action potential. *Therefore, chloride conductance is well suited to inhibit slow alterations in membrane potential without greatly inhibiting action potentials*.

The dominant ion in setting the resting membrane potential is potassium. Potassium conductance accounts for about 20 % of the resting membrane conductance. The small amount of sodium conductance in the resting skeletal muscle membrane results in the resting membrane potential being slightly positive or depolarized compared to the equilibrium potential for potassium (Table 53.1). The specific class of potassium channels that determines the resting membrane potential is the inward or anomalous rectifier potassium channel. The ATP-dependent potassium channel is one of several types of inward rectifier potassium channels. Resting calcium conductance is exceedingly small. Therefore, calcium does not contribute to determining the resting membrane potential.

Ion channel normally conducts ions only through a central pore or ion channel. However, some mutations of calcium or sodium channels result in the appearance of a secondary new pathway for conducting ions. This alternative pathway is referred to as a gating pore because it appears only with mutations of segments of the calcium or sodium channels that involve the gating mechanism. The gating mechanism of an ion channel consists of segments of that channel containing charged amino acids. Under the influence of the transmembrane potential, these segments with charged amino acid partially translate across the membrane when the membrane potential changes. The translation of charged portions of the ion channel when the membrane potential changes results in a charge movement, called a gating charge [2–4]. Some mutations that occur in segments of sodium or calcium channels involved in gating can result the formation of an alternative pathway for ion current flow that is independent of the normal ion channel. The alternative pathway created by mutations in the channel segments involved in gating is referred to as a gating pore [5–10].

Important Properties of Ion Channels in Skeletal Muscle

As mentioned above, the skeletal muscle chloride channel is gated by chloride ion concentrations. The other important skeletal muscle ion channels are gated by membrane potential. We discuss the voltage-gated sodium channel first.

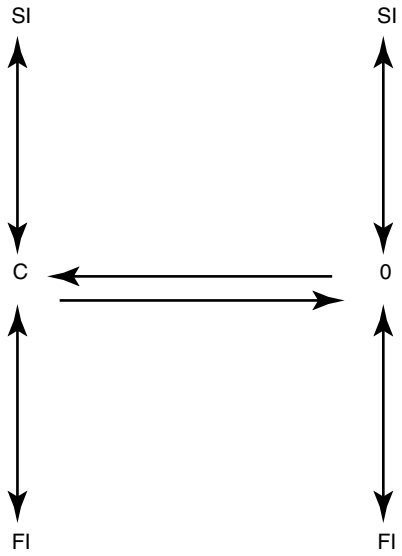

Fig. 53.1 Possible transitions that the sodium channel can undergo. *FI* fast inactivated, *SI* slow inactivated, *C* closed, *O* open

Table 53.2 States that the sodium channels are in at different membrane potentials

Hyperpolarized resting potential (<−90mv) – most in closed state, some in SI state
Depolarized resting potential (>−80 mV) – most in SI state, some in closed or FI state
Rising phase of action potential – open state with channels beginning O→ FI transition
Falling phase of the action potential – most are in the FI state

FI fast inactivated, *SI* slow inactivated, *O* open

Sodium Channel Gating Properties

Membrane depolarization activates sodium channels via conformation changes from closed, nonconducting states to an open, current-conducting state [2, 11–13]. The declining portion of I_{Na} elicited by prolonged depolarization results from late openings of sodium channels and transition of open channels to a nonconducting fast inactivated state [12, 14, 15]. Sodium channels can also transit directly between closed and fast inactivated states [2, 11, 12, 14]. Inactivated channels do not open when the membrane is depolarized. The transition rate from the open to the fast inactivated state is independent of voltage over part of its operative range, [14] and the transition rate increases with depolarization at potentials more positive than about −30 mV [12]. The transition rate from the closed to the fast inactivated state increases with depolarization (Fig. 53.1) [16].

Mammalian skeletal muscle sodium channels have two inactivation processes with different kinetics and voltage dependence [12]. Fast inactivation closes channels on a ms time scale, whereas slow inactivation takes seconds to minutes. In *rat and human skeletal muscle, fast inactivation helps to terminate the action potential* [17, 18]. Slow inactivation is too slow to affect action potential termination. However, *slow inactivation operates at more negative potentials than fast inactivation, so that the distribution of channels between the closed and slow inactivated state regulates the number of excitable sodium channels as a function of the membrane potential* (Table 53.2) [12, 16, 19, 20]. Gating charge studies show that fast and slow inactivated states are distinct conformations of the sodium channel [16, 21]. Protease treatment of the intracellular membrane surface or other chemical treatments may selectively alter slow inactivation or fast inactivation [22–24]. Sodium channel mutations can independently change fast or slow inactivation [12, 25, 26]. Therefore, the slow and fast inactivated states probably represent independent sodium channel conformations. Slow inactivation represents the accumulation of sodium channels into the inexcitable slow inactivated state [12]. Slow inactivation changes the number of excitable channels, but does not change the single-channel conductance or open time [12].

Potassium Channel Gating Properties

Different potassium channels are responsible for the resting membrane conductance and for terminating the action potential. The potassium channel that is responsible for the resting membrane conductance is called the *inward rectifier or anomalous rectifier potassium channel*. This channel has unique properties that enable it to provide the resting membrane conductance for potassium without resulting in excessive potassium loss during an action potential [2, 11]. The inward rectifier potassium channel gets its name from having a larger conductance for inward potassium currents. When the membrane is depolarized more than 10–15 mV with respect to the equilibrium potential for potassium, the conductance of the inward rectifier potassium channel decreases. Consequently, once the membrane has depolarized to about the threshold for triggering an action potential, the conductance of the inward rectifier potassium channel decreases and little potassium exits the cell during the rising phase of the action potential. The nonlinear conductance properties of the inward rectifier potassium channel enable it to set the membrane potential and not cause excessive potassium loss during an action potential. Since the cell has to utilize ATP to pump potassium back into the cell, the conductance properties of the inward rectifier potassium channel reduce the energy expenditure of the muscle cells. Note that in skeletal muscle cells, an action potential indirectly triggers a great deal of ATP breakdown to fuel the movement of the contractile proteins and the reuptake of calcium released from the sarcoplasmic reticulum.

The second potassium channel in skeletal muscle is the *delayed rectifier potassium channel*. This voltage-gated channel gets its name because at physiological temperatures, the delayed rectifier potassium channel opens slower than

the voltage-gated sodium channel. *Delayed rectifier potassium channels are opened by the membrane depolarization produced by the action potential. However, due to the delay in their openings, most of the delayed rectifier channels do not open until after the rising phase of the action potential has completed. The delayed opening of these potassium channels enables them to assist in terminating the action potential without hindering the rising phase of the action potential*. Hence, the gating properties of the delayed rectifier potassium also conserve intracellular potassium [2, 11].

The Course of Events During an Action Potential

The first step in generating an action potential is membrane depolarization, which in skeletal muscle is initiated by the endplate potential. The depolarization causes some voltage-gated sodium channels to open, which augments the membrane depolarization. The process of depolarization causing more sodium channels to open continues until threshold is reached. *At threshold, the sodium conductance just exceeds the combined chloride and potassium conductances that are resisting membrane depolarization*. The factors that contribute to determining threshold membrane potential for triggering an action potential are the voltage dependence of sodium channel opening and the decreasing conductance of the inward rectifier potassium channel with depolarization. *Once threshold is reached, the membrane potential depolarizes very quickly during the rising phase of the action potential. During the rising phase of the action potential, most of the voltage-gated sodium channels are in the open state* (Table 53.2). The large membrane conductance for sodium results in the membrane potential approaching the equilibrium potential for sodium (Table 53.1).

The declining phase of the action potential results from two processes: (1) the membrane depolarization triggers sodium channels to undergo conformation changes from the open state to the fast inactivated state and (2) the delayed rectifier potassium channels begin to open. The membrane repolarizes because the sodium conductance decreases and potassium conductance increases resulting in the membrane moving toward the potassium equilibrium potential (Table 53.1). *Immediately after an action potential, most sodium channels are still in the fast inactivated state*. Consequently, there are not enough excitable sodium channels to trigger a second action potential immediately after the first action potential.

The period during which the population of excitable sodium channels (those in the closed state) is too small to support an action potential (i.e., there are not enough excitable sodium channels to overcome the chloride and inward rectifier potassium conductances) is referred to as the *absolute refractory period*. During this period, an action potential cannot be triggered by even a very large depolarization. The period of time from the end of the absolute refractory period until the sodium channels have redistributed among their possible states to return to the steady-state population of channels in the closed and inactivated states is referred to as the *relative refractory period*. In this period, a larger than usual stimulus is needed to trigger an action potential. During the refractory periods, sodium channels are changing from the fast inactivated to the closed state.

Perturbation of the fast inactivation process can make the muscle membrane hyperexcitable. The membrane becomes hyperexcitable if some sodium channels do not undergo fast inactivation, producing a persistent inward sodium current that can trigger repeated action potentials during the relative refractory period. The refractory periods are shortened if sodium channels rapidly recover from the inactivated state. The effect of potassium accumulation in the transverse tubules on membrane electrical stability is discussed below.

Skeletal Muscle Needs a Large Resting Chloride Conductance to Counter the Destabilizing Effect of the Transverse Tubule System

Skeletal muscle membrane has a transverse tubule (T-tubule) system. The T-tubules are relatively thin and long. They serve to conduct the action potential into the muscle fiber. The T-tubules are essential for coupling surface membrane action potentials with release of calcium from the sarcoplasmic reticulum inside a muscle fiber. Because they are very thin, potassium leaving the muscle fiber during an action potential can accumulate in the T-tubule. The elevated extracellular potassium concentration in the T-tubules makes the equilibrium potential for potassium across the T-tubule membrane less negative. For example, increasing the potassium concentration in the T-tubule space to 12 mM, which likely happens after a series of action potentials, would result in the potassium equilibrium potential depolarizing by more than 40 mV to become −64 mV. The membrane potential of the T-tubules remains depolarized after an action potential until the sodium-potassium pumps are able to remove the excess extracellular potassium. Under physiological conditions, sodium channels recover from inactivation faster than the sodium-potassium pump can remove the excess potassium in the T-tubules. The depolarized T-tubules can depolarize adjacent membrane and trigger repeated action potentials. Therefore, the T-tubules provide a depolarizing current that could trigger subsequent action potentials. Muscle needs to have a high resting chloride conductance to hinder the ability of the T-tubules to depolarize the muscle membrane and to prevent repeated action potentials from developing after a single depolarizing stimulus. If one removes the T-tubules by chemically disrupting them, one inhibits the muscle membrane from generating a string of action potentials in

response to a depolarizing stimulus. In addition, muscle studied under conditions where chloride channels do not contribute to membrane stability – blocking chloride channels or studying the skeletal muscle in a bathing solution that does not have chloride – will result in a muscle membrane hyperexcitable state [27].

Clinical Disorders

Having reviewed the relevant physiology, discussion focuses next on the mechanism by which different disorders of membrane excitability result from alterations of (1) chloride conductance, (2) sodium channel gating, (3) the density of sodium channels, (4) the gating of potassium channels, or (5) the presence of a pathological depolarizing current. Mutations in a calcium channel that is present in the surface membrane result in the most common forms of hypokalemic periodic paralysis. However, the membrane pathology in hypokalemic periodic paralysis is a complex consequence of the calcium channel mutations. The altered calcium channels induce membrane pathology by changing the properties of other ion channels and by showing a gating pore current.

Chloride Channel Disorders: Autosomal Dominant Myotonia Congenita (Thomsen's Disease) and Recessive Generalized Myotonia Congenita (Becker-Type Myotonia)

Introduction and Clinical Presentation

Two forms of myotonia congenita are classically recognized. An autosomal dominant form, *Thomsen's disease*, was first described in 1876 by the Danish physician Julius Thomsen who was himself affected [28]. An autosomal recessive form was described by Becker in the 1950s, which is also called *Becker-type myotonia* or *recessive generalized myotonia congenita* [29]. Both disorders arise from mutations in the skeletal muscle voltage-gated chloride channel gene (CLC1) on chromosome 7q [30]. The recessive generalized form occurs much more frequently than the dominant form [29, 31]. A potassium-sensitive form of myotonia congenita has also been recognized, associated with mutations in the α-subunit of the voltage-gated sodium channel on chromosome 17q. The sodium channel myotonias are discussed below along with the other sodium channel disorders including hyperkalemic periodic paralysis (HyperPP) and paramyotonia congenita.

The myotonia congenitas are differentiated from the myotonic dystrophies by the lack of weakness in most patients and the absence of extramuscular abnormalities such as cataracts, cardiac defects, and pulmonary or endocrine dysfunction [1].

Autosomal Dominant Myotonia Congenita (Thomsen's Disease)

Onset is generally in infancy or early childhood in dominant myotonia congenita. Patients present with painless myotonia resulting in muscle stiffness (Table 53.3). *The hallmark clinical finding in myotonia congenita is stiffness that manifests when the patient attempts to initiate movement and diminishes with repeated muscle contractions. The stiffness is seen especially with a forceful muscle contraction after a period of rest* [33, 34]. Thus, patients describe a "warm-up" period during which they can work through the muscle stiffness by continued exercise. For example, the patient may find it difficult to arise from a chair after sitting for a few minutes or to climb the first few steps of a stairway. However, once movement is initiated, such as climbing the first few steps, the stiffness lessens and movement is easier. Some patients describe worsening of symptoms in the cold. Stiffness is not progressive over time, and there is no associated weakness. In fact, patients are often quite strong. Muscle hypertrophy is common, probably due to the almost constant state of muscle contraction. It is often noted in the proximal arms, thighs, calves, and facial muscles, giving rise to the characteristic "Herculean" appearance (Fig. 53.2). Grip and percussion myotonia and the lid lag phenomenon are easily elicited.

Autosomal Recessive Myotonia Congenita (Becker-Type Myotonia, Recessive Generalized Myotonia Congenita)

The autosomal recessive form of myotonia congenita is more common than the dominant form. Onset is usually later in childhood compared to the dominant form, although may rarely occur in the first 2–3 years of life (Table 53.3). As in the autosomal dominant form, stiffness is most prominent with muscle contractions after a period of rest and diminishes with further activity. Some patients describe worsening of symptoms in the cold. The stiffness typically appears initially in the lower extremities and slowly progresses over the first several years before stabilizing. Males are more severely affected than females, and stiffness may be more severe than in the dominant form, especially in the lower extremities. While weakness is not a feature of autosomal dominant myotonia congenita, minor progressive weakness and wasting of distal muscles may occur in the recessive form [35–37]. Furthermore, some patients experience transient attacks of true weakness that tend to occur after initiating a sudden movement after rest and are relieved with exercise [37, 38]. This transient weakness may be quite disabling as it is often generalized. Muscle hypertrophy is common in the legs and gluteal muscles, while the upper extremities may appear underdeveloped in contrast [30, 39]. Grip and percussion myotonia and the lid lag phenomenon are easily elicited.

Table 53.3 Clinical features of myotonic and periodic paralysis disorders

	Myotonic dystrophy, type I	Myotonical dystrophy, type II	Myotonia congenita – dominant	Myotonia congenita – recessive	Sodium channel myotonia	Paramyotonia congenita	Hyperkalemic periodic paralysis	Hypokalemic periodic paralysis, types I, II

Fig. 53.2 Muscle hypertrophy of calf muscles in myotonia congenita associated with chloride channel mutations

Etiology and Pathogenesis

In both the autosomal dominant (Thomsen's disease) and the autosomal recessive (Becker-type) forms of myotonia congenita, the primary membrane defect is *reduced chloride conductance* [40–44]. The chloride channel is formed as a polymer of one subunit, but the exact stoichiometry is unknown. In both forms of myotonia congenita, chloride conductance is reduced due to a fewer functional chloride channels in the skeletal muscle membrane. The autosomal recessive form is believed to result when both copies of the subunit are defective. The subunit mutation responsible for the recessive form of myotonia congenita produces a nonfunctional subunit that is poorly expressed. In the case of a heterozygote, the normal subunit is expressed in great excess compared with the mutant subunit so that normal chloride channels form. The mechanism for the dominant form of myotonia congenita is not well understood. A possible explanation is that the dominant mutation produces a subunit that is well expressed and which when combined with a normal subunit results in a nonfunctional channel [30, 45–48].

The reduction in chloride conductance may result in removal of a major portion of the inhibition against membrane depolarization. The chloride conductance would normally counter the depolarizing current from the T-tubules and, thereby, prevent a string of action potentials from developing after the muscle fiber has fired one or more action potentials. The interplay between chloride conductance and the T-tubules is demonstrated experimentally as follows: if chloride conductance is lowered by using a chloride channel blocking agent, such as 9-anthracene carboxylic acid, or by replacing chloride with an impermeant anion, such as methane sulfonate, then the muscle membrane becomes hyperexcitable and manifests myotonic behavior. The myotonic membrane behavior can be blocked by chemically disrupting the T-tubules. *Thus, reduced chloride conductance will produce myotonic membrane behavior only if the T-tubules are intact.*

Differential Diagnosis

The differential diagnosis of myotonia congenita is limited, including other disorders associated with myotonia as a prominent symptom. Other diseases to consider include sodium channel myotonia, paramyotonia congenita, HyperPP, the myotonic dystrophies, and rarer neurologic disorders with myotonia including Schwartz-Jampel syndrome (chondrodystrophic myotonia). Myotonia congenita can usually be distinguished from these disorders based on characteristic clinical features; distribution of myotonia; factors that provoke, worsen, or alleviate symptoms; findings on electrodiagnostic (EDX) and exercise testing; and, where appropriate, DNA testing (Tables 53.3 and 53.4).

Patients with myotonia congenita usually describe muscle stiffness present from childhood. The neurologic exam reveals diffuse easily elicited myotonia. There may be muscle hypertrophy. Physical exam should include a search for grip and percussion myotonia, eyelid myotonia, lid lag phenomenon, muscle hypertrophy, distinctive physical features, and extramuscular manifestations (e.g., frontal balding, cataracts, endocrine dysfunction). Distinguishing the dominant from recessive form of myotonia congenita may be difficult. Family history should be studied in detail to determine the mode of inheritance. Since the recessive form of myotonia congenita is more common than the dominant form, there may be no family history. In the recessive form, the stiffness may be quite prominent, and males are more severely affected than females. Patients with the recessive form may have minor progressive distal weakness, and attacks of periodic weakness brought on by movement after rest, not seen in the dominant form. The distinction between chloride and sodium channel myotonia (see below) may be difficult based on clinical grounds, but the following clues are helpful (Table 53.3). There is a characteristic worsening of symptoms with potassium ingestion in patients with sodium channel myotonia, not seen in chloride channel myotonia. Some patients with

Table 53.4 Electrodiagnostic findings in myotonic and periodic paralysis disorders

	Myotonic dystrophy, type I	Myotonia congenita – dominant	Myotonia congenita – recessive	Sodium channel myotonia	Paramyotonia congenita	Hyperkalemic periodic paralysis	Hypokalemic periodic paralysis, types I, II
Nerve conductions	Normal or ↓ distal CMAPs	Normal	Normal	Normal	Normal	Normal between attacks. ↓ CMAP amplitude during attack of weakness	Normal between attacks. ↓ CMAP amplitude during attack of weakness
EMG							
Myotonia	++ (D>P)	+++ (P and D	+++ (P and D)	+ to ++++ (P and D, depending on variant)	++ (P and D)	++ (P and D, esp, during attack)	No myotonia
MUAPs	Myopathic D	Normal	Usually NL, +/− myopathic	Normal	Normal	Myopathic late in course	Myopathic late in course
Effect of muscle cooling (20 °C) on EMG	No effect	May lead to ↑ duration of myotonic bursts, easier to elicit	No effect	No effect	1. Transient dense fibrillations that disappear below 28 °C 2. Myotonic bursts disappear below 20 °C 3. Electrical silence, long-lasting muscle contracture when cooled to 20 °C	No effect	No effect
Short exercise	1. Drop in CMAP amplitude 2. Quick recovery over 2 min 3. Drop does not persist on subsequent trials	1. Variable drop in CMAP amplitude 2. Quick recovery over 2 min	1. Large drop in CMAP amplitude 2. Quick recovery over 2 min 3. Drop persists on subsequent trials	Unknown	With muscle cooling: 1. Drop in CMAP amplitude 2. Very slow recovery over an hour	No effect or transient increase in CMAP amplitude during an attack of weakness	No effect or transient increase in CMAP amplitude during an attack of weakness
Prolonged exercise	Small decrement immediately after exercise, with recovery over 3 min	Unknown	Small decrement immediately after exercise, with recovery over 3 min	Unknown	Moderate decrement immediately after exercise, maximal at 3 min, with slow recovery over an hour	Most with initial increase in CMAP amplitude (~35 %). sodium channel myotonia display the phenomenon of *exercise-induced delayed-onset myotonia*, whereby muscle contractions induce myotonia after a period of delay. This is in contrast to the "warm-up" phenomenon seen in chloride channel myotonia congenita, whereby repeated muscle contractions alleviate the myotonia. Additionally, many patients with sodium channel myotonia have painful myotonia, not seen in chloride channel myotonia congenita. Since fluctuating symptoms were reported in some patients with chloride channel myotonia congenita [31], this is not a reliable method of distinguishing these patients from the subset of patients with sodium channel myotonia with a fluctuating course (myotonia fluctuans).

Distinguishing myotonia congenita from paramyotonia congenita may be difficult, as both conditions present with generalized stiffness, and muscle hypertrophy is common in both. Furthermore, some patients with myotonia congenita note worsening of symptoms in the cold. However, patients with paramyotonia congenita display *extreme cold sensitivity resulting in severe stiffness followed by true weakness*, features not seen in myotonia congenita. In contrast, the attacks of weakness in recessive generalized myotonia are provoked by movement after rest, rather than cold temperature. Additionally, patients with the dominant and recessive forms of myotonia congenita display a "warm-up" phenomenon whereby myotonia is relieved with repeated muscle contractions, in contrast to the *worsening* of symptoms with repeated muscle contractions noted in paramyotonia congenita.

Patients with recessive generalized myotonia who experience periodic weakness may be confused with the subgroup of patients with HyperPP and myotonia. However, exercise testing can be helpful in this regard. With short exercise testing (see below), patients with myotonia congenita show a drop in the compound muscle action potential (CMAP) amplitude with a quick recovery, not seen in periodic paralysis. In contrast, with prolonged exercise testing, patients with periodic paralysis show a progressive decline in the CMAP amplitude over 20–40 min, which is not seen in myotonia congenita (see below).

Hypokalemic periodic paralysis (HypoPP) and Andersen-Tawil syndrome (ATS), both of which are associated with periodic weakness, should be considered in the differential diagnosis of patients with recessive generalized myotonia and attacks of weakness. However, both disorders can usually be eliminated from consideration based on the lack of myotonia on physical examination and the lack of myotonic discharges on needle electromyography (EMG). Furthermore, patients with ATS have distinctive facial and skeletal features and a prolonged QT interval on electrocardiogram (EKG), not seen in myotonia congenita (see below).

The myotonic dystrophies should be considered in the differential diagnosis of myotonia congenita (see Chap. 59). However, these disorders can usually be eliminated based on the history and physical examination, looking for extramuscular manifestations such as early cataracts, cardiac conduction and pulmonary defects, endocrine dysfunction, hypersomnia, and in some patients mild to moderate cognitive impairment (Table 53.3). Furthermore, the myotonic dystrophies are associated with a progressive myopathy, not seen in myotonia congenita, except for those patients with recessive generalized myotonia and mild distal weakness. Some patients with myotonic dystrophy type I have only a small expansion of the cytosine-thymine-guanine (CTG) trinucleotide repeat associated with the disorder and thus only minor distal weakness and subtle extramuscular manifestations at the time of presentation. In such patients, the diagnosis may be unclear, and DNA testing for myotonic dystrophy type I is warranted. It is important to distinguish the myotonic dystrophies from myotonia congenita since the extramuscular manifestations have important implications for management and treatment. Myotonia congenita is easily distinguished from Schwartz-Jampel syndrome by the characteristic facial and skeletal features associated with Schwartz-Jampel syndrome (see below).

Myotonic discharges, seen on EDX testing, occur in various metabolic, inflammatory, and congenital myopathies (Table 53.5 III). These disorders can usually be easily distinguished from myotonia congenita by their associated proximal weakness and lack of clinical myotonia (grip, percussion, or lid lag). Some drugs can precipitate or unmask electrical myotonia (Table 53.5 IV) and should be questioned, especially if onset of symptoms is later than childhood, there is no family history of myotonia, and muscle hypertrophy and other typical features of myotonia congenita are not present.

Diagnosis and Evaluation

Electrodiagnostic Testing (Table 53.4)

EDX findings in several of the disorders of muscle membrane excitability are noted in Table 53.4. In myotonia congenita, routine motor and sensory nerve conduction studies are normal. Needle EMG generally shows widespread myotonic discharges that are easily elicited with minimal needle movement or muscle contraction in proximal and distal muscles. In the dominant form, the motor unit action potentials (MUAPs) and recruitment pattern are normal. In the recessive form, the MUAPs may be small, short, and polyphasic with early recruitment in distal muscles, consistent with a mild myopathy.

Muscle Cooling

The responses to muscle cooling and the short exercise test can differentiate myotonia congenita from paramyotonia congenita [50, 51]. Muscle cooling is best accomplished by wrapping the limb in a plastic bag and submerging it in ice water

Table 53.5 Classification of myotonic and periodic paralysis disorders

I. Inherited myotonic muscle/periodic paralysis disorders
A. Dystrophic myotonic myopathies
Myotonic dystrophies, types I and I
B. Non-dystrophic myotonic myopathies
Autosomal dominant myotonia congenita (Thomsen's disease)
Autosomal recessive myotonia congenita (Becker-type myotonia)
Paramyotonia congenita (Eulenburg disease)
Sodium channel myotonia
C. Hyperkalemic periodic paralysis (+/– myotonia)
D. Hypokalemic periodic paralysis, types I and II
E. Andersen's syndrome (periodic paralysis with cardiac arrhythmias)
II. Acquired periodic paralysis disorders
A. Secondary hyperkalemic periodic paralysis (may be associated with myotonia)
May be seen in association with:
Renal failure
Adrenal failure
Hypoaldosteronism
Metabolic acidosis
Potassium-sparing diuretics
B. Secondary hypokalemic periodic paralysis (not associated with myotonia)
May be seen in association with:
Thyrotoxicosis – especially in Asian adults
Primary hyperaldosteronism (Conn's syndrome)
Bartter's syndrome
Potassium-depleting diuretics
Inadequate potassium intake
Excessive potassium loss through sweat
Gastrointestinal or renal potassium wasting
Chronic licorice ingestion
Steroid use
Alcoholism
Lithium
III. Muscle disorders associated with myotonic discharges on needle EMG
A. Metabolic – acid maltase deficiency
B. Inflammatory – polymyositis
C. Congenital – myotubular myopathy
D. Associated with systemic disorders – malignant hyperpyrexia
IV. Drugs that unmask or precipitate clinical myotonia or myotonic discharges on needle EMG
Propranolol
Fenoterol
Terbutaline
Colchicine
Penicillamine
Cyclosporin
Clofibrate
HMG-CoA reductase inhibitors (lipid-lowering agents)

Adapted from Preston and Shapiro [32]

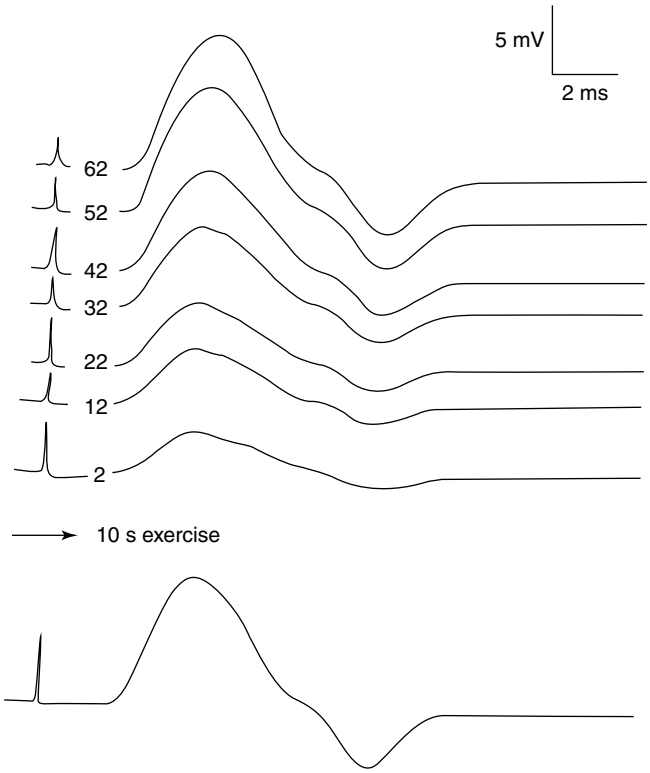

Fig. 53.3 Short exercise testing in the myotonias

for 10–20 min. After the skin temperature is lowered to 20 °C, needle EMG of the extremity is repeated. In dominant myotonia congenita, muscle cooling to 20 °C may produce myotonic bursts that are longer in duration and more easily elicited than at room temperature. In paramyotonia congenita, muscle cooling to 20 °C produces electrical silence as the muscle goes into a prolonged contracture, which is pathognomonic for paramyotonia congenita (Table 53.4).

Short Exercise Test

To perform the short exercise test [1], a routine distal CMAP is evoked with supramaximal stimulation (e.g., stimulating the ulnar nerve at the wrist, recording the abductor digiti minimi). The nerve is then stimulated at 1-min intervals for several minutes to ensure a stable baseline. The patient is then asked to perform maximal voluntary contraction for 5–10 s. Immediately afterwards, a CMAP is evoked. If a decrement in amplitude is seen, a CMAP is then recorded every 10 s until the CMAP recovers to baseline (typically 1–2 min) (Fig. 53.3). If a decrement occurs after brief exercise and then recovers, the same procedure is repeated several times to see if the decrement continues to occur or habituates to help differentiate among the myotonic syndromes [1].

In chloride channel myotonia congenita, the short exercise test produces a drop in CMAP amplitude immediately follow-

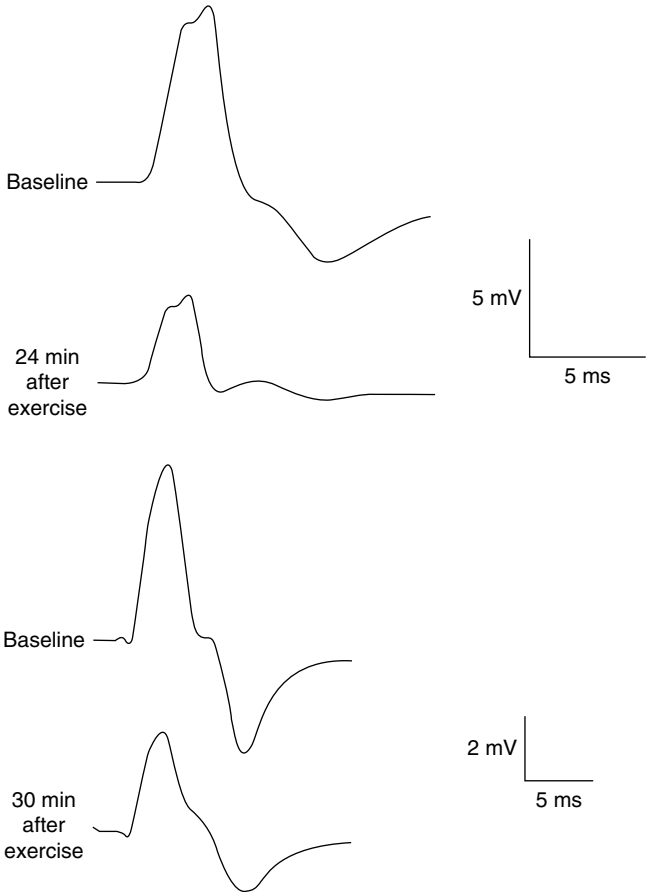

Fig. 53.4 Prolonged exercise test in periodic paralysis

ing exercise, which recovers over 1–2 min with repeated recording of the CMAP every 10 s. In the recessive form of myotonia congenita, the initial drop in amplitude is often profound and is more likely to continue to show an initial decremental response on repeated trials of the short exercise test [1]. This is unlike paramyotonia congenita, where a decremental response occurs that recovers very slowly over many minutes, if the short exercise test is done when the muscle is cooled (Table 53.4).

The responses to the short exercise test can also differentiate recessive myotonia congenita, where weakness may be present, from myotonic dystrophy type I. The short exercise test in myotonic dystrophy type I produces a drop in the CMAP amplitude immediately after exercise, which recovers to baseline over 2 min. If short exercise is then repeated, the decremental response habituates after one or two cycles. In recessive myotonia congenita, the decremental response does not habituate over repeated trials (Table 53.4) [1].

Prolonged Exercise Test

The prolonged exercise test helps distinguish recessive myotonia congenita, where periodic weakness may be present, from the periodic paralyses [1, 52, 53]. The recording procedure is the same as for the short exercise test. However, for the prolonged exercise test, after ensuring a stable baseline, the patient is asked to voluntarily contract their muscle maximally for 3–5 min, resting for a few seconds every 15 s. After the 5 min of exercise are over, the patient relaxes completely. A CMAP is evoked immediately and then every 1–2 min for the next 40–60 min. No decline of the CMAP is seen in myotonia congenita. In contrast, in the periodic paralysis syndromes, the CMAP amplitude may be unchanged or slightly larger immediately after prolonged exercise and then declines substantially over the next 20–40 min (Fig. 53.4).

Laboratory Testing

Serum creatine kinase (CK) level in the dominant form of myotonia congenita may be slightly elevated and in the recessive form, moderately elevated. Muscle biopsy in myotonia congenita may show a lack of type IIB fibers [54].

Treatment and Management

The choice of treatment depends on whether symptoms require daily versus intermittent treatment and on the side effect profile of the various medications. Some patients with minor complaints may need no treatment at all and learn to accommodate their activities and lifestyle to reduce symptoms. When treatment of myotonic stiffness is required, medications that stabilize the muscle membrane are most effective. The mainstay of treatment is the lidocaine derivative mexiletine, beginning at 150 mg bid by mouth and increasing slowly as needed up to 300 mg tid by mouth [55, 56]. The most common potential side effects include gastrointestinal distress, lightheadedness, and tremor which are reversible with dose reduction. Rash has been reported. Although tocainide, another lidocaine derivative, is useful in reducing myotonia in some patients at a dose of 400–1,200 mg a day, who may not respond to mexiletine, it should be used with extreme caution because of the potential for bone marrow suppression [57]. Alternatively, procainamide or quinine can be used and may be used intermittently as needed. Phenytoin 300–400 mg a day by mouth is often effective and can be used on a daily basis with few side effects [34].

Less commonly used medications include dantrolene, which has shown benefit in some severe cases [55, 58]. However, fatal and nonfatal hepatotoxicity have been reported, and the risk-benefit ratio must be weighed on an individual basis. Liver function studies must be measured at baseline and at appropriate intervals during therapy. Dantrolene must be discontinued if abnormal values are obtained. Acetazolamide is also beneficial in some

patients [59]. Doses generally begin at 125 mg by mouth twice a day, slowly increasing to 250 mg by mouth three times a day, as required and as tolerated by the patient. Common side effects include nausea, anorexia, and paresthesias, and patients must be warned about the formation of kidney stones [60]. Rash has been reported, and liver function studies and blood count should be monitored. As with other myotonic disorders, care must be taken with the use of depolarizing muscle relaxants during anesthesia, which aggravate myotonia and may cause adverse anesthesia-related events.

Prognosis

Patients with chloride channel myotonia congenita have a normal life span. As noted above, autosomal recessive myotonia congenita may be associated with minor progressive weakness and wasting of distal muscles. Rare patients experience disabling progressive weakness. Transient attacks of weakness experienced by some patients with recessive myotonia congenita may be disabling as it is often generalized. These tend to occur after initiating a sudden movement after a period of rest, and patients learn to avoid precipitating factors.

Sodium Channel Disorders: Sodium Channel Myotonia (Potassium-Aggravated Myotonia), Paramyotonia Congenita (Eulenburg Disease), and Hyperkalemic Periodic Paralysis

Patients with skeletal muscle sodium channel disorders present with a variety of symptoms including myotonia, stiffness, pain, and weakness. Those with sodium channel myotonia experience painful stiffness and spasms secondary to myotonia but do not experience true weakness. There may be day to day variation in the severity of myotonia, and symptoms are worsened or provoked by potassium [39]. In contrast, patients with paramyotonia congenita and HyperPP experience periodic weakness, and symptoms are worsened or provoked by the cold. Those with paramyotonia congenita and some patients with HyperPP experience stiffness secondary to myotonia. Sodium channel mutations involving the positively charged arginines in S4 segments of the sodium channel can produce a phenotype of hypokalemic periodic paralysis (HypoPP) [5, 8, 61], which is described below along with the more frequently seen form of HypoPP associated with calcium channel mutations that are substitutions of uncharged amino acids for positively charged arginines in S4 segments [62–64]. The mechanisms underlying these phenotypic differences are discussed below. There is not a strict relationship of the sodium channel mutation to the phenotype. For example, within a given family, some members may manifest only myotonia and others myotonia and paramyotonia or HyperPP [39].

The phenotypic variations associated with many mutations suggest that several as yet unrecognized factors may modify the phenotype. Only a few families with HyperPP without myotonia have been studied. Consequently, the single-channel defects associated with this phenotype are not known. There are some alterations in single sodium channel behavior that can predict the phenotype. Impaired sodium channel slow inactivation is usually associated with HyperPP [39, 65–68], while impaired deactivation has only been associated with paramyotonia and myotonia [69].

Sodium Channel Myotonia (Potassium-Aggravated Myotonia)

Introduction and Clinical Presentation

Several variants of sodium channel myotonia, also referred to as potassium-aggravated myotonia, have been described. These variants include *myotonia fluctuans*, *myotonia permanens*, and *acetazolamide-responsive myotonia* [70–72]. They are all associated with mutations in the α-subunit of the human skeletal muscle voltage-gated sodium channel gene (SCN4A) on chromosome 17q23 and inherited in an autosomal dominant fashion. Like recessive generalized myotonia, sodium channel myotonia is much more common than Thomsen's myotonia congenita [73].

Patients present in childhood or adolescence with episodes of generalized stiffness secondary to myotonia. Distinguishing features include painful myotonia which is quite potassium sensitive, with worsening of symptoms induced by potassium ingestion (Table 53.3), hence the designation "potassium-aggravated myotonia." Patients do not experience true episodic weakness, and in most patients, there is no worsening of symptoms with cold. There is considerable overlap in the clinical presentations of the different variants of sodium channel myotonia discussed below.

Myotonia Fluctuans

Patients present in adolescence with muscle stiffness that fluctuates in frequency and severity, sometimes not occurring for days or weeks [72]. The myotonia may be painful and has a peculiar feature of being *exercise induced and delayed in onset,* i.e., the myotonia is exercise induced but with a delay in onset for several minutes after exercise [74, 75]. This is not to be confused with *paramyotonia*, where myotonia occurs immediately after exercise (see below). The myotonia is worsened by the intake of potassium but not by the cold.

The fluctuating myotonia is such that on some days, patients experience no stiffness at all, while on other days myotonic stiffness of the bulbofacial, extraocular, or distal hand muscles may incapacitate a patient [74, 75]. On examination, patients may have well-developed musculature but without hypertrophy. Percussion and grip myotonia, and lid lag phenomenon may be present. There is no weakness.

Myotonia Permanens

In myotonia permanens, patients present in childhood with severe and unremitting generalized myotonia, hence the term *myotonia permanens*. Examination reveals marked hypertrophy of the neck and shoulders. Worsening of symptoms with potassium intake may be very severe and may affect thoracic muscles, resulting in hypoventilation, cyanosis, and loss of consciousness, which can be life-threatening [76]. To date, all reported cases have been de novo mutations [72, 76].

Acetazolamide-Responsive Myotonia

In the acetazolamide-responsive variant, also known as *atypical myotonia congenita*, patients experience intermittent painful myotonia beginning in childhood [77]. The myotonia has a predilection for axial and proximal limb musculature. The painful stiffness may be so marked at times that it results in severe disabling spasms and acute lumbar scoliosis [33], while on other days symptoms are barely present. Symptoms are provoked or worsened by fasting, infection, and intake of potassium. Cold temperature may worsen the myotonia but does not induce paralysis. Symptoms are markedly reduced with acetazolamide, although mexiletine is also effective. As with the other sodium channel myotonias, there is no periodic weakness. Percussion and grip myotonia are noted on neurologic examination [70, 71, 77].

Etiology and Pathogenesis

To better understand how the sodium channel mutations produce myotonia, the structure of the skeletal muscle voltage-gated sodium channel is reviewed (Fig. 53.5). The sodium channel from mammalian skeletal muscle is a glycopeptide composed of a large 260 kDa α-subunit and a smaller β-subunit [78, 79]. The gene (SCN4A) encoding the adult isoform of the sodium channel α-subunit of skeletal muscle (SKM1 or μ-1) which is sensitive to tetrodotoxin (TTX) is located on chromosome 17q in humans. The gene for the fetal isoform of the human α-subunit (SKM2), which is insensitive to TTX and is also expressed in denervated muscle fibers, is located on chromosome 3. The human and rat α-subunits contain 1,836 amino acids. The α-subunit contains 4 internally homologous repeating domains. Within each domain, a stereotypic pattern of 6 relatively hydrophobic segments exists, which theoretical models predict may form from 6 to 8 membrane-spanning

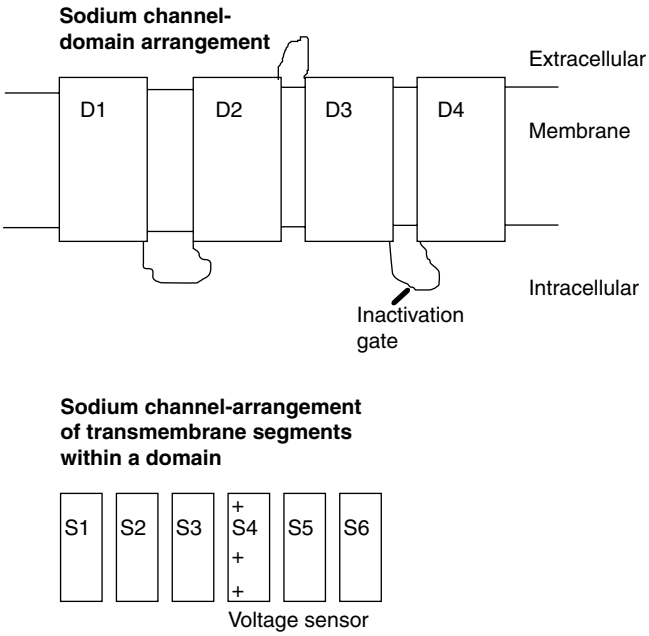

Fig. 53.5 Schematic of the structure of the sodium channel

alpha helices. Each of the 4 domains of the α-subunit contains a positively charged S4 segment which may function as a voltage sensor. Changing the net charges in the S4 segments alters the sodium channel activation-voltage relationship.

The channel pore is guarded by intra- and extracellular charged vestibules. Altering amino acids within the putative vestibules or changing amino acids within the pore itself can alter sensitivity to TTX or change the permeability characteristics of the channel [80].

The intracellular peptide between domains 3 and 4 of the sodium channel α-subunit is associated with fast inactivation and has been postulated to be part of the "ball and chain" that binds to the intracellular channel orifice and blocks current flow [78, 79]. Antibodies specific for, or disruption of, the intracellular peptide between domains 3 and 4 caused a reduction in the rate of fast inactivation without appreciably changing activation.

Fast inactivation can be disrupted in several different ways to produce myotonia

1. The voltage dependence of fast inactivation can be shifted (alone or along with the voltage dependence of activation) so that a voltage range exists over which channels can be opened and not develop fast inactivation. In the range of membrane potentials over which activation occurs with incomplete fast inactivation, persistent sodium currents can develop. Such sodium currents are often referred to as window currents, because they develop within a window of membrane potential values.
2. The development of fast inactivation can be inhibited so that many mutated channels do not enter the fast inactivated state in response to membrane depolarization.

3. Mutated sodium channels can develop a gating pattern (referred to as modal gating) in which the channels repeatedly jump between the open state and the inactivated state without having the channel persistently close.
4. Channels can recover from the fast inactivated state very quickly so that the channels rapidly transit from the inactivated state to the excitable closed state during membrane repolarization.

The first three types of disruption result in an inward sodium current that will augment the depolarizing effect of potassium accumulation in the T-tubules and result in sufficient membrane depolarization to trigger repeated action potentials. The fourth type of disruption greatly shortens the absolute and relative refractory periods allowing repeated action potentials to fire at high frequency. Many mutations result in a combination of these disruptions [39, 78, 79].

For a given site in the sodium channel protein, the severity of functional alteration of inactivation may relate to the amino acid that was substituted by the mutation. Amino acids with larger side chains such as valine or tryptophan may interfere with conformation changes to a greater extent than smaller amino acids such as glycine or alanine. Hence, altered behavior such as impaired ability to enter the fast inactivated state or instability of the fast inactivated state may be more pronounced when a larger amino acid substitutes for the native amino acid [39].

Differential Diagnosis

The differential diagnosis of sodium channel myotonia is limited and similar to that of chloride channel myotonia congenita. Disorders that should be considered include myotonia congenita associated with chloride channel mutations, paramyotonia congenita, the myotonic dystrophies, and Schwartz-Jampel syndrome. Precipitating or relieving factors, distribution of myotonia, the presence of extramuscular findings, distinctive facial or skeletal features, and findings on EDX and exercise testing are useful in distinguishing among these disorders (Tables 53.3 and 53.4).

The distinction between sodium and chloride channel myotonia can usually be made based on the characteristic worsening of myotonia with potassium ingestion in patients with sodium channel myotonia. Additionally, the myotonia in sodium channel myotonia is painful, unlike chloride channel myotonia. While fluctuating symptoms are characteristic of myotonia fluctuans and acetazolamide-responsive myotonia, fluctuating symptoms were also reported in patients with myotonia congenita associated with chloride channel mutations [31] and cannot necessarily be used to distinguish these disorders. Patients with myotonia fluctuans display the characteristic phenomenon of exercise-induced, delayed-onset myotonia, not seen in myotonia congenita associated with chloride channel mutations. The marked relief of symptoms with acetazolamide in patients with acetazolamide-responsive myotonia helps differentiate these patients.

Patients with sodium channel myotonia and paramyotonia congenita experience generalized stiffness and worsening of symptoms in the cold. However, patients with paramyotonia congenita display *extreme cold sensitivity resulting in true weakness*, not seen in sodium channel myotonia. Additionally, the exercise-induced, *delayed-onset* myotonia noted in myotonia fluctuans differs from the *immediate* worsening of myotonia with exercise noted in patients with paramyotonia congenita (see below). Patients with sodium channel myotonia do not experience periodic weakness and are therefore unlikely to be confused with any of the periodic paralyses.

Patients with sodium channel myotonia congenita lack the characteristic facial and skeletal features seen in Schwartz-Jampel (see below). The myotonic dystrophies can also be excluded because of their association with extramuscular manifestations (frontal balding, early cataracts, cardiac conduction and pulmonary defects, endocrine dysfunction, hypersomnia, and in some patients mild to moderate cognitive impairment). Additionally, patients with dystrophic disorders develop a progressive myopathy, not seen in sodium channel myotonia.

Various metabolic, inflammatory, and congenital myopathies may be associated with myotonic discharges on needle EMG (Table 53.5 III). These can usually be easily distinguished from sodium channel myotonia by associated features such as proximal weakness and lack of generalized myotonia. Certain drugs can precipitate or unmask electrical myotonia (Table 53.5 IV) and should be questioned, especially if onset of symptoms is later than childhood, there is no family history of myotonia, and painful myotonia and potassium sensitivity, typical features of sodium channel myotonia, are absent.

Diagnosis and Evaluation

Electrodiagnostic Testing (Table 53.4)

On EDX testing, routine motor and sensory nerve conduction studies are normal. Needle EMG examination generally shows myotonic discharges which are elicited in proximal and distal muscles. In myotonia permanens, the myotonic discharges are continuous. In contrast, in myotonia fluctuans and acetazolamide-responsive myotonia, the degree of myotonic discharges varies depending on the patient's symptoms. The MUAPs are normal in amplitude and duration with normal recruitment. In contrast to paramyotonia congenita, muscle cooling does not induce electrical silence with contracture [81]. In one family with the acetazolamide-responsive variant, there was no decrease in the CMAP amplitude with

cooling, as seen in paramyotonia congenita [70]. However, in another family with sodium channel myotonia, a decrease in CMAP amplitude was noted during motor conduction testing when the limb was cooled [81].

Short and prolonged exercise testing are not well studied in the sodium channel myotonias. Short exercise testing in one patient produced no decrement in CMAP amplitude at room temperature but a 10 % decrement after potassium administration and cooling of the limb [81].

Laboratory Testing

Serum CK level may be normal or slightly elevated. Muscle biopsy may be normal or show generalized fiber hypertrophy in the acetazolamide-responsive variant [77].

Treatment and Management

Symptomatic treatment with acetazolamide, especially in those patients with acetazolamide-responsive myotonia, helps reduce stiffness and pain. Doses generally begin at 125 mg by mouth twice a day, slowly increasing to 250 mg by mouth three times a day, as required and as tolerated by the patient. Common side effects include nausea, anorexia, and paresthesias, and patients must be warned about the formation of kidney stones [60]. Rash has been reported. Liver function studies and blood count should be monitored. Membrane-stabilizing agents including mexiletine and tocainide are also helpful. Mexiletine is especially helpful in patients with myotonia fluctuans, starting at 150 mg bid by mouth, increasing slowly as needed up to 300 mg tid by mouth [55, 56]. Common side effects include gastrointestinal distress, lightheadedness, and tremor which are reversible with dose reduction. Rash has been reported. Muscle relaxants may be helpful and necessary if the stiffness is severe, as in some patients with acetazolamide-responsive myotonia. Nonsteroidal anti-inflammatory medications are helpful adjuncts in reducing severe muscle pain in some patients.

General anesthesia may produce worsening of stiffness and myotonia, even in patients with normal contracture testing for malignant hyperthermia. Care must be taken with the use of depolarizing muscle relaxants during anesthesia, which aggravate myotonia and may cause adverse anesthesia-related events, especially in patients with myotonia fluctuans [82].

Prognosis

Patients in general have a normal life span. Those with continuous myotonic stiffness or severe spasms can be quite disabled, especially patients with myotonia permanens who experience severe stiffness of thoracic muscles resulting in hypoventilation. Some patients can learn to avoid triggering factors such as fasting, intake of potassium, and in some cases cold temperature.

Paramyotonia Congenita (Eulenburg Disease)

Introduction and Clinical Presentation

Paramyotonia congenita is an autosomal dominant inherited disorder that was first described by Eulenburg in 1886 [83]. The disorder arises from mutations in the α-subunit of the human skeletal muscle voltage-gated sodium channel gene (SCN4A) on chromosome 17q23, with complete penetrance in both sexes. In *paramyotonia*, muscle stiffness is brought on by repeated muscle contractions or exercise and is extremely cold sensitive. This is in contrast to *myotonia* where a warm-up period of repeated muscle contractions alleviates the muscle stiffness. Thus, the designation paradoxical, myotonia, or "*paramyotonia*."

Patients with paramyotonia congenita present in infancy with muscle stiffness primarily affecting bulbofacial, neck, and hand muscles. The stiffness is brought on by repeated muscle contractions (exercise) and worsened by exposure to cold, especially during repeated muscle contractions (Table 53.3). Indeed, parents often note the first signs of muscle stiffness in their infants when they observe prolonged eye closure after crying, or when they sleep near a fan with cool air blowing on them, or when they wash the infant's face with cool water. In most patients, cold induces attacks of stiffness followed by true weakness, especially during prolonged exercise in cold temperatures. Despite warming, it may take hours to regain strength. Patients learn to avoid those situations that trigger myotonia, such as eating ice cream or drinking a cold drink. Similar to patients with myotonia congenita, patients are often very muscular. Grip and percussion myotonia and the lid lag phenomenon are easily demonstrated on examination [39].

Paramyotonia congenita has appreciable overlap with sodium channel myotonia and HyperPP. Different mutations are associated with different presentations that may include periodic weakness or stiffness not precipitated by cold. For example, in one variant, patients experience spontaneous attacks of flaccid weakness resembling HyperPP (hyperkalemic periodic paralysis with paramyotonia), which can be provoked by potassium loading but is unprovoked by cold or exercise. Attacks of weakness appear during the teen years. Patients eventually develop fixed weakness between attacks [39, 84, 85]. In another variant, exercise-induced stiffness is not provoked by cold and may occur at room temperature, which is quite disabling. The clinical presentations of affected family members, with the same mutation, may also vary.

Etiology and Pathogenesis

Paramyotonia congenita is an autosomal dominant disorder of skeletal muscle membrane excitability [78, 79, 86]. It overlaps clinically with HyperPP and is associated with mutations of the sodium channel gene, SCN4A. While patients with paramyotonia congenita may have myotonia at normal temperature, they differ from myotonia congenita patients in three ways: (1) in paramyotonia, the myotonia is aggravated or elicited by cooling, (2) cold-induced weakness follows myotonia, and (3) there is worsening of myotonia by exercise (paradoxical myotonia). As stated above, paramyotonia refers to the development of muscle stiffness when a muscle is cooled. Paramyotonia results from repeated action potentials in muscle fibers. The distinction between myotonia and paramyotonia is not precise, and the two conditions overlap. For example, patients with paramyotonia congenita usually have myotonia when studied in a warm environment, and patients with myotonia often note that their muscle stiffness is more severe in a cold environment.

Paramyotonia usually results from sodium channel mutations that alter fast inactivation [78, 79]. *Consequently, paramyotonia congenita joins sodium channel myotonia and HyperPP as a sodium channelopathy* [87]. Muscle biopsies from paramyotonia congenita patients demonstrate normal membrane properties at 37 °C, but cooling to 27 °C triggers depolarization to about −40 mV. A pathological persistent inward sodium current causes the depolarization [78, 79, 86, 88]. Single-channel studies of mutant sodium channels usually demonstrate alterations in fast inactivation. *The defects in sodium channel gating present in most sodium channel mutations associated with paramyotonia are similar to those that produce myotonia*. However, physiological studies of sodium channel mutations that are associated with paramyotonia do not explain why the pathological persistent sodium current and paralysis are elicited by cooling.

One suggestion for the paramyotonia congenita mutations is that mutant channels can directly transit from the fast inactivated state to the open state, thereby enabling a fraction of channels to be open at depolarized potentials [88]. However, the hypothesis that depolarized mutant channels would transit between fast inactivated and open channel states does not consider that unless slow inactivation is perturbed, depolarized mutant channels would accumulate in the slow inactivated state, which would terminate the pathological sodium current. Two mutations associated with paramyotonia congenita have gating abnormalities that are distinct from those found in mutations associated with HyperPP or sodium channel myotonia [89, 90]. *One paramyotonia congenita mutation has impaired deactivation in addition to impaired inactivation* [89]. Deactivation refers to the conformation change of channels changing from the open state to the closed state when the membrane is hyperpolarized. Impaired deactivation coupled with impaired inactivation results in many mutant channels remaining open as the membrane repolarizes during the falling phase of the action potential. The open mutant channels provide a depolarizing current that triggers a chain of action potentials. *The second mutation does not affect fast inactivation and is speculated to alter slow inactivation* [90]. Plassart-Schiess et al. [90] found that fast inactivation was not appreciably altered by the Ile 693 Thr mutation, which was associated with the clinical manifestation of cold-induced weakness with myotonia. They suggested that the cold-induced weakness might result from altered slow inactivation.

Study of mutant channels has not elucidated how reducing temperature increases membrane excitability in paramyotonia congenita. One of the practical problems is that it is difficult to perform electrical recordings from single cells at physiological temperatures. Most physiological studies are performed at room temperature (20 °C or 68 °F). Consequently, a difference in sodium channel gating associated with cooling from a physiological to a subphysiological temperature would not be detected.

Possible Role of Slow Inactivation in Paramyotonia

Alteration in the temperature dependence of slow inactivation of sodium channels could result in increased membrane excitability at reduced temperatures. Skeletal muscle membrane excitability is a complex interplay of sodium, potassium, and chloride conductances. At a physiological temperature of 37 °C, most skeletal muscle sodium channels are excitable at the resting potential because most channels are in the closed state. At lower temperatures, the voltage dependence of slow inactivation shifts so that more than half of the channels of fast twitch skeletal muscle fibers are in the slow inactivated state at 19 °C [12, 91]. In contrast, the voltage dependence of fast inactivation and sodium channel opening have much less temperature sensitivity. Reducing the population of excitable sodium channels at lower temperature may help to prevent membrane hyperexcitability. At 37 °C, the kinetics of mammalian skeletal muscle delayed rectifier potassium channels are sufficiently fast to assist in terminating the action potential [92]. In contrast, at 23 °C mammalian skeletal muscle delayed rectifier potassium channels open too slowly compared to sodium channels to affect action potential termination [17]. Consequently, reducing the numbers of excitable sodium channels at lower temperatures may compensate for the slower opening of delayed rectifier potassium channels and allow the muscle membrane to maintain an appropriate level of excitability.

A reduction in the effect of temperature on the voltage dependence of slow inactivation would prevent depolarized

mutant channels from entering the slow inactivated state at reduced temperatures. Normal sodium channels are more susceptible to slow inactivation with cooling, which would facilitate the ability of a pathological persistent sodium current produced by the mutant channels to render the membrane inexcitable due to inactivation of the normal sodium channels. The pathological depolarizing current would initially trigger a string of action potentials, cold-induced myotonia. As the normal sodium channels accumulated in inactivated states, the membrane would become inexcitable producing clinical weakness. Consequently, a pathological depolarizing current could produce myotonia followed by paralysis. The theme of a pathological current producing myotonia followed by paralysis is echoed in the discussion of HyperPP. Richmond et al. [93] suggested mutations associated with weakness in addition to myotonia may have altered slow inactivation that allows a paralyzing persistent sodium current to exist.

Differential Diagnosis

The differential diagnosis of paramyotonia congenita comprises a small group of diseases with prominent myotonia. These include myotonia congenita associated with chloride channel mutations, sodium channel myotonia, HyperPP, the myotonic dystrophies, and Schwartz-Jampel syndrome. Paramyotonia congenita can usually be distinguished from these disorders based on characteristic clinical features including *the extreme cold sensitivity resulting in stiffness followed by true weakness*, as well as the phenomenon of *worsening of symptoms with repeated muscle contractions* (Table 53.3). Family history, distribution of myotonia, and pathognomonic findings on needle EMG with muscle cooling and exercise testing are also helpful.

The distinction between paramyotonia congenita and chloride channel myotonia congenita may be somewhat difficult, since generalized stiffness and muscle hypertrophy are common to both disorders. Furthermore, some patients with myotonia congenita may note worsening of symptoms in the cold. However, patients with paramyotonia congenita display *extreme cold sensitivity resulting in true weakness*, while those with myotonia congenita associated with chloride channel mutations rarely experience weakness. Furthermore, in paramyotonia congenita there is *worsening of symptoms with repeated muscle contractions*, in contrast to the "warm-up" phenomenon noted in chloride channel myotonia congenita.

In sodium channel myotonia and a subset of patients with paramyotonia congenita, potassium ingestion may worsen symptoms; however, patients with sodium channel myotonia do not experience weakness as in paramyotonia congenita.

Patients with paramyotonia congenita who experience attacks of weakness unprovoked by cold or exercise are clinically indistinguishable from the subset of patients with HyperPP and clinical myotonia including those with HyperPP with paramyotonia. With muscle cooling, most patients with paramyotonia congenita show a characteristic finding of paralysis of the cooled limb, accompanied by electrical silence with contracture at 20 °C, not seen in periodic paralysis (Table 53.4) [1, 50, 51]. However, it is not clear whether this finding is also seen in the subset of patients with paramyotonia congenita who develop attacks of weakness unprovoked by cold.

Paramyotonia congenita can be distinguished from patients with ATS, who experience periodic paralysis, and Schwartz-Jampel syndrome, where myotonia is prominent, by the lack of characteristic facial and skeletal features associated with these two disorders (see below). Furthermore, ATS is not associated with myotonia. Paramyotonia congenita can be differentiated from the myotonic dystrophies by their extramuscular manifestations and progressive weakness, not seen in paramyotonia congenita. In fact, patients with paramyotonia congenita are often quite muscular and strong.

Various metabolic, inflammatory, and congenital myopathies associated with myotonic discharges on EMG are noted in Table 53.5 III. These can be easily distinguished from paramyotonia congenita by associated features including proximal weakness and lack of generalized myotonia. Drugs that precipitate or unmask electrical myotonia (Table 53.5 IV) should also be questioned, especially if onset of symptoms is later than childhood, there is no family history of myotonia, and muscle hypertrophy and other typical features of paramyotonia congenita are not present.

Diagnosis and Evaluation

EDX Testing (Table 53.4)

Routine motor and sensory nerve conduction studies are normal. Needle EMG generally shows easily elicited myotonic discharges in proximal and distal muscles, although not as easily elicited as in the myotonia congenitas. The myotonic discharges may be more prominent in distal muscles. The MUAPs are normal in amplitude and duration with a normal pattern of recruitment.

Muscle Cooling

Muscle cooling to 20 °C may have a profound effect on the needle EMG, which is pathognomonic for paramyotonia congenita. Transient dense fibrillation potentials appear with cooling which eventually disappear below 28 °C. As the muscle cools down further, the myotonic discharges completely disappear below 20 °C, giving way to muscle paralysis. At this point, the muscle is inexcitable to electrical or mechanical stimulation and goes into a long-lasting

electrically silent contracture. This state may last over an hour after the muscle is warmed to room temperature [1].

Short Exercise Test

If the short exercise test is performed with the muscle cooled, there is a drop in CMAP amplitude, with a marked delay in recovery to the baseline CMAP amplitude with repeated recording of the CMAP up to an hour [1]. This is unlike the myotonic dystrophy type I or the chloride channel myotonia congenitas, where short exercise produces a drop in CMAP amplitude that rapidly recovers to baseline over a minute or two (Fig. 53.3).

Laboratory Testing

Serum CK level is often mildly to moderately elevated. Potassium level during attacks of weakness may be low, normal, or elevated, depending on the phenotype. In patients with cold-induced weakness, the potassium level is usually low or normal. In those with periodic weakness that is not temperature related (HyperPP with paramyotonia), the potassium level may be elevated, and attacks may be provoked by potassium ingestion. It is important to make this distinction through careful questioning of what factors induce weakness, as well as measuring the potassium level during weakness, since this may have important implications for treatment, discussed below.

Treatment and Management

Many patients with paramyotonia congenita do not require daily treatment, as they learn to avoid situations such as exposure to the cold, especially during exercise, that provoke symptoms of stiffness and weakness. For patients who require treatment, the lidocaine derivative mexiletine is helpful in preventing or alleviating stiffness and weakness induced by cold, as well as the periodic weakness experienced by some patients [94]. Doses beginning at 150 mg bid by mouth are used, increasing slowly as needed up to 300 mg tid by mouth. Common potential side effects include gastrointestinal distress, lightheadedness, and tremor which reverse with dose reduction. Rash has been reported.

Patients with spontaneous attacks of periodic weakness that are not related to temperature usually require treatment and may benefit from a combination of mexiletine with hydrochlorothiazide (HCTZ). The mexiletine is used to reduce the cold-induced stiffness, and the HCTZ is used to prevent spontaneous attacks of weakness not precipitated by cold or exercise, presumably by lowering the potassium level [95, 96]. Tocainide can reduce stiffness and weakness in some patients with paramyotonia congenita, at doses of 400–1,200 mg a day [1, 97]. However, it should be used only with extreme caution because of the potential for bone marrow suppression [57]. Acetazolamide, either alone or in combination with mexiletine, has proved beneficial in some patients with temperature-independent periodic weakness [59, 98]. Doses generally begin at 125 mg by mouth twice a day, slowly increasing to 250 mg by mouth three times a day, as required and as tolerated by the patient. Common side effects include nausea, anorexia, paresthesias, and rash, and patients should be warned about the formation of kidney stones [60]. Liver function studies and blood count should be monitored. It should be noted, however, that acetazolamide has also provoked weakness in some patients with paramyotonia congenita with cold-induced weakness, probably by lowering the potassium level [59, 98]. Thus, it is crucial to determine whether weakness is temperature dependent, as there are clear implications regarding treatment options. As with other myotonic disorders, care must be taken with the use of depolarizing muscle relaxants during anesthesia, which aggravate myotonia and may cause adverse anesthesia-related events.

Prognosis

Patients with paramyotonia congenita have a normal life span. Most learn to refrain from situations, such as cold exposure and exercise, that provoke symptoms of stiffness and weakness. However, those patients who experience spontaneous periodic weakness, unprovoked by cold, can be quite disabled by these and usually require daily treatment.

Hyperkalemic Periodic Paralysis

Introduction and Clinical Presentation

Hyperkalemic periodic paralysis (HyperPP) was initially described in the 1950s and differentiated from hypokalemic periodic paralysis (HypoPP) by the elevated potassium during attacks [99–101]. Gamstorp used the term *adynamia episodica hereditaria* to refer to the disorder. HyperPP arises from mutations in the α-subunit of the human skeletal muscle voltage-gated sodium channel gene (SCN4A) on chromosome 17q23. There is usually complete penetrance for both sexes, though rare patients were described with mutations where penetrance was incomplete [102, 103].

Three variants are described as follows: (1) HyperPP without myotonia, (2) HyperPP with clinical or EMG evidence of myotonia, and (3) HyperPP with paramyotonia (discussed in the previous section). Patients present in early childhood with attacks of periodic weakness that commonly occur in the morning after awakening from sleep. Attacks of weakness are usually brief, lasting from minutes to hours, and are generally accompanied by hyporeflexia. However, rare patients experience prolonged attacks of weakness.

Weakness is usually generalized but spares the facial and respiratory muscles. Some patients report focal limb or hemibody weakness, perhaps secondary to cold exposure confined to those limbs. Attacks vary in frequency, occurring daily in some patients and weekly or monthly in others. Myotonia, if present, can be variable. In some patients, the myotonia is detected only on needle EMG, while in others myotonia is elicited on physical examination. The frequency of attacks generally lessens in middle age, and some patients develop fixed progressive proximal weakness in adulthood [104].

Provocative factors include rest after exercise, fasting, emotional stress, cold, and potassium loading. Patients often anticipate an attack by a sense of muscle discomfort. The potassium level is usually elevated during attacks, though rarely reaches life-threatening levels. In some patients, the potassium level is normal during attacks of weakness. In all cases, the potassium level returns to normal after the attack. Symptoms are relieved by ingesting carbohydrates or inhaling a β-adrenergic agent [105]. Some patients can forestall an attack for a while with mild exercise, though an attack will eventually occur. During an attack, if exercise is possible, the attack may be shortened.

Etiology and Pathogenesis

Sodium channels from HyperPP patients with myotonia or from rat channels mutated to resemble one of the HyperPP mutants demonstrate abnormal sodium channel gating with repeated channel openings during depolarization that resembles the "slow" or "modal" gating discussed above, in which channels repeated flip between the inactivated state and the open state [106–108]. Single-channel conductance of the abnormally gating channels was reduced in one case [108] and was normal in others [12, 106, 107, 109–111]. Several mutations producing HyperPP and myotonia showed persistent inward sodium current attributed to (1) disrupted fast inactivation with an excessive amount of "slow" gating [66, 106, 112–114] or (2) "window" currents created by shifting the voltage dependence of activation [25, 26, 115] or activation and inactivation [116] resulting in a voltage range over which some channels will open and do not fast inactivate.

Possible Role of Slow Inactivation in Hyperkalemic Periodic Paralysis

As discussed in the section on myotonia, inhibition of fast inactivation is sufficient to produce myotonia [117, 118]. Disrupting slow inactivation enables a persistent depolarizing current that can facilitate the genesis of a HyperPP phenotype. Inhibiting slow inactivation enables the HyperPP phenotype by permitting the pathological persistent sodium current associated with HyperPP to last for minutes and therefore enables depolarization-induced paralysis to last for minutes to hours, the typical duration of paralytic attacks [12, 65, 119–121]. If slow inactivation is not disrupted, the depolarized mutant sodium channels will accumulate in the inexcitable slow inactivated state, which will terminate the pathological depolarizing current. Cummins demonstrated that slow inactivation was disrupted in the human Thr704Met mutation [26], which is the most common sodium channel mutation associated with HyperPP, and in the rat Thr698Met mutation, which is the rat analog of the human Thr704Met mutation producing HyperPP with myotonia [25]. Additional physiological evidence supports the importance of impaired slow inactivation in HyperPP [119, 120].

The difference between sodium channel mutations that produce only myotonia and those that produce prolonged depolarization-induced paralysis and myotonia may be that disrupting slow inactivation can produce prolonged depolarization [12, 25, 67, 119]. Slow inactivation was disrupted in three of four mutations of sodium channels associated with HyperPP including the most common mutations, Thr704 Met and Met 1592 Val [25, 119, 120]. One mutation, Met 1360 Val, displayed the same pattern of slow inactivation of I_{Na} as wild-type channels when studied at room temperature [119].

The slow inactivation results for the Met 1360 Val mutation can be reconciled in two ways. First, slow inactivation may be incomplete in vivo so that it need not be disrupted for mutant sodium channels to produce persistent depolarizing sodium current [119]. The second way of reconciling the Met 1360 Val slow inactivation data is to note that the mutation produced HyperPP with cold-induced weakness [122]. Consequently, the Met 1360 Val mutation could have abnormal temperature dependence for slow inactivation that would reduce the impact of slow inactivation at normal and slightly subnormal body temperatures with slow inactivation at room temperature being similar to wild-type channels. For example, the voltage dependence of slow inactivation of the mutant channels at 37 °C could have a positive voltage shift, meaning that very large depolarizations would be needed to have channels enter the slow inactivated state, and a larger temperature dependence compared with normal channels. Consequently, at normal and slightly subnormal temperatures, larger-than-usual depolarizations would be required to slow inactive mutant sodium channels. Hence, slow inactivation would not terminate the pathological persistent sodium current. A larger temperature dependence could result in slow inactivation for the mutant sodium channels being similar to normal channels at room temperature. Thus far, there does not seem to be a discernible pattern in either the mutation location or in the channel behavioral change that can predict which mutation will be associated with progressive weakness.

Differential Diagnosis

The differential diagnosis of HyperPP is limited, including HypoPP, ATS, and secondary hyperkalemic periodic paralysis disorders. These can usually be differentiated based on factors that provoke, worsen, or alleviate symptoms, findings on needle EMG, muscle cooling and exercise testing, and DNA testing when appropriate.

The distinction between HyperPP and HypoPP can usually be made based on age of onset, factors that provoke or alleviate an attack (Table 53.3), and determining the potassium level during an attack. Patients with HyperPP generally present in early childhood, in contrast to HypoPP, which usually manifests in adolescence. HyperPP attacks are provoked by fasting or ingestion of potassium, while attacks in HypoPP are provoked by carbohydrates. In contrast, carbohydrate ingestion prevents or relieves attacks in HyperPP, while potassium ingestion prevents or relieves attacks in HypoPP. Cold and rest after exercise may provoke attacks in both conditions. The prolonged exercise test produces a decremental response in both conditions and cannot distinguish between them. Clinical DNA diagnostic screening for the sodium or calcium channel mutations associated with HyperPP and HypoPP can be done in specialized laboratories.

Patients with HyperPP and myotonia may be confused with patients with recessive generalized myotonia who experience periodic weakness. However, exercise testing can be helpful in this regard. With prolonged exercise testing, patients with periodic paralysis show a progressive decline in the CMAP amplitude over 20–40 min, not seen in myotonia congenita (Table 53.4) [1, 52]. With short exercise testing, patients with myotonia congenita show a drop in the CMAP amplitude with a quick recovery, not seen in periodic paralysis. HyperPP can usually be distinguished from ATS by the lack of characteristic facial and skeletal features and prolonged QT interval that are found in ATS (see below). However, EKG may be a useful screening test in all patients with periodic paralysis even without distinctive facial and skeletal features, which may be lacking in some patients with ATS.

Secondary causes of HyperPP should be considered in those patients with later age of onset, no family history, or an atypical presentation. In such cases, appropriate laboratory screening should be done to screen for disorders associated with acquired hyperkalemic periodic paralysis (Table 53.5 II).

Diagnosis and Evaluation

EDX Testing (Table 53.4)

Routine motor and sensory nerve conduction studies are normal in HyperPP if performed between attacks of weakness. During an attack of weakness, the CMAP amplitudes may decline proportionate to the degree of weakness. Needle EMG exam between attacks may be normal, but in some patients, myopathic MUAPs may be found. In patients with HyperPP with myotonia, myotonic discharges may either increase or appear for the first time during an attack of weakness. Myotonic discharges are seen early in the attack but then disappear as weakness progresses. During an attack of weakness, there is a reduction in the size and number of MUAPs recruited in weak muscles.

Exercise Testing and Muscle Cooling

The prolonged exercise test often produces an immediate increase in the CMAP amplitude, especially if the initial amplitude is low. This is followed by a progressive decline in the CMAP amplitude by about 50 % over 20–40 min, with most of the decline occurring in the first 20 min [52]. A similar drop in the CMAP amplitude may also be noted by simply immobilizing the muscle without exercise. If there is a decline in the CMAP amplitude with rest, then exercise may produce a brief increment in the CMAP amplitude. The drop in CMAP amplitude with prolonged exercise does not distinguish HyperPP from HypoPP. However, as noted above, if myotonic discharges are noted on needle EMG, the diagnosis of HyperPP must be considered. The short exercise test produces no decrement, and muscle cooling has no appreciable effect on the needle EMG exam.

Laboratory Testing

Serum CK level may be mildly elevated. Serum potassium level is usually elevated during attacks of weakness. Muscle biopsy may show a vacuolar myopathy with fiber necrosis and degeneration. Tubular aggregates may be present. Clinical DNA diagnostic screening for HyperPP can be done in specialized laboratories. If the diagnosis cannot be established by the above methods, provocative testing can be done by administering potassium chloride after fasting and exercise, in an attempt to induce an attack of weakness [123]. This should not be done in patients who are already hyperkalemic nor in those with impaired renal or cardiac function and must be done under strict supervision with close EKG and serum electrolyte (including potassium) monitoring.

Treatment and Management

Management of HyperPP is directed toward preventing or decreasing the frequency of attacks and treating major paralytic attacks once they occur. To prevent attacks, patients are advised to eat regular meals, especially carbohydrate-rich and low-potassium meals, and to avoid situations that precipitate attacks, such as strenuous activity followed by rest. Many patients can forestall an impending attack, at least for a while, by engaging in mild exercise, ingesting carbohydrates

such as a candy bar, or inhaling a β-adrenergic agent once they note an impending attack [105].

Thiazide diuretics, such as hydrochlorothiazide (HCTZ), or the carbonic anhydrase inhibitor acetazolamide is effective in reducing the frequency and severity of attacks in the majority of patients. Patients are often unaware of minor daily attacks of weakness until beginning daily preventative therapy, when they note improvement in daily functioning. However, it is unclear whether preventing attacks will preclude later development of fixed proximal weakness [104].

Diuretics can be taken daily or intermittently as needed, using the lowest dose and frequency needed to prevent attacks. A reasonable starting dose of acetazolamide is 125 mg orally twice a day that can be slowly increased as tolerated to 250 mg orally four times a day, though some patients may require a higher dose, up to 1,500 mg a day, to prevent attacks or reduce the severity of attacks. Side effects include nausea, anorexia, and paresthesias. Rash has been reported. Patients should be warned about the formation of kidney stones [60]. Liver function studies and blood count should be monitored. A randomized double-blind placebo-controlled trial showed that dichlorphenamide, a potent carbonic anhydrase inhibitor, reduced the frequency and severity of attacks in HyperPP [124]. Dichlorphenamide can be used at a starting dose of 25 mg by mouth twice a day and slowly increased to 25–50 mg two to three times a day. The side effect profile is similar to acetazolamide. Some patients report confusion.

Rarely, acute paralytic attacks require more aggressive treatment than ingesting carbohydrates or inhaling a β-adrenergic agent if they are severe or associated with life-threatening hyperkalemia. Intravenous glucose and insulin can be used to lower the potassium level but must be done under strict supervision, with EKG and serum electrolyte monitoring. Finally, care must be taken with the use of depolarizing muscle relaxants during anesthesia, which aggravate myotonia and may cause adverse anesthesia-related events.

Prognosis

The elevated potassium levels during attacks are generally not life-threatening in terms of cardiac manifestations. Respiratory and bulbar involvement is exceedingly rare. Progressive fixed weakness may occur in adulthood.

Hypokalemic Periodic Paralysis: Types I and II

Introduction and Clinical Presentation

Hypokalemic periodic paralysis (HypoPP) type I is the most common of the inherited periodic paralyses. It is an autosomal dominant inherited disorder with reduced penetrance in women. The first genetic linkage of HypoPP (type I) was with mutations in the S4 segments of the α-subunit of a voltage-sensitive muscle calcium channel gene (CACNA1S) on chromosome 1q [125]. Calcium and sodium channels are close cousins with similar structures of four domains each containing six transmembrane spanning segments [126]. A few point mutations can convert the conductance properties of a sodium channel into those of a calcium channel [80].

In 1994, Plassart et al. [127] reported a large French family with HypoPP that did not link to the calcium channel gene on chromosome 1q32. The subjects were clinically indistinguishable from patients in whom HypoPP was associated with calcium channel mutations. Subsequently, mutations were identified in the α-subunit of the sodium channel gene on chromosome 17q accounting for this phenotype, and the term HypoPP type II was used to designate patients with HypoPP associated with sodium channel mutations [128, 129]. Because of the similarities in clinical presentation and pathogenesis, these disorders are discussed together below.

Patients generally present in adolescence with periodic attacks of weakness, although rare patients present in childhood or in their twenties. Attacks are provoked by cold, carbohydrate ingestion, alcohol, emotional stress, and rest after exercise. Some patients report a peculiar sensitivity to Chinese food, precipitating attacks of weakness. Typical attacks occur upon awakening from sleep, especially after strenuous physical activity or a large carbohydrate meal the day before. Patients may have a warning of an impending attack, describing muscle discomfort or stiffness [130]. Minor attacks can be forestalled for at least a short period of time by exercise or potassium ingestion. Untreated, attacks of weakness may be quite prolonged, lasting from several hours to days, generally occurring upon awakening from sleep. Weakness is usually generalized and often accompanied by hyporeflexia. Some patients experience focal limb weakness, perhaps if that limb was exposed to the cold during sleep.

In some patients, the weakness may be quite severe, resulting in flaccid quadriplegia with loss of reflexes. Major attacks may be preceded by diaphoresis and followed by oliguria. In rare individuals, bulbar and respiratory muscles are involved, which can be life-threatening during prolonged attacks. The potassium level is usually low during attacks (2.0–3.0 mEq/l) [98]. This may lead to bradycardia or sinus arrhythmias if the hypokalemia is profound [39, 130, 131]. In some patients, the potassium level is normal during attacks. Myotonia is not present either clinically or electrically, with the exception of eyelid myotonia in few patients.

Attacks are more frequent in males than females. It is not uncommon for females to be asymptomatic or so minimally affected by periodic weakness that they are unaware of their disorder. Even patients with attacks of periodic weakness

may be unaware of minor daily attacks until they are treated, when they note improvement in daily functioning. While the frequency of attacks tends to diminish in adulthood, most patients invariably develop progressive proximal weakness during adulthood, whether they have had attacks of periodic paralysis or not [132, 133].

Etiology and Pathogenesis

Hypokalemic Periodic Paralysis Results from Loss of Muscle Membrane Excitability

Muscular weakness in HypoPP develops in parallel with reduced surface membrane excitability [134]. Skeletal muscle membrane excitability is reduced in HypoPP, and membrane hyperexcitability is not typically associated with HypoPP. HypoPP muscle fibers have normal excitation contraction coupling [135]. Paralysis in HypoPP is caused by membrane depolarization triggering inactivation of sodium channels [39, 136]. Insulin administration may trigger a paralytic attack without appreciable hypokalemia [39, 136]. Muscle fibers in HypoPP are very susceptible to depolarization-induced inexcitability [39, 136] and have slow conduction velocities [137].

Hypokalemic Periodic Paralysis Is Linked to Sodium or Calcium Channel Mutations

HypoPP has been linked to mutations in a skeletal muscle calcium channel (HypoPP type I) or a sodium channel (HypoPP type II). The first recognized linkage of HypoPP was to chromosome 1q31-32 [125, 138]. The defective gene (CACNA1S) encodes a skeletal muscle dihydropyridine (DHP)-sensitive or L-type calcium channel, with a structure similar to that of the sodium channel (Fig. 53.5). Two mutation sites are on segment 4 of domain 2 (D2/S4, R528H) and D4/S4 (R1239H/G) of the α-subunit of the skeletal muscle L-type calcium channel [39, 138]. The other mutation sites are R879S, R900S, and V876E (Fig. 53.6) [64, 139].

Following identification of the calcium channel gene as a locus for HypoPP, studies demonstrated that point mutations in the SCN4A gene affecting D2/S4 of the α-subunit of the skeletal muscle sodium channel can also produce the phenotype of HypoPP [128, 129]. About 60 % of people with HypoPP have type I, 20 % have type II, and 20 % have undefined mutations.

The Sodium and Calcium Channel Mutations Have Similar Phenotypes

HypoPP associated with calcium channel mutations (HypoPP type I) or sodium channel mutations (HypoPP type II) is clinically indistinguishable [128, 129]. Bulman et al. [128] and Jurkat-Rott et al. [129] demonstrated that both types share the following four salient clinical features: (1) reduced membrane excitability, (2) depolarization in response to hypokalemia, (3) insulin-induced paralysis, and (4) episodic hypokalemia (Table 53.6).

Some Alterations in Membrane Excitability Are Directly or Indirectly Explained by the Sodium or Calcium Channel Mutations

A challenge in HypoPP is to understand how the sodium or calcium channel mutations produce the membrane abnormalities that lead to the clinical phenotype. Table 53.6 lists four important physiological features of HypoPP. Some of the pathological properties of skeletal muscle membrane in HypoPP muscle are directly understood from the sodium channel mutations for HypoPP type II. In contrast, several of the membrane abnormalities in HypoPP type I probably result from alteration of sodium or potassium channels. Because the membrane pathology associated with the calcium channel mutations do not result directly from the mutations, HypoPP type I has been called an *indirect channelopathy* [140, 141].

The Sodium Channel Mutations Directly Explain Reduced Membrane Excitability

Susceptibility to depolarization-induced paralysis and slow muscle fiber conduction velocities both suggest impaired sodium channel function in HypoPP. Jurkat-Rott et al. [129] explained the slow skeletal muscle fiber conduction velocities for patients with HypoPP with sodium channel mutations by demonstrating reduced action potential rates of rise due to lower sodium current density on isolated muscle fibers. The reduced sodium current resulted from two factors. First, mutant sodium channels did not conduct current because they were in an inactivated state at the resting membrane potential, due to a shift in the voltage dependence of fast inactivation. Second, the density of normal (wild type) sodium channels was only 50 % of the usual density. The pattern of insertion of wild-type sodium channels was what would be expected if the mutant channels were expressed at a similar rate to wild-type sodium channels and the mutant channels competed on an equal basis with the wild-type channels for membrane insertion. Skeletal muscle fibers did not upregulate sodium channel production or membrane insertion of wild-type sodium channels to accommodate for the reduced current carried by the mutant channels. The sodium current density in the muscle fibers of patients with HypoPP was about 50 % of that in normal muscle fibers.

Calcium Channel Mutations May Indirectly Explain Reduced Membrane Excitability in Hypokalemic Periodic Paralysis

The reduced excitability of muscle fibers from patients with HypoPP due to the R528H calcium channel mutation

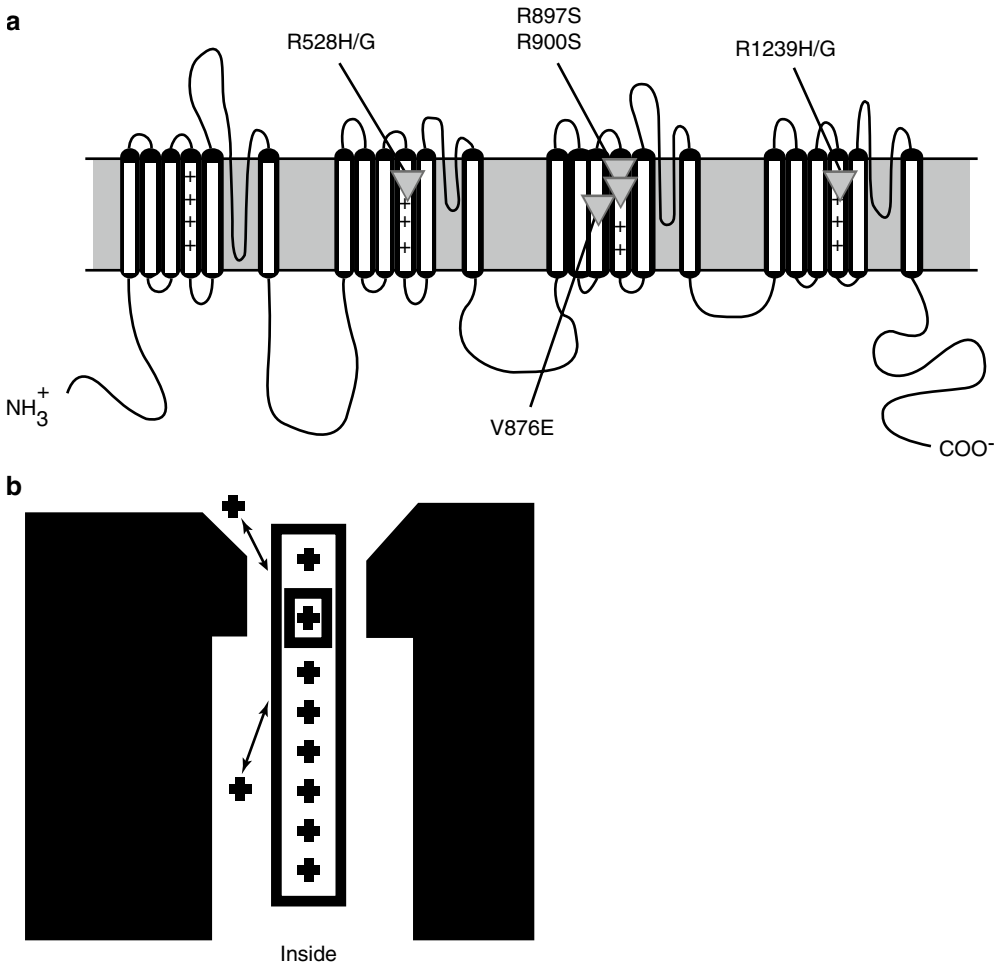

Fig. 53.6 Calcium channel mutations involved in HypoPP. (**a**) A cartoon of the calcium channel mutations identified in HypoPP and (**b**) a cartoon to suggest that mutations in which a positively charged arginine is replaced by an uncharged or negatively charged ion could create a binding site for cations on the S4 segment and enable the S4 segment to form an alternative pathway for ions to travel across the membrane – i.e., a "gating pore"

Table 53.6 Characteristics of hypokalemic periodic paralysis caused by sodium or calcium channel mutations

Characteristic of HypoPP	Present with calcium channel mutations	Present with sodium channel mutations	Explained by calcium channel mutations	Explained by sodium channel mutations
Reduced interictal skeletal muscle membrane excitability	Yes	Possibly – studies done before mutations were recognized	Indirectly via reduced sodium channel density	Yes
Muscle membrane depolarizes in response to reduced extracellular K^+	Yes	Yes	No	No
Insulin potentiates depolarization	Yes	Yes	Indirectly via altered impact of insulin on potassium conductance	No
Episodic hypokalemia	Yes	Yes	No	No

is associated with reduced sodium current amplitude [141, 142]. Reduced sodium current amplitudes result from a lower density of sodium channels without any alteration in the voltage dependence of sodium channel activation, fast inactivation, or slow inactivation. Consequently, the R528H calcium channel mutation reduced the expression or membrane trafficking of normal sodium channels via an undetermined mechanism. The commonality of reduced sodium current amplitude in HypoPP types I and II suggests that reduced sodium current may be an important pathophysiological change needed to produce the phenotype of HypoPP.

How do the calcium channel mutations alter the regulation of other ionic channels to produce the membrane changes present in HypoPP? One possibility is that the steady-state intracellular calcium levels may be altered in response to the mutations. The change in intracellular calcium may alter the production and membrane insertion of voltage-gated sodium

channels [143]. Hence, intracellular calcium concentration can modulate surface membrane sodium channel density, which provides a way for altered calcium channels to influence sodium channels [142].

Gating Pore Current Causes Muscle Fibers to Depolarize

Normal skeletal muscle fibers hyperpolarize in response to hypokalemia (Table 53.7). Paradoxically, muscle fibers from patients with HypoPP due to sodium or calcium channel mutations depolarize in response to hypokalemia (Table 53.7). The depolarization of muscle fibers is due in part to a depolarizing current arising from gating pore channels that are created by mutations in the charged S4 segments of mutated calcium or sodium channels (Fig. 53.6) [5, 8, 61, 64, 144–146]. An additional factor is that reduced activity of inward rectifier potassium channels enables a small current to produce a large depolarization [142].

The pathological depolarizing was initially recognized as resulting from an abnormal cationic-specific ion current that was not impaired by blockers of skeletal muscle sodium or calcium channels is and that was opened by reduced extracellular potassium concentration [140]. Thus, the depolarizing current was not carried through the normal ion channel pore of sodium or potassium channels. The genesis of the pathological depolarizing current was explained by the observation that mutations which replaced positively charged amino acids in the charged S4 segments of sodium channels produced a gating pore pathway for current flow (Fig. 53.6) [5–8]. Evaluation of comparable S4 mutations in potassium channels showed the positively charged arginines prevented gating pore currents [9, 10]. The presence of gating pore currents with mutations of arginines in S4 segments of either sodium or calcium channels partially explains why mutations of S4 segments of either skeletal muscle sodium or calcium channels can produce a similar phenotype.

The finding of gating pore currents associated with both forms of HypoPP raises the question of whether the gating pore currents are sufficient to produce the HypoPP phenotype [61, 147]. Types 1 and 2 HypoPP are associated with reduced voltage-gated sodium channel current and reduced inward rectifier potassium channel current [129, 140, 142, 148, 149]. In addition, reducing the conductance of inward rectifier potassium channels can result in an HypoPP-like skeletal muscle behavior [150, 151]. However, increasing membrane leak, which simulates the impact of gating pore currents, also produces HypoPP-like muscle behavior [152]. Thus, the extent to which gating pore currents cause the clinical HypoPP phenotype remains to be determined.

Table 53.7 The resting membrane potentials, percent of muscle fibers that could generate an action potential with a peak amplitude that reached or exceeded 0 mV, and the membrane potentials (mV) at which action potentials were triggered (action potential thresholds) in bathing solutions with different K^+ concentrations and with or without insulin (12 mU/ml) for intercostal muscle fibers from patients with hypokalemic periodic paralysis associated with the Arg-528-His Ca^{2+} channel mutation and control subjects

Solution	Control	HypoPP
Resting membrane potentials (mV)		
4.0 mM K^+	−93.4 ± 1.2 (n = 16)	−87.9 ± 1.5 (n = 16)
4.0 mM K^+ + insulin	−97.2 ± 1.1 (n = 16) p < 0.01	−74.9 ± 1.3 (n = 15) p < 0.001
2.5 mM K^+	−97.2 ± 1.0 (n = 16)	−83.3 ± 1.1 (n = 15)
2.5 mM K^+ + insulin	−99.8 ± 1.0 (n = 16) p < 0.05	−65.0 ± 1.4 (n = 15) p < 0.001
Percent of fibers that can produce an action potential		
4.0 mM K^+	100 %	100 %
4.0 mM K^+ + insulin	100 %	33 % p = 0.00014
2.5 mM K^+	100 %	67 % p = 0.0177
2.5 mM K^+ + insulin	100 %	0 % p < 0.0001
Action potential thresholds of excitable fibers (mV)		
4.0 mM K^+	−58.4 ± 2.0	−52.2 ± 2.2 p < 0.01
4.0 mM K^+ + insulin	−60.2 ± 1.9	−44.1 ± 4.5 p < 0.001 p < 0.05
2.5 mM K^+	−60.3 ± 1.8	−49.1 ± 3.9 p < 0.001
2.5 mM K^+ + insulin	−60.8 ± 2.1	None

Insulin-Induced Depolarization Results from Altered Potassium Channel Response to Insulin: An Indirect Consequence of the Calcium Channel Mutations

Insulin hyperpolarizes normal fibers and depolarizes fibers from patients with both types of HypoPP. Insulin hyperpolarizes normal muscle fibers by activating the electrogenic sodium/potassium-ATPase and by altering the resting membrane sodium and potassium conductances so that the membrane is biased more toward the potassium equilibrium potential to produce hyperpolarization [136, 140, 148]. The effects of insulin on the membrane K_{ATP} channels are dramatically altered in type 1 HypoPP. Insulin markedly reduces the conductance of the inward rectifier class of potassium channels, particularly the K_{ATP} channels [140, 148]. The reduced potassium channel conductance produced by insulin

shifts the balance of membrane conductances so that the membrane potential moves away from the potassium equilibrium potential and closer to the sodium equilibrium potential, which causes membrane depolarization. Because insulin reduces the membrane potassium conductance, insulin will augment the hypokalemia-induced depolarization associated with activation of a depolarizing inward current. The impact of the gating pore current is increased when the potassium conductance is reduced.

It Is Not Known How the Calcium or Sodium Channel Mutations Make Patients with Hypokalemic Periodic Paralysis Have Episodic Hypokalemia

Insulin appears to induce excessive potassium uptake by muscle and other cells in both types of HypoPP. The pathophysiology of excessive cellular uptake of potassium is not known.

Summary of the Pathophysiology of HypoPP

HypoPP is a muscle disease with the following four cardinal features: (1) there is reduced membrane excitability, (2) muscle fibers depolarize in response to hypokalemia, (3) insulin potentiates depolarization, and (4) patients experience episodic hypokalemia. HypoPP is linked to mutations in the skeletal muscle L-type calcium or sodium channel. The HypoPP mutations produce gating pore currents in sodium and calcium channels that contribute to the paradoxical depolarization. Sodium channel mutations provide a direct explanation for reduced membrane excitability in HypoPP. Calcium channel mutations may reduce membrane excitability by reducing the expression of sodium channels. In association with calcium channel mutations, membrane depolarization in response to hypokalemia results from reduced conductance of inward rectifier potassium channels, especially K_{ATP} channels, and gating pore currents which produce a depolarizing inward current. Insulin potentiates depolarization in type 1 HypoPP by reducing the conductance of inward rectifier potassium channels, particularly K_{ATP} channels. For either class of ion channel mutation, the origin of episodes of hypokalemia is not known.

Differential Diagnosis

The differential diagnosis of HypoPP is limited, including HyperPP, ATS, and secondary HypoPP disorders. These can usually be differentiated based on factors that provoke, worsen, or alleviate symptoms, findings on EDX and exercise testing, and when appropriate DNA testing. Family history should always be questioned. However, because sporadic cases are not uncommon, likely representing new mutations, family history is not always helpful [125].

The distinction between HypoPP and HyperPP can often be made by age of onset, factors that provoke or alleviate an attack (Table 53.3), and measuring the potassium level during an attack. Patients with HypoPP generally present in adolescence, while those with HyperPP have a younger age of onset, in childhood. Weakness in HypoPP is triggered by carbohydrates, and symptoms are relieved with potassium ingestion. In contrast, in HyperPP weakness is provoked by fasting or potassium ingestion, and carbohydrate ingestion prevents or relieves attacks. Cold and rest after exercise provoke attacks in both conditions. Serum potassium levels are generally low during attacks in patients with HypoPP and elevated during attacks in patients with HyperPP.

The prolonged exercise test produces a decremental response in both conditions and is not useful in distinguishing between the two conditions. However, the finding of myotonic discharges on needle EMG, which can be seen in a subset of patients with HyperPP, excludes the diagnosis of HypoPP. Clinical DNA diagnostic screening for HypoPP can be done in specialized laboratories.

While patients with recessive generalized myotonia congenita (Becker-type myotonia) may also experience periodic weakness, they can be easily distinguished from HypoPP by the myotonic discharges on needle EMG, not seen in HypoPP. Furthermore, patients with recessive generalized myotonia congenita do not display the progressive decline in CMAP amplitude with prolonged exercise testing noted in HypoPP. HypoPP can be distinguished from ATS by the lack of characteristic facial and skeletal features and prolonged QT interval associated with ATS (see below). However, EKG may be a useful screening test in patients with periodic paralysis even without distinctive facial and skeletal features, which may be lacking in some patients with ATS.

Some patients with HypoPP never experience periodic paralysis yet develop a progressive proximal myopathy in adulthood. This is especially common in females. Such patients may be confused with inflammatory myopathy. However, muscle biopsy specimen in such patients reveals no inflammation. Nevertheless, it may be difficult to distinguish such patients from inclusion body myositis because of the vacuolar changes present in muscle biopsy specimens in both populations. However, other histologic findings in inclusion body myositis are distinctive, including endomysial inflammation, rimmed vacuoles lined with granular material, and intranuclear and cytoplasmic tubulofilaments noted on electron microscopy, not seen in HypoPP (see Chap. 65). Family history may also be helpful, since HypoPP is

dominantly inherited. Careful questioning for family members with periodic paralysis is crucial, especially in females with progressive weakness but without episodes of periodic weakness.

Secondary causes of HypoPP should be considered in those patients with later age of onset, no family history, or an atypical presentation. In such cases, appropriate laboratory screening should be done to screen for disorders and medications associated with acquired HypoPP (Table 53.5 II, IV).

Diagnosis and Evaluation

EDX Testing (Table 53.4)

Routine motor and sensory nerve conduction studies are normal. During an attack of weakness, the CMAP amplitudes generally decline proportionate to the degree of weakness. There are no myotonic discharges on needle EMG. The MUAPs and recruitment pattern are normal in the early stages of the disorder. There is a reduction in the size and number of MUAPs recruited in weak muscles during a paralytic attack. As patients develop fixed proximal weakness, small, short-duration MUAPs with early recruitment are noted in proximal muscles. In end-stage myopathy, the MUAPs may be large and of long duration, with poor recruitment, resembling MUAPs associated with chronic neurogenic disorders.

Exercise Testing and Muscle Cooling

The prolonged exercise test often produces an immediate increase in the CMAP amplitude, especially if the initial amplitude is low. This is followed by a progressive drop in the CMAP amplitude by about 50 % over 20–40 min, with most of the decline occurring in the first 20 min. A similar decline in the CMAP amplitude may also be noted by just immobilizing the muscle without exercise. If there is a decline in the CMAP amplitude with rest, then exercise may produce a brief increment in the CMAP amplitude. The decrement in CMAP amplitude with prolonged exercise does not distinguish between HyperPP and HypoPP. However, as noted above, if myotonic discharges are noted on needle EMG, the diagnosis of HypoPP is eliminated. The short exercise test produces no decrement, and muscle cooling has no appreciable effect on the needle EMG exam.

Laboratory Testing

Laboratory findings may show an elevated serum CK level. The potassium level is usually low during attacks of weakness. Muscle biopsy shows a vacuolar myopathy, characterized by large, central vacuoles, that may be present in patients with or without fixed weakness. Muscle fiber necrosis and degeneration may also be seen. Thyroid function tests as well as screening for secondary causes of HypoPP (Table 53.5 II) should be done, particularly when there is no family history or with late age of onset. Clinical DNA diagnostic screening for HypoPP can be done in specialized laboratories.

If the diagnosis cannot be established by the above methods, infusion of glucose with insulin can be used to provoke an attack. Several methods have been described [123]. However, provocative testing with glucose and insulin should only be used as a measure of last resort when the diagnosis cannot be otherwise established. Testing should not be done in patients who are already hypokalemic or in patients with known cardiac conduction defects. Since this testing can provoke a severe attack, it should only be done under the strict supervision of a knowledgeable physician, with continuous EKG monitoring as well as sequential monitoring of electrolytes, including potassium and glucose levels.

Treatment and Management

Management of HypoPP is directed toward preventing attacks and aggressively treating major paralytic attacks once they occur. To prevent attacks, patients are advised to follow a low-carbohydrate, low-sodium diet and avoid situations that precipitate attacks, such as strenuous activity or a high-carbohydrate meal or alcohol followed by rest. Most patients require some form of maintenance therapy to prevent attacks. Patients may be unaware of minor daily attacks of weakness until beginning preventative therapy, when they note improvement in daily functioning.

Acetazolamide is effective in reducing the frequency and severity of attacks and reducing inter-attack weakness in 50–60 % of patients [153–155]. A reasonable starting dose is 125 mg orally twice a day that can be slowly increased as tolerated to 250 mg orally four times a day, to prevent attacks or reduce the severity of attacks. Common side effects include nausea, anorexia, and paresthesias. Rash has been reported. Patients should be warned about the formation of kidney stones [60]. Liver function studies and blood count should be monitored. There have been few reports of patients with HypoPP who worsen with acetazolamide [156]. A randomized double-blind placebo-controlled trial showed that dichlorphenamide, a potent carbonic anhydrase inhibitor, reduced the frequency and severity of paralytic attacks in HypoPP [124]. Dichlorphenamide can be used at a starting dose of 25 mg by mouth twice a day and slowly increased to 25–50 mg two to three times a day. The side effect profile is similar to acetazolamide. Some patients report confusion.

Patients who do not respond to carbonic anhydrase inhibitors may respond to potassium-sparing diuretics, such as triamterene or spironolactone, although these must be used with caution in patients who are also taking oral potassium supplements [156]. Daily maintenance therapy with oral potassium chloride, either alone or in conjunction with a

carbonic anhydrase inhibitor, is useful in preventing or reducing the frequency and severity of attacks.

Acute paralytic attacks are treated with oral potassium chloride, 0.25 mEq/kg body weight, repeating every half hour until weakness improves. Electrolyte monitoring should be done during severe attacks requiring extensive potassium supplementation. Intravenous potassium is best avoided, unless oral potassium cannot be administered, and should always be done with close monitoring of the EKG and serum potassium level. Intravenous potassium may exacerbate the hypokalemia when mixed in a solution of glucose and saline or may cause acute hyperkalemia when given as a continuous infusion.

Prognosis

The lowered potassium levels during attacks are generally not life-threatening in terms of cardiac manifestations. However, respiratory and bulbar involvement may occur and may be life-threatening. Close monitoring during prolonged severe attacks involving respiratory and bulbar muscles is warranted. A mortality rate as high as 10 % was reported, but this was prior to modern medical care [157]. Progressive fixed weakness may occur in adulthood, even in those patients with no prior history of periodic weakness [133].

Thyrotoxic Periodic Paralysis

Thyrotoxic periodic paralysis (TPP) is seen in a subset of patients with thyrotoxicosis [153, 158]. Patients present with attacks of weakness associated with hypokalemia [159, 160]. The syndrome is clinically indistinguishable from primary HypoPP, except age of presentation, which is generally in adulthood [136, 139, 161]. Similar to primary HypoPP, attacks may be provoked by a high-carbohydrate meal, rest after exercise, or cooling of the limb. It occurs more commonly in males than females, despite the fact that thyrotoxicosis is more prevalent in females. Just as in the primary periodic paralyses, the prolonged exercise test results in a progressive decline in the CMAP amplitude.

The incidence of TPP is highest in adults of Asian origin, although it has been reported in all races [162, 163]. Susceptibility to developing TPP may be transmitted in an autosomal dominant fashion [164, 165]. Periodic paralysis and hypokalemia may be the initial presentation of thyrotoxicosis, without any of the usual features of hyperthyroidism. Patients with TPP manifest periodic paralysis associated with muscle fiber membrane depolarization when they are thyrotoxic, but not when euthyroid [142]. In spite of the similarities between TPP and either forms of HypoPP, patients with TPP do not have any of the sodium or calcium channel mutations associated with HypoPP [166–168]. Rather TPP is associated with a loss-of-function mutation of an inward rectifier potassium channel [169].

Treatment consists of correcting the thyrotoxicosis. In some patients, propranolol may prevent attacks of weakness. Acetazolamide is not effective in preventing periodic weakness in TPP [170]. As in primary HypoPP, acute attacks are treated with oral potassium. Untreated, TPP may result in progressive myopathy. The etiology of the paralysis is thought to be sodium channel inactivation secondary to sarcolemmal depolarization, which leads to loss of membrane excitability [18, 171]. Membrane depolarization is likely abetted by the reduced inward rectifier potassium channel current, and loss of membrane excitability is fostered by overall reduced sodium channel conductance (which may reflect fewer channels) [142, 169].

Related Syndromes

Andersen-Tawil Syndrome (ATS)

Introduction and Clinical Presentation

In 1971, Andersen described a syndrome characterized by the triad of *periodic paralysis, ventricular arrhythmias, and dysmorphic facial features* [172], though there were a few previous reports of patients with periodic paralysis and cardiac arrhythmias. In 1994, Tawil et al. reported four patients with autosomal dominant inherited periodic paralysis [173], ventricular ectopy, and dysmorphic features similar to Andersen's original description [174].

Patients present in childhood or adolescence with all or some features of the clinical triad of (1) periodic paralysis, (2) prolonged QT interval and ventricular arrhythmias, and (3) characteristic physical features [174, 175]. Clinical heterogeneity is noted within families. The periodic paralysis may be accompanied by hypokalemia, normokalemia, or hyperkalemia. Attacks may occur spontaneously or triggered by rest after exercise or alcohol. Some patients report intermittent muscle pain without attacks of weakness. As with other types of periodic paralysis, some patients can work through the muscle pain by continuing with mild exercise. Prolonged QT interval is the most consistent cardiac manifestation, present in about 80 % of patients, and may be the only finding in some individuals from a family with typical ATS [175]. In some patients, the long QT interval may be asymptomatic. However, patients may present in childhood with cardiac arrest, with no history of periodic paralysis, though they may experience periodic paralysis in later years. Others with periodic paralysis and characteristic facial features do not have a prolonged QT interval at rest, although other EKG findings may occur, such as a prominent U wave in the chest leads.

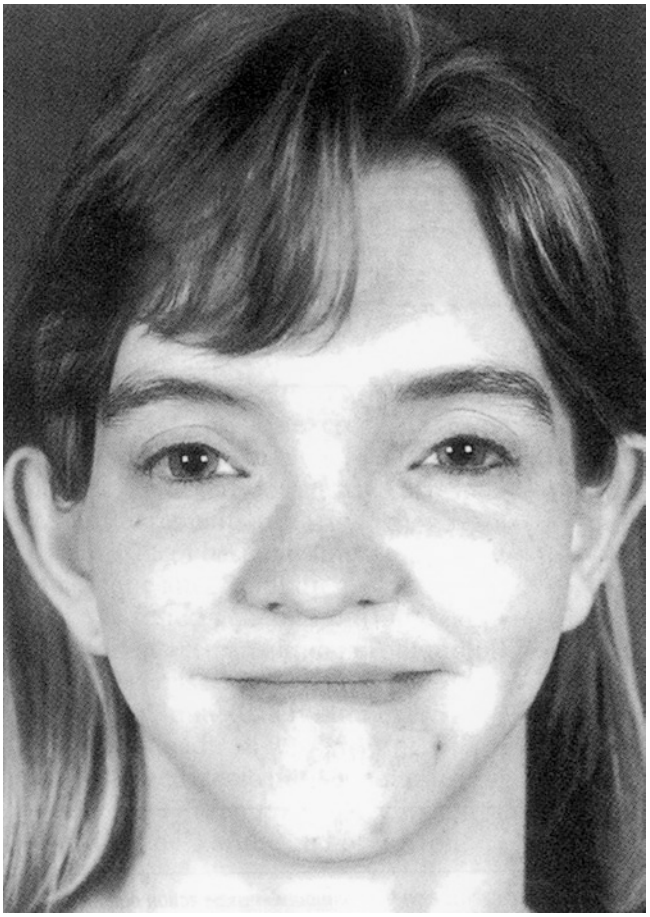

Fig. 53.7 Characteristic facial features in Andersen-Tawil's syndrome. Note low-set ears, broad nose, and hypertelorism

Characteristic physical features include short stature, high-arched palate, low-set ears, broad nose, micrognathia, hypertelorism, clinodactyly of the fingers, short index finger, and syndactyly of the toes (Fig. 53.7) [174, 175]. Scoliosis may be present. Neurologic examination between paralytic attacks may reveal generalized limb and neck flexor weakness, without grip or percussion myotonia.

Etiology and Pathogenesis

The etiology and pathogenesis of ATS are beginning to emerge. It is inherited in an autosomal dominant fashion with incomplete penetrance. The responsible gene encodes an inward rectifier potassium channel $K_{IR}2.1$ [176, 177]. That mutations of inward rectifier channels are involved with both TPP and ATS suggests that disturbing inward rectifier potassium channel function likely contributes to periodic paralysis.

Differential Diagnosis

The differential diagnosis of ATS includes HyperPP and HypoPP, as well as recessive generalized myotonia congenita with periodic weakness. However, the presence of distinctive facial and skeletal features and a long QT interval usually differentiate ATS from the other primary periodic paralyses and recessive generalized myotonia congenita. If myotonic discharges are noted on needle EMG, the diagnosis of ATS is excluded, in favor of recessive generalized myotonia congenita or the subset of patients with HyperPP and myotonia. In patients who report muscle pain with exertion and in whom it is unclear whether the pain is accompanied by true weakness, metabolic myopathies should be considered. However, the distinctive facial and skeletal features will usually differentiate ATS from these other disorders.

Evaluation and Diagnosis

EDX Testing

Routine motor and sensory nerve conduction studies are normal. There are no myotonic discharges on needle EMG, even with muscle cooling.

Exercise Testing

The short exercise test produces no decrement. The prolonged exercise test often produces an immediate increase in the CMAP amplitude, especially if the initial amplitude is low. This is followed by a progressive drop in the CMAP amplitude by about 45 % over 20–30 min [178]. Although there may be minor differences in the degree and time course of the decrement in CMAP amplitude with prolonged exercise, one cannot use this test to definitively distinguish among ATS, HyperPP, and HypoPP.

Laboratory Testing

Serum CK level is mildly to moderately elevated. Muscle biopsy may be normal, or there may be mild chronic myopathic changes, often with tubular aggregates [175]. Evaluation should include an EKG looking for evidence of a long QT interval and 24-h Holter monitoring looking for evidence of arrhythmias. In some cases, exercise stress testing may be needed to bring out a prolonged QT interval or other cardiac abnormalities and should be done under the strict supervision of a knowledgeable cardiologist. *Provocative hyperkalemic and hypokalemic challenges, as described above, should be avoided in patients suspected of ATS because of the possibility of precipitating a life-threatening arrhythmia by exacerbating an underlying prolonged QT interval.*

Management and Treatment

Treatment of ATS is empiric and complicated by the fact that both skeletal and cardiac muscle are involved, and treatment of one set of symptoms may exacerbate the other through paradoxical responses to changes in potassium levels. Additionally, cardiac arrhythmias may be refractory to standard antiarrhythmic agents. Treatment with carbonic anhydrase inhibitors (acetazolamide, dichlorphenamide) may be

helpful in controlling periodic weakness while only minimally lowering the potassium level. A reasonable starting dose of acetazolamide is 125 mg orally twice a day that can be slowly increased to the lowest dose needed to prevent or reduce the severity of attacks, while monitoring cardiac function closely. Common side effects include nausea, anorexia, and paresthesias. Rash has been reported, and patients should be warned about the formation of kidney stones. Liver function studies and blood count should be monitored. Dichlorphenamide can be used at a starting dose of 25 mg by mouth twice a day and slowly increased to the lowest dose needed to control paralytic attacks while monitoring cardiac function. The side effect profile is similar to acetazolamide, though some patients report confusion.

Arrhythmias are poorly responsive to commonly used antiarrhythmic agents, including tocainide, procainamide, flecainide, quinidine, sotalol, and amiodarone, which may also worsen the weakness or prolong the QT interval [174]. Imipramine, a mild antiarrhythmic, was used in some patients to treat the arrhythmias without causing further weakness [174, 179]. Patients should be evaluated by a cardiologist for close cardiac monitoring and coordination of treatment of arrhythmias.

Prognosis

The major complication of ATS is sudden death from cardiac arrhythmias, and close cardiac monitoring is warranted.

Schwartz-Jampel Syndrome (Chondrodystrophic Myotonia)

Introduction and Clinical Presentation

Schwartz-Jampel syndrome (SJS) is a rare, inherited myotonic disorder characterized by short stature, skeletal deformities, facial anomalies, and muscle stiffness [180]. Dwarfism and prominent facial and skeletal anomalies distinguish SJS from other myotonic disorders. SJS has several synonyms including chondrodystrophic myotonia, chondrodystrophica myotonica, osteochondromuscular dystrophy, spondyloepimetaphyseal dysplasia with myotonia, and Aberfield syndrome. The syndrome is usually transmitted as an autosomal recessive condition, but in occasional families, the inheritance pattern suggests an autosomal dominant disorder [181, 182].

The characteristic skeletal anomalies that contribute to dwarfism include bony dysplasia with metaphyseal enlargement and cortical thickening, bowing and shortening of the long bones of the upper and lower extremities, arachnodactyly, hip dysplasia with abnormalities of the acetabulum, kyphoscoliosis, and pectus carinatum. Facial anomalies include small mouth with micrognathia and pursed lips, upward slanting eyes, blepharophimosis, exotropia, microcornea, low-set ears, and prominent eyebrows (Fig. 53.8). Other dysmorphic features include hypoplastic larynx, short neck, and hypertrichosis. Patients with SJS may have prominent proximal upper and lower extremity muscle hypertrophy and distal predominant generalized weakness and atrophy [182, 183]. In contrast to the pseudohypertrophy seen in dystrophinopathies, proximal limb muscles in SJS are genuinely enlarged. Approximately 20 % of people with SJS have some degree of cognitive impairment [184]. Other features associated with SJS include malignant hyperthermia and susceptibility to carpal tunnel syndrome.

The clinical manifestations may vary among affected members of the same family. However, there are three common presentation patterns for families with SJS: type 1A, 1B, and 2 [184]. SJS type 1A manifests in childhood with moderate bone dysplasia, muscle enlargement, myotonia, and dysmorphic facial features. SJS type 1B is similar to type 1A but is recognizable at birth and has more prominent bone dysplasia. SJS type 2 is the most severe and manifests at birth with contractures, severe long bone bowing (campomelia), prominent myotonia, and severe facial and pharyngeal deformities that preclude normal feeding and lead to infantile death. SJS type 2 is very similar to the Stuve-Wiedemann syndrome. Some authors suggested that Stuve-Wiedemann syndrome and SJS type 2 may be the same disease [185]; however, the underlying genetic abnormalities differ [186, 187].

Etiology and Pathogenesis

SJS is autosomal recessive and characterized by skeletal dysplasia with varying degrees of myotonia and chondrodysplasia, with close to normal survival. The variability in the severity of SJS within a family and between families suggests that the SJS phenotype is modified by several genes. SJS type 1 is linked to chromosome 1q34-36 or 1p34-36 in different families [184, 188]. SJS type 1 is associated with mutations of the gene encoding perlecan (HSPG2). Perlecan is a large heparan sulfate proteoglycan and is a component of the basement membrane and other extracellular matrices and has been implicated in multiple biological functions. Mutations in HSPG2 cause two classes of skeletal disorders: the relatively mild SJS and severe neonatal lethal dyssegmental dysplasia, Silverman-Handmaker type. At least some of the skeletal dysmorphic features such as campomelia and pectus carinatum may result from increased muscle tone associated with myotonia. Reducing myotonia appears to reduce the severity of campomelia and pectus carinatum [189].

Muscle fiber hyperexcitability is prominent, with spontaneous individual muscle fiber activity occurring even during sleep [180, 183]. The excessive muscle fiber contraction likely contributes to skeletal muscle hypertrophy [189].

Fig. 53.8 Characteristic facial and skeletal features in Schwartz-Jampel syndrome. Note skeletal and facial anomalies including short neck, small mouth, micrognathia, pursed lips, upward slanting eyes, blepharophimosis, low-set ears, and prominent eyebrows. Patients with SJS may have prominent proximal upper and lower extremity muscle hypertrophy and distal predominant generalized weakness and atrophy

The physiological basis for myotonia in SJS is complex. The single fiber hyperexcitability raised the possibility that SJS was associated with abnormal function of skeletal muscle membrane ion channels. However, SJS is not associated with sodium or chloride channel mutations. Chloride conductance is not sufficiently altered to produce myotonia [190]. Sodium channel gating is altered. In response to membrane depolarization, sodium channel openings are delayed and the channels open repeatedly during the depolarization. The delayed openings indicate that the transition from the closed to the open state of the sodium channel is altered. The repeated openings during depolarization indicate destabilization of the fast inactivated state so that channels can repeatedly jump between the inactivated and open channel states [190].

More recent studies following identification of the HSPG2 mutations underlying SJS type 1 demonstrated peripheral nerve hyperexcitability and suggest that myotonic behavior is in part due to neuromyotonia [191]. Schwann cell basement

membrane and its molecular interactions with axons are critical for proper myelination and node of Ranvier structure. Perlecan-deficient mice had shorter internodes, more numerous Schmidt-Lanterman incisures, and a higher density of internodal delayed rectifier potassium channels [192]. The increased number of intermodal potassium channels would oppose hyperexcitability. Thus, the increased potassium channel number is perhaps a cellular adaptation in response to peripheral nerve hyperexcitability [192]. The origin of the hyperexcitability of skeletal muscle and peripheral nerve membranes in SJS is likely due to altered function of membrane ion channels related to altered basement membrane.

Differential Diagnosis

The clinical presentation of SJS is so characteristic that the differential diagnosis is quite limited. The diagnosis of SJS is usually established by the combination of characteristic dysmorphic features, dwarfism, and myotonia accompanied by muscle enlargement. SJS differs from myotonia associated with chloride and sodium channel mutations by the prominent dysmorphic features characteristic of SJS. Skeletal anomalies and blepharophimosis distinguish SJS from the myotonic dystrophies. In addition among the myotonias, the combination of proximal muscle enlargement and generalized muscle weakness is unique to SJS [182, 183]. The skeletal and facial anomalies of SJS are similar to those found in the Marden-Walker syndrome. However, Marden-Walker syndrome is not associated with myotonia or proximal muscle hypertrophy [181, 184, 185]. As discussed above, SJS type 2 and Stuve-Wiedemann syndrome have very similar clinical patterns [181, 184, 185].

Diagnosis and Evaluation

EDX Testing

Routine motor and sensory nerve conduction studies are normal. Needle EMG shows continuous spontaneous high-frequency, low-voltage discharges in proximal and distal extremity muscles that wax and wane in frequency and amplitude (myotonic discharges) as well as high-frequency discharges with no change in frequency and amplitude (complex repetitive discharges) [180, 182, 183, 189, 193]. Myotonia is present in patients with SJS type 1A and 1B but is more prominent in SJS type 1B. The abnormal electrical activity represents spontaneous action potentials arising from individual muscle fibers. These can be found during sleep or general anesthesia. Electrical activity persists after motor nerve block and after neuromuscular block with curare, indicating that the abnormal electrical activity arises from primary hyperexcitability of skeletal muscle membrane [182, 183]. Procainamide [190] or carbamazepine [189] reduces the spontaneous electrical activity.

In one family where both father and son were affected, spontaneous rhythmic bursts of motor unit action potentials (myokymia) were described, indicating peripheral nerve involvement in this family [182].

Laboratory Testing

Serum CK level may be mildly to moderately elevated. Skeletal muscle is usually normal on light microscopy [182, 183, 189]. Occasional patients have mild myopathic features including excessive variability in fiber size [194]. Electron microscopic studies may reveal subsarcolemmal membrane abnormalities and mild changes in intracellular organelles [183, 189]. The myofibrils have a normal configuration, but the distributions of isoforms of myosin, myosin light chains, and other contractile or structural proteins are slightly altered in SJS [195].

Management and Treatment

Management is primarily symptomatic. Plastic surgery may be needed for severe blepharophimosis. Both procainamide [183, 190] and carbamazepine [189] can reduce myotonia and muscle stiffness in SJS. Early and aggressive treatment of myotonia during infancy and childhood may reduce the severity of some of the skeletal anomalies such as bowing of the long bones [189]. As with patients with other myotonic syndromes, patients with SJS may be subject to malignant hyperthermia, and depolarizing muscle relaxants are best avoided during anesthesia [196].

Prognosis

For SJS type 1A, the skeletal anomalies and dysmorphic features progress during childhood and reach a plateau in adolescence. For SJS type 1B, some skeletal anomalies and dysmorphic features are present at birth or early infancy and progress during childhood. Both type 1A and 1B patients have delayed acquisition of gait, slowness of gait, and reduced walking stability. Gait impairment is more severe in patients with type 1B SJS due to greater severity of hip dysplasia. Patients with SJS type 1A and 1B develop visual impairment due to the blepharophimosis, lens anomalies, and small corneas. Infants with type 2 SJS, the most severe form, have extreme difficulty feeding owing to severe micrognathia and laryngeal hypoplasia [181, 184].

The life expectancy of patients with SJS type 1A appears to be normal, while those with SJS type 2 usually die in infancy or childhood. The life expectancy of patients with SJS type 1B has not been clearly established but is probably reduced [181, 184].

Rippling Muscle Disease

Introduction and Clinical Presentation

Rippling muscle disease (RMD) is a very rare autosomal dominant inherited disorder of skeletal muscle originally described in 1975 by Torbergsen [197]. In 1989, Ricker, Moxley, and Rohkamm used the term "rippling muscle disease" to describe several members of two German families with the disorder [198]. Subsequently, two large families from the United States and two other German families were described [199, 200]. Rare sporadic cases associated with myasthenia gravis were also described [201, 202].

Patients present in childhood or adolescence with stiffness and intermittent pain and cramps induced by exercise, though rare patients present in adulthood. Mechanical percussion of muscle or muscle stretch after contraction induces continuous rolling, "rippling" waves of muscle contractions that begin in the proximal portion of the muscle and spread laterally across the muscle. The rippling can be induced again after a few minutes of rest. The quadriceps and biceps brachii were the most commonly affected muscles in two families [203]. Direct percussion of muscle produces two other phenomena: a distinctive rapid muscle contraction and a mounding up of the muscle with direct percussion which may be painful. Direct percussion of the muscle may also produce a prolonged muscle contraction identical to the percussion myotonia seen in the myotonic disorders. Ricker et al. [198] showed that the speed of the muscle waves during a contraction was 0.6 m/s, about ten times slower than the speed of a muscle fiber action potential, with the direction of the ripple at right angles to the long axis of the muscle fiber. The contractions are accompanied by needle EMG silence. Muscle hypertrophy, especially of the calves, is common. In one family, mild weakness of facial and proximal muscles was noted [200].

RMD has incomplete penetrance. Not all patients exhibit all of the clinical findings. In some of the families reported, males appear to be more severely affected than females, who may lack the rippling muscle phenomenon altogether. Muscle contraction and mounding of the muscle with percussion appear to be more constant features than muscle rippling in most affected individuals. In one family, a cardiac conduction defect was noted as part of the clinical picture [198]. In another family, some affected members reported recurrent pigmenturia precipitated by exercise [203].

Etiology and Pathogenesis

The etiology and pathogenesis are unknown. Genetic linkage was made to the distal end of the long arm of chromosome 1 (1q41) in a large family from Oregon [199, 204], while the German families studied by Ricker et al. [198] and Vorgerd et al. [203] and a large family from the United States described by So et al. [200] did not map to this locus, thus demonstrating genetic heterogeneity. However, the gene responsible for the disease is not known.

The mechanism by which abnormal contractions are induced by percussion or stretch is not clear. Some have postulated involvement of mechanosensitive or stretch-activated human skeletal muscle channels [201]. Direct percussion or stretch of muscle may induce intracellular events leading to the abnormal contractions. Defective regulation of calcium transport and homeostasis may be responsible for the abnormal cellular events [203]. Mechanically induced calcium release from the sarcoplasmic reticulum may be extremely high, uncompensated for by calcium reuptake, leading to abnormal accumulation of calcium in the cytosol and abnormal muscle contractions [203]. Extracellular communication may then initiate a similar train of events in neighboring muscle, given that thousands of muscle fibers act concurrently [199]. There is also an autoimmune form of RMD associated with myasthenia gravis, with or without thymoma, that resembles the inherited form [201, 202].

Diagnosis and Evaluation

The presentation of RMD is so idiosyncratic that the diagnosis is made when the distinctive characteristics are recognized. A search for associated cardiac abnormalities is warranted. If there is no family history, and presentation occurs in adulthood, an evaluation for myasthenia gravis is indicated. Needle EMG shows slightly increased insertional activity at rest and electrical silence during the rippling muscle movements. Muscle biopsy shows mild nonspecific abnormalities including increased variability in fiber size and increased central nuclei [198, 203]. Serum CK level may be slightly to markedly elevated [198].

Treatment and Prognosis

In general, there is little to no disability associated with RMD, although stiffness and cramps can be bothersome, and patients learn to avoid situations that cause painful mounding of the muscles. The subset of patients with cardiac conduction defects needs close cardiac monitoring. Some patients responded to dantrolene sodium or benzodiazepines to reduce stiffness, but tocainide was not helpful in reducing cramps or stiffness [199, 203, 204]. In the rare reported patients with RMD associated with myasthenia gravis, symptoms improved with immunosuppressive therapy or thymectomy.

Malignant Hyperthermia

54

Tulio E. Bertorini

Introduction

Malignant hyperthermia (MH) is a condition that manifests acutely by rigidity, increased body temperature, and muscle necrosis. This usually occurs during surgery under exposure to certain inhalable anesthetics, such as ether, or halogenated compounds such as halothane usually but not always together with depolarizing relaxants, such as succinylcholine. The syndrome, which was initially described by Denborough in 1960 [1], produces acidosis, hypermetabolism, and myoglobinuria with excessive intracellular calcium accumulation and muscle necrosis. The reported incidence of MH varies from approximately 1 of every 5,000 to 10,000 to 1 of every 50,000 to 100,000 surgeries [2]. It occurs more frequently in males than in females, and the incidence is higher in children [3–8].

Pathogenesis

MH is believed to be caused by an excessive release of calcium from the sarcoplasmic reticulum (SR) in subjects at risk because of specific genetic mutations. MH also has been reported sporadically in patients with certain neuromuscular disorders, but in some of these patients, the attacks are atypical. The typical syndrome usually has an autosomal-dominant inheritance pattern, most often associated with genetic mutations of the ryanodine receptor (RYR1) calcium channel gene [9–11] in muscles, and less frequently, the dihydropyridine (DHP) voltage-gated calcium channel gene [12, 13]. Both of these proteins are involved in muscle calcium release by the SR [10, 11, 13, 14], and the mutations appear to lower the threshold for calcium release for electrical contraction coupling [15]. A similar condition, known as the *porcine stress syndrome*, occurs in pigs and is also caused by a RYR1 gene mutation.

Located in the SR, the RYR1 receptor, so named because of its binding to the alkaloid of ryanodine, is a large protein with a molecular weight of 2,200 kd, with 5,000 amino acids [16]. Intimately connected with the RYR1 at the triads of the SR and the T tubules is the DHP receptor calcium channel, which acts as a voltage sensor for the RYR1 receptor, and gets its name for its sensitivity to DHP [16] (Fig. 54.1). The actions of

these receptors are closely coupled by mechanisms that are not fully understood, but it is believed that the opening of the DHP channel stimulates the RYR1 channel to release calcium. This channel is regulated by adenosine 5′-triphosphate and calmodulin and is activated by caffeine and ryanodine [17, 18].

In MH-susceptible individuals, the RYR1 receptor is activated by lower than the typical calcium concentrations, and higher than normal calcium levels are required to inhibit the channel opening during special circumstances that cause excessive calcium release [19]. The exact mechanism by which some anesthetics trigger excessive calcium release and the association of MH with the RYR1 and DHP receptors mutations have not been seen completely elucidated [14, 18, 20], but it appears that the effects of anesthetics is dose related. The additional use of succinylcholine increases the risk of MH, likely because this drug increases membrane depolarization [21, 22], but the causative effect of the drug when used alone is not clear [21]. The role of other drugs in the development of the syndrome is controversial and based only on individual reports [21, 23]. An excessive muscle calcium release also causes increased contractures during the muscle in vitro muscle contracture test, which is used to identify individuals predisposed to MH attacks in susceptible muscle.

During MH attacks, the excessive muscle contractions [14, 20] lead to elevated oxygen consumption, glycogenolysis with depletion of high-energy phosphates in muscle, and elevation of body temperature (Fig. 54.2). The energy exhaustion limits reuptake of calcium into the SR impairing muscle relaxation and resulting in a further increase of intracellular calcium causing necrosis [24]. The necrosis leads to a leak of phosphates, potassium, and uric and lactic acids into the blood stream, and severe systemic acidosis develops. Creatine kinase (CK) and other muscle constituents, including myoglobin, are also released, and myoglobinuria ensues.

In genetically predisposed pigs, stress (e.g., when they are confined to small pens before slaughter) also causes spontaneous muscle contractions leading to the devastating metabolic cascade of events as is seen in humans [25, 26]. MH also may occur in humans during extreme stress or excessive exercise [27–31]. The similarity of the swine and the human

Idiopathic hyperCKemia
Exercise-induced myoglobinuria
Statin myopathy

diseases allows the pig to be an excellent animal model for the study of the human condition [25, 26].

Variations of the syndrome, manifesting by muscle rigidity during anesthesia, occur in some hereditary myopathies (Table 54.1), and it also has been suggested that some patients with neuroleptic malignant syndrome, heat stroke, sudden infant death syndrome, or frequent muscle cramps may have genetic defects that predispose them to MH [30, 32]. There is, however, no evidence of MH-associated mutations in patients with malignant neuroleptic syndrome, which is caused by dopamine deficiency or blockade myoglobinuria could also occur in MH-susceptible individuals during stress and exercise.

Genetics

Most patients with MH have mutations of the RYR1 gene located on chromosome 19q13.1 [4, 19], and this has been classified as *malignant hyperthermia syndrome 1* or *MHS1* [4, 32–36]. False exclusion of linkage to the RYR1 locus in some families, however, cannot be excluded [16]. The gene expands 158 kb and contains 106 exons and transcribes an RNA molecule of 15 kb length [37]. Another locus is located at chromosome 17q11-224 on the gene of the sodium channel a-subunit or *MHS2* [38]. A third locus maps to chromosome 7q21-q22, which encodes to the α2/d-subunit of the L-type DHP voltage-gated calcium channel receptor (CACNL2A); this is considered *MHS3* [12, 13]. Mutations of a gene in chromosome 3q13.1 also have been reported in some families [39], and these are classified as *MHS4*. A mutation of the α1-subunit of the calcium channel receptor (CACNL1A3) in chromosome 1q31-q32, found in about 1 % of patients [13, 40], is designated *MHS5*. *A* mutation in chromosome 5p also has been identified, and this has been called *MHS6* [41] (Table 54.2). Patients with King-Denborough syndrome can manifest MH, and some but not all might also have a mutation in the RYR gene [42]. Finally, the calsequestrin gene in chromosome 1q21 has been suggested as a candidate gene [43]. Calsequestrin is a calcium-binding protein of the terminal cysterna of muscle that also regulates calcium release [44]. This group could be considered *MHS7*.

Table 54.2 Genetic classification of malignant hyperthermia susceptibility syndrome (MHS)

Classification	Gene location	Gene product
MHS1[a]	19q13.1	Ryanodine receptor
MHS2	17q11.2-q24	Close to α subunit of the sodium channel
MHS3	7q21-q22	Unknown but close to α2/δ subunit of the L-type dihydropyridine calcium channel
MHS4	3q13.1	Unknown
MHS5	1q31-q32	α1 subunit of the dihydropyridine calcium channel
MHS6	5p	Unknown

[a] 70–80 % of all MHS cases

Attacks of MH occur in multicore disease and central core disease [45, 46], and most patients with this disorder have mutations of the RYR 1 gene [47–49].

It has been suggested that some patients with idiopathic hyperCKemia might also have MH and mutations of the RYR1 gene [50]. Furthermore, important research also has been done on patients with statin myopathies who appear to be at risk of MH [51], and some of these have a positive caffeine-halothane contracture test [52], suggesting that statins might have an effect on the regulation of calcium function. These drugs have been suggested to upregulate genes connected with muscle calcium regulation homeostasis and membrane repair [53, 54]. A similar effect has been detected with the use of fluoroquinolones, which increase susceptibility to myotoxicity and cause alteration of calcium metabolism associated with abnormal contraction tests [55]. Patients with exercise-induced myoglobinuria might be suspected to be at risk to develop MH and should be tested for this disorder [28].

The MH-like attacks that occur in various myopathies without RYR1 gene mutations are atypical in most. These may be associated with muscle rigidity, usually without fever, during anesthesia caused by excessive muscle depolarization or elevations of baseline cytosolic calcium levels from different mechanisms. Those disorders include myotonia congenita, myotonic dystrophy, dystrophinopathies, phosphorylase deficiency, Brody's disease, periodic paralysis, and carnitine palmitoyl transferase deficiency [56–61].

Clinical Characteristics

MH attacks are characterized by muscle spasms and contractures, a rapid rise in temperature, tachycardia, hypoxemia, cyanosis, hypermetabolism, acidosis, and sometimes cardiac

Table 54.3 Criteria used in the clinical grading scale for malignant hyperthermia

Clinical finding	Manifestation
Respiratory acidosis	End-tidal CO_2 > 55 mmHg: $PaCO_2$>60 mmHg.
Cardiac involvement	Unexplained sinus tachycardia, ventricular tachycardia, or ventricular fibrillation
Metabolic acidosis	Base deficit >8 m/Eql, pH <7.25
Muscle rigidity	Generalized rigidity: severe masseters muscle rigidity
Muscle breakdown	Serum creatine kinase concentration >20,000/L units: cola-colored urine, excess myoglobin in urine or serum, plasma [K+] >6 mEq/L
Temperature increase	Rapidly increasing temperature: T >38.8°C
Other	Rapid reversal of MH signs with dantrolene. Elevated resting serum creatine kinase concentration
Family history	Consistent with autosomal-dominant inheritance

Table 54.4 Testing protocols for malignant hyperthermia

Designation[a]	North American protocol	European protocol
MHS	Contracture of >0.7 g to 3 % halothane	Contracture of ≥0.2 g to ≤2 % halothane
	OR	AND
	Contracture of >0.3 g to 2.0 mmol/L caffeine	Contracture of ≥2 g to ≤2.0 mmol/L caffeine
MHE[b]	Contracture of 0.5–0.7 g to 3 % halothane	Contracture of halothane only or caffeine only
	No contracture	
	OR	
MHN	Contracture of <0.5 g to halothane	No significant contractures with either agent
	OR	
	Contracture of <0.3 g to 2.0 mmol/L caffeine	

Note: (1) Studies to determine the sensitivity and specificity of the contracture test show that both protocols have a sensitivity of about 100 %. Specificity is generally between 80 % and 97 %, according to several studies with these protocols malignant hyperthermia susceptibility [85]. (2) Some laboratories employ 1.0 or 1.0 micromolar ryanodine or 4-chloro-m-chlorocresol in addition to halothane and caffeine to clarify equivocal results; however, these agents have not been incorporated into the standardized test

[a]MHS, malignant hyperthermia susceptible; MHE, malignant hyperthermia equivocal; MHN, malignant hyperthermia negative

[b]In the North American protocol, the MHE designation is "optional," and most centers report results as either MHN or MHS using a threshold of 0.5 g

arrhythmia [3, 24]. Muscle necrosis causes a markedly elevated serum CK, potassium, lactic acid, and myoglobinuria, which may result in renal failure [3, 7, 24, 62, 63] (Table 54.3).

Anesthesiologists usually are suspicious of an attack early when patients develop excessive masseter muscle contractures or elevation of end-tidal carbon dioxide (CO_2) during induction of anesthesia. Masseter contractures are not always present and may occur in patients who never develop MH [64]; therefore, their presence is not a reliable indicator of MH [65].

Because MH occasionally occur during the postoperative period, patients at risk should be monitored for at least 24 h in the intensive care unit, even after minor surgery or minimally invasive procedures such as muscle biopsy [66].

The muscle histology in classic MH patients includes variation in muscle fiber size, "moth-eaten" and opaque fibers, and an increased number of internal nuclei. These are nonspecific findings that are not diagnostic [67]. The histologic features on muscle biopsy of patients with central core disease show central areas devoided of oxidative enzyme activity in type I fibers. These areas have a decreased number or an absence of mitochondria on electron microscopy. In minicore disease, these are small and multiple in individual muscle fibers.

Other than those patients with classical central core or minicore disease, the phenotype or histology in most MH patients has no distinct features. Those with the King-Denborough syndrome, however, are identified by short stature, undescended testes, high-arched palate, small chin, low-set ears, ptosis, dislocated shoulders, lordosis, scoliosis, kyphosis, and pectus carinatum [68, 69]. Another group of patients have Evans myopathy, with nonspecific features of proximal muscle wasting; hypertrophy of some muscles, such as the sternocleidomastoid; partial ptosis; elevated CK; and nonspecific muscle biopsy findings [30].

Diagnosis

The diagnosis of MH is suggested by a rise in end-tidal CO_2, an elevated temperature, tachycardia, or acidosis and prominent contractures [2, 20, 30, 62]. Any of these events should alert the anesthesiologist to suspect the condition and treat it properly before the development of the complete syndrome.

Recognition of susceptible patients before surgery is most important in order to take preventive measures. A family history of an abnormal reaction to anesthesia or death associated with anesthesia should raise concern for MH.

The muscle contracture test is based on the increased susceptibility of an MH patient's muscle to electrical stimuli that cause calcium release and contractions [70]. To perform the test, which is done at only a few medical centers, a fresh muscle biopsy is required. A strip of muscle is stimulated, and contractures are produced with varying concentrations of halothane or caffeine [70–73] (Table 54.4). Other compounds, such as ryanodine and 4-chloro-m-cresol, also appear promising substances to be used in the test [7, 16, 73, 74]. Muscle tension is measured with a strain gauge, and an

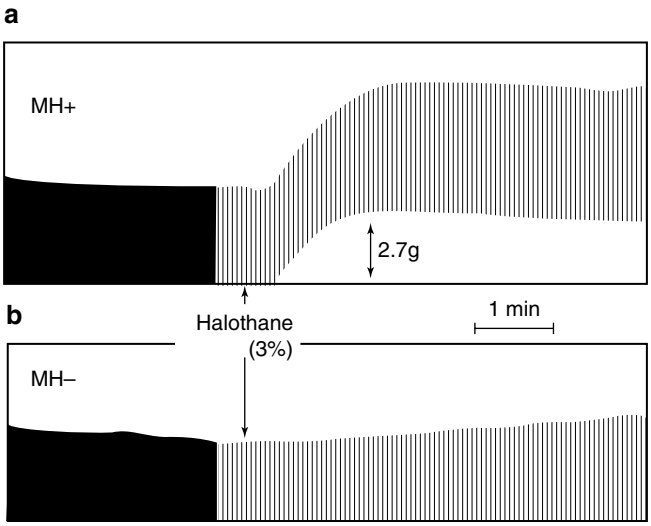

Fig. 54.3 Muscle contracture test after halothane (**a**) in a patient at risk of malignant hyperthermia; normal test (**b**) (Reproduced from [85], p. 13. With permission)

abnormal response is detected – for example, when tension exceeds 0.2–0.7 g during 3 % halothane administration (Fig. 54.3). These excessive contractions occur in those predisposed to MH, and the same test detects swine at risk for the porcine stress syndrome [75].

Standardization of the technique allows for a more accurate diagnosis and eliminates the occurrence of false-positives [76, 77]. The standardized American and European protocols differ somewhat, but both produce adequate recognition of at-risk individuals [77, 78]. The test should be performed on patients with a family history of MH or those with a previous abnormal reaction to anesthesia. A novel, promising screening test is the use of in vivo magnetic resonance spectroscopy [74], although its value in a large population of patients has not been proven.

Individuals at risk may have a baseline elevation of serum CK, which is useful in recognizing an increased risk for surgery in individuals with an affected family member. However, this is not a sensitive indicator because baseline CK values may be normal in MH patients. Genetic testing is available, but the identified genetic abnormalities do not occur in all families. An increasing number of mutations are now recognized using modern techniques that increase the yield of detection [79].

Differential Diagnosis

The differential diagnosis of an attack of MH is limited. Attacks of myoglobinuria during anesthesia are considered to be caused by MH, but some individuals may develop rigidity without all the features of the typical syndrome, while others might not have the characteristically abnormal increased release of calcium by the SR, or a positive contracture test. As discussed previously, patients with myopathies, particularly those with muscular dystrophy, might become rigid during anesthesia and even develop myoglobinuria, but the pathogenesis appears to be different from the classic syndrome. This is called *hyperkalemic cardiac arrest* [2] and usually occurs during exposure to succinylcholine and is associated with severe hyperkalemia [2]. Some of these patients also might develop fever, although they do not have the mutations associated with MH, but some have a positive muscle contracture test. Despite the similar clinical presentation in these patients, there could also be muscle necrosis with excessive calcium accumulation. In the channelopathies, such as myotonias, rigidity during anesthesia is believed to be caused by increased myotonia from depolarizing drugs or low temperature.

Other acute changes observed in patients receiving anesthesia also should be considered, including arrhythmias from other causes, such as electrolyte imbalance, seizures, allergy to drugs, and shock [80]. These conditions should be easily recognized and do not have all the findings of MH. Because myoglobinuria in patients at risk of MH also may be induced by stress and exercise, metabolic myopathies that manifest with myoglobinuria during exercise should be considered in the differential diagnosis, including glycogen storage disorders, such as McArdle's disease, and other metabolic myopathies, such as carnitine palmitoyl transferase deficiency [24, 56, 81].

The differential diagnosis of an unexplained increase in end-tidal CO_2 during surgery includes hyperthermia secondary to sepsis, drug overdose, introgenic warming, and anesthesia machine malfunction [2]. Other differential diagnoses includes hyperthyroidism and pheochromocytoma.

The use of high ionic, water-soluble radiologic contrast agents intrathecally might result in fever and seizures as the contrast material enters the ventricles; these patients also might have acidosis and respond to dantrolene, but there does not seem to be a close correlation with MH, and those patients do not have the genetic mutations associated with MH.

Treatment

The most important treatment for MH is the discontinuation of anesthesia and the use of dantrolene, a muscle relaxant that decreases the release of calcium from the SR and therefore inhibits the contractures induced by halothane, reducing the cascade of metabolic events on muscle during attacks [20, 82]. Treatment of acute attacks also consist in hydration and cooling with correction of electrolyte imbalance and reversal of cardiac arrhythmia. The preoperative use of dantrolene and the early identification of at-risk individuals and prompt therapy have reduced mortality from 80 % in the past to the current 10 % [81, 83].

Patients identified as being at risk for MH should never receive any of the precipitating agents listed in Table 54.5 [24]. In addition, all equipment used in administering anesthesia must be appropriately cleaned and maintained to remove any traces of offensive agents that might trigger an attack. In at-risk patients, dantrolene can be administered orally for several days before surgery.

A list of recommended steps in the management of an acute attack of MH was developed by the Malignant Hyperthermia Association of the United States. [84] These steps are summarized as follows:

1. Discontinue the anesthetic and deliver 100 % O_2.
2. Use dantrolene intravenously in doses of 2–3 mg/kg every 5 min for a total of 10 mg/kg.
3. Administer sodium bicarbonate and iced intravenous saline infusions, avoiding Ringer's lactate.
4. Lavage the stomach, bladder, and rectum with iced saline and use cooling blankets, while closely monitoring body temperature.
5. Treat arrhythmias by reducing hyperkalemia and with antiarrhythmic drugs, but do not use calcium blockers.
6. Monitor end-tidal CO_2 and blood gases.
7. Treat hyperkalemia with hyperventilation, bicarbonate, glucose, and insulin, and when life threatening, use calcium chloride.
8. Assure urinary output of greater than 2 mL/kg per hour by hydration or mannitol and furosemide, or both.
9. Treat unexpected cardiac arrest in children by treating hyperkalemia first.
10. Continue monitoring in the recovery room and intensive care unit for a minimum of 24 h; monitor blood gases, potassium, and calcium; determine myoglobin in urine; and administer dantrolene 1 mg/kg intravenously every 6 h for 24–48 h, followed by oral dantrolene for another day.
11. Contact the MH Association hotline (800 – MH-Hyper) (8006449737).
12. Refer individual and family to a MH Diagnostic Center, for further diagnostic testing and counseling.

Part VIII

Neuromuscular Disorders: Myopathies

Approach to Myopathies

55

Björn Oskarsson

Introduction

Muscle is the largest organ system in the human body. Severe disturbances of muscle function are life threatening, and more minor problems may cause marked disability.

This chapter will describe how to approach a myopathy for which the cause is not already established. A structured approach is the best for reaching a specific diagnosis in the majority of cases. Although a comprehensive knowledge of muscle diseases and other diseases that may cause weakness can be most helpful, eventually allowing for the recognition of the specific pattern of a myopathy in an increasing number of cases, a structured guide to the evaluation of weakness which does not demand such expert knowledge is provided here. As the clinician accumulates more knowledge, he/she will increasingly be able to rely on recognizing patterns specific to each myopathy; without such understanding, this approach is less often fruitful. However, even a novice may be able to recognize a pattern when a patient has a clear family history of a specific disease or an archetypical presentation of a common disease, and therefore, in these cases a more targeted approach will serve best. The pattern recognition strategy uses the specific if not pathognomonic aspects of myopathies such as in the rash in dermatomyositis, severe contractures in Emery-Dreifuss, or the pattern of extraocular and pharyngeal muscle involvement in oculopharyngeal muscular dystrophy.

A structured guide to evaluating myopathies is presented in this chapter combined with tables of common disease patterns are discussed, but more extensive text on this approach exists. Some 20 of the most useful patterns will be covered, but any pattern recognition system requires a certain amount of expertise. Otherwise the three basic steps in a myopathy workup are (1) a neurologic evaluation composed of history and examination, (2) electromyography (EMG) and creatine kinase (CK) testing, and (3) muscle histology (Fig. 55.1). After these have been performed, either a specific diagnosis will have been reached or a limited number of disease-specific tests will be indicated in the vast majority of cases.

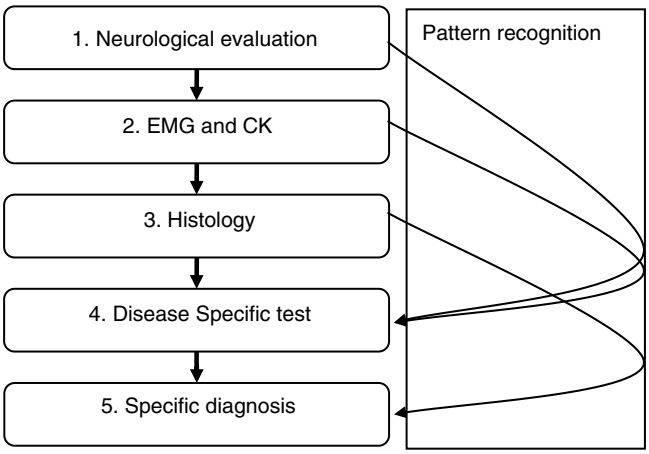

Fig. 55.1 Basic steps in myopathy evaluation

The pattern recognition approach will circumvent the need for EMG and histology in many patients. This book contains detailed chapters on the myopathies that can be discovered using this approach. Clinically, muscle problems most often present as weakness, but sometimes muscle pain, fatigue, or myotonia are the initial complaints. An ever increasing number of referrals are also seen in response to diagnostic abnormalities such as elevated creatine kinase values (CK), abnormal MRI imaging, or other tests.

History

When approaching a patient presenting for a myopathy evaluation, the first question to answer is whether or not a myopathy is present or not, and the starting point is to capture the history of the complaint. There are few absolute truths about

Table 55.1 Weakness: Disease entities to consider in the differential

Systemic disorders (*many of these diseases may, in their extreme forms, cause muscle damage*)
Joint disease (causing pain and weakness)
Metabolic disturbances (hypo/hyperkalemia, hypernatremia, hypoglycemia)
Endocrinopathy (thyroid disease, adrenal insufficiency)
Anemia
Neurological disorders
Central nervous system disorders (parkinsonism, central pontine myelinolysis, myelopathy)
Motor neuron disease
Polyradiculopathy
Plexopathy
Neuropathy
Neuromuscular junction disorders

Table 55.2 Common acute myopathies

Toxic (statins, alcohol, and others)
Electrolyte disturbance (hypokalemia, other)
Inflammatory myopathies
Metabolic myopathies (McArdle's disease, carnitine palmitoyltransferase II deficiency)
Infectious (influenza, mycoplasma, other)
Rhabdomyolysis secondary to central nervous system activation (exercise, status epilepticus, neuroleptic malignant syndrome)

symptoms as they by definition are subjective events experienced by a person and then described to the physician. Some patients can describe symptoms in an accurate and concise manner that is easy to follow, but many have difficulty with articulating unfamiliar and disturbing experiences. The clinician's task is to discern whether a patient presenting with complaints of weakness is suffering from actual muscle weakness, because many other diseases can result in a feeling of weakness in a broad sense (Table 55.1).

Patients experiencing *muscle weakness* often will mention difficulties in performing specific tasks that are dependent on the strength of the affected muscle groups. If no task-specific problems are divulged spontaneously, then the patient should be prompted with a question such as "Give me an example of something that is hard to do due to the weakness." The by far most common myopathic pattern of weakness is the one involving proximal limb muscles, leading to complaints of standing out of chairs, walking up stairs, washing ones hair, or performing other tasks with the arms above the head. More distal weakness may be experienced as problems opening jars, turning keys when affecting the hands or stumbling, and tripping when affecting the legs. Quadriceps muscle weakness tends to lead to leg buckling. Leg buckling is also often reported in psychogenic weakness and presyncopal weakness.

On the list of diseases to consider that also cause more focal task-specific weakness, *joint diseases* are relatively common. Particularly hip weakness is not infrequently caused by hip arthropathy and history, and in rare cases clinical exam is not always conclusive in separating muscle weakness from joint pain, as they can cause similar functional limitations. The most distinguishing feature is pain which is normally present in joint problems, but rarely prominent in myopathies. Examination can normally identify a joint problem, and if not, then imaging, laboratory studies, and EMG should be able to distinguish joint from muscle disease. The conditions can coexist and the presence of one does not prove the absence of the other.

Fatigue is often described by patients as weakness, but fatigue is rarely due to muscle problem. Other words used to describe fatigue is tiredness and decreased stamina. Fatigue does not normally produce difficulties with specific tasks. Fatigue results in inability to engage in more general tasks such as shopping or cleaning or tasks that take longer periods of time compared to the specific tasks limited by muscle weakness. Fatigue is more commonly a symptom of systemic medical problems. However, fatigue can also be caused by myopathies. In particular, exercise-induced fatigue is commonly seen in the metabolic myopathies. Fatigue and weakness can also occur together from myopathies. This combination of symptoms can occur when a myopathy causes systemic symptoms due to inflammation. The myopathies that results in concomitant cardiomyopathy or respiratory muscle weakness will also frequently result in both fatigue and weakness. Fatiguing weakness is typical of neuromuscular junction disorders, and they need to be seriously considered in the differential when both appear to be present. Myasthenia gravis and several other less common neuromuscular junction disorders tend to markedly involve the bulbar region, which is unusual in myopathies. Others, such as the Lambert-Eaton myasthenic syndrome, may have a proximal leg distribution that is similar to most myopathies.

The temporal course of weakness can also provide clues as to the nature of the underlying myopathy. The periodic severe weakness often seen in the periodic paralyses is very specific, and no other myopathic conditions cause quite this pattern. There are relatively few myopathies that have an acute presentation with any frequency (Table 55.2).

Numbness is sometimes used by patients as a word to describe weakness, and clarification of what a person using the term is referring to is necessary. According to Collins English dictionary, numb can mean "unable to move; paralyzed," while in medicine the term tends to be used to relate to only a loss of sensation [1]. Using this correct definition, numbness can be a symptom of myopathy. Sensory loss and paresthesias should be queried in detail since they can suggest a peripheral or central nerve problem.

Table 55.3 Common conditions where myalgia commonly exceeds weakness

Fibromyalgia
Polymyalgia rheumatica
Toxic myopathy (statin, alcohol)
Hypothyroid myopathy
Infectious myopathy (influenza)
Metabolic myopathies (McArdle's disease, mitochondrial, myoadenylate deficiency, others)
Inflammatory myopathies (rarely polymyositis or dermatomyositis)

Pain can limit functional strength. If severe muscle pain i.e. myalgia exist, it may not be possible to discern whether there is any weakness by history alone. Most myopathies are painless, but some can be quite painful. When pain clearly exceeds weakness, then fibromyalgia and polymyalgia rheumatica might be considered. While these disorders are not considered to be myopathies in a strict sense, persons practicing myology need to have some familiarity with them, and they are covered in this book. Myalgia is one of the diagnostic features of influenza infection and is common in mycoplasma and several other systemic infectious diseases. In the vast majority of such infectious cases, symptoms are brief and the association with an obvious systemic infection precludes a referral to a myologist. Occasionally, patients for which the myalgia or weakness were dominating (or an underlying myopathy was unmasked) will be referred for further evaluation. Exercise-induced myalgia is common with statin use and several of the metabolic myopathies. Mild myalgia as a symptom does not narrow the differential of possible myopathies in a meaningful way, but when it is severe or when it is the dominating complaint, then it can help direct the workup (Table 55.3).

Past events of rhabdomyolysis should also be explored, with more fulminant events being easy to remember and of clear diagnostic value. A nonspecific milder episode of muscle pain and tenderness requires more careful consideration. Myoglobinuria should be asked about, and if brown or dark-colored urine has been noted, then try to discern if there is a pattern to it (e.g., it occurs after exercise).

Pattern Recognition and Rarely Involved Muscles

The pattern recognition approach to myopathies is particularly powerful when applied to the clinical pattern of muscle involvement. The myopathies that deviate from the proximal and symmetric distribution patterns that are characteristic of the majority of myopathies can often be identified clinically. When the differential diagnoses are few, genetic or other specific testing can often be done without the need for electrodiagnostic and histological evaluations.

Table 55.4 Myopathies with involvement of extraocular muscles

Oculopharyngeal muscular dystrophy (OPMD)
Mitochondrial myopathy
Thyroid orbitopathy

Muscles of eye movement are the only involved muscles and, more rarely, the most affected muscles in a minority of myopathies. This is a situation when the pattern recognition approach with reasonable certainty limits the number of possible myopathies to oculopharyngeal myopathy, thyroid orbitopathy, and several of the mitochondrial myopathies (Table 55.4). To exemplify eye movement weakness and marked ptosis, a patient with a large mitochondrial deletion is depicted in Fig. 55.2 a and b.

Likewise when *facial muscles* weakness is prominently reported, this suggests a short list of common myopathies (Table 55.5).

Shortness of breath, a weak cough, and orthopnea are symptoms attributable to weakness of *respiratory muscles*. Again a relatively short list of diseases is likely when respiratory muscles are involved early (Table 55.6).

A *cardiomyopathy* can cause some of the same symptoms and does in turn suggest another set of myopathies (Table 55.7).

Other symptoms that can markedly reduce the differential include skin changes, muscle cramps, muscle hyper- or hypotrophy, joint stiffness, or laxity. The majority of myopathies are quite symmetric, and if there is a striking left versus right difference, then this suggests one of the few myopathies which often are asymmetric (Table 55.8).

Most myopathies tend to affect proximal muscles more than distal muscles. However, if the history suggests mostly distal weakness with complaints of hand and foot weakness, then a distal myopathy should be considered. Neuropathies are certainly more common with this pattern of involvement, and a relatively large portion of the distal myopathies are made up of diseases that are rare (Table 55.9).

Family History

The family history may guide a workup in the direction of a certain disease if a typical inheritance pattern is described or if a specific ethnic origin or known consanguinity is apparent (Table 55.10).

The number or family members affected and unaffected often help clarify an inheritance pattern. A single affected individual – a "simplex case" – in a small family does not have quite the same implications as one in a larger family. Not only should a family history cover muscle problems, but autoimmune and rheumatologic conditions as well as other neurological conditions are of particular importance. There

are diseases such as mitochondrial problems where the symptoms of a common genetic defect may produce very different types of phenotypes including diabetes, deafness, and anemia. When different family members are affected in such disparate ways, a familial pattern is harder to perceive. There are also de novo mutations and cases of mistaken paternity that can confound a carefully crafted family tree.

Medical History

A detailed current and past medical history needs to be obtained. The purpose of the medical history is to allow the examiner to discern other diseases that associate with specific myopathies (Table 55.11).

Treatment History

Patients who have been treated with prednisone and other immunosuppressants before coming for evaluation and biopsy present special challenges. Corticosteroids appear to have an effect on creatine kinase (CK) that is independent of its effect on immune-mediated myotoxicity. CK can be lowered by corticosteroid administration in noninflammatory myopathies and in patients without a myopathy [3]. After corticosteroid treatment, an immune-mediated myositis may lose many of its histologically distinguishing features, and the clinical information may be more presentable. In dermatomyositis, a history of a rash normally is recalled, but sometimes skin changes such as mechanic's hands or an unrelated skin rash may not be remembered as a rash from dermatomyositis. Many patients with IBM will report some benefit from prednisone or other immunosuppressant medication treatment, but the positive effects are not generally apparent by examination, and the benefit does not last for any longer period [4].

Medications and toxins are relatively common causes of myopathy, and a detailed review of current and recent medications and exposures should be undertaken. Some toxic exposures can coast and continue to cause a myopathy for some time after the end of the exposure. A common example of this is the statin myopathies where symptoms often coast for a few months after discontinuation of the offending statin drug [5]. The emerging statin-induced myositis associated with antibodies to HMGCR does not only coast after the discontinuation of statin medication but may continue to worsen [6]. The use of some medications are not readily admitted such as ipecac use in an anorexic patient or illegal muscle building supplements and should be queried (Table 55.12).

Exacerbating factors are useful for understanding myopathies with impaired muscle relaxation (i.e., myotonia). Asking for situations in which an eye closed shut, or a hand grip or limb movement might have locked up, and any triggering events of the symptoms can help identify the illnesses (Table 55.13).

In conclusion, the history is a very important tool in discerning what type of muscle problem might be present or whether the problem experienced is due to another cause such as a systemic medical problem, central nervous system problem, neuromuscular junction issue, or a peripheral nerve problem (see Table 55.1).

Table 55.11 Common disease associations in myopathies

Violaceous rash → dermatomyositis
Interstitial lung disease → antisynthetase syndrome, other inflammatory myopathies
Cataracts → myotonic dystrophy
Mechanics hands → antisynthetase syndrome, other inflammatory myopathies
Malignancy → paraneoplastic inflammatory myopathy
Diabetes → mitochondrial myopathy
Cognitive impairment → congenital myopathy, muscular dystrophies (Duchenne, myotonic), mitochondrial disorders
Osteomalacia → vitamin D deficiency
Paget's disease → familial inclusion body myositis

Table 55.12 Common agents causing toxic myopathies

Table 55.13 Common myotonic conditions and their exacerbating factors

Myotonia congenita, Thompsen type → none or mild effect of stress and cold
Myotonia congenita, Becker type → initial exercise
Myotonic dystrophy type I → cold, myotonia often mild
Myotonic dystrophy type II → warmth
Paramyotonia → increased by sustained exercise

General Physical Examination

The physical examination is the most important component of the diagnostic evaluation. It serves to confirm the diagnostic hypotheses that is suggested by the history and may raise new diagnostic possibilities. Furthermore, the examination is the most useful tool to use in order to follow the effect of a treatment on a myopathy. While surrogate biomarkers such as creatine kinase may be useful, strength as tested on bedside examination is normally more strongly associated with the functional limitations experienced by the affected individual. Bracing and therapy needs are also best judged by examination and history.

The physical examination may of a patient with a suspect muscle problem should include *vital signs* such as blood pressure, pulse, respiration, and temperature. In more acute disease processes, they may be useful to illustrate the severity

of the disease. Height and weight are also notable and can be of importance. The general exam should include an assessment of the body habitus. Short stature is associated with some mitochondrial myopathies and others myopathies such as Schwartz-Jampel syndrome.

Examination of the *eye, ear, nose*, *and throat* should include looking for dysmorphic features such as high arched palate. Dysmorphic features are often features of the congenital myopathies. Eye examination may reveal retinal abnormalities such as a cherry red spot in mitochondrial myopathies, cataracts in myotonic dystrophy type I, and Coats' disease in facioscapulohumeral muscular dystrophy.

Examination of the *skin* may be useful in both acquired and inborn muscle diseases. Dermatomyositis has a rash that often is pathognomonic for the condition. The rash is reddish-purplish in color and sometimes slightly raised; it has a preference for the hairline, eyelids, neck, and limb extensor surfaces. Not all patients have a striking rash, and with treatment the changes may be difficult to definitively identify. Calcification of the skin and underlying fascia can also occur and will normally linger. Gottron's papules are violaceous papules and plaques over the knees or extensor surfaces, the hands, and other joints. Inflammatory myopathies, particularly the antisynthetase syndromes, frequently also cause skin changes in the hands. This pattern of skin thickening and callusing with small cracks has been referred to as mechanics hands. Collagen VI disorders may show keloid formation and abnormal scars. Corticosteroid myopathy often exhibit striae and stretch marks.

Lungs should be auscultated with attention to crackles from interstitial lung disease and to how much air is moved to give a quick bedside impression of respiratory muscle strength. A weakened forced cough may suggest a thoracic muscle weakness. Pulmonary function testing (PFT) is relatively simple and many muscle clinics routinely perform basic spirometry on patients. If PFT is not available in clinic, a less accurate option is to have the patient take a deep breath and count out loud. A person who cannot count to more than 20 probably does have significantly impaired vital capacity.

Cardiac examination should be performed with attention to both arrhythmias and signs of a cardiomyopathy. The cardiac examination may suggest the need for further studies such as EKG and echocardiograms even in muscle diseases where cardiac involvement is rare. Detected abnormalities can increase the urgency which further studies are done in diseases where cardiac involvement is frequent.

Joints are important to consider as many myopathies can lead to different types of changes. Contractures may be seen in many myopathies, but they are often severe in Emery-Dreifuss dystrophy. The pattern of limited finger extension due to contractures is typical of the collagen VI disorders. Arthritis is seen in many rheumatologic conditions and the overlap syndromes where a myopathy occurs with one of the rheumatologic conditions. With arthritis there is typically pain on passive joint movement, which is rare in a pure myopathy.

Neurological Examination

The neurological examination should start with a cognitive evaluation, recognizing that cognitive impairment is a feature of many inborn myopathies. Cognitive impairments can be seen in the dystrophinopathies, myotonic dystrophy, several other dystrophies, and many congenital and mitochondrial myopathies (Table 55.14).

The *cranial nerve examination* can reveal extraocular muscle weakness which is a relatively rare feature in myopathies and therefore very helpful in narrowing the differential (see Table 55.4). The eye movements should be checked in the six cardinal directions and any ptosis should be noted. A fatiguing ptosis would be more typical of a neuromuscular junction disorder, whereas a fixed ptosis would be more likely in a myopathy. Similarly, facial muscle weakness may help reduce the number of possible myopathies (see Table 55.5). The muscles of mastication which are supplied from cranial nerve V should be included. Temporalis muscle atrophy is particularly striking in myotonic dystrophy type I. Facial-innervated muscles including the frontalis, orbicularis oculi, orbicularis oris, and the zygomatic and other muscles of smiling should be tested. A transverse smile is common in FSH. Normally forceful eye closure results in an upward and outward eye movement, but an absence of the phenomenon may be normal or caused by many types of neurological problems. Eyelid myotonia is observed by having the patient quickly open the eyes after a forceful contraction (see Table 55.13). Pharyngeal muscles should also be observed, and a gag reflex can be provoked to visualize pharyngeal muscle function. Accessory muscles should be observed and tested. Myotonic dystrophy I often causes striking atrophy of the sternocleidomastoid muscles. The size of the tongue should also be considered; amyloidosis

and Duchenne dystrophy are among the diseases causing tongue enlargement.

Motor examination is certainly the most telling part of the examination, and the patient should undress appropriately to allow inspection of the muscle bulk.

In order to complete an accurate neuromuscular examination, the patient should expose their limbs and trunk muscles; this can be done sequentially with respect to the patient's modesty. Relative muscle group involvement is easier to appreciate on a completely undressed individual. The use of examination shorts and other ways to keep the patient comfortable while allowing for a thorough inspection is useful.

Physical exam can be painful for patients with tender muscles. Explaining the importance of the physical examination as the single most important test in establishing the diagnosis of myopathy helps many patients comply with the examination and gives good effort. If the patient is encouraged to provide good effort, the examination is thereby more rapid and results in less discomfort for the patient. The physical examination also establishes physical contact between the examiner and the patient, and this helps in building the therapeutic relationship.

Any pattern of atrophy or hypertrophy should be carefully documented to enable the recognition of a pattern of involvement. Palpation of the muscle for size, consistency, and tenderness can be useful particularly when there is fat overlying the muscle. Large muscles are often seen in myotonia congenita, myotonic dystrophy type II, and rippling muscle disease (LGMD 1c). Enlargement of calf muscles is common in the dystrophinopathies and a few other limb girdle dystrophies. Generally, small muscles are seen throughout the body in patients with congenital myopathies or some mitochondrial myopathies. Some degree of muscle atrophy is common in most myopathies, and the pattern of atrophy can help distinguish which myopathy is present. The phenotypic expression from a genotype may vary significantly, and there is also significant overlap between different conditions (Table 55.15).

Increased firmness of muscles may be due to fibrosis in chronic myopathies and amyloid deposits. Tenderness is most often seen in the inflammatory myopathies but also in some metabolic myopathies and any condition where rhabdomyolysis has recently occurred. Adventitious muscle activity such as myotonia (see Table 55.13), rippling, or cramps should be noted. To provoke myotonia the patient should be instructed to squeeze two fingers with maximal force for 15 s and then quickly release the grip. In myotonia the relaxation will be slowed and a characteristic writhing movement is often employed by the patient when disengaging the hand.

Muscles should be percussed with a reflex hammer to view if this causes a persistent muscle contraction. The thenar muscles are good targets for percussion. Percussion should normally result in thumb abduction/opposition as the muscles contract, and the contraction due to direct percussion should be immediate, but then quickly relax. The quadriceps and deltoid muscles are other good targets where a clear dimpling of the muscle can often be observed after percussion. Percussing the muscles where the patient notes symptoms increases the chance of finding an abnormality. Another abnormality that can be observed after muscle percussion is myoedema which is a swelling lasting a few seconds that can be seen with hypothyroidism and cachexia. Muscle tone should also be examined but, outside of contractures, it is generally not affected by muscle disease. The muscle strength should be rated and the modified Medical Research Council (MRC) rating which grades muscles on a scale of 0 to 5 is the almost universally used scale [7] (Table 55.16).

Muscle groups to examine include the neck extensors and flexors, shoulder abduction, internal and external rotation, elbow flexion and extension, wrist flexion and extension, finger extensors and flexors. Often additional muscle groups such as forearm pronators and specific hand muscles can be useful to assess if there is any weakness in those regions. The hip extensors should be examined as well as the flexors. The hip adductors and abductors should be included as well as the knee flexors and extensors, and the foot plantar and

dorsiflexors. Other distal foot muscles can sometimes provide additional information.

Muscle stretch reflexes are often mildly reduced in amplitude due to muscle weakness, but even though the amplitude of muscle contraction may be diminished, the force of the reflex hammer needed to exert the response will still be normal. The sensory exam is normal in the majority of myopathic conditions were no concomitant neuropathy exists.

Coordination is not normally affected by muscle disease, and thus, it is a less important aspect of the motor examination when evaluating myopathies. A patient's stance can reveal hyperlordosis in the limb girdle dystrophies, and toe standing is particularly common in the dystrophinopathies.

Gait and station examination demonstrates leg weakness and both distal and proximal patterns can be discerned. Other functional tests to perform include standing from a seated position with and without the use of arms. If standing out of a chair presents little or no difficulty, then rising out of a squatting position should be attempted. Standing on heels and toes can reveal more distal weakness. A patient's stance can reveal hyperlordosis in the limb girdle dystrophies, and toe walking is particularly common in the dystrophinopathies.

Laboratory Testing

Electromyography

After the history and physical examination have been completed, a differential diagnosis should be constructed. This is discussed in detail in Chap. 7. When a myopathy is considered in the differential, this normally should be confirmed by an electromyogram (EMG). Occasionally, the differential diagnosis includes only one or two myopathies; then, confirmatory laboratory testing may be more appropriate. However, in the majority of cases, further differentiating or supporting information should be sought starting with an EMG. Most importantly, the EMG serves to confirm the presence of a myopathy and exclude mimicking conditions such as motor neuron disease. The nerve conduction studies also provide information regarding polyneuropathies and repetitive nerve stimulations regarding neuromuscular junction disorders. The sensitivity of needle EMG varies depending on the myopathic process. For example, hypokalemic periodic paralysis is not normally apparent on routine EMG and corticosteroid myopathy has to be severe before it is apparent on needle EMG. The early recruitment of brief, small amplitude, and polyphasic motor unit action potentials is the most typical appearance of a myopathy. In chronic myopathies, particularly inclusion body myositis, there are additional large, long, and polyphasic motor unit action potentials, which can be recruiting in a reduced pattern. This EMG pattern can be misinterpreted as representing a pure neurogenic condition. Additional information regarding the myopathy such as the presence of myotonia can be revealed by EMG. Electrical myotonia is not always associated with clinical myotonia, and disorders associated with electrical myotonia only by EMG are listed (Table 55.17).

Table 55.17 Myopathies with Myotonia by needle EMG only

Dystrophinopathies
LGMD II (most types)
Necrotizing myopathies (paraneoplastic, antisynthetase syndrome, HMG-Co R)
Pompe's disease

Many myopathies also exhibit fibrillations and positive sharp waves by EMG. The origin of these discharges may be from myocytes or parts of myocytes that are no longer functionally connected to a neuromuscular junction due to injury [8]. Fibrillations and positive sharp waves can occur in most myopathies, and their discriminatory value is limited, except that it reduces the likelihood of a pure corticosteroid myopathy. The EMG should also be used to guide a subsequent muscle biopsy because it can confirm active myopathic involvement of a specific muscle.

Creatine Kinase

Another basic laboratory test that often is indicated in myopathies is creatine kinase (CK). This is discussed in detail in Chap. 3. Creatine kinase is increased in many myopathic conditions, but persistently very high values do suggest a narrower list of diseases (Table 55.18).

Muscle Histology

In most myopathies, muscle histology provides important diagnostic information. In cases in which the histology

C-reactive protein → acute phase reactant, nonspecific marker of inflammation

does not in itself provide a final diagnose, it can inform and direct additional specific diagnostic testing. The main types of myopathies tend to be distinguishable by biopsy, and the more common histological patterns include inflammatory myopathies, necrotic myopathies, and dystrophic myopathies. This is discussed in Chap. 12. Many other distinct types of myopathies can be seen including glycogen storage, lipid storage, and mitochondrial myopathies. Although some cases are hard to identify, when an inflammatory myopathy is seen on routine histochemistry, it is often straightforward to discern between polymyositis, dermatomyositis, inclusion body myositis by routine histochemical, and immunostains. Clinical information most often convincingly will identify which one of the inflammatory myopathies is present, but some dystro-phies also can have striking inflammation on biopsy (Table 55.19).

The necrotizing myopathies may occur due to autoimmune mechanisms, but myonecrosis can also be noted in many toxic myopathies. In the absence of inflammatory cells, MHC-1 and enzyme stains such as alkaline phosphatase, acid phosphatase, and esterase does not exclude an immune-mediated cause (Table 55.20) [9].

Other Specific Testing

After the basic muscle histology has been performed, confirmatory diagnostic testing is often indicated. For an inflammatory myopathy where poly- or dermatomyositis is considered, further diagnostic tests such as the antisynthetase antibodies may be informative. When present they certainly strengthen the inflammatory myopathy diagnosis, as they have a high degree of specificity, but they are often not present and have low sensitivity for inflammatory myopathies as a group. The antisynthetase antibodies also suggest a higher risk for interstitial lung disease (ILD). ILD may occur without antisynthetase antibodies, and clinical consideration of this severe condition is always warranted in poly- and dermatomyositis. Other markers of inflammation and autoimmunity that can be considered for testing are listed (Table 55.21).

Genetic Testing

When a muscular dystrophy is suspected, the phenotype should guide further testing. For dystrophies with a specific phenotype (such as OPMD, DM1, or FSH), genetic testing for the disease can be ordered, often before EMG or muscle biopsy is performed. If genetic testing does not confirm a reasonably suspected diagnosis, then performing an EMG and biopsy would be indicated. The limb girdle syndromes are numerous, sometimes not due to dystrophies, and often difficult to reduce to a few diagnostic entities by phenotypical features alone. Today, immunostaining of the proteins affected by the dystrophies helps identify the condition. The recessively inherited conditions (LGMD2) currently are better covered by immunostains, and genetic testing covers more of the dominantly inherited conditions. Often a generic limb girdle muscular dystrophy presentation will require multiple tests to be performed because of marked phenotypic overlap between conditions. The mitochondrial myopathies can be approached by specific genetic testing when they have other associated features and/or an inheritance pattern. The investigation of an otherwise featureless mitochondrial myopathy can be started with respiratory complex testing to provide further details to direct the next step of testing. Testing muscle for coenzyme Q10 deficiency is worth special consideration as some patients are helped a great deal by replacement [10].

Dystrophinopathies

56

Zarife Sahenk and Louise R. Rodino-Klapac

Introduction

The dystrophinopathies include a spectrum of muscle diseases caused by mutations in dystrophin gene (*DMD*) at Xp21 which encodes the protein dystrophin. The mild end of the spectrum includes the phenotypes of asymptomatic increase in serum concentration of creatine kinase (CK) and muscle cramps with myoglobinuria and isolated quadriceps myopathy. Variable phenotypic expression in dystrophinopathies relates mainly to the type of mutation and its effect on the amount of functional dystrophin production. Duchene muscular dystrophy (DMD) is in the most severe end of the spectrum and is typically associated with <5 % of normal levels of dystrophin in skeletal muscle. The diagnosis is made in most patients at approximately 5 years of age when their physical ability lacks behind their peers. In the milder allelic form Becker muscular dystrophy (BMD), dystrophin mutations do not disrupt the open reading frame; a shortened but functional dystrophin protein is produced, enabling most patients to remain ambulatory until the age of 15. Clinical phenotypes of other patients, so-called intermediate or outliers that do not fit the typical DMD or BMD, also exist. In general, manifesting carriers are in the milder end of the spectrum. Some dystrophin mutations cause an isolated cardiac phenotype resulting in *DMD*-associated dilated cardiomyopathy (DCM) when the heart is primarily affected.

DMD is the most common form of childhood muscular dystrophy with an estimated birth prevalence of about 1 in 3,500 (2.9 per 10,000) live male births [1]. A recent two-tier system of analysis for newborn screening for DMD that included a large cohort in the United States reports a lower incidence rate, 1 in 6,000 [2]. The disease carries the name of the French neurologist, Duchenne, who published his first description of DMD in 1861 with a more comprehensive account in 1868, establishing diagnostic criteria and accurately describing muscle biopsy features. British neurologist Gowers, in 1886, illustrated the characteristic features of calf muscle hypertrophy and described the way in which an affected child rises from the floor to reach the standing posture [3]; this sign was subsequently named after him. A milder form of the disease with later onset was recognized by Becker and Kiener in 1955 [4]. In the second half of the twentieth century, the histopathological characterization became more precise and the associated marked increases in CK were recognized in affected males and in carrier females to a lesser degree.

Advances in molecular genetics led to mapping of the gene responsible for DMD to band p21 of the short arm of the X chromosome [5–8] and then to the cloning of its DNA sequence in 1987 [9]. Subsequently, Kunkel's group was able to identify the muscle protein dystrophin encoded by the cloned gene [10], localized dystrophin in the sarcolemma of muscle fibers, and demonstrated its almost complete absence in DMD and its decrease in BMD. These advances permit unequivocal diagnosis of DMD and related phenotypes and allow accurate genetic counseling, reliable prenatal testing, and newborn screening.

Etiology and Pathogenesis

All dystrophinopathies are allelic conditions, resulting from different mutations of the dystrophin gene.

Dystrophin

Dystrophin is a scaffolding protein in muscle encoded by the DMD gene. The gene is the largest identified to date in humans, spanning approximately 2.4 megabases on the short

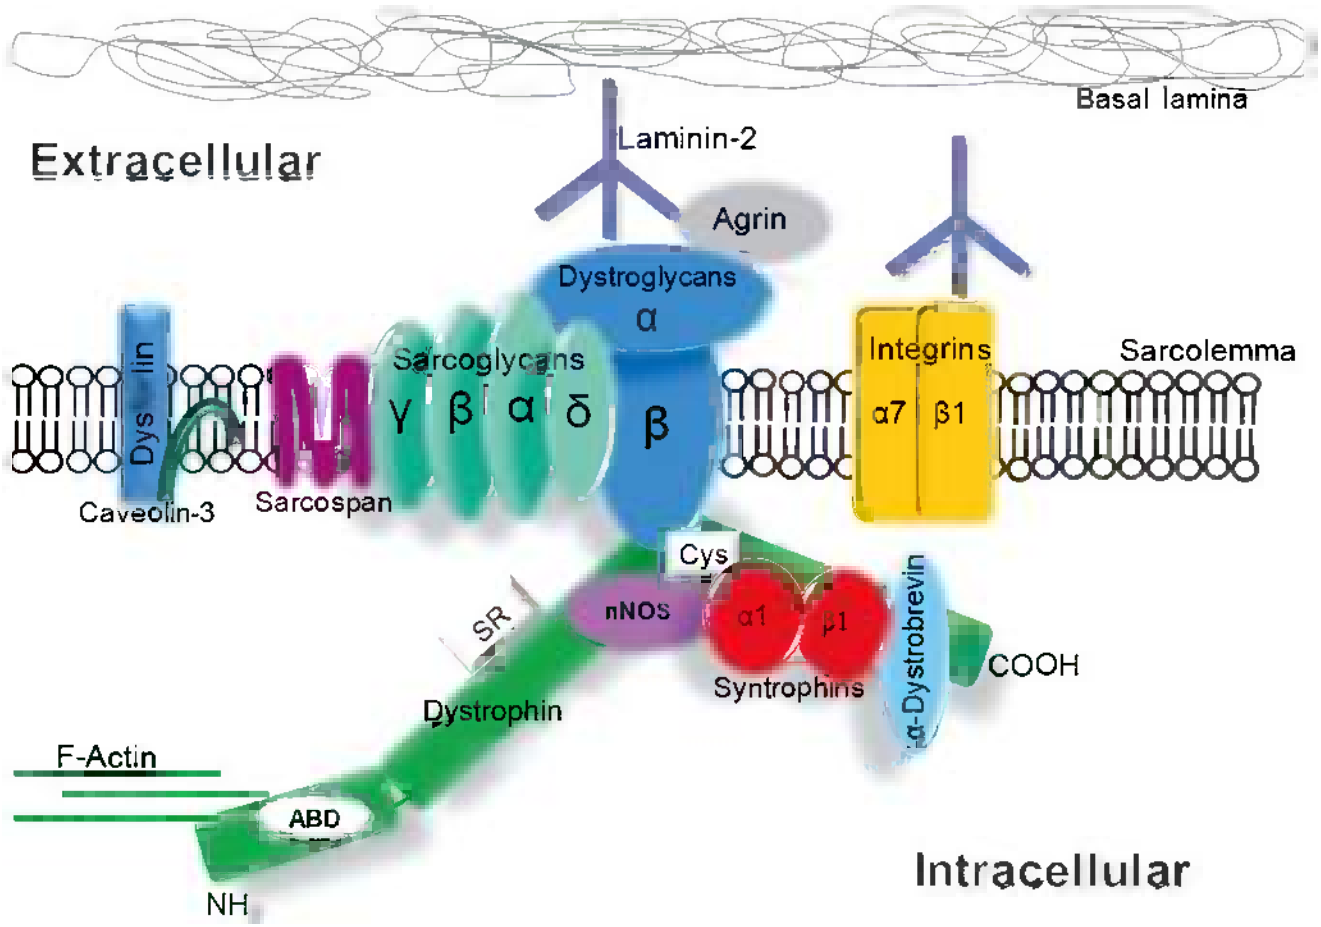

Fig. 56.1 The dystrophin-associated protein complex. The DAP is a large protein network that spans the sarcolemmal membrane comprised of dystrophin and interacting proteins to stabilize muscle fibers during contraction and relaxation. *NH_2* amino-terminal domain, *COOH* carboxy-terminal domain, *ABD* actin-binding domain, *SR* spectrin repeats, *CYS* cysteine-rich domain, *F-actin* filamentous actin, *nNOS* neuronal nitric oxide synthase

arm of the X chromosome (Xp21). The DMD gene contains 79 exons encoding for a 3685 amino acid, 427 kDa protein [9]. Dystrophin has four primary functional domains which together link the actin cytoskeleton to the extracellular matrix to provide stability and strength to muscle fibers (Fig. 56.1). These include (1) the amino-terminal actin-binding domain; (2) the central rod domain comprised of 24 triple helical spectrin-like repeats interspersed by 4 putative hinge domains imparting flexibility [11]; (3) the cysteine-rich domain containing two EF hands [12], a WW domain [13], and ZZ domain [14] important for signaling and binding β-dystroglycan, the link to the extracellular matrix; and (4) the carboxy-terminal domain which binds critical structural and signaling molecules the syntrophins and α-dystrobrevin [15].

The dystrophin gene can generate several tissue-specific isoforms of different molecular weight, each driven by a distinct promoter (Table 56.1) [16–18]. There are four full-length, large molecular weight (427 kDa) dystrophins: M-dystrophin (Dp427m) present in skeletal and smooth muscle [9], C-dystrophin (Dp427c) in the cerebral cortex and hippocampus [19], P-dystrophin (Dp427p) in Purkinje cells [20], and L-dystrophin (Dp427l) in lymphocytes [21]. Alternative promoters drive expression of five nonmuscle truncated isoforms including Dp260 found in the retina [22], Dp140 expressed in the central nervous system and kidney [23], Dp116 in Schwann cells [24], and two ubiquitously expressed forms, Dp71 and Dp40 [25, 26]. Dp71 is the most abundant isoform in the brain [17] and mutations that affect its expression correlate with the severity of mental retardation in DMD and BMD patients [27].

The Dystrophin-Associated Protein Complex

Dystrophin is part of a large, tightly associated glycoprotein complex containing structural and signaling proteins (Fig. 56.1), referred to as the dystrophin-associated protein (DAP) complex. The DAP is a large protein network that spans the sarcolemmal membrane stabilizing it during contraction and relaxation [28, 29]. This complex system,

Table 56.1 Dystrophin isoforms

comprised of three subcomplexes, links the intracellular cytoskeletal actin to the basal lamina, through the extracellular matrix (ECM). The ECM is situated between the sarcolemma and the extracellular basal lamina composed mainly of laminin, collagen, fibronectin, and proteoglycans. Several forms of muscular dystrophy are caused by defects in the function and assembly of the DAP complex [28, 30]. As a central molecular scaffold of the DAP, dystrophin is critical to the structural integrity of the sarcolemma. Severing this link from the subsarcolemmal actin cytoskeleton to the ECM results in secondary deficiencies in other components of the DGC [28, 31]. The DAP can be classified into three domains: extracellular including laminin and α-dystroglycan, transmembrane (sarcoglycans and β-dystroglycan), and subsarcolemmal (dystrophin, syntrophins, dystrobrevins).

Skeletal muscle laminin is a heterotrimer made up of β1-, γ1-, and α2-laminin subunits which binds dystroglycan to the surface of muscle cells [32]. Mutations in laminin-α2 (also designated as merosin) have been described in a subset of patients with congenital muscular dystrophy [33]. In addition to dystroglycan, α7β1 integrin has been identified as a receptor for laminin [34]. Dystroglycan is composed of two subunits generated from a common precursor and cleaved to form α-dystroglycan, which binds to laminin-α2, and β-dystroglycan [35], which spans the membrane and binds to the cysteine-rich domain of dystrophin on the subsarcolemmal side [36].

The sarcoglycan group, comprised of four sarcolemmal transmembrane proteins (α-, β-, γ-, δ-sarcoglycans) along with the stabilizing protein sarcospan [37], demonstrates side-association linkage with dystroglycan [38]. Although the exact role of the sarcoglycans in the molecular organization of the DAP is not well defined, it is clear that it plays both structural and signal transduction roles [39]. Deficiency of the sarcoglycan complex proteins is responsible for several limb-girdle muscular dystrophies, known as sarcoglycanopathies, and secondary deficiencies of the sarcoglycans in DMD patients likely contribute to the dystrophic phenotype [39]. Dystrophin itself resides in the subsarcolemmal domain binding actin through its N-terminal domain and intracellular signaling molecules, the syntrophins [40], dystrobrevins [41], and neuronal nitric oxide synthase (nNOS) [42] via its C-terminal domain. The quantity of dystrobrevin is reduced in both DMD and patients with sarcoglycanopathies [41].

Dystrophin Gene Mutations

Accurate dystrophin mutation analysis is critical not only for diagnostic purposes but also for considering potential treatments due to mutation specificity. Dystrophin gene mutation analysis reveals a predominance of deletions of one or more exons in 60–70 % of DMD/BMD cases primarily clustering in two hotspots of the gene, proximal (exons 2–20) and distal (exons 45–55) [43, 44]. Duplications resulting in in-frame or out-of-frame transcripts account for 6 % of mutations in DMD and for about 10 % in BMD [44]. Point mutations (which can include small deletions or insertions, single base changes, and splice-site mutations) account for ~25–35 % of mutations in DMD but are less common in BMD, comprising about 10–20 % of cases [44–46]. Nonsense mutations occur more commonly in DMD, in approximately 20–25 % of cases as compared to <5 % in BMD [44, 46]. Splice-site mutations and small insertions or deletions account for a considerable proportion of sequence changes found in both DMD and BMD while missense mutations are rare. *DMD*-associated dilated cardiomyopathy (DCM) is caused by mutations in *DMD* that affect the muscle promoter (P_M) and the first exon (E1), resulting in no dystrophin transcripts being produced in cardiac muscle; however, two alternative promoters that are normally only active in the brain (P_B) and Purkinje cells (P_P) are active in the skeletal muscle, resulting in dystrophin expression sufficient to prevent manifestation of skeletal muscle symptoms [47–49]. *DMD*-associated DCM may also be caused by alteration of epitopes in a region

of the protein of particular functional importance to cardiac muscle [50] or possibly by mutations in hypothetic cardiac-specific exons [51].

Germline Mosaicism

Dystrophinopathies are familial diseases; however, sporadic cases do occur resulting from a spontaneous mutation in a single germ cell of the mother or perhaps in the proband's dystrophin gene early in postzygotic embryo development. If the mother is not a somatic carrier but has more than one affected offspring, that may be related to the phenomenon of germline mosaicism [52, 53]; the latter accounts for about 20 % of new DMD mutations [54, 55]. This phenomenon may be due to a mutation at a mitotic stage of germ cell lineage development. If this type of mutation occurs in a female, there is a substantial risk for more than one affected male offspring. If the germline mutation occurs in a male, his female offspring are at significant risk for becoming carriers [53]. Because of the possibility of germline mosaicism, if the mother of an affected male is not a carrier by deletion analysis of her lymphocyte DNA, her risk of having another affected son could be at least 7–10 % [56].

Dystrophinopathies in Females

During early embryonic development, random inactivation of one of the two X chromosomes occurs (lyonization), leaving active 50 % of the maternally derived chromosomes and 50 % of the paternally derived ones [57]. Thus, if the maternal X chromosome carries a mutated dystrophin gene, 50 % of the remaining nuclei have an active normal dystrophin gene and thus will produce enough dystrophin to prevent muscle necrosis [58]. In the case of nonrandom X chromosome inactivation, less than 50 % of the nuclei may have the normal dystrophin gene in an active state, thus resulting in dystrophin deficiency and clinical manifestations in females [59]. This happens most commonly in cases of twin pregnancies [59]. Cases of X-autosomal translocations with breakpoints at Xp21 resulting in preferential inactivation of the normal chromosome have also been described [5, 8]. In Turner syndrome (karyotype XO) or Turner mosaic (XO/XX or XO/XX/XXX) syndrome, if the X chromosome carries a mutated dystrophin gene, the female child will be clinically affected also.

Pathogenesis

More than a decade prior to the cloning of dystrophin, ultrastructural observations were made in DMD muscle biopsies which alluded to the pathogenesis of the disease. In 1975, Mokri and Engel noted focal plasma membrane defects in nonnecrotic fibers in DMD muscle [60]. These regions, referred to as delta lesions, were accompanied by nearby cytoplasmic defects where myofibrils were usually contracted. Histopathological findings and experiments in the *mdx* mouse model of DMD support the conclusion that reduced or absent dystrophin results in a mechanically weakened plasma membrane [61, 62], which is prone to focal tears during contractile activity [63]. This allows a massive influx of extracellular calcium, which activates proteolytic enzymes and leads to gradual necrosis of muscle fibers explaining why dystrophinopathies are progressive diseases [64]. A second aspect of DMD pathology is functional ischemia which was proposed as a pathogenic mechanism of muscle fiber damage in DMD over 30 years ago based on experimental findings reproducing the histopathological pattern of muscle necrosis and regeneration [65]. Recent studies reinforce the potential role of ischemia through molecular-based findings demonstrating deficiency of nitric oxide synthase (NOS) in DMD muscle as a contributory factor in muscle damage [66]. As a result, therapeutic strategies helping to circumvent ischemia by modulation of the NOS pathway are emerging (see section "Emerging Therapies").

Clinical Presentation

There is a great heterogeneity in the clinical presentation and course of the various dystrophinopathies, creating a spectrum ranging from very severe to very mild presentations.

Duchenne Muscular Dystrophy

In children with DMD, although there is histologic and laboratory evidence (elevated serum CK ≥ 2,000 [2]) of myopathy at birth, clinical manifestations are usually absent at this age. During the first 2 years of life, some affected boys exhibit mildly delayed gross motor development presenting primarily as delayed walking. The mean age of walking is approximately 18 months (range 12–24 months). Weakness is usually noted between 2 and 3 years of age; in some cases, however, it may be delayed and become apparent after the age of 3 years (Table 56.2). The first symptoms are usually difficulty with running, jumping, and going up the stairs, related to weakness that selectively affects proximal limb muscles before distal and the lower extremities before the upper ones. Between 3 and 6 years of age, a broad-based waddling gait, exaggerated lumbar lordosis, and calf enlargement are usually observed. Early on, toddlers may complain of leg pains. In arising from a supine position on the floor, affected boys turn their face to the floor, spread their legs,

Table 56.2 Genetic, clinical, and laboratory features of the dystrophinopathies

Type	Clinical features	Laboratory features	Mutations
Duchenne	Onset before age 5, progressive weakness of girdle muscles, Calf hypertrophy	Striking CK elevation 50–100× of NL up to age 3; ~20 % drop per year	Deletions (60–70 %)
	Wheelchair confinement by age 12, scoliosis, respiratory failure in second or third decade	Dystrophin <5 % on WB	Duplications (6 %)
	Cardiac involvement	Absent dystrophin by IHC; revertant fibers may occur	Point mutations[a] (20–25 %)
	Rapid decline		Nonsense (<15–25 %)
Intermediate	Intermediate severity	Decreased or altered dystrophin 5–20 %	Spectrum unknown
	Ability to walk after age 12 but not age 15		
Becker	Onset after age 5, progressive weakness of girdle muscles, Calf hypertrophy	CK > 20–75 % of NL	Deletions (60–70 %)
	Ability to walk after age 15	Decreased or altered dystrophin >20–40 % on BW	Duplications (10 %)
	Cardiac involvement	Variable staining intensity for dystrophin by IHC	Point mutations (10–20 %)
	Variability in clinical severity		Nonsense (<5 %)

CK creatine kinase, *WB* Western blot, *IHC* immunohistochemistry
[a]Includes small deletions or insertions, single base changes, and splice-site mutations

Fig. 56.2 A boy with Duchenne muscular dystrophy demonstrating Gowers' sign. To rise from the floor, he is faced to the floor, his legs are spread, and his buttock is raised; subsequently he will use his hands to climb up his thighs (Courtesy of Dr. John Kissel, The Ohio State University, Columbus, OH)

and use their hands to climb up their thighs to an upright position (Gowers' sign) (Fig. 56.2). Neck flexor weakness often goes unnoticed but it does occur at all stages of the disease; when lying on his back, a child with DMD is unable to lift his head against gravity [67]. This sign is helpful in distinguishing boys with DMD from patients with milder phenotypes, such as "outliers" and BMD.

Physical examination shows firm enlargement of the calf muscles and, in some instances, of the quadriceps, gluteal, deltoid, and rarely masseter muscles. Increased muscle bulk, early in the course of the disease, is the result of true hypertrophy, however later on is related to replacement of the muscle fibers by fat and connective tissue (pseudohypertrophy) [68]. The ankle plantar flexors and invertors remain very strong throughout the course of the disease, while the tibialis anterior muscles become weak gradually, resulting in heel cord contractures and toe walking; eventually, this imbalance in muscle strength will lead to bilateral equinovarus foot deformities.

Between 3 and 6 years of age, there may be some improvement; this is related to normal motor development of the child which outpaces disease evolution, to be followed gradually by relentless deterioration. Between 6 and 11 years, muscle strength decreases linearly and the ability to climb stairs, rise from a supine position, climb stairs with rails, and walk a short distance declines rapidly in the mentioned order [54, 68]. As the disease progresses, muscle stretch reflexes diminish or cannot be elicited; before the age of 10 years, the triceps, biceps, and knee reflexes become hard to elicit in approximately 50 % of patients. The brachioradialis stretch reflex remains active longer with the ankle reflex being elicited in one-third of patients even during the last phase of the disease [69]. Cranial and sphincter muscles are spared [70].

The development of joint contractures is another almost constant clinical feature of DMD. By age 6 years, the majority of DMD patients have contractures of the heel cords, iliotibial bands, and hip joints, causing toe walking and limitation of hip flexion. By age 8 years, knee, wrist extensor, and elbow contractures appear and correlate with decreasing ambulation [68]. Shoulder contractures occur only late in the disease course. At around age 10 years in most patients, the weakness leads to dependency on long leg braces for ambulation [68] and wheelchair confinement by approximately the age of 12 years [71]. The use of steroids prolongs ambulation 1 to 2 years. Scoliosis rarely occurs prior to age 11 while they are still ambulatory; severe curvatures usually evolve after wheelchair confinement requiring medical intervention [72]. Increasing scoliosis and gradual

deterioration of pulmonary function related to the weakening of respiratory muscles are leading cause of respiratory failure. Patient's age at respiratory failure correlates well with the degree of thoracic kyphoscoliosis [73].

Historically the patients, usually around age 20, succumbed to restrictive lung disease or complications but also died from cardiac failure secondary to progressive cardiomyopathy [74], but now improved care, including antibiotics, vaccines, and other ancillary methods, protects the cardiorespiratory system and prolongs life.

Involvement of Other Organ Systems

Heart, brain, and smooth muscle are also involved in the disease process, resulting from the lack of dystrophin expression in these organs.

Cardiac involvement is inevitable in DMD and the incidence of *cardiomyopathy* increases steadily in the teenage years. Approximately one-third of patients are affected by age 14 years, one-half by age 18 years, and all after age 18 years [75]. The majority of patients, however, remain free of cardiovascular symptomatology until late in the disease, probably due to their inability to exercise, which may mask the cardiac symptoms [54]. In the late stages of the disease, congestive heart failure and arrhythmias may develop, especially during infections. In very rare cases, congestive heart failure dominates the picture and can be the immediate cause of death without marked compromise of respiratory function [68].

At the time when boys with DMD are wheelchair dependent, the dystrophin-deficient myocardium may or may not demonstrate measurable changes by echocardiography [76]. In contrast, electrocardiographic (ECG) abnormalities can be detected from a young age (<6 years of age), identified in about 76 % of patients. The most common ECG abnormality noted in very young boys is related to left ventricular pathology, manifesting most commonly by a Q wave >98th percentile in lead III or V6 [77]. Prominent Q waves in leads II, aVF, and V_5 were also reported [78]. The characteristic changes in older boys include short PR interval, right ventricular hypertrophy, and deep Q waves in leads I, aVL, and V_5 [71, 72]. Intra-atrial conduction disturbances, sinus tachycardia, or other sinus arrhythmias are more frequent than atrioventricular conduction defects and infranodal/ventricular abnormalities. ECG changes are similar in patients with DMD regardless of presence of dilated cardiomyopathy (diagnosed by an ejection fraction <55 %) suggesting that ECG may not be predictive of disease course [78].

Autopsy studies of the heart in patients with DMD show the initial site of myocardial fibrosis and fatty infiltration to be in the posterobasal epicardium, progressing to involve the epicardial half of the left ventricular free wall, then occasionally involving septal segments as the fibrosis becomes more severe and more transmural [76, 79]. The right ventricle and the atria seldom are involved. Fibrosis and fatty infiltration can also involve the conduction system, the sinoatrial and the atrioventricular nodes [80, 81]. As in autopsy studies, cardiovascular magnetic resonance studies find that scar predominantly involves left ventricular segments and that septal segments are involved less frequently and only in patients with significant left ventricular free wall involvement [82]. Ultimately the fibrosis leads to dysfunction and dilation, to a severe generalized cardiomyopathy. In some instances, the left ventricle dilatation cannot occur if the wall is severely fibrotic, creating a restrictive myopathy. With dilation, patients can develop mitral regurgitation and, occasionally, aortic regurgitation. With left ventricular failure, there can be secondary pulmonary hypertension and right ventricular failure associated with pulmonary and tricuspid regurgitation [83].

Most patients with DMD exhibit nonprogressive *impairment of intellectual function*, initially described as a general leftward shift in the spectrum of IQ scores [84], reduced approximately one standard deviation from the normal population. In some cases, an occasional child with DMD may have average or above-average intelligence.

Although the neuropsychological profile of DMD has not yet been fully characterized, studies show significantly lower performances in verbal IQ, verbal short-term memory, and phonological abilities, as well as in praxis and executive functioning domains [85]. These deficits in executive function are often confused with attention deficit/hyperactivity disorder warranting appropriate neuropsychological testing for correct diagnosis. A neuropathologic abnormality underlying the cognitive deficit in DMD has not been found [68]. Loss of Dp71, the major DMD gene product in brain, is thought to contribute to the severity of cognitive impairment [27]. Studies in animal models suggest a role for Dp71 in excitatory synapse organization and function [86].

Degeneration of gastrointestinal tract smooth muscle resulting from dystrophin deficiency may lead to an important and even life-threatening complication, intestinal hypomotility, also known as *intestinal pseudo-obstruction*. It may present with acute gastric dilatation, vomiting, abdominal pain, and distension [68, 87]. Degeneration of the outer, longitudinal, smooth muscle wall of the stomach has been documented pathologically.

Osteoporosis in boys with DMD begins to develop early, while they are still ambulating; it is more severe in the lower extremities and may lead to frequent fractures that, sometimes in older children, hasten the loss of ambulation [88]. Corticosteroids further increase the risk of vertebral compression fractures.

Becker Muscular Dystrophy

BMD has been estimated to occur approximately one-tenth as frequently as DMD with an incidence of 1 individual per

30,000 male births (Table 56.2). Compared to fairly stereotypical clinical features of DMD, BMD comprises a more heterogeneous group, which can vary from mildly symptomatic forms to more significant muscular and cardiac involvement. In BMD, the age of onset of symptoms is later than DMD, usually between the ages of 5 and 15 years, sometimes even in the third or fourth decade or later [89]. Most patients with BMD remain ambulatory until 15 years of age and older, although this is an arbitrary cutoff, since these disorders represent a continuous spectrum related to the quantity and quality of dystrophin. In most cases dystrophin is reduced in amount and size [90, 91]. The pattern of muscle wasting is similar to DMD. Pelvic girdle and thigh muscles are involved first and calf muscle pseudohypertrophy occurs early in most patients. Tibialis anterior and peroneal muscle groups are less affected. Shoulder girdle weakness develops later after the onset of proximal lower extremity weakness. One exception is the relative preservation of neck flexor muscle strength, a helpful distinguishing feature of the BMD from DMD; neck flexors become weak later in the disease. Contractures are less likely to develop, and scoliosis is also less common, but becomes evident after the patient is confined to a wheelchair. Muscle pain can be very prominent in some patients with BMD and myoglobinuria occurs infrequently [92]. Serum CK levels can be very high, falling into the same range as the patients with DMD (usually >20 to 75 times normal).

Mental retardation is not as common or severe as in DMD, and gastrointestinal symptoms are essentially absent. Cardiac involvement is that of a dilated cardiomyopathy, sometimes starting with right ventricular dilation and progressing to a generalized dilated cardiomyopathy [93, 94]. Recent cardiac magnetic resonance imaging studies in BMD patients show many of the same findings seen in DMD, including fibrosis, and are more sensitive in detecting abnormalities of ejection fraction than echocardiogram [95]. The ECG findings in patients with BMD are also similar to those in patients with DMD with prominent Q waves in I, aVL, and V6, or in II, III, and aVF; tall R waves in V1; and increased QT dispersion [96]. Rarely, cardiac symptoms can be severe in patients with only mild skeletal muscle weakness [97–102] or can precede muscle weakness by several years [103]. The mean age at cardiomyopathy diagnosis is around 14 years, similar to that in DMD [104]. Despite the milder skeletal muscle involvement, heart failure from DCM is a common cause of morbidity and the most common cause of death [105]. Patients usually survive beyond the age of 30 years [68], with death from dilated cardiomyopathy/cor pulmonale or respiratory insufficiency occurring between 30 and 60 years [105].

Earlier studies have reported the presence of cardiac involvement with BMD is associated with deletions in two regions of the *DMD* (5′ end and exons 47 through 49) [93]. An extensive analysis of genotype–phenotype correlation in BMD patients shows that early-onset cardiomyopathy is associated with mutations in the amino-terminal domain; in contrast deletions removing portions of the rod domain along with the hinge 3 domain have a later onset, likely due to preservation of the spectrin-repeat structure of the protein [51].

Late-onset dystrophinopathy could in rare instances present with a myopathy involving predominantly, but not exclusively, the quadriceps [106–108]. Some of these patients may have cardiac involvement. In earlier reports of four patients, dystrophin deficiency, proved by immunoblot analysis, was demonstrated to be the cause of the myopathy which was considered "atypical form" of BMD [106]. Several other cases of isolated quadriceps myopathy have been reported since then and proven to be due to mutations in the dystrophin gene [107–109], thus demonstrating that quadriceps myopathy can sometimes be the only manifestation of dystrophin deficiency.

X-linked exercise-induced myalgias and cramps without skeletal muscle weakness, starting in childhood, especially in a family with cardiomyopathy, can be caused by mutations in the dystrophin gene [110, 111]. However, a longer follow-up period is necessary to definitely rule out late-onset skeletal muscle weakness, which could classify these cases as BMD [103, 110]. Two molecular regions on the dystrophin gene have been linked to the phenotype of cramps and myalgias: exons 10–44 [109, 110] and exons 45–52 [103, 111]. Some of the patients in these studies also had fixed weakness [109].

Dystrophin Gene-Associated Dilated Cardiomyopathy

X-linked *DMD*-associated DCM is a progressive and fatal type of heart disease that presents in the second or third decade of life with congestive heart failure in patients with minimal skeletal muscle symptoms [47, 112–114]. It should be noted that four separate genetic disorders with cardiac and skeletal myopathies are X-linked. DMD and BMD already have been discussed. Those with no or minimal abnormalities in skeletal muscle dystrophin but showing abnormal dystrophin in heart muscle are classified here as *DMD*-associated DCM. The other X-linked cardiomyopathies include Emery-Dreifuss muscular dystrophy, resulting from abnormalities in LINK components at nuclear envelope [115, 116], and Danon disease [117], also known as X-linked vacuolar cardiomyopathy and myopathy, which is caused by a mutation in the gene encoding lysosome-associated membrane protein-2 (LAMP2). Another disorder of this group is Barth syndrome [118] a mitochondrial disease caused by a mutation of the tafazzin gene associated with decreased amounts and altered structure of cardiolipin, the main phospholipid of the inner mitochondrial membrane.

Boys with *DMD*-associated DCM complain of exercise intolerance, muscle fatigue, pain, and cramping but do not manifest the weakness seen in patients with BMD and DMD [119]. Calf hypertrophy and elevated serum CK levels can be present [94]. Symptoms of congestive cardiomyopathy usually develop in late teen years to early adulthood that usually progresses to death within 2 years of the onset of the myopathy diagnosis. Arrhythmias and atrioventricular block can occur with much greater frequency than that seen in patients with either DMD or BMD. Female carriers develop mild dilated cardiomyopathy later in life with slow progression and often fatal outcome [47, 105].

Different mutations in the dystrophin gene cause selective absence of dystrophin in heart muscle [47, 54]. A review of families with *DMD*-associated DCM points out that mutations involving the 5′ end of the gene result in more severe cardiomyopathy than mutations in the spectrin-like region (centered around exons 48–49) [120]. With mutations involving the 5′ end of the dystrophin gene, the exclusive cardiac involvement seems to be related to a difference in RNA splicing regulation between heart and skeletal muscle. The skeletal muscle maintains dystrophin production by using exon skipping or alternative splicing, while the heart muscle is apparently unable to employ such mechanisms. Studies demonstrated that in individuals with the most severe cardiac phenotype the cardiac muscle is usually unable to produce functional dystrophin in the heart, while in skeletal muscle reduced levels of virtually normal dystrophin transcript and protein are present [121, 122]. Classification of *DMD*-associated DCM as a separate entity in dystrophinopathy spectrum is somewhat controversial. *DMD*-associated DCM may be the presenting finding in individuals with BMD who have little or no clinical evidence of skeletal muscle disease. Some investigators classify such individuals as having subclinical or benign BMD, whereas others may classify them having DCM with increased serum CK concentration [123].

Manifesting DMD/BMD Carrier Females

Carriers are usually free of symptoms but may have mildly increased serum CK and usually mild calf hypertrophy. In approximately 8 % of the cases they can, however, present with mild myopathy of the limb-girdle type or even typical DMD/BMD [124–128]. Cardiac involvement is usually subclinical, although few investigators have evaluated DNA-proven DMD and BMD female carriers. Earlier studies demonstrated that 8 % of DMD carriers have dilated cardiomyopathy versus none in BMD carriers. Only 38 % of the studied carrier population had a completely normal heart investigation. The remaining had subclinical EKG or echocardiographic abnormalities [129]. Severe cardiac symptoms can occur in some carriers [130].

A more recent study shows DMD carriers (mothers) can have significant left ventricular systolic dysfunction, which is unmasked by exercise, [131] implying the need for evaluation of proven female carriers, even if they are asymptomatic.

Differential Diagnosis

The process of making an accurate diagnosis in suspected DMD/BMD patients depends on the mode of presentation, in particular the pattern of muscle involvement, and additional clinical features, the serum CK level, and any informative family history. If there is clear evidence for autosomal dominant transmission, a dystrophinopathy can easily be excluded. If not, a diagnostic workup may include a muscle biopsy. Immunohistochemistry with antibodies against dystrophin epitopes, α-, β-, γ-, and δ-sarcoglycans, α- and β-dystroglycans, and merosin (laminin-alpha 2) may offer a specific biopsy diagnosis. Western blot analysis is useful for quantitation of dystrophin, calpain, or other proteins. However, DNA mutation analysis should ultimately be done to confirm the results from these biochemical studies.

Salient features of the following disorders that can be considered in the differential diagnosis of the DMD and BMB are discussed below.

Limb-girdle muscular dystrophy (LGMD) encompasses a heterogeneous group of muscle disorders characterized by a predominantly proximal distribution of weakness with the age of onset of symptoms varying from early childhood to late adulthood. Typically, the onset is not congenital. Pathogenic genes reported so far include those that encode integral components of DGC as well as other structural proteins, and even enzymes such as calpain 3. In certain types of LGMD there may be clinical clues, but there is substantial overlap in different forms. Recessive forms are far more common than autosomal dominant forms that have more heterogeneous clinical presentation with some families showing syndromic features.

LGMD2A or calpain 3 deficiencies, the most common recessive form, represent about 10 % of LGMD population and can present within the first decade with very high serum CK levels with a pelvifemoral pattern of weakness. Early contractures and absence of cardiac involvement are helpful clinical features. Presentation of calpainopathy with high serum CK can also occur, usually observed in children or young individuals, in which symptomatic individuals have only high serum CK concentrations. Clinical findings include the tendency to walk on tiptoes, difficulty in running, scapular winging, waddling gait, and slight hyperlordosis.

Other well-characterized LGMD subtypes are sarcoglycanopathies (α-sarcoglycanopathy, LGMD2D; β-sarcoglycanopathy, LGMD2E; γ-sarcoglycanopathy, LGMD2C;

δ-sarcoglycanopathy, LGMD2F). Clinical features range from early childhood onset with severe progression similar to DMD to later onset with milder progression as seen in BMD (see Table 56.2). Calf hypertrophy is commonly observed but scapular winging is more prominent than DMD/BMD. Heart involvement is variable, but typically less severe than in the dystrophinopathies. Overall, about 30 % of individuals have evidence of cardiomyopathy by ECG and echocardiogram; cardiomyopathy is common in β-, γ-, and δ-sarcoglycanopathy, but rare in α-sarcoglycanopathy [132, 133].

Most individuals with severe, childhood-onset LGMD are suspected to have sarcoglycanopathy [134]. Thus, a boy with a clinical presentation and progression similar to DMD but with normal dystrophin immunostaining in muscle is likely to have a primary sarcoglycanopathy. In contrast, only about 10 % of individuals with LGMD with milder disease (onset in adolescence or adulthood) have a sarcoglycanopathy.

LGMD2I is an important type of LGMD associated with abnormal α-dystroglycan labeling on the muscle biopsy and caused by mutations in genes encoding proteins involved in the glycosylation of dystroglycan such as *FKRP*, the gene encoding fukutin-related protein [135]. The phenotype ranges from severe to mild with no clinically apparent skeletal muscle involvement [136–140]. Cardiomyopathy without skeletal muscle involvement has been reported. In severe cases loss of ambulation occurs in the beginning of the second decade. The milder end of the spectrum more closely resembles BMD, with ambulation continuing into the third decade. Cardiac involvement occurs in 10–55 % of affected individuals.

Emery-Dreifuss muscular dystrophy (EDMD) in early childhood typically presents with prominent contractures involving ankles, elbows, and spine together with a slowly progressive muscle weakness and wasting initially in a humeroperoneal distribution and later extending to the scapular and pelvic girdle muscles. In some patients contractures may be less prominent and muscle weakness is more proximal with a slowly progressive course. The cardiac involvement is an important part of the clinical feature that may include palpitations, presyncope and syncope, poor exercise tolerance, and congestive heart failure. A pure cardiac presentation is seen in some families. The X-linked form is caused by mutations in EMD, the gene encoding emerin; the dominant/recessive forms are caused by mutations in LMNA, the gene encoding lamin A/C.

If symptoms of limb-girdle dystrophy are found in a girl, one should always consider the rare possibility of DMD or BMD occurring in a female with an abnormal karyotype (e.g., 45 XO) or nonrandom X chromosome inactivation.

Acid maltase deficiency (AMD) and spinal muscular atrophy (SMA) type III may be considered in the differential diagnosis with proximal muscle weakness and sometimes calf muscle hypertrophy; however, the serum CK, electrodiagnostic studies, and muscle biopsy features (i.e., glycogen storage in AMD, neurogenic changes in SMA) will easily permit the distinction from these disorders [54].

In rare instances, dystrophinopathies may present similarly to congenital muscular dystrophies [3, 141] with neonatal weakness, hypotonia, and subsequent developmental delay. The differential diagnosis can be made clinically by the modestly increased CK level and the frequent facial and eye muscle involvement and contractures in congenital muscular dystrophies. Muscle biopsy immunostaining for dystrophin may also be helpful in differentiating the two entities.

Dermatomyositis before the onset of the rash in rare instances can be mistaken for a dystrophinopathy, but the acute onset of symptoms permits easy distinction from DMD or BMD.

An unexplained persistent elevation of liver enzymes should always alert the clinician to the possibility of an underlying muscular dystrophy including females, who could prove to be symptomatic females, asymptomatic carriers of DMD/BMD, asymptomatic males with DMD/BMD, or patients with other muscular dystrophies [142]. In these instances, measurement of serum CK, which is a more specific muscle enzyme, should always be made to prove the myogenic origin of the elevated liver enzymes. Finally, a dystrophinopathy should be considered in all cases of dilated cardiomyopathy.

Laboratory Features and Diagnosis

The new era of advanced molecular diagnostic tools provides an accurate and prompt diagnosis of DMD/BMD, allowing initiation of appropriate measures, continuing support and education, and avoiding a potentially pervasive diagnostic process. Suspicion of clinical diagnosis for DMD or BMD should be considered irrespective of family history on the basis of the clinical presentation and level of serum CK. Reduced motor skills, particularly the inability of run and jump in a boy between ages 3 and 5 years, bring the possibility of DMD to attention. Older boys with later age of onset for similar pattern of weakness involving pelvic girdle and thigh muscles followed by proximal upper extremity weakness are suspect for BMD diagnosis. In both situations, testing for serum CK is indicated. The next step in the diagnostic strategy should be confirming the clinical diagnosis of DMD/BMD using available new tools for identifying precise genetic defect. Extensive mutation analysis is a necessity, not to satisfy academic interest but because evolving treatment paradigms depend on the full characterization of the deletion/duplication endpoints and the identification and position of point mutations.

Serum Muscle Enzymes

CK is the most important serum enzyme in the diagnosis of DMD. Striking CK elevation may be present even in the first years of life, preceding clinical manifestations of obvious motor impairment. Before the age of 5 years, the serum CK levels are usually 50–100 times of normal in DMD and can be markedly increased to 20–100 times of normal in BMD [68, 143] and, therefore, cannot be used as a way of differentiating between the two types of dystrophy. The concentration of CK, however, tends to decline with age, at a rate of about 20 % per year. In about 70 % of carriers, CK levels are elevated, but decrease with age.

Serum aminotransferases, AST and ALT, both produced by muscle as well as liver cells are also usually elevated in DMD and BMD. Their increased levels are thought to be related to leakage through muscle membranes [142]. Therefore, diagnosis of DMD should be considered before liver biopsy in a male child particularly with unintended discovery of increased transaminases.

Electromyography

Patients with classic features of DMD or BMD do not need electrodiagnostic studies for diagnostic purposes, but in sporadic cases of BMD or carrier females with modest serum CK elevation (less than 1,000 IU/L) and proximal muscle weakness, electromyography may have to be considered to exclude a neuropathic process (e.g., SMA) and before undergoing genetic testing for confirming the diagnosis. Nerve conduction studies including compound muscle action potentials (CMAPs) are normal in the early phases of the disease. Needle EMG in DMD/BMD shows myopathic changes, usually short-duration, low-amplitude polyphasic early-recruited motor unit action potentials (MUAPs), particularly in proximal muscles. It may also show increased insertional activity with fibrillation potentials. With disease progression, the CMAPs decrease in amplitude, the insertional activity diminishes, MUAPs become very small with decreased recruitment, and the fibrillation potentials disappear. At the advanced stages of DMD/BMD, the muscle may become electrically silent.

Molecular Genetic Testing

Until recently, multiplex PCR and Southern blotting were utilized for dystrophin gene deletion/duplication analysis. New tools for mutation detection have been introduced including multiplex ligation-dependent probe amplification (MLPA) and multiplex amplifiable probe hybridization (MAPH) providing relatively rapid and inexpensive exon screening [144]. When MLPA or MAPH are negative, DNA sequencing is required to detect subexonic rearrangements or point mutations [43] (see Dystrophin Gene Mutations).

Muscle Biopsy

Muscle biopsies derived from DMD/BMD patients are processed for examination of histopathological features, immunohistochemistry for detection of dystrophin in muscle membrane, and Western blot analysis for quantitation of dystrophin protein.

Histopathological Findings

Overall the muscle biopsy features of DMD include fiber size variability with atrophy and hypertrophy, an alteration in fiber type resulting in type I fiber predominance, muscle fiber degeneration, regeneration, isolated "opaque" hypertrophic fibers, and significant replacement of muscle by fat and connective tissue. The degenerating necrotic fibers are recognized on H&E and trichrome staining by their lighter-stained glassy or homogenous cytoplasm (Fig. 56.3a). Small groups of basophilic regenerating and necrotic fibers are an important feature of DMD biopsies. Hypercontracted large opaque and darkly stained fibers are seen commonly. Their origin is unclear but thought to be due to segmental hypercontraction resulting from plasma membrane defects that allow the influx of calcium-rich extracellular fluid [145]. Fiber splitting and central nuclei are less often, present in 2–4 % of the fibers compared to other dystrophies.

Inflammatory cells are seen in the perimysium, endomysium, and perivascular spaces. They consist mostly of T lymphocytes and macrophages. Most T cells are CD8+ and occasional nonnecrotic muscle fibers are focally surrounded and invaded by CD8+ cells [68]. A striking increase in the endomysial and perimysial fibrosis occurs with disease progression. The differences in the microscopic appearance of muscle between DMD and BMD correlate well with the severity of the disease, with fewer necrotic, hypercontracted, and regenerating fibers seen in milder phenotypes and the frequency of hypertrophic fibers and internal nuclei increase with age (Fig. 56.4a).

Dystrophin Immunostaining

In muscle biopsies derived from DMD patients, there is no detectable staining of the sarcolemma using commercially available anti-dystrophin antibodies against amino-terminal (dys3), carboxy-terminal (dys2), and rod domains (dys1) of the protein. However, in about greater than 50 % of DMD patients, antibodies against different epitopes show membrane staining for dystrophin in about 1 % of fibers in small clusters, which are called "revertant" fibers [146] (Fig. 56.3b–d). They arise from a somatic mutation

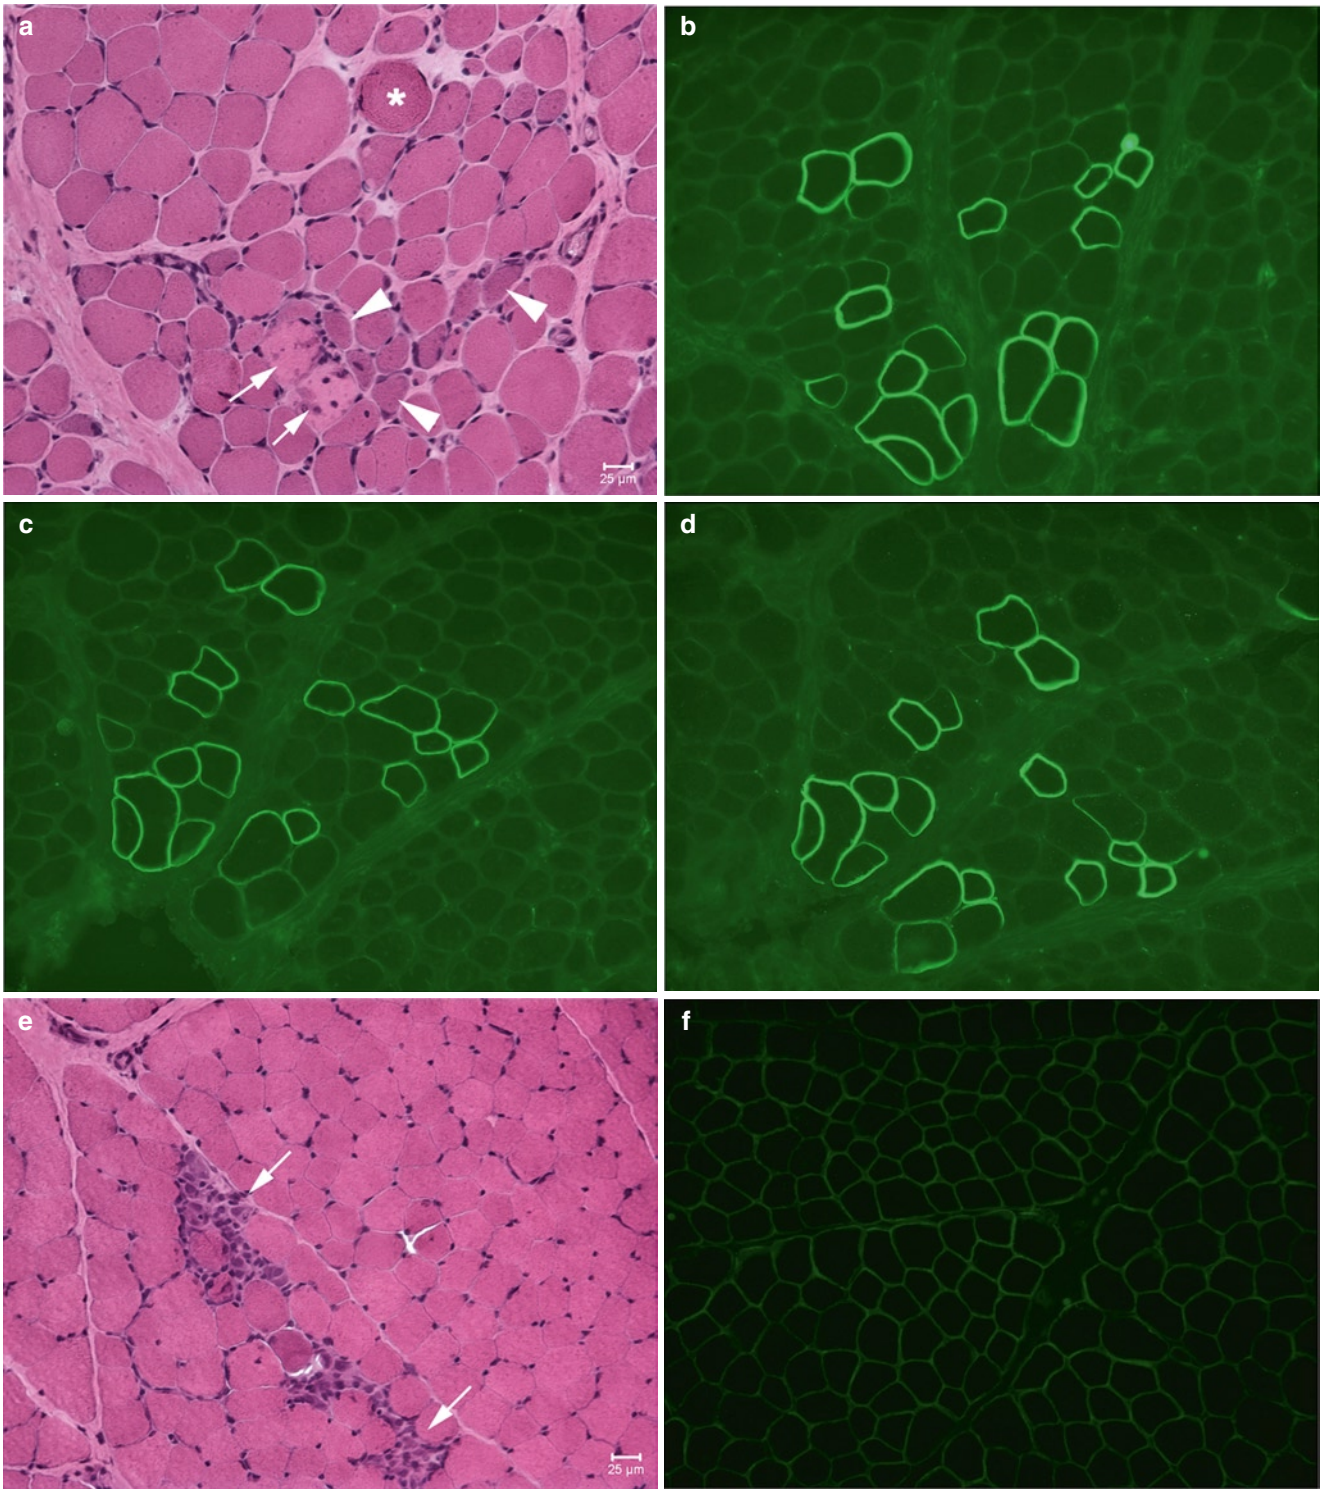

Fig. 56.3 H&E and immunofluorescence staining of frozen sections of skeletal muscle biopsies with anti-dystrophin antibodies. (**a**–**d**) From a 5-year-old boy who has DMD with a duplication of exons 55 through 63 in the dystrophin gene. H&E stained section (**a**) shows a small group of basophilic regenerating muscle fibers (between *arrowheads*) and necrotic fibers (*arrows*) among fibers with increased variability in size; *asterisk marks* a hypercontracted fiber. Membrane staining for dystrophin using specific antibodies to amino-terminal Dys3 (**b**), rod domain Dys1 (**c**), and carboxy-terminal Dys2 (**d**) is absent with the exception of small clusters of revertant fibers. H&E stained section (**e**) from a 5-year-old boy who has BMD with a duplication of exons 19 through 29 in the dystrophin gene, presented with history of exercise-induced myalgias and CK elevation at 2,000–11,000 IU/L range and no muscle weakness on examination. A small focal area of inflammation is present (*arrows*). Membrane staining for Dys3 is severely reduced (**f**), while membrane staining for Dys1 (**g**) and Dys2 (**h**) is present, compatible with an in-frame duplication mutation

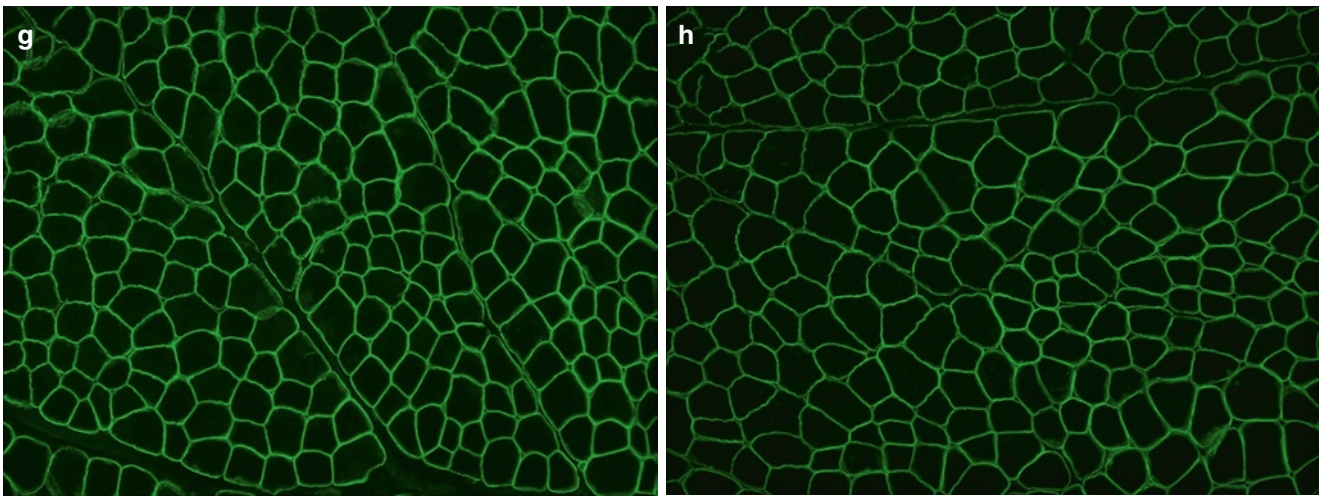

Fig. 56.3 (continued)

at a second site of the gene that corrects the original frame shifting mutation and restores the reading frame [147, 148]. In BMD patients, either normal or partial staining of the sarcolemma is observed (Figs. 56.3f–h and 56.4b). Immunohistochemistry for dystrophin is useful in identifying sporadic cases of symptomatic or asymptomatic female DMD carriers with high serum CK levels in families without a male proband, or in families with no detectable deletion/duplication results. Thus, symptomatic and asymptomatic DMD carriers with elevated CK values may exhibit a characteristic mosaic pattern of dystrophin immunostaining.

Immunostaining of muscles, from DMD patients or the mdx mouse model of the disease, shows that loss of dystrophin leads to a selective reduction or absence in the staining of the DAPs such as α-, β-, γ-, and δ-sarcoglycans and α- and β-dystroglycans [149]. However, another dystrophin-related protein, utrophin, which has homology to dystrophin shows diffuse membrane staining outside of neuromuscular junctional folds resulting from a compensatory upregulation in dystrophin-deficient muscle [150] (Fig. 56.4c).

Western Blot Analysis

Western blot for dystrophin quantitation accurately predicts the severity of the muscular dystrophy phenotype (Table 56.2), especially in cases with no family history (Fig. 56.4). Because of the exceptions to the reading frame rule, the type of the deletion (in-frame versus out-of-frame) is not always a reliable predictor of the severity of the disease. The Western blot assesses not only the amount of dystrophin but also the molecular size of the dystrophin molecule, which is often decreased (80 %) (Fig. 56.4d) and rarely increased (5 %) in BMD patients (in deletion and duplication cases, respectively). Antibodies against carboxy and rod domains should be utilized in the Western blot assay in order to avoid false-negative results. Given the qualitative nature of dystrophin immunostaining and the possibility of normal appearance in patients with BMD, Western blot has become the gold standard for dystrophin analysis.

Algorithm for Diagnosis of DMD/BMD

Familial or Sporadic Cases with Clear Phenotype

If the diagnosis of DMD/BMD has been made clinically in other family members but has not been confirmed previously by molecular diagnosis, the first step is DNA testing for detection of a dystrophin gene deletion/duplication mutation, by MLPA or MAPH (Fig. 56.5). If testing for deletion/duplication is negative, the next step is DNA sequencing to detect subexonic rearrangements or point mutations [43]. The mutation detected in the dystrophin gene may then be used as a marker for testing other at-risk family members, for carrier detection, and also for prenatal diagnosis, by means of amniocentesis or chorionic villus biopsy.

In sporadic cases (i.e., family history negative for DMD/BMD), the same diagnostic approach, outlined for familial cases, is recommended if the clinical presentation is clear and highly suggestive of DMD or BMD.

Sporadic Cases with Unclear Phenotype

In sporadic cases with unclear phenotype (outliers), if a deletion or duplication is found by MLPA or MAPH, its reading frame status will allow in most instances prediction of the phenotype (DMD or BMD). Because of the rare occurrence of exceptions to the "in-frame/out-of-frame" rule, some clinicians justify the option of a muscle biopsy for Western blot analysis to predict the severity of the disease, although this information has no clinically useful application since these cases represent the spectrum of dystrophinopathy.

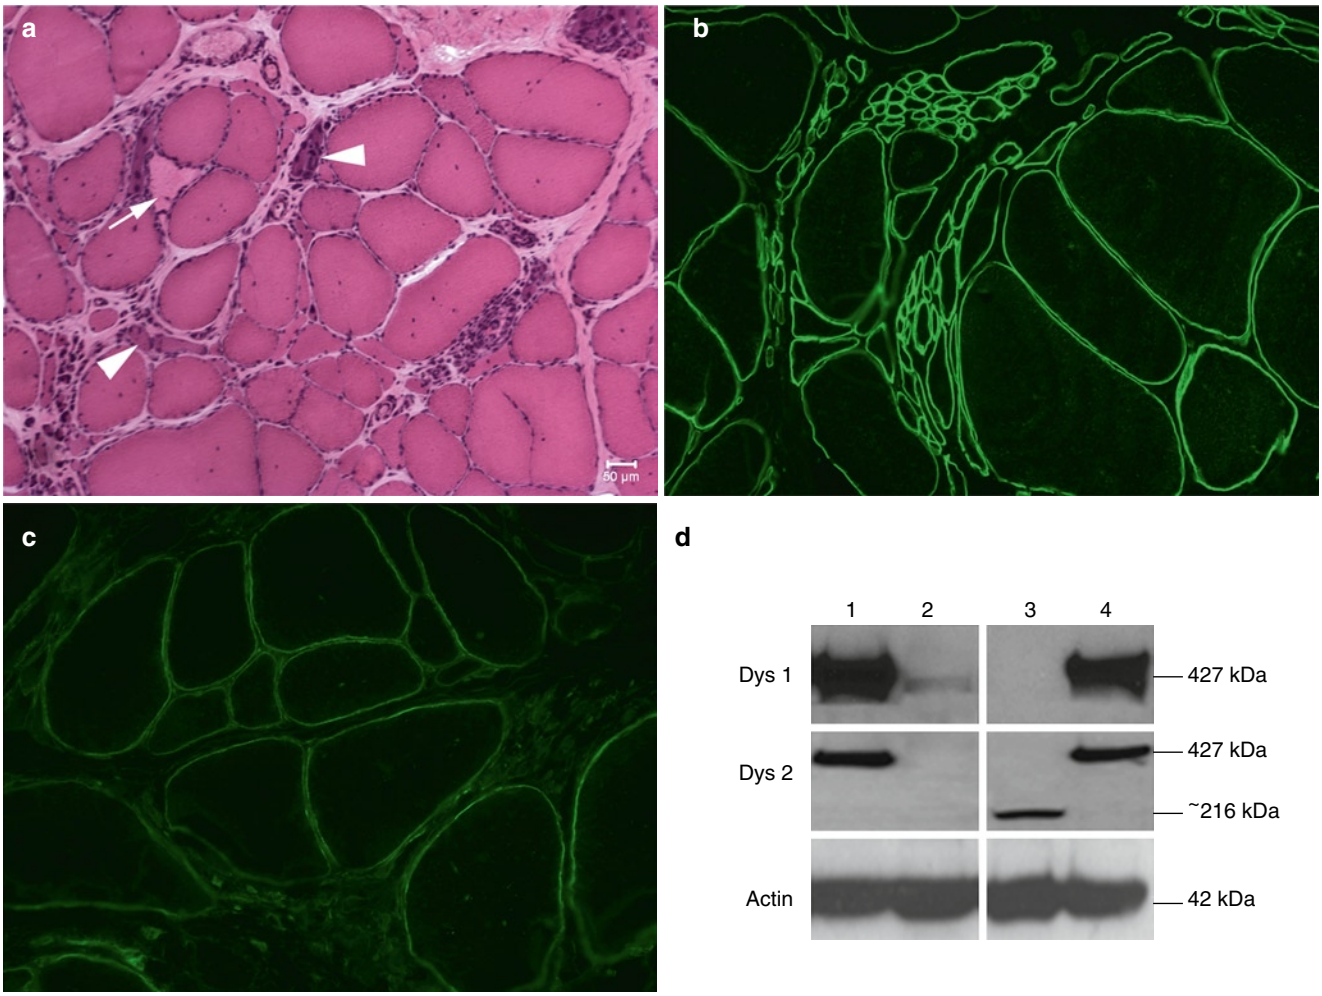

Fig. 56.4 H&E stained section (**a**) from a 12-year-old boy with BMD who has exons 10 through 44 and promoters Dp260 and Dp140 in-frame deletion. He is ambulatory and has CK levels over 14,000 IU/L. Marked variability in muscle fiber size (<10 to over 150 µm in diameter), an increase of internal nuclei, and rare necrotic (*arrow*) or regenerating fibers are seen. Immunofluorescence staining for Dys2 shows normal membrane staining (**b**); membrane staining for Dys1 and Dys3 is absent (not shown). Membrane staining for utrophin is present suggesting compensatory upregulation (**c**). Western blot analysis shows a truncated protein reduced in size with Dys2 antibody; dystrophin band is absent with Dys1 antibody (**d**, lane 2). Lane 3 shows severely reduced dystrophin with Dys1 and Dys2 from a DMD muscle

If DNA analysis fails to detect a dystrophin deletion/duplication, a muscle biopsy for dystrophin assay will need to be considered, particularly in (1) clinically atypical cases, (2) families without a clear-cut X-linked pattern of inheritance, and (3) families with affected male and female siblings, suggesting an autosomal recessive form of muscular dystrophy. If the Western blot demonstrates dystrophin deficiency, the symptoms may be due to a point mutation or subexonic rearrangements. If dystrophin immunostaining and Western blot analysis are normal, another muscular dystrophy (e.g., sarcoglycanopathy) must be considered.

Females with Dystrophinopathy

Female patients can have an early-onset, progressive muscular dystrophy if they have the following: (1) 45X0, 46XY, or Turner mosaic karyotypes; (2) an apparently balanced X/autosome translocation with breakpoints in Xp21, within the dystrophin gene, and preferential inactivation of the normal X; and (3) a normal karyotype but nonrandom (skewed) X chromosome inactivation leading to diminished expression of the normal dystrophin allele. Therefore, following the exclusion of other neuromuscular diseases (e.g., polymyositis, spinal muscular atrophy) by EMG and muscle biopsy, chromosomal analysis should be considered in all symptomatic females, especially those with highly elevated serum CK levels. Further study with a DNA deletion test may be diagnostic in a symptomatic female, especially in cases with 45XO, 46XY, or Turner mosaic karyotypes. About 2.5 to 10 % of manifesting carriers may have clinically apparent muscle weakness. Almost all symptomatic female carriers of mutant dystrophin genes show skewed X-inactivation, which can be detected by a PCR-based androgen receptor assay.

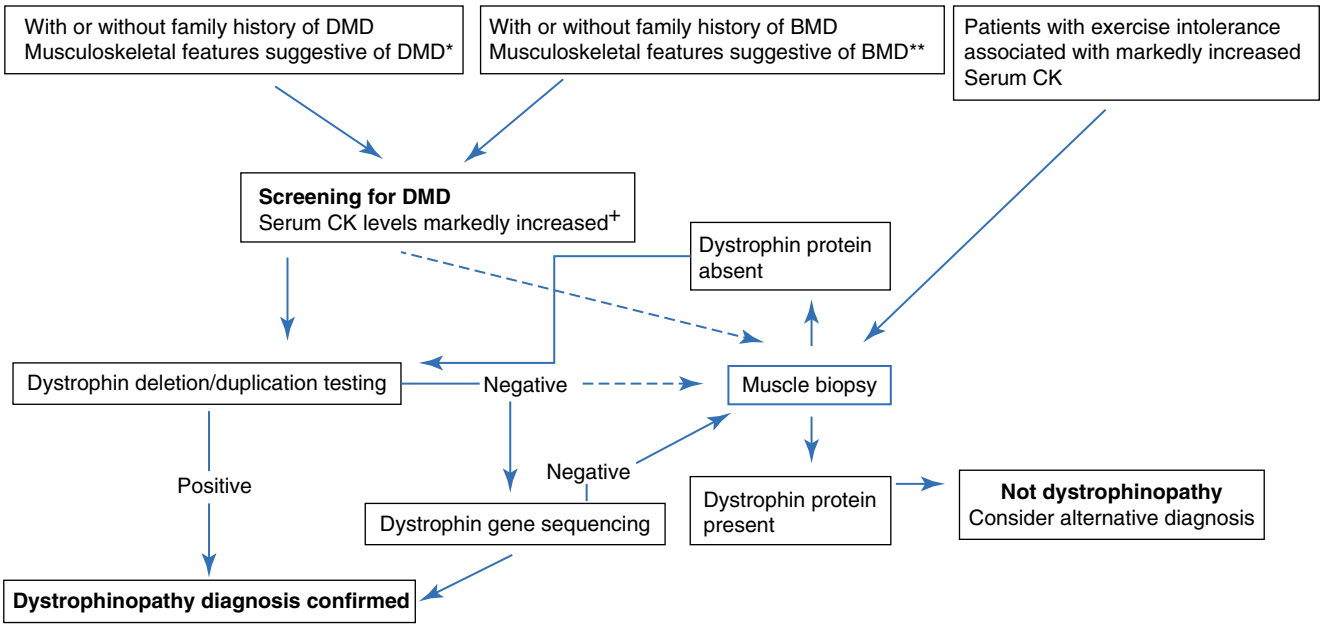

Fig. 56.5 Algorithm to guide diagnostic workup in suspected DMD/BMD patients for confirmation of dystrophinopathy diagnosis. For patients diagnosed by muscle biopsy, dystrophin genetic testing is also necessary. For patients diagnosed by genetic testing, muscle biopsy is not necessary, and if at all possible, defer muscle biopsy until patient participates in a later clinical trial. *DMD* Duchenne muscular dystrophy, *BMD* Becker muscular dystrophy, *CK* creatine kinase (*, ** see Table 56.2 for musculoskeletal features; + see Table 56.2 for serum CK levels)

Immunohistochemical stains in muscle biopsies from manifesting carriers with significant elevation of CK levels generally show high proportions of dystrophin-negative fibers, creating a mosaic pattern of dystrophin immunofluorescence. In asymptomatic carriers with increased CK, there may be dystrophin-negative fibers by IF; however, if the CK levels are normal, dystrophin-negative fibers are difficult to detect.

Genetic Counseling

With clear X-linked transmission, genetic counseling is similar to that for all X-linked recessive diseases. However, mothers of children with DMD or BMD should be made aware of the rare risk of mild skeletal muscle weakness or dilated cardiomyopathy in carriers, for the purpose of an adequate follow-up evaluation of themselves and their daughters.

In sporadic cases, with a negative mutation analysis in the mother of the proband, the parents should understand that germline mosaicism cannot be excluded; because of its relatively high incidence (20 %), there will be at least a 7–10 % statistical risk (may be higher in individual cases) of recurrence of DMD/BMD in subsequent male offspring. Again, because of possible germline mosaicism, sisters of a sporadic case should be tested for carrier status also, even if the mother of the sporadic proband is DNA deletion negative.

Treatment and Management

Supportive Treatment

The main goal in the management of DMD/BMD is to maintain ambulation for as long as possible and manage the associated complications, such as joint complications, scoliosis, cardiomyopathy, respiratory insufficiency, and weight gain. Therefore, therapeutic interventions in DMD/BMD patients require a multidisciplinary approach, aimed at maintaining function, management of pulmonary and cardiac complications, improving quality of life, and providing psychological support.

Contractures begin early; daily passive *stretching exercises* to minimize and delay contractures of iliotibial bands, Achilles tendons, and hip flexors are the mainstays of physical therapy. Lightweight plastic ankle-foot orthoses (AFOs) can be applied during sleep to prevent equinus contractures. Contractures of shoulders and elbows are usually not a major functional problem because of the patient's inability to abduct the arms or fully extend the elbows at advanced stages of the disease. Contractures of wrists and fingers should be treated by passive mobilization and by wearing wrist orthoses at night [71]. Exercise during physical therapy should be limited, especially if it induces muscle pain.

By the age of 9 years, standing and walking can be maintained by using lightweight plastic ankle-foot *orthoses* or long leg braces (knee–ankle–foot orthoses, KAFOs), the latter usually in conjunction with a walker to help maintain

balance [151]. The fitting and use of KAFOs may involve and orthopedic surgical intervention (Achilles tendon release) and intense physical therapy. The use of a standing frame should be introduced before the child is no longer able to walk. A standing frame used for a few hours a day, even with minimal weight bearing, can be important in preventing and reducing the severity of contractures, decubitus ulcers, and scoliosis and also improves bone density and gastrointestinal and respiratory functions.

Surgical release of contractures of the hip flexors, iliotibial bands, and Achilles tendons combined with the use of braces has been demonstrated to prolong the ability to walk by 1–3.5 years [72, 151–158]. Although this is a relatively short period of time, it can be functionally and psychologically very important for the patient and his family [159]. Furthermore, it appears that prolongation of ambulation, or even standing, delays the onset of scoliosis [158]. Several combined or isolated surgical procedures and techniques, such as release of tensor fasciae latae, tenotomy of the Achilles tendon, and posterior tibial tendon transfer, are used to obtain these results. However, timing of the surgical procedures, the type of operation, and the need for postoperative bracing are the subject of considerable debate in the literature [159]. Controversy has focused on the potential benefit of hip abduction contractures, which provide a more stable broad-based gait, and the need to correct them [159]. The current approach in many centers is strictly individualized and some patients elect not to have surgery. Markedly weak hip and quadriceps muscles are often deterring factors from surgery since reambulation can be difficult even if the knees and feet are straight. It is preferable to operate on patients while they are still ambulatory, because recuperation is easier and there is less need for postoperative bracing. Patients still ambulating with isolated equinus contractures often benefit from heel cord lengthening with posterior tibial tendon transfer [151, 159].

Scoliosis inevitably happens with wheelchair confinement. In order to avoid asymmetric positioning, the wheelchair should be properly fitted with a reclining back and neck extender and lateral chest wall supports, which may retard the development of scoliosis. During the ambulatory phase a spinal radiography is warranted if scoliosis is observed clinically and is indicated as a baseline for all patients around the time that wheelchair dependency becomes evident. Monitoring with an anteroposterior spinal radiography is recommended yearly for curves less than 15°–20° and every 6 months for curves more than 20° irrespective of steroid treatment up to skeletal maturity [160]. *Surgical correction of scoliosis* should be considered when the spine is at Cobb angle between 20° and 40° and should be planned before respiratory and cardiac functions decline significantly. To decrease the operative risk, it is optimally performed when FVC is still >30 % [160, 161]. The main reason for anterior spinal fusion is to prevent further progression of spinal deformity. Long-term objectives of the surgery are to achieve a good sitting posture, comfort, and quality of life by avoiding the complications of progressive scoliosis [160]. Cardiac and pulmonary evaluations should always precede surgery. Adverse anesthetic reactions during surgery can be minimized by the use of appropriate agents [162]. Boys who have been treated with daily corticosteroids have a greatly decreased risk of scoliosis [163]. Thoracic-lumbar-sacral orthoses are not very helpful in the prevention or arrest of evolving scoliosis [157, 164–169].

Weight control is important and should be monitored carefully. As mobility declines, weight gain is common and contributes to the loss of ambulation. Dietary consultations are recommended in patients who are receiving prednisone therapy to ensure an adequate intake of vitamin D and calcium, provide guidance regarding weight control, plan a healthy diet, and monitor calorie and sodium intake.

Symptomatic involvement of gastrointestinal smooth muscle is more common in older patients and may lead to constipation, impaction, and even acute gastric dilatation. Care givers should be encouraged to promote a diet rich in fiber and adequate hydration of patients. Vaccinations against influenza and pneumococcal infections should be performed regularly and can be administered to patients treated with corticosteroids.

After the age of 6 years or older, pulmonary function studies should be performed yearly. In nonambulatory patients, respiratory assessment may become necessary during clinical visits at least every 6 months. During nonambulatory stage, overnight monitoring of oxygen saturation with pulse oximetry allows the detection of early nocturnal hypoventilation and is recommended at least once every 6 months [170]. Nocturnal hypoventilation responds well to initiation of *noninvasive intermittent positive pressure* ventilation. Daytime lung function parameters predict sleep hypoventilation [171] and may prove to be useful in appropriate scheduling of polysomnography and noninvasive ventilation during sleep. Respiratory assistance may be used during periods of respiratory infections.

Baseline assessment of cardiac function is recommended at the diagnosis or by the age of 6 years and the care team should include a cardiologist who should be involved in diagnosis and management of cardiomyopathy. A minimum cardiac assessment to include EKG and echocardiogram is recommended once every 2 years until the age of 10 [170]. Annual cardiac assessments could begin at the age of 10 or at an earlier age if abnormalities are detected. *Cardiac transplantation* is a therapeutic option that can be lifesaving for patients with Becker MD assuming that they have first had a careful trial of medical therapy and, in some, implantable cardiac defibrillators [102, 172, 173].

Anesthesia must be approached with caution in patients who have dystrophinopathies [174]. Patients with DMD and

BMD can have severe complications from anesthesia, including cardiac arrest. Most complications seem to be related to use of succinylcholine, a muscular relaxant that may trigger hyperkalemia [174]. Others have been attributed to use of volatile anesthetic agents. Patients also can have a reaction similar to malignant hyperthermia [174], develop rhabdomyolysis, and have masseter muscle spasm.

Pharmacologic Treatment

Corticosteroids are the best treatment option currently available. Randomized control trials have shown that oral prednisone produces a significant increase in muscle strength, pulmonary function, and overall functional ability in DMD [175, 176]. The mechanism of improvement seen in individuals with DMD treated with prednisone is not well understood but thought to be through an anti-inflammatory effect related to reduction in total T cells and cytotoxic–suppressor T cells [175]. This improvement is most effective with a single daily dose of 0.75 mg/kg regimen, begins within 10 days, and reaches a plateau after three months. Observed side effects include weight gain, hypertension, behavioral changes, growth retardation, and cataracts [175, 176]. There is also an increased frequency of vertebral and long bone fractures with prolonged corticosteroid use [163]. Deflazacort, a synthetic derivative of prednisolone (0.9 mg/kg/day), appears to be equally effective but is not available in the United States [177]. Daily corticosteroids improve muscle strength and function, significantly slow the progression of weakness, prolong ambulation to the mid teens or later, and delay the onset of respiratory and cardiac dysfunction [178, 179]. Asymptomatic cataracts are more common with deflazacort, and weight gain is more prominent with prednisone. If adverse effects require a reduction in prednisone dosage, doses as low as 0.3 mg/kg/day produce improvement that is less prominent but still significant. High-dose weekly prednisone, 5 mg/kg, given each Friday and Saturday, can be considered as an alternative to daily treatment in males on a daily regimen with excessive weight gain and behavioral issues [180].

Data regarding the optimal age to begin treatment with corticosteroids or the optimal duration of such treatment are insufficient. Thus, at this point corticosteroid therapy remains the treatment of choice for affected individuals between ages 5 and 15 years. It is recommended that boys with DMD who are older than age 5 years should be offered treatment with prednisone (0.75/mg/kg/day, maximum daily dose: 40 mg) as soon as plateauing or decline in motor skills is noted. Prior to the initiation of therapy, the potential benefits and risks of corticosteroid treatment should be carefully discussed with parents and caregivers individually.

Information about the efficacy of prednisone in treating individuals with BMD is limited. Many clinicians advocate continuing treatment with glucocorticoids after loss of ambulation for the purpose of maintaining upper limb strength, delaying the progressive decline of respiratory and cardiac function, and decreasing the risk of scoliosis. Retrospective data suggest that long-term daily corticosteroid treatment may reduce the progression of scoliosis; however, an increased risk for vertebral and lower limb fractures has been documented [163].

Emerging Therapies

Although there is no curative treatment for DMD, there are many areas of therapeutic intervention under investigation. Three major treatment strategies have emerged to repair the DMD gene defect which include viral-mediated gene replacement, exon skipping, and mutation suppression. Additional strategies include but are not limited to utrophin upregulation, muscle enhancement, fibrosis reduction, and nNOS modulation which will be discussed in brief.

Gene Replacement

Adeno-associated virus (AAV) delivery remains the most promising strategy for replacement of the dystrophin gene. It is nonpathogenic and remains stable in nonreplicating cells (i.e., muscle), and multiple serotypes exhibit tropism for muscle. One caveat for AAV delivery as a treatment for DMD is the large size of the dystrophin gene which exceeds the packaging capacity of AAV (<5kb). Fortunately, the modular structure of dystrophin allows some flexibility; deletions of nonessential coding regions allow dystrophin to retain significant function if the reading frame is intact. This conclusion was initially based on a clinical observation in a BMD patient with a large in-frame deletion of exons 17–48 removing a significant portion of the rod domain [181]. The patient remained ambulatory until age 61 despite the absence of 46 % of the dystrophin gene. This led to the design of mini- and micro-dystrophin transgenes that were able to fit into AAV. Numerous proof-of-principle studies using AAV delivery of miniature dystrophin genes have shown reversal of the dystrophic phenotype in the *mdx* mouse model for DMD. The first trial of AAV-mediated delivery of mini-dystrophin defined potential hurdles to consider for future trials that restore dystrophin regardless of approach [182]. These lessons include the potential for an immune response generated against novel epitopes presented by exogenous dystrophin in patients with large endogenous deletions as well as immunity primed by revertant fibers. Revertant fibers result from spontaneous second-site mutations which restore the reading frame of dystrophin. Once thought to be tolerizing, the AAV mini-dystrophin trial revealed that revertant fibers

could be immunogenic and accelerate responses following gene transfer.

Upregulation or replacement of utrophin is another therapeutic strategy for DMD that has shown promise. Utrophin shares 80 % sequence homology with dystrophin and has been shown to partially restore function as a dystrophin surrogate in preclinical transgenic mice [183] or gene replacement studies [184]. Utrophin expression is limited to the neuromuscular and myotendinous junctions in normal muscle. However, in both dystrophic mice and DMD patients, it is overexpressed in the sarcolemma of all muscle fibers, partially compensating for the mechanical role of dystrophin in the membrane. Upregulation of utrophin holds particular advantage because of the unlikely occurrence of an immune response as seen following mini-dystrophin gene replacement [182]. Alternative strategies have also emerged to upregulate utrophin at the sarcolemma including several small molecules which demonstrate transcriptional upregulation through the utrophin-A promoter [185–187] or by the use of DAP-stabilizing molecules such as biglycan (rhBGN) [188].

Exon Skipping

Exon skipping is a second molecular treatment approach which is targeted at the messenger RNA (mRNA) level allowing one or more exons to be omitted to restore the dystrophin reading frame. This is accomplished with antisense oligonucleotides (AONs) that are artificially synthesized to hybridize in a complementary fashion to mRNA to modify splicing. Preclinical efficacy has been demonstrated in the mdx mouse, dystrophin/utrophin knockout mouse, and CXMD dog [189–191]. It has been predicted that through targeted skipping of particular exons, as many as 60–80 % of DMD mutations could be corrected. Two phase I safety trials were conducted in DMD patients targeting exon 51 using AONs with two different chemical backbones, 2-*O*-methyl AON-PRO051 and phosphorodiamidate morpholino oligomer (PMO) – AVI-4658 [192, 193]. Safety was demonstrated in both studies which were limited to an intramuscular injection of the AON in a single muscle. Phase I/II extension studies were performed with both AONs to assess efficacy and tolerability following systemic delivery. In the PRO051 trial, dose-related efficacy was achieved with evidence of new dystrophin expression in approximately 60–100 % of muscle fibers in 10 of 12 patients and modest improvement in the 6-min walk test [194]. In the AVI UK phase II open-label study with AVI-4658 (Eteplirsen), 7 of 19 patients saw a modest response with a mean increase of sarcolemmal dystrophin from 8.9 % to 16.4 % [195]. Additional phase II randomized, double-blind, placebo-controlled trials are under way to assess multiple-dose efficacy.

Mutation Suppression

A second molecular approach involves suppression of stop codon mutations of the *DMD* gene that comprise approximately 15 % of DMD cases. Two pharmacologic tactics have shown preclinical efficacy and have also been tested clinically. In mdx mice, in vivo mutation suppression was shown with the aminoglycoside antibiotic, gentamicin [196]. In the most definitive trial, DMD patients ($n = 16$) with stop codons, treated weekly or twice weekly for 6 months (7.5 mg kg IV), showed a significant increase in dystrophin levels with the highest levels reaching 13 % and 15 % of normal. Muscle strength was stabilized and a modest increase in forced vital capacity was achieved. Although this study demonstrates the therapeutic potential of gentamicin, higher doses might be necessary to improve functional outcomes. The known renal toxicity of aminoglycoside antibiotics and the nuisance of intravenous administration have pushed the field to identify an orally administered agent.

Ataluren, formerly referred to as PTC124 (PTC therapeutics), demonstrated promise as an orally administered pharmacologic read-through agent for stop codon mutations [197]. Preclinical studies in the *mdx* mouse revealed dystrophin expression in skeletal, cardiac, and diaphragm muscle and protected skeletal muscle from eccentric contraction-induced injury. A phase I study in healthy volunteers established safety and tolerability at doses exceeding what was required for preclinical efficacy [198]. Dystrophin appeared to increase posttreatment in a phase IIa proof-of-concept 28-day study in DMD/BMD patients. Following these results, a randomized, double-blind, placebo-controlled phase IIb trial was conducted evaluating safety and efficacy over a 48-week treatment period. PTC, Inc., released preliminary results indicating a very strong safety profile; however, the primary endpoint of the 6-min walk test did not reach statistical significance [199]. Ataluren is under continued development for the treatment of cystic fibrosis [200] and hemophilia (clinicaltrials.gov NCT00947193); positive results from these studies may provide evidence for further pursuit as a treatment option for DMD.

Muscle Growth Products

Increasing muscle fiber size and strength is another treatment strategy for DMD under intense investigation. Inhibition of the myostatin pathway shows promise for clinical application. Myostatin is a member of the transforming growth factor beta (TGF-β) family and is a potent regulator of muscle growth. Accordingly, myostatin knockout mice demonstrate dramatic muscle hypertrophy and hyperplasia [201]. The role of myostatin as a negative regulator of muscle mass is highly conserved across species including humans, as shown by the

identification of a myostatin splice-site mutation leading to the loss of myostatin protein in a hypermuscular family [202]. As a disease characterized by progressive muscle loss, DMD is a natural therapeutic target for myostatin blockade. In one approach, a recombinant human antibody (MYO-029) that binds with a high affinity to myostatin and inhibits its activity [203] was shown to increase muscle mass in immunodeficient mice by approximately 30 % over 3 months, similar to the biological response demonstrated for other myostatin-neutralizing antibodies [204]. MYO-029 was subsequently studied in a double-blind randomized clinical trial in Becker, limb-girdle muscular dystrophy (including multiple types), and facioscapulohumeral muscular dystrophy where safety but not clear efficacy was established [203]. Based on this principle, a potentially more potent agent is follistatin, a myostatin inhibitor that has been demonstrated to lead to muscle growth in vivo. Delivery of the follistatin gene by adeno-associated virus (AAV) in mice or nonhuman primates shows dramatic increases in muscle size and strength, and this approach is poised for gene therapy [205, 206].

Apart from myostatin inhibition, insulin growth factor-1 (IGF-1) treatment is another strategy to increase muscle mass and strength under investigation for DMD. IGF-1 is a growth factor and key mediator of anabolic pathways in muscle which stimulates whole body protein metabolism [207]. It is involved in muscle repair and regeneration by stimulating the proliferation and differentiation of skeletal muscle cells [208–210]. Preclinical studies found that transgenic overexpression of IGF-1 in DMD mice increased skeletal and diaphragm muscle mass, increased force generation, and reduced fibrosis and myonecrosis [211, 212]. IGF-1 is already FDA approved for severe primary IGF deficiency. A prospective, randomized, open-label, controlled phase II clinical trial of recombinant IGF-1 (INCRELEX™) has been initiated in glucocorticoid (GC)-treated DMD patients to test its ability to preserve muscle function.

Several other therapeutic strategies are also on the horizon for DMD in either proof-of-principle animal studies or in clinical trial. Fibrosis is a confounding factor for any treatment for DMD. Proliferation of endomysial connective tissue limits muscle regeneration, contributing to progressive muscle weakness. Strategies to prevent or reduce fibrosis alone or in combination with other therapies are under exploration including TGF-β blockade and altering expression of micro-RNAs [213, 214]. Another therapeutic target is neuronal nitric oxide synthase (nNOS). Two variants of nNOS contribute to normal muscle metabolism by attenuating vasoconstriction and helping maintain the ability of contracting muscle to generate force following exercise. nNOS is either downregulated or mislocalized in dystrophic tissue [215] and contributes to overall disease pathology; therefore, reversal of ischemic-induced pathology by upregulating nNOS expression has potential as a treatment strategy. To summarize, multiple therapeutic strategies are on the horizon for treating dystrophinopathies with the goal of replacing the missing dystrophin gene or reversing resultant pathology. This multifaceted disease may not be curable by any one therapy as demonstrated by various treatments under investigation presented here.

Limb-Girdle Muscular Dystrophies

57

Stanley Jones P. Iyadurai and Darine Kassar

Introduction

The limb-girdle muscular dystrophies (LGMD) are a heterogeneous group of hereditary neuromuscular disorders with predominant or selective weakness in proximal limb and axial muscles, having an estimated incidence of 1:100,000. While they are congenital in nature, most of them manifest in adulthood with a range of presentation from early childhood to late adulthood, even into 70s and 80s. LGMD has onset of weakness of pelvic and shoulder girdle muscles although specific disorders may initially manifest more prominently in the pelvic or the shoulder girdle. During the progressive course, weakness may spread outside of the pelvic and the shoulder girdle. Depending on the type of LGMD, the lungs and heart may be involved. Creatine kinase (CK) levels may be normal, mildly elevated, or highly elevated. Usually extraocular muscles are spared. Cranial muscles are spared as well, except, in some special cases, facial muscles may be involved. A large number of LGMDs have been described – both clinically and molecularly.

The current classification system of LGMD bases nomenclature on inheritance pattern. Dominant forms of the LGMD are classified as type 1 (LGMD 1), and the recessive forms are classified as type 2 (LGMD 2), with a progressive alphabetical letter indicating the order of gene mapping/identification [1]. The X-linked LGMDs are not numbered or alphabetized. These are listed as a separate group in this chapter. About one third of LGMD patients defined clinically are without genetic identification, and they are classified according to disease mechanism [2].

Historical Perspective

Since the 1800s children with "muscular dystrophies" were found with variable inheritance patterns – X-linked recessive, autosomal recessive, and autosomal dominant. Most such patients presented with proximal weakness, specifically weakness of the muscles of the limb and pelvic girdle. In 1910, Batten classified muscular dystrophies into seven specific categories, based on pattern of presentation, clinical progression, and age of onset [3]. The muscular dystrophy class termed "juvenile type of Erb" comprises the current-day limb-girdle muscular dystrophies (LGMD). The term LGMD was coined by Stevenson in 1953 [4] and was further expanded by Walton and Nattrass in 1954 [5]. Walton and Nattrass described sporadic manifestations of a Duchenne muscular dystrophy (DMD)-like phenotype in three women [5] and suggested that LGMD must be a form of muscular dystrophy. After evaluating several LGMD patients, Walton summarized the clinical manifestations of this heterogeneous disorder that included the following criteria: (1) manifestation in both sexes; (2) common manifestation in the second or third decade (but occasionally later in mid-life); (3) sporadic, autosomal recessive, or autosomal dominant inheritance patterns; (4) primary involvement of shoulder and pelvic girdle muscles, with variable presentation and progression; (5) pseudohypertrophy of the calves (Fig. 57.1); (6) abortive cases which are uncommon; (7) variability in severity and rate of progression but usually severe disability in 20 years after onset; (8) severe disability by mid-life; and (9) later occurrence of contractures and skeletal deformities. The heterogeneity in the LGMD patient population was soon recognized in the late 1980s leading to consideration that LGMD had various pathological mechanisms [6, 7]. The

subtle overlap (and differences) between previously described conditions was beginning to be noticed (e.g., facioscapulohumeral muscular dystrophy). Since the dawn of molecular genetics in the 1990s, several individual LGMD entities have been defined based on clinical and molecular criteria.

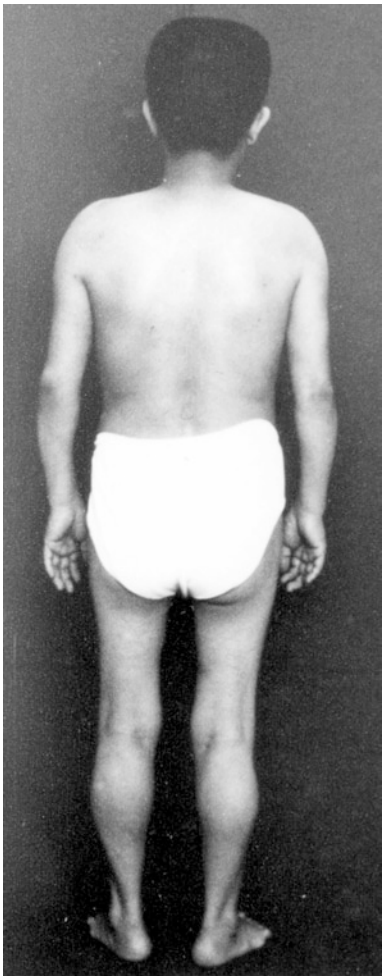

Fig. 57.1 A male patient with calpainopathy with very mild calf hypertrophy

LGMD 1 (Dominant Forms of LGMD)

Eight LGMD 1 loci with dominant inheritance patterns have so far been described based on clinical criteria, but the heterogeneity of the dominant forms of LGMD is expected to expand. Sporadic forms of the disease are often not appreciated, since de novo dominant mutations can present with the disease phenotype but with an obvious lack of family history of the disease. The LGMD 1 forms are usually of an adult-onset pattern and are mild. Affected patients are usually in good health at reproductive age. Thus far, mutations in five genes have been identified to underlie forms of LGMD 1. The LGMD 1 subtypes, characteristic features, clinical features, and limited gene information are provided in Table 57.1. Individual LGMD 1 subtypes are described below.

LGMD 1A (Myofibrillar Myopathy 3, Myotilinopathy)

Over 15 families have been described with women equally as affected as men. The gene responsible for this syndrome is located on chromosome 5q31.2 and identified to be myotilin. Most of the mutations are missense mutations (Lys36Glu, Ser55Phe, Thr57Ile, Ser60Cys, Ser60Ile, Gln74Lys, Ser95Ile, Ala115Thr) and are localized in the serine-rich area of myotilin (see below). The mode of inheritance may be dominant, or sporadic. The onset of the disease is between 42 and 77 years of age except in Virginia family (Thr57Ile), in which the onset was at 27 years of age.

Table 57.1 Listing of subtypes of LGMD 1 and their characteristics

	Clinical phenotype			Gene information		
	Typical onset	Progression	CK increase	Allelism	Gene/locus	Protein
LGMD 1A	Adulthood	Slow	1–15 X	Myofibrillar myopathy, spheroid body myopathy	TTID	Myotilin
LGMD 1B	Variable; childhood to adults	Slow	1–6 X	Several, EDMD2, CMD1A	LMNA	Lamin A/C
LGMD 1C	Childhood	Slow to moderate	10–15 X	Rippling muscle disease	CAV3	Caveolin
LGMD 1D	Adulthood	Slow	1–3 X	None noted	DNAJB6	HSP40
LGMD 1E	Adulthood	Slow	2–4 X	Myofibrillar myopathy	DES	Desmin
LGMD 1 F	Variable; infancy to adults	Rapid	Variable; normal to 6 X	None noted	7q32	To be identified
LGMD 1 G	Adulthood	Slow	Variable; normal to 9 X	None noted	4q21	To be identified
LGMD 1H	Variable; childhood to adults	Slow	Variable; normal to 10 X	None noted	3p23	To be identified

EDMD Emery–Dreifuss muscular dystrophy, *CMD* congenital muscular dystrophy

Weakness is symmetric and starts in the lower extremities and then progresses to the upper extremities. Distal weakness is observed with further progression. Many patients initially present with foot drop. When the upper extremities are involved, the weakness is noticed in the wrist extensors and finger extensors and in the deltoid muscle. Facial and neck extensor muscle weakness may occur. Some patients develop dysarthria (palatal weakness) [8], myalgias, and joint contractures mainly of the ankles. Cardiomyopathy is present in half of patients with onset between the sixth and seventh decade.

Tendon reflexes are absent at the knees and the ankles, but loss of tendon reflexes may be diffused. Progression of the weakness is slow with loss of ambulation 10 years after onset. Serum CK can be normal to 15-fold elevated. Needle electromyography reveals myopathic changes, and in addition fibrillations or myotonic discharges are seen in some patients.

Muscle biopsy reveals a myopathic pattern: significant size variability, rounded fibers, rimmed or autophagic vacuoles, and hyaline inclusions. Abnormal internal architecture can be observed. ATPase stains may reveal spheroid bodies. On immunocytochemistry, myotilin stain is normal, but in abnormal fibers, patches of increased staining may be seen. Increased immunoreactivity of other proteins such as desmin, plectin, gelsolin, and ubiquitin is frequent.

Myotilin, a 498 amino acid protein, is associated with the Z disc and is expressed in skeletal and, to a lesser extent, cardiac muscle. The exact function of the protein is unknown. However, the protein binds to α-actinin and filamin C, cross-links actin filaments, controls sarcomere assembly, and is probably important in stabilizing and anchoring thin filaments to the Z disc during myofibrillogenesis. Defects in the myotilin gene have been associated with the LGMD 1A phenotype [9] and, in a variant syndrome, spheroid body myopathy.

LGMD 1B (Emery–Dreifuss Muscular Dystrophy 2, Laminopathy)

Manifestations of the disease usually begin before the age of 20 years. The most common presentation is symmetrical weakness affecting the proximal lower extremities. A variant of this syndrome (Arg377His mutation of the lamin A/C gene; see below) affects mainly the quadriceps. The progression is slow. The upper extremities are usually involved in the third or fourth decade. Cardiomyopathy is present in about 60 % of patients and is typified by atrioventricular conduction block, bradycardia, and sudden cardiac death [10]. Dilated cardiomyopathy is present before onset of the weakness with Arg377His mutation [11]. Serum CK is normal to mildly elevated. Muscle biopsy shows myopathic changes, and mutated lamin is mislocalized and aggregated in the nucleus and the cytoplasm.

Mutations in the lamin A/C gene are responsible for the LGMD 1B phenotype. Patients with EDMD2 also harbor mutation in the lamin A/C gene, but the clinical manifestations differ. These include contractures of the posterior cervical muscles, the elbows, and the ankles, cardiac involvement, slowly progressive weakness involving the humeral and peroneal muscles with some pelvic girdle involvement, tendon areflexia, and slight elevation in CK levels. The clinical manifestation is similar to the classic X-linked Emery–Dreifuss muscular dystrophy, but the mode of inheritance of EDMD2 is autosomal dominant.

Lamins A and C are members of the intermediate filament family and are present in terminally differentiated cells. The lamin gene is located on chromosome 1. Together, they form part of the nuclear lamina, a fibrous layer on the nucleoplasmic side of the inner nuclear membrane thought to provide a framework for the nuclear envelope. Lamins form dimers through their rod domain and interact with chromatin and integral proteins of the inner nuclear membrane through binding sites located in their rod domains and their carboxy-terminal globular tail. Lamins are structural protein components of the nuclear lamina, a protein network underlying the inner nuclear membrane that determines nuclear shape and size.

LGMD 1C (Rippling Muscle Disease, Caveolinopathy)

In LGMD 1C the onset of symptoms is between 5 years of age and adulthood. Manifestations are moderate and start with proximal weakness in the lower extremities, with difficulty walking and a positive Gowers' maneuver. Multiple reports support the clinical variability of LGMD 1C in presentation and age of onset [12, 13]. For example, a 4-year-old girl with myalgias in the lower limbs but no muscle weakness; a 4-year-old girl with myalgias and a dystrophic pattern in the skeletal muscle biopsy; an 11-year-old girl with a history of floppiness at birth, marginally delayed motor milestones, progressive proximal muscle weakness, and exercise-induced myalgias; a 71-year-old woman, without any previous neuromuscular symptoms, who has mild proximal muscle weakness, scapular winging, slight calf hypertrophy, and a positive Gowers' sign, and two boys (3 and 6 years old) who have muscle pain, calf hypertrophy, increased CK levels, but no muscle weakness; a 57-year-old woman with mild proximal weakness of the lower limbs, calf pseudohypertrophy, and high CK levels; and a 58-year-old woman with myalgias, proximal weakness, calf pseudohypertrophy, and dilated cardiomyopathy were all shown to have LGMD 1C based on molecular genetic analyses. Cramps after exercise may be a complaint. Variable clinical manifestations may occur in single family. The disorder is

characterized by a generally benign clinical course. There is no evidence of respiratory impairment and life expectancy is not reduced.

In LGMD 1C patients, electromyographic results range from a normal to a myopathic pattern, whereas muscle biopsy analysis can show variably sized, degenerating/regenerating muscle fibers, with an increased number of central nuclei, and a mild substitution of connective tissue. Mutations in caveolin-3 (*CAV3*) gene were shown to be responsible for the LGMD 1C phenotype. As might be expected, the expression of CAV3 is reduced invariably both by immunohistochemistry and immunoblot analysis of muscle fibers.

Patients with mutations in *CAV3* may present with a rippling muscle disease (RMD) phenotype. RMD is characterized by signs of increased muscle irritability such as percussion-induced rapid contraction and percussion-induced muscle mounding. Clinically, mechanical stimulation of the muscle leads to electrically silent muscle contractions that spread to neighboring fibers that cause visible ripples to move over the muscle. RMD is usually inherited as an autosomal dominant trait, but autosomal recessive inheritance is also noted. Age of onset of disease varies between 3 and 36 years of age. Muscle hypertrophy is also frequent. At times, a parent may be a benign carrier with muscle hypertrophy but no other signs or symptoms. The presenting manifestations are usually fatigue, tiptoe walking difficulty, and myalgias. The patients usually experience muscle cramps, pain, and stiffness, particularly with exercise. Balling of muscle occurs after percussion, and a characteristic lateral rolling movement of the muscle occurs after contraction followed by stretching. Serum CK levels are usually more than ten times normal. Electromyography reveals myopathic activity. Histological assessment reveals fiber diameter variability and hypertrophy of type 2 fibers. Immunohistochemical evaluation for caveolin is often abnormal.

The gene mutation underlying the LGMD 1C phenotype has been associated with mutations in caveolin-3 gene (*CAV3*). Caveolins are proteins that are localized in the ultrastructural components of the plasma membrane called caveoles. Caveoles were initially described by electron microscopy and described as flask-shaped invaginations of the plasma membrane [14]. Caveolar architecture is thought to be orchestrated by caveolins, a family of proteins composed of the three isoforms, caveolin-1, caveolin-2, and caveolin-3. CAV3 protein is 151 amino acids long and is divided in separate functional domains including N-terminal, scaffolding, transmembrane, and C-terminal domains. In adult myofibers, CAV3 is present throughout the T-tubule system where it assists in the electrical transmission of the contractile impulse. The CAV3 is also present within the sarcolemma where it provides a link between the cytoskeleton and the extracellular matrix and therefore is essential to confer stability to the muscle cell membrane. Most of the caveolinopathies are inherited by autosomal dominant inheritance pattern. Only six autosomal recessive CAV3 mutations have been described.

The critical role of CAV3 in muscle cell physiology was shown by in vitro and in vivo studies and was confirmed by the findings that mutations in caveolin-3 gene lead to distinct neuromuscular and cardiac disorders such as LGMD 1C, idiopathic elevation of serum CK, rippling muscle disease, distal myopathy, and familial hypertrophic cardiomyopathy. Mutations in the *CAV3* gene have been found in patients with the arrhythmogenic long QT syndrome and in sudden infant death syndrome as well.

LGMD 1D (Myofibrillar Myopathy Type 1, HSP40-Opathy)

LGMD 1D is characterized by proximal muscle weakness beginning in the hip girdle region, resulting in waddling gait, and then usually progressing to the shoulder girdle; however, not all patients develop arm weakness. The age of onset is between 20 and 60 years of age, although most patients recall being slow and clumsy as children. The progression is gradual with need for wheelchair 20–30 years or later after disease diagnosis. Most patients have walking difficulties by the eighth decade, and dysphagia occurs in one of five patients. Dysarthria may occur. Mild calf hypertrophy may be present. Cardiac or respiratory involvement has not been observed with LGMD 1D. Most patients have elevated serum CK (up to five times normal). Electromyography shows myopathic changes. Skeletal muscle biopsy reveals dystrophic changes, including variation in fiber size, rounded fibers, endomysial fibrosis, rimmed vacuoles, and eosinophilic cytoplasmic bodies.

The gene mutation underlying the LGMD 1D phenotype has been localized to mutations in the *DNAJB6* gene [15]. The protein product belongs to the heat shock protein 40/DNAJ group which regulates molecular chaperone activity by stimulating ATPase activity. While the exact function of this protein is unknown, it may protect other proteins from undergoing irreversible aggregation. HSP40 is expressed in muscle and other tissues and interacts with proteins implicated in causing myofibrillar myopathies.

LGMD 1E (Familial Cardiomyopathy with Conduction Deficit, Desminopathy)

LGMD 1E is characterized by dilated cardiomyopathy, cardiac conduction-system disease, and adult-onset myopathy [16]. Cardiac manifestations include arrhythmia which becomes manifest in age of 20–25 years and congestive heart failure with 4-chamber enlargement with onset between the

third and fifth decade. Sudden cardiac death without prior cardiac symptoms has been reported.

Muscle pathology reveals variation in fiber size, increased connective tissue, and eosinophilic inclusions and cytoplasmic bodies.

The mutation underlying this phenotype was found in the Desmin gene. The most common mutation was the intron splice donor site mutation (IVS3+3A>G). Desmin is an intermediate filament protein, present abundantly in both skeletal and the cardiac muscles.

LGMD 1F

LGMD 1F was first described in a Spanish family with 32 affected members, spanning five generations. The patients developed proximal muscle weakness with variable age of onset ranging from less than 1 year to 58 years. Genetic anticipation was suggested by the age of onset of the third through fifth generations being significantly less than the preceding generations. Two groups of patients were identified based on the age at onset and clinical progression: a juvenile group (66 %) with manifestations prior to age 15 years and rapid progression and an adult group (28 %) with slow progression and disease onset in the third or fourth decade. All affected patients showed characteristic pelvic and shoulder girdle proximal weakness. Pelvic girdle impairment was more severe and occurred earlier than shoulder girdle weakness, and distal weakness often occurred later. Respiratory muscles were clinically affected in four patients with juvenile onset.

Symptoms of pelvic girdle muscular weakness were noted at onset in 80 % of patients. Commonly affected muscles were the iliopsoas (nearly all), gluteal, hip adductors, deltoid, biceps brachii, paraspinal, and neck flexors. Pelvic girdle impairment was more severe and occurred earlier than in the shoulder girdle. Proximal muscle weakness ranged from MRC grade 0 to 4+, with symmetric distribution. Distal weakness appeared late in the disease course or accompanied initial presentation in severely affected juvenile-onset patients, frequently affecting the extensor digitorum, tibialis anterior, and toe extensor muscles. Scapular winging was reported, and mild facial weakness was seen in juvenile-onset disease. Early-onset patients had generalized muscular wasting, predominantly involving the quadriceps, gluteus, deltoid, biceps, infraspinatus, and supraspinatus muscles. Late in the disease course, contractures are seen at the Achilles tendon, and respiratory muscles might be affected in juvenile onset [17].

Serum CK was normal in 40 % of patients and varied between normal and highs close to 3,000. Electromyography demonstrated myopathic changes with short duration, polyphasia, and low-amplitude potentials, which were more pronounced in the proximal muscles. Sensory and motor nerve conduction velocities were normal.

Muscle histology revealed abnormal fiber size and shape variation, increased endo- and perimysial connective tissue, and scattered degenerative fibers with myophagia. Rimmed vacuoles and central nuclei were reported. Desmin was overexpressed in some fibers, but was not abundant enough for consideration as a significantly abnormal desmin accumulation. LGMD 1F has been linked to chromosome 7q32.1-32 [18]. The causative gene is unknown.

LGMD 1G

LGMD 1G was described in twelve members of a Brazilian-Caucasian family who had mild late-onset proximal weakness associated with progressive finger and toe flexion limitation with an age at onset from 30 to 47 years. The initial symptoms were proximal lower limb involvement in eight patients and muscular cramps followed by lower limbs weakness in one individual and by upper limbs weakness in another. The disability progressed slowly over years. With exception of the youngest patient in the family, all others showed progressive and permanent finger and toe flexion limitation, with reduced movement range in interphalangeal joints. However, intrinsic hand muscles were not amyotrophic and had normal strength. Serum CK was normal or slightly increased (up to 10-fold).

Muscle biopsy revealed fiber size variation with very discrete perimyseal fibrosis and several necrotic fibers with rimmed vacuoles. Scattered groups of small atrophic angulated fibers were also observed. Some of the vacuoles were clearly labeled with antibodies for sarcolemmal proteins, such as dystrophin and α-sarcoglycan, confirming the presence of sarcolemmal membrane in the vacuoles [19]. The gene mutation underlying this LGMD phenotype is yet to be discovered.

LGMD 1H

LGMD 1H was described in 11 members of a large family from Southern Italy. The disease was segregating in four generations with incomplete penetrance with the variable expressivity observed in age at onset and muscular manifestations. With few exceptions, the disease was characterized by slowly progressive proximal muscle weakness in upper and lower limbs, with onset during the fifth decade of life and a relatively benign course. Hypotrophy of both upper and lower limb-girdle muscles, reduced deep tendon reflexes, and calf hypertrophy were present. Cranial nerve innervated and cardiac muscle involvement was not found, and early joint contractures were not observed. Serum CK levels were elevated ranging from 997 to 2,300 U/L.

Table 57.2 The subtypes of LGMD 2

	Clinical phenotype			Gene information		
	Typical onset	Progression	CK	Allelism	Gene/locus	Protein
LGMD 2A	12–30 years	Slow	Mildly elevated	None	CAP3	Calpain-3
LGMD 2B	Adolescence	Slow	10 X	Miyoshi distal myopathy	DYSF	Dysferlin
LGMD 2C	Early childhood	Moderate to rapid	20 to 30 X	SCARMD	SGCG	γ-Sarcoglycan
LGMD 2D	Variable	Rapid	20 X	None	SGCA	α-Sarcoglycan
LGMD 2E	Early childhood	Moderate to rapid	20 X	None	SGCB	β-Sarcoglycan
LGMD 2 F	Early childhood	Rapid	10 to 50 X	None	SGCD	δ-Sarcoglycan
LGMD 2 G	Childhood, adolescence	Moderate	3 to 30 X	DCM 1 N CMD	TCAP	Telethonin
LGMD 2H	Adolescence, adult	Slow	1 to 20 X	Manitoba Hutterite dystrophy, sarcotubular myopathy	TRIM32	E3 ubiquitin ligase
LGMD 2I	Early childhood	Rapid to slow	5 to 40 X	MDC 1C, myopathy with abnormal merosin, Walker–Warburg syndrome	FKRP	Fukutin-related protein
LGMD 2 J	Childhood, adult	Slow	10 to 15 X	Finnish distal myopathy	TTN	Titin
LGMD 2 K	Childhood	Slow	10 to 40 X	MDDGC 1	POMT1	O-Mannosyl transferase 1
LGMD 2 L	Adult	Slow	1 to 100 X	Miyoshi-like myopathy 3	ANO5	Anoctamin 5
LGMD 2 M	Early infancy	Slow	50 to 100 X	MDDGC 4	FKTN	Fukutin
LGMD 2 N	Prenatal to infancy	Rapid	6 to 12 X	Walker–Warburg syndrome, MDDGC 2	POMT2	O-Mannosyl transferase 2

SCARMD severe childhood autosomal recessive muscular dystrophy, *DCM* dilated cardiomyopathy, *CMD* congenital muscular dystrophy, *MDC* muscular dystrophy, congenital, *MDDGC* muscular dystrophy–dystroglycanopathy

Myopathic changes without evidence of denervation were identified by electromyography. Muscle histology showed abnormal fiber size and shape variation and increased presence of endo- and perimysial connective tissues on hematoxylin–eosin staining. Central nuclei were occasionally present. Ragged red fibers were observed in one patient, and subsarcolemmal accumulation of mitochondria on succinate dehydrogenase staining and fibers negative for cytochrome *c* oxidase staining were seen in two patients, suggesting a defect in oxidative phosphorylation and mitochondrial dysfunction. Mitochondrial DNA deletions were reported in two patients, but the significance of this observation is unclear.

The LGMD 1H mutation has been linked to region on chromosome 3p23–p25.1 [20].The transmission model of the disease is consistent with an autosomal dominant inheritance pattern with variable expressivity and incomplete penetrance.

LGMD 2 (Recessive Forms of LGMD)

Fourteen distinct LGMD 2 loci with dominant inheritance patterns have thus far been described based on clinical criteria. There appear to be a heterogeneity in presentation, and the number of recessive forms of LGMD is expected to be greater than what has thus far been described. CK is normal in most patients, even those with significant disability. The LGMD 2 forms are usually of an early childhood onset and can be debilitating. Adult-onset forms have been described. A variable, progressive course is typical. Mutations in 15 genes have been shown to underlie LGMD 2. The LGMD 2 subtypes, characteristic features, clinical features, and limited gene information are provided in Table 57.2. Individual LGMD 2 subtypes are described below.

LGMD 2A (Calpainopathy)

Although LGMD 2I is the most common form of all LGMDs in northern Europe, LGMD 2A is the most prevalent in many European countries, Turkey, Brazil, Japan, Russia, and Australia, with variable frequencies that differ depending on ethnic clusters and geographic origin. Estimates based on molecular data indicate that LGMD 2A frequency ranges from about 10 % of LGMD cases in the United States to 80 % in the Basque Country of Spain and Russia.

LGMD 2A is characterized primarily by a symmetric, selective atrophic involvement of limb-girdle and trunk muscles [21]. Muscle weakness usually begins in the pelvic girdle, with problems running, climbing stairs, or rising from a chair. The lower limb-girdle muscles are the most severely affected, even in the few patients in whom the disease began in the shoulder girdle or both simultaneously. Hip adductors and gluteus maximus are the earliest clinically affected muscles, and to a lesser degree, the hip flexor hamstring muscles are also involved. Hip abductors are relatively better preserved as well as distal muscles in the lower limbs. Clinical complaints about shoulder girdle and upper limb weakness

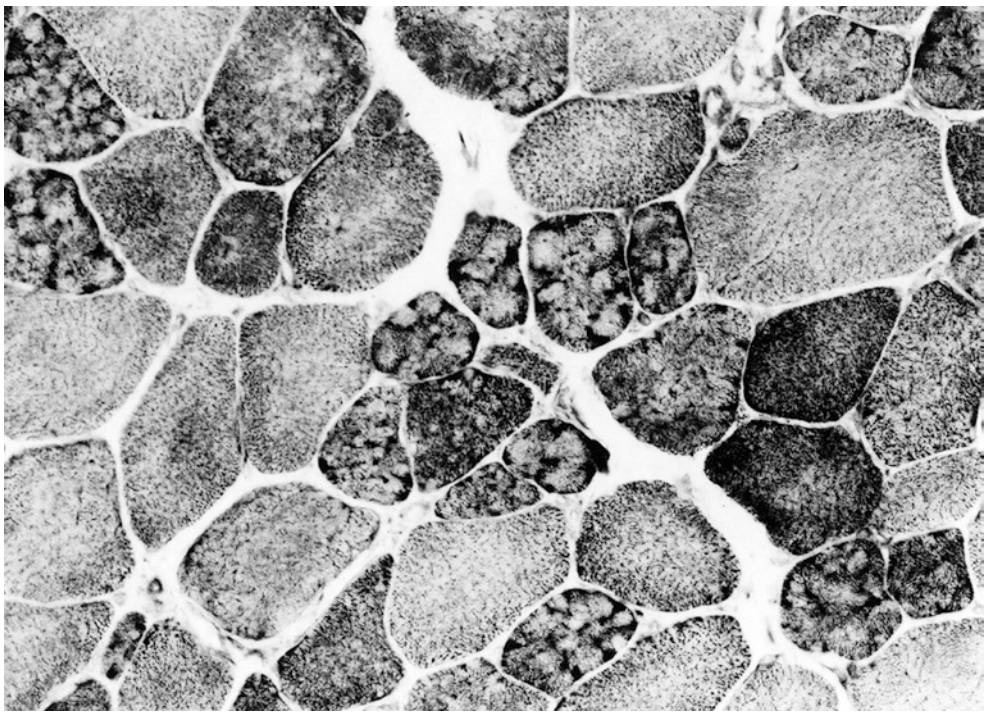

Fig. 57.2 NADH–TR-stained muscle from a 27-year-old man with a calpain gene mutation. Note the disorganized intermyofibrillar network showing "lobulated" appearance in darkly stained small type 1 fibers. ×350

appear later in the disease course. However, the neurological examination shows early muscle involvement in the scapular girdle muscles, including predominantly the latissimus dorsi, rhomboids, serratus magnus, and pectoralis causing scapular winging. To lesser degrees, the trapezius, deltoid, biceps brachii, brachialis, and brachioradialis are involved. As disease progresses, weakness and atrophy also involve the quadriceps and the tibialis anterior in the lower extremities, the triceps brachii, and the forearm muscles. Abdominal muscles become weak. Facial, extraocular, and pharyngeal muscles are usually spared. Muscle hypertrophy is unusual but observed in three quarters of patients in the Brazilian population. Contractures are common at the early stages of the disease in the calves with toe walking as a presenting sign and at wrists, elbows, and fingers. Later in the disease, contractures can involve the spine. No primary cardiac involvement has been observed, but with increasing respiratory insufficiency, cardiac complications may develop. Atypical clinical presentations can include the Leyden–Mobius variant with onset between 13 and 29 years of age with weakness of the pelvic and thigh muscles as well as a late-onset variant, which begins in the fourth decade of life with pelvic girdle weakness.

LGMD 2A is characterized by a wide variability in clinical features and rates of progression. The mean age at onset is at about age 14 years but a considerable variation between 2 and 40 years. The average age that inability to walk occurs is around 17 years but again with a wide range from 5 to 39 years but may occur earlier with infantile onset. However, the age of onset is not an exact predictor of progression or use of wheelchair. No sex difference is evident in age at onset or disease progression. Patients with two null mutations usually have a rapid course, but in the remaining cases (two missense mutations or compound heterozygote mutations), prognosis is uncertain. Serum CK varies from normal to the high tens of thousands. Serum CK is markedly raised in the first stages of the disease and gradually decreases as the muscular atrophy and weakness progresses and the muscles become more atrophic. CK levels are not as high as in other common muscular dystrophies such as Duchenne muscular dystrophy, dysferlinopathies, or LGMD 2I.

Electromyography shows increased insertional activity and spontaneous activity in the form of fibrillation potentials and positive sharp waves. Muscle histology shows (1) variability of fiber size and interstitial fibrosis. Necrotic and regenerating fibers are seen. (2) ATPase staining shows type 1 predominance in severely affected patients. (3) Lobulation of type 1 fibers is seen later in the disease (Fig. 57.2). (4) Inflammation is seen in perivascular or endomysial areas [22]. Eosinophilic infiltrates are fairly characteristic. Computed tomography of the thighs has shown marked atrophy of the hamstrings and hip adductors and moderate atrophy in quadriceps with sparing of the sartorius. MRI has shown involvement of the posterior thigh muscle. With progression of the disease, other thigh muscles are also affected depending on clinical severity: the adductors and semimembranosus muscles are involved in young patients with minimal functional motor impairment. In patients with restricted ambulation, a diffuse involvement of the posterolateral muscles of the thigh and of the vastus intermedius is found, with

relative sparing of the vastus lateralis, sartorius, and gracilis. MRI of the legs reveals involvement of the soleus muscle and the medial head of the gastrocnemius with relative sparing of the lateral head.

LGMD 2A is caused by mutations in the *CAPN3* gene mapped to 15q15.1–q21.1 encoding for a muscle-specific proteolytic enzyme called calpain-3 that is involved in the complex process of sarcomere remodeling. The calpains, or calcium-activated neutral proteases, are nonlysosomal intracellular cysteine proteases. CAPN3 plays a role in the dysferlin protein complex and that disruption of CAPN3 function may affect muscle membrane repair and remodeling. More than 300 CAPN3 mutations have been identified with a distribution that varies according to specific regions or ethnic groups.

Western blot analysis of muscle biopsy shows reduced level of calpain-3 although this has also been observed in other forms of LGMD such as dysferlinopathy and tibial muscular dystrophy. In about a fifth of patients with LGMD, normal levels of calpain-3 are observed by Western blot indicating protein expression levels are normal, but the mutation suppresses autocatalytic function of the enzyme, either by affecting inter-domain protein interaction or by lowering calcium sensitivity. About a third of patients with mutations in the CAPN3 gene show normal proteolytic activity, suggesting that other functions of the protein must be impaired. These results suggest that Western blot can be an initial screening test for LGMD 2A, but a normal calpain-3 level does not rule a calpainopathy, and therefore, mutational analysis of CAPN3 gene must be performed for definitive diagnosis.

LGMD 2B (Dysferlinopathy)

The LGMD 2B has a wide range of presentations including being found to be allelic to Miyoshi muscular dystrophy type 1 and distal myopathy with anterior tibial onset (Fig. 57.3). Symptom onset of LGMD 2B ranges between 10 and 39 years of age, with intra- and interfamilial heterogeneity. Muscle weakness in LGMD 2B starts in the proximal pelvic girdle and presents as difficulty with running and climbing stairs. Early inability to walk with involvement of distal posterior muscles, especially gastrocnemius, is often observed. The upper extremities (mainly biceps) are involved approximately 10 years after the lower extremities [23]. The progression is slow and loss of ambulation is seen after 30 years of age. Some patients may still be able to walk into the sixth decade. Hypertrophy of the deltoids with biceps atrophy and calves hypertrophy at the earlier stage of the disease is observed in some patients. Typically at the time of symptom onset, the medial gastrocnemius shows atrophy. Cramps and muscle discomfort are reported.

When the disease manifests as Miyoshi distal myopathy (also known as distal anterior dysferlinopathy), the onset is usually in the early adulthood, presenting mainly with foot drop and steppage gait. The upper limbs and proximal muscles become involved later. Serum CK levels are considerably increased. Muscle imaging confirms a selective involvement of the soleus and gastrocnemius and early muscle edema. Miyoshi and LGMD phenotypes can be present in the same family.

The serum CK is usually high (10–70 X the normal value). In presymptomatic patients, levels up to 3,000 may be seen [24]. Electromyography shows typical myopathic changes. Muscle pathology shows necrosis and degeneration of muscle fibers, fiber size variability, fiber splitting, and inflammation. Increase in endomysial connective tissue is seen in more involved muscles. Amyloid deposition at the surface of the muscle fiber, in the endomysial connective tissue and perivascular area, is present in muscles of some patients [25]. Some mutations are associated with T-cell infiltrates in the perimysial and perivascular spaces. In patients with LGMD 2B, the dysferlin tissue staining is absent or reduced. However, the absence of staining is more specific for LGMD 2B than reduced staining. However, there is no correlation between level of staining and clinical severity. Western blot may identify the presence, absence, or reduced levels of dysferlin.

LGMD 2B is caused by mutations in the gene encoding the skeletal muscle protein dysferlin on chromosome 2p13.2 [26]. More than 300 mutations have been described. Eighteen percent of patients with dysferlin deficiency have only 1 (heterozygous) mutation on 1 allele. Certain mutations have geographical distributions: 1624delG is common in Libyan Jews; G3370T, G3510A, 3746delG, and 4870delT are common in Japan; and Arg1905X is common in Spain.

Dysferlin is a ubiquitously expressed 230 kDa molecule that is localized to the periphery of muscle fibers, T-tubule, and cytoplasmic vesicles. Dysferlin is composed of a short C-terminal hydrophobic transmembrane domain and a longer cytoplasmic-oriented hydrophilic region that harbors six C2 domains. C2 domains can bind calcium and thus mediate calcium-dependent signaling events. C2 domains can also bind phospholipids, inositol polyphosphates, and intracellular proteins; interact with cellular membranes; and mediate molecular trafficking, vesicle transport, lipid modifications, and protein phosphorylation. Dysferlin interacts with multiple proteins, including annexins A1 and A2, caveolin-3, calpain-3 (CAPN3), affixin (ß-parvin), and the dihydropyridine receptor (DHPR). Dysferlin also interacts with AHNAK, a protein implicated in cell membrane differentiation, repair, and signal transduction.

Dysferlin is one of the sarcolemmal proteins located at the plasma membrane or within the basal lamina, whose reduced expression cause inherited degenerative myopathies. Proteins in this group include dystrophin; α-, β-, γ-, and δ-sarcoglycan; the laminin a2 chain of merosin; the integrin

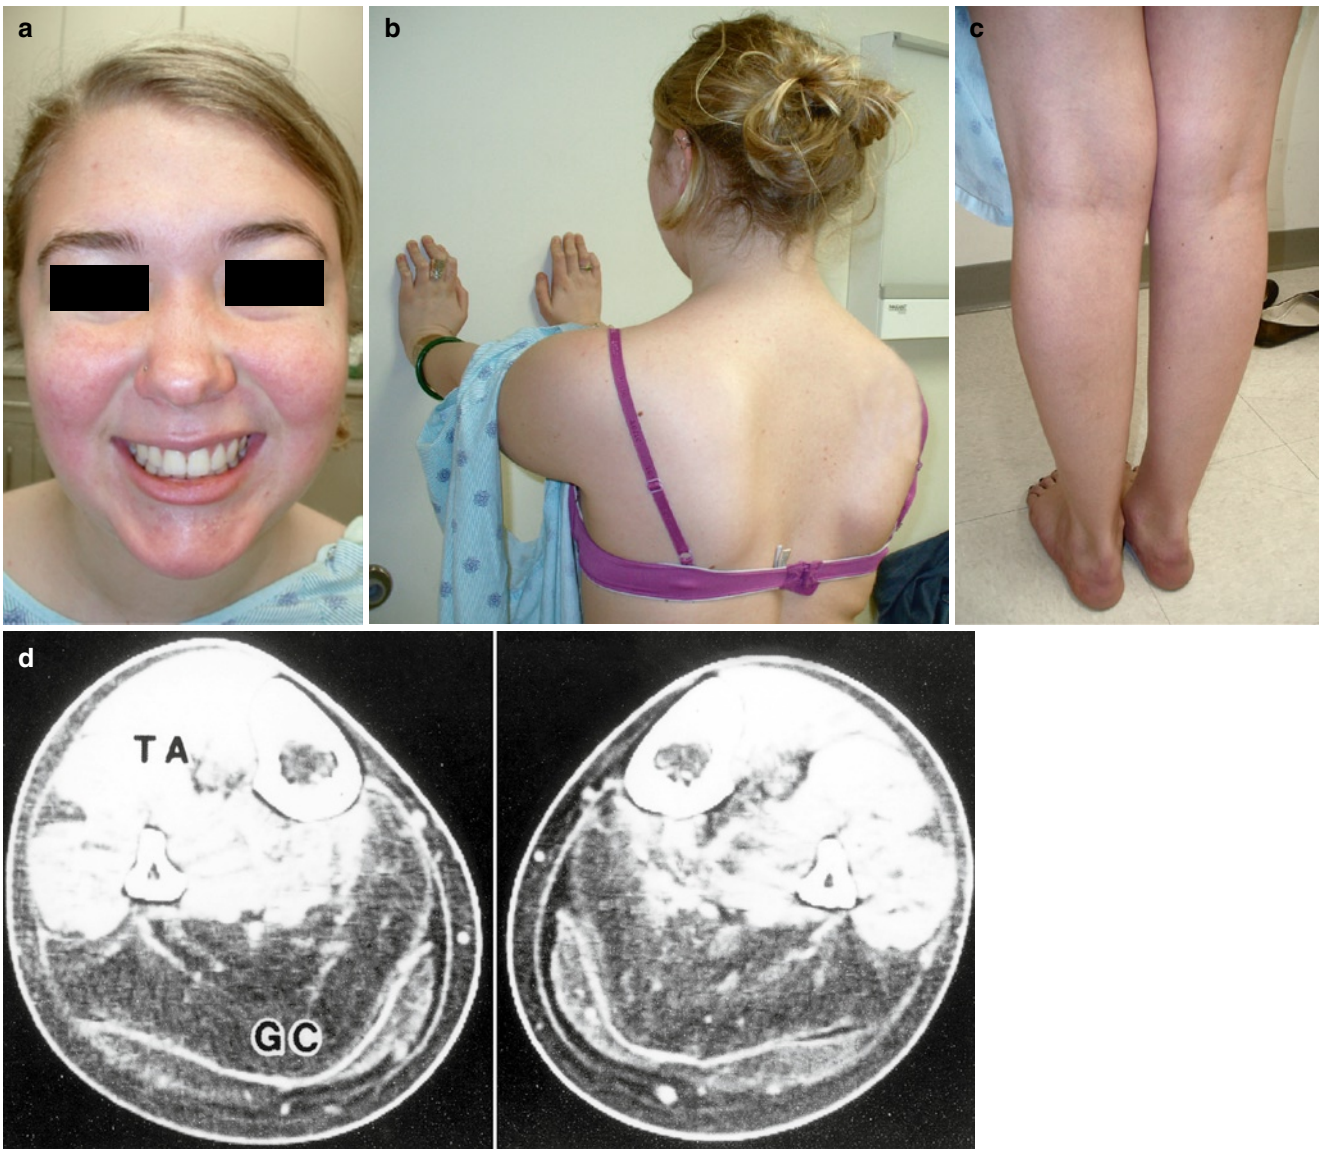

Fig. 57.3 Clinical features of limb-girdle muscular dystrophy 2B (dysferlinopathy). (**a**) No facial weakness or atrophy or asymmetry is noticed. (**b**) Scapular winging. (**c**) Selective atrophy of the medial gastrocnemius muscle is observed in early course of the disease. Note the fairly preserved lateral gastrocnemius muscle. (**d**) Muscle CT in dysferlinopathy. In later course of the disease, the gastrocnemius muscle (both heads) is largely replaced by fat tissue, while the tibialis anterior (*TA*) and the anterior compartment of the leg are spared

a7 chain; and caveolin 3. The function of some or all of these proteins may be structural, whereby the loss of protein leads to muscle fiber degeneration. Given the homology of dysferlin to a nematode spermatogenesis factor (Fer-1) that is required for successful membrane fusion, the lack of dysferlin may cause faulty myotube fusion and thereby impair muscle regeneration.

LGMD 2C (Gamma-Sarcoglycanopathy)

The sarcoglycans, which are deranged in the pathology of LGMD 2C, 2D, 2E, and 2 F, appear to play a structural role in maintaining muscle membrane integrity. Defects in sarcoglycans cause a similar type of LGMD. The plasma membrane cytoskeleton of muscle fibers is composed of several protein components. Dystrophin, a large rod-like protein present on the intracellular surface of the myofiber plasma membrane, is a principal component. Additional protein components of the myofiber plasma membrane cytoskeleton, known collectively as dystrophin-associated proteins, classified into the dystroglycan, sarcoglycan, and syntrophin subcomplexes were identified as important proteins to maintain the integrity of myofiber plasma membrane. Localized within the myofiber plasma membrane, the sarcoglycan complex consists of at least four transmembrane proteins: α-, β-, γ-, and

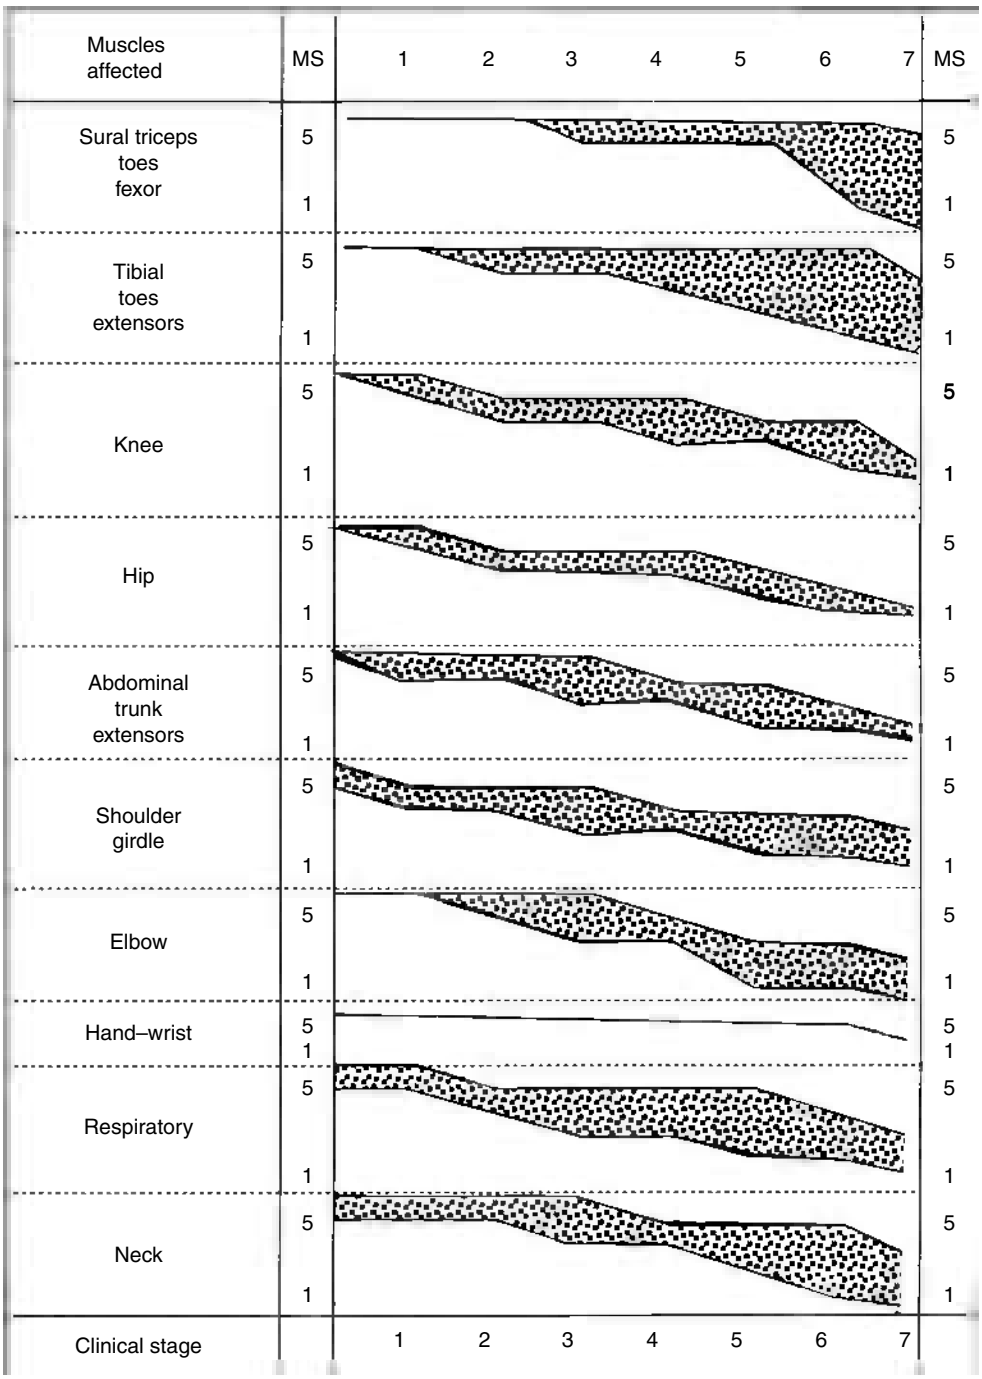

Fig. 57.4 The chronology of involvement of the different muscle groups in SCARMD [3, 62] . The dotted area corresponds to the limits of scores in different stages. Stage 1. Unable to run. Stand without using the arms. Stage 2. Waddling gait. Climbs stairs without using the banister. Stage 3. Climbs stairs only with the banister. Stage 4. Unable to climb stairs. Stage 5. Unable to rise from a chair without assistance. Stage 6. Walks only with assistance. Frequent falls. Stage 7. Unable to walk or stand erect. Confined to bed. Requires help for all activities. *MS* muscular strength

δ-sarcoglycan [27]. The sarcoglycan complex is thought to associate with dystrophin and the dystroglycan complex; however, the exact binding sites have not been identified. Like dystrophin and the other dystrophin-associated proteins, the sarcoglycan complex may impart structural integrity to the myofiber plasma membrane and prevent contraction-induced damage through maintenance of the sarcolemma (basal lamina, plasma membrane, cytoskeleton complex) [28]. The individual LGMDs will be described below.

The age of onset and clinical pictures of LGMD 2C have a wide inter- and intra-familial heterogeneity (Fig. 57.4). The clinical presentation can vary from a Duchenne-like course to intermediate to a mild Becker-like phenotype in a given family (Fig. 57.5). The onset of the disease is approximately 5 or 6 years of age with involvement mainly of proximal muscles, although distal involvement may occur. Inability to walk may occur anywhere between 10 and 37 years of age. The glutei, adductors, paraspinal, abdominal, subscapular, and soleus muscles are affected whereas quadriceps is spared in some patients [29]. Patients may develop calf and tongue hypertrophy (specifically with the C283Y mutation) and

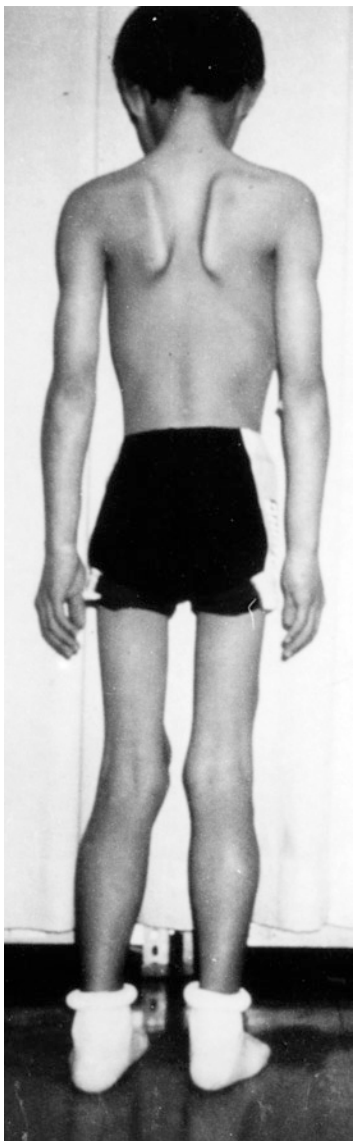

Fig. 57.5 Boy with SCARMD. Note proximal atrophy, calf hypertrophy, and winged scapulae

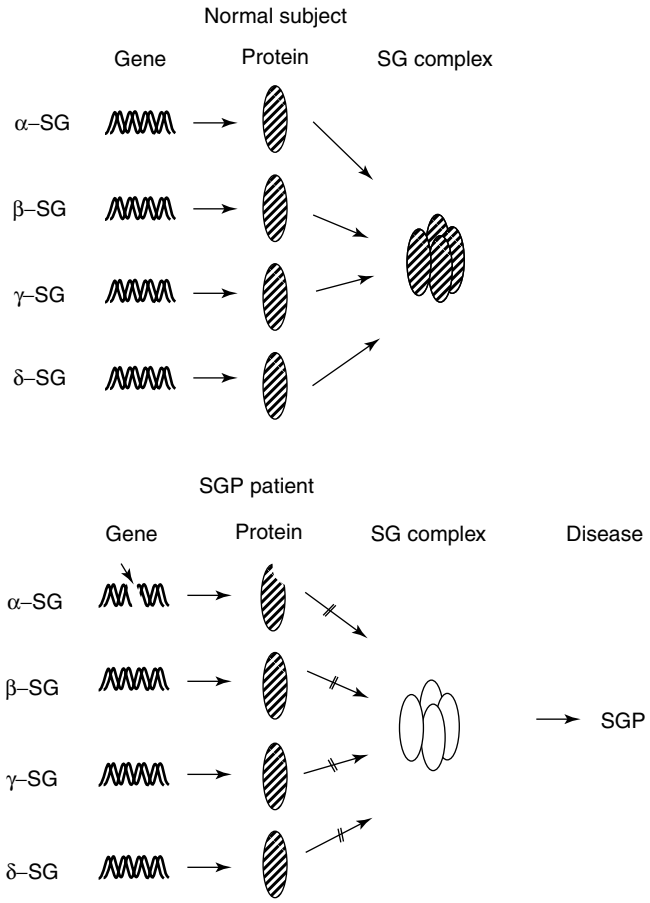

Fig. 57.6 Mutation of a single SG gene results in the defect of the single sarcoglycan, affecting localization of multiple sarcoglycans. Loss of a subunit of SG complex results in the absence or great reduction of all subunits of SG complex

deafness. Respiratory failure occurs in the third decade of life. The C283Y mutation has been associated with lumbar hyperlordosis, scapular winging and subclinical electrocardiographic abnormalities, diastolic dysfunction, and right ventricular hypertrophy.

The serum CK is usually extremely high and electromyography shows myopathic changes. Muscle histology shows a myopathic or dystrophic pattern. Inflammatory infiltrates can be present. γ-Sarcoglycan immunoreactivity is reduced or absent. The other sarcoglycans are usually reduced, but there is no correlation with the phenotype. Dystrophin may be normal or reduced.

LGMD 2C is caused by mutation in the γ-sarcoglycan gene located on chromosome 13q12.12 [30]. It is most commonly seen in patients from Maghreb, Tunisia [31], and India. Del521-T mutation is most commonly reported in Tunisia and North Africa and C283Y in the gypsies.

LGMD 2D (Alpha-Sarcoglycanopathy)

In patients with LGMD 2D, the onset of the disease symptoms is usually between 2 and 15 years (Figs. 57.6 and 57.7). The manifestations can vary from a mild to severe phenotype [32]. Early-onset disease has more rapidly progressive weakness, which is associated with absence of α-sarcoglycan. Patients with late-onset symptoms have reduced α-sarcoglycan levels and have a slower course of the disease. The weakness is symmetric and proximal. In the severe phenotype, quadriceps and scapular weakness occurs. Some patients will present with calf hypertrophy and rarely cardiomyopathy.

The serum CK is high (often more than 5,000 IU/L). Muscle pathology shows fiber size variability, increase in endomysial connective tissue, and evidence of degeneration and regeneration of muscle fibers. On sarcoglycan

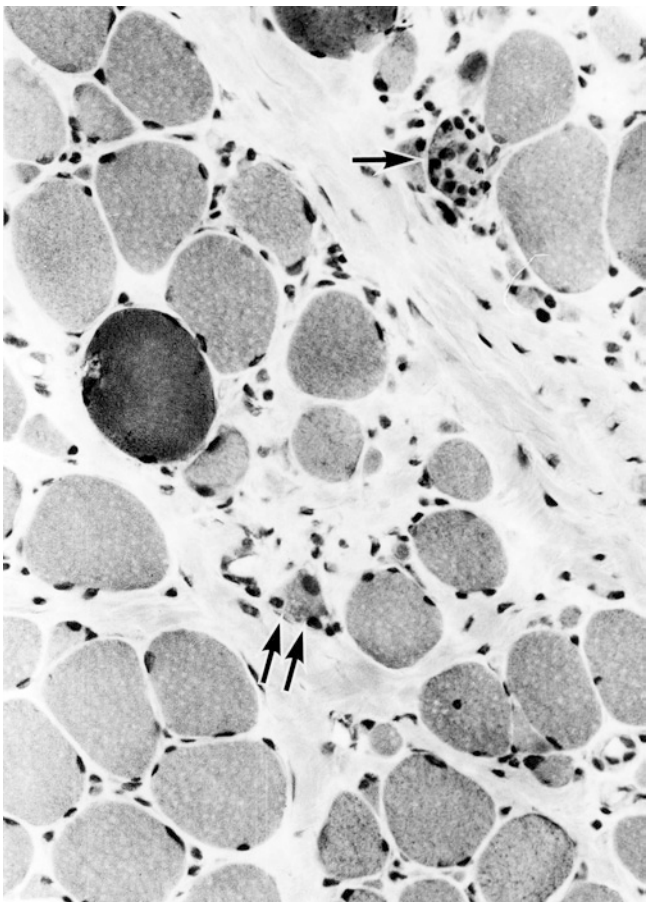

Fig. 57.7 Muscle biopsy from a 7-year-old girl with α-sarcoglycan deficiency. In addition to marked variation in fiber size with notable interstitial fibrosis, there are necrotic (a *single arrow*) and regenerating (*double arrows*) fibers, showing active necrotic and regenerating processes. Notice the hyper-contracted fiber (dark-staining fiber on the *left*). The overall findings are similar to those seen in Duchenne muscular dystrophy. Hematoxylin and eosin, ×300

immunostaining, there is absence of α-sarcoglycan and reduction or absence of other sarcoglycans.

This disease is caused by mutation in the alpha-sarcoglycan gene which encodes adhalin, located on chromosome17q21.33 [32, 33]. Missense and nonsense mutations have been described. In cases of null mutations, the α-sarcoglycan is usually absent, whereas it is only reduced in cases of missense mutations. Some patients who are heterozygous for Ile124Thr missense mutation may report myalgias. Scapular winging is seen in 60 % of patients, calf hypertrophy in 15 %.

LGMD 2E (Beta-Sarcoglycanopathy)

LGMD 2E is usually a severe disease, with onset in early childhood and adolescence (between 3 and 17 years) and shows significant intra-familial variability. Patients are wheelchair bound at the age of 10–25 years. The weakness is usually proximal at the limb girdles (pelvic worse than the shoulder girdle). Tongue hypertrophy and scapular winging can be present. Cardiomyopathy can be seen in occasional patients. At least 4 of the described mutations cause a Duchenne-like phenotype. The serum CK is very high (7 to 80X). Muscle histology shows myopathic changes. All sarcoglycans are usually absent or markedly reduced.

LGMD 2E is caused by mutation in the gene encoding beta-sarcoglycan on chromosome 4q12 [34, 35]. This disease is common in northern and southern Indiana in Amish population [36] and in Bern, Switzerland.

LGMD 2F (Delta-Sarcoglycanopathy)

LGMD 2F is associated with severe weakness with most mutations producing myopathy. The disease starts early, between 2 and 10 years of age, with loss of the ability to walk anywhere between 9 and 16 years and death between 9 and 19 years of age. The weakness initially involves the proximal muscles bilaterally and symmetrically. In some patients, calf hypertrophy and cramps occur. Dilated cardiomyopathy may develop without skeletal myopathy. Milder phenotypes have been described.

The serum CK levels are elevated 10–50 times normal. Muscle pathology shows degeneration and regeneration of muscle fibers. Immunostaining shows absence of δ-sarcoglycan. α- and β-sarcoglycans are absent; γ-sarcoglycan is reduced or absent.

LGMD 2F is secondary to mutations in the delta-sarcoglycan gene on chromosome 5q33.3 [37]. Frameshift mutation (premature truncation of protein: del656C) has been reported in African-Brazilian ancestry. Other mutations include missense (Glu262Lys) and nonsense mutations (premature truncation of protein: E93Ter, Arg165Ter, Trp30Ter).

LGMD 2G (Telethoninopathy, Dilated Cardiomyopathy 1N)

Patients with LGMD 2G have a mean age of 12.5 years at symptom onset. Patients present with difficulty walking, running, and climbing stairs. Walking on heels is usually more difficult to perform than walking on toes, suggesting greater involvement of tibialis anterior and sparing of gastrocnemius, in contrast with LGMD 2B or Miyoshi myopathy. As a result, the patients are unable to perform ankle dorsiflexion, and foot drop is a characteristic feature. In the upper limbs, proximal muscle atrophy is marked, whereas, in the lower limbs, proximal and distal muscle atrophy is evident. Approximately 40 % of patients usually become non-ambulatory by third or fourth decade. Calf atrophy or hypertrophy as a manifesting sign has been reported in approximately half of patients. The

neck muscles are mildly or not affected, and extraocular and facial muscles are spared in all patients. Cardiac involvement is observed in about half of patients.

The serum CK is increased 3- to 30-fold normal. Muscle histology reveals marked variation in fiber size. Necrotic and regenerating fibers are found with an increase in central nuclei. Rimmed vacuoles are seen in great proportions of the muscle fibers. There is no predominance of type 1 or type 2 and no fiber-type grouping. In Western blot analysis, telethonin is absent in LGMD 2G patient muscle biopsies.

LGMD 2G is caused by mutations in the gene encoding telethonin, located on chromosome 17q12 [38, 39]. Mutations are point mutations or small deletions that produce stop codons. It has been reported in Brazilian patients with Italian ancestry and in Europe. Other variant telethonin syndromes include dilated cardiomyopathy 1N and congenital muscular dystrophy.

Telethonin is a sarcomeric protein of 19 kDa found exclusively in striated and cardiac muscle. In adult skeletal muscle, it is localized to the Z-disc. Telethonin interacts with titin, which acts as a molecular "ruler" for the assembly of the sarcomere by providing spatially defined binding sites for other sarcomeric proteins. After activation by phosphorylation and calcium/calmodulin binding, titin phosphorylates the carboxy-terminal domain of telethonin in early-differentiating myocytes. The mutations in the telethonin gene cause the disruption of a functionally important domain of telethonin, the carboxy-terminal region, which appears to alter in sarcomeric structure [40].

LGMD 2H (Manitoba Hutterite Dystrophy, Sarcotubular Myopathy)

LGMD 2H is a mild form of autosomal recessive muscular dystrophy, with a variable clinical presentation. The onset of disease symptoms is usually within the second or third decade of life, and progression is slow. Most patients continue to walk into their sixth decade. Quadriceps and pelvic girdle musculature are primarily involved. The patients show a waddling gait and difficulty rising from the squatting position. Cardiac and facial involvement does not occur.

The serum CK is high (between 250 and 4,500 IU/L). Electromyography shows myopathic changes. Muscle histology reveals mild dystrophic changes including fiber size variability, endomysial fibrosis, and muscle fiber degeneration and regeneration. Fiber splitting and internal nuclei are observed. To date, the disorder has been described only in the Hutterite population of North America [41].

Sarcotubular myopathy, another variant of LGMD 2H, presents with exercise-induced fatigue and myalgias. Proximal limb-girdle weakness and neck flexor weakness is present in all patients. Winged scapula, hypertrophied calf muscles, and Gowers' sign are present. Muscle atrophy is proportional to muscle weakness. Mild facial weakness may be observed. Achilles tendon contractures occur. Tendon reflexes are normal or reduced. The serum CK levels are increased up to 5- to 20-fold greater than normal. Muscle histology shows varied fiber size. Small rounded vacuoles (less than 4 μm) are observed in 20–30 % of the type 2 fibers and less than 4 % of the type 1 fibers. Segments of many muscle fibers harbor a myriad of small abnormal spaces. Electron microscopy reveals that the small spaces arise from focal dilations of sarcoplasmic reticulum. Small foci of Z-disc streaming are seen.

The gene mutations underlying LGMD 2H are mutations in the gene encoding tripartite motif-containing protein-32 (TRIM32) on chromosome 9q33.1. The specific mutation at codon 487 of TRIM32 gene, with an amino acid change from aspartate to asparagine (D487N), is described, both in Hutterite dystrophy and in sarcotubular myopathy. A subset of Hutterite patients with LGMD have LGMD 2I, which is caused by L276I mutation in the FKRP gene on chromosome 19q13. Hutterite LGMD 2I patients have an earlier age at diagnosis, a more severe course, and higher serum CK than LGMD 2H patients. In addition, some of the LGMD 2I patients show calf hypertrophy, cardiac symptoms, and severe reactions to general anesthesia; none of these features occur among LGMD 2H patients.

TRIM32 is a member of a growing family of TRIM, or RING–B-box coiled-coil, proteins [42]. The RING-finger domain indicates that it may have intrinsic ubiquitin-ligase activity, and all RING-finger proteins may be E3-ubiquitin ligases. The ubiquitin–proteasome pathway is a specialized mechanism for the posttranslational regulation of protein levels. The initial step in the ubiquitin–proteasome pathway is the activation of ubiquitin by an E1-ubiquitin-activating enzyme. The activated ubiquitin is transferred to the E2-ubiquitin-conjugating enzyme. The E3 ligase interacts with E2-ubiquitin complex and recruits a protein to be targeted to the 26S proteasome. The E3 ligase catalyzes the transfer of ubiquitin to the target protein. The ubiquitinated protein is released from the complex and is recognized by factors associated with the 26S proteasome. The 26S proteasome digests the ubiquitinated protein into small peptides.

The E3 enzymes are responsible for the selection of proteins for ubiquitination by this pathway. The RING-finger domain of an E3 ligase mediates interaction with the E2-ubiquitin-conjugating enzyme and is the source of the ligase activity. Therefore, recognition of target proteins by E3 ligases occurs through protein–protein interactions with areas of the protein other than the RING-finger domain. In the case of TRIM32, this function may be fulfilled by a series of NHL domains. Mutations in the NHL domain abolish an interaction with another protein, thereby leading accumulation of protein in tissue, in this case muscle, with a toxic effect.

LGMD 2I (Fukutin-Related Proteinopathy)

LGMD 2I is characterized by limb-girdle weakness, dilated cardiomyopathy, and respiratory insufficiency [43]. The age of onset is between 5 months and 40 years of age. The patients with early onset of symptoms present in the first 2 years of life with hypotonia and delayed motor milestones followed by muscle hypertrophy, primarily of the legs but at times involving the tongue. Patients never acquire the ability to run or hop and followed a Duchenne-like disease course, with loss of independent walking in the early teens, followed by development of cardiomyopathy [44]. The patients with later onset of symptoms have milder disease and a relatively benign course. Calf muscle and, to a lesser extent, thigh muscle, brachioradialis, and tongue hypertrophy is present in most patients. Muscle cramps following exercise are also relatively common. Myoglobinuria may occur. Intelligence and brain MRI are normal [45]. Serum CK is elevated between 10 and 30 times normal.

LGMD 2I is caused by mutation in Fukutin-related protein gene (FKRP) on chromosome 19q13.32 [46]. This disease is mostly common in Denmark and parts of England. The most common genetic finding in northern Europe is the homozygous mutation (C826A) in FKRP. FKRP encodes a putative Golgi-based glycosyltransferase and is involved in posttranslational glycosylation of α-dystroglycan. Mutations in FKRP lead to α-glycosylation defect and subsequently downregulation of α-dystroglycan which constitutes an essential component of the proteoglycan–dystrophin complex [47].

LGMD 2J (Titinopathy)

The onset of symptoms in LGMD 2J occurs between childhood and the third decade. Weakness is more proximal than distal and is worse than that observed in the allelic form "distal myopathy." Muscle wasting is seen in anterior tibialis muscle. Patients are unable to walk within 20 years of symptom onset [48]. No associated cardiomyopathy is usually seen. The serum CK is up to 20 times normal. Muscle histology shows myopathic changes and secondary reduction in calpain-3 [49].

Mutations in the titin gene (located on chromosome 2q31.2) are responsible for LGMD 2J. Common mutations are missense mutations Leu293,356Pro in French (both leucine amino acids changed to proline) and 11-base-pair deletion at last exon (exon 363) in the Finnish patients. Titin protein is an enormous protein that spans the entire sarcomere from the M line to the Z-disc. Titin may assist in assembly of contractile elements, provide elasticity to the sarcomere, regulate the size of the Z-disc, and be involved in cell signaling [50].

LGMD 2K (Muscular Dystrophy–Dystroglycanopathy (Limb-Girdle) Type C1)

LGMD 2K was first reported in Turkish families with disease onset ranging from 1 to 6 years of age with difficulty in walking and climbing stairs. LGMD 2K is characterized by slow progression, proximal muscle weakness, mild pseudohypertrophy, microcephaly, and mild mental retardation with IQ ranging from 50 to 76. Joint contractures occur in about half of patients [51]. The serum CK is 40 times normal. Muscle histology shows fiber size variability and reduced α-dystroglycan. Brain MRI is typically normal.

Mutations in the POMT1 gene were shown to underlie the LGMD 2K phenotype [52]. POMT1 and POMT2 are mannosyl transferase enzymes. In humans, impaired protein O-mannosylation results in congenital muscular dystrophies that are referred to as secondary α-dystroglycanopathies since a common pathologic feature is the hypoglycosylation of α-dystroglycan. The most severe disorder is Walker–Warburg syndrome characterized by congenital muscular dystrophy associated with severe brain malformations and ocular abnormalities. Patients often die within the first year of life. In contrast, the mildest disorders may not present until adulthood, such as LGMD without brain or ocular involvement. The proteins O-mannosyl transferases POMT1 and POMT2 initiate the biosynthesis of O-mannosyl glycans in the endoplasmic reticulum.

LGMD 2L (Miyoshi Muscular Dystrophy 3, Anoctaminopathy)

LGMD 2L is characterized by late-onset proximal scapular and pelvic girdle muscle weakness with a range of onset from 20 to 55 years. Prominent asymmetrical atrophy of quadriceps femoris and biceps brachii occurs. Though calf hypertrophy may be observed at presentation, calf atrophy, often asymmetric, occurs later in the disease, unassociated with weakness. Distal weakness of the upper extremities does not occur. The patients usually maintain the ability to walk, despite difficulties with climbing stairs because of proximal weakness. Facial weakness may be observed in some patients. Muscle pain, with or without exercise, is a major complaint in approximately the great majority of patients.

The serum CK ranges between normal and 80 times normal. Electromyography reveals myopathic alterations and spontaneous activity has been reported. Muscle histology shows dystrophic changes, increased connective tissue, and fiber splitting. Inflammation is observed in patients with more severe disease. One patient was found to have amyloid deposition in perivascular spaces and muscle fibers. A variant syndrome of LGMD 2L is termed Miyoshi

myopathy 3, in which significant calf hypertrophy is a common feature.

Mutations in the Anoctamin 5 (ANO5) gene on chromosome 11p14 underlie the LGMD 2L phenotype, in French-Canadian families [53]. The human Anoctamins include a family of at least ten proteins all exhibiting eight transmembrane domains. These proteins are capable of functioning as calcium-activated chloride channels. Mutations in ANO5 gene may cause defective membrane repair. Mutations in ANO5 gene were also identified in patients with Miyoshi muscular dystrophy 3 [54].

LGMD 2M (Muscular Dystrophy–Dystroglycanopathy (Limb-Girdle) Type C 4, Fukutinopathy)

This disease was named first LGMD 2L by Godfrey et al., and then renamed as LGMD 2M, and now designated as muscular dystrophy–dystroglycanopathy type C4 [55, 56]. LGMD 2M was described in Israeli Jewish, Indian, Portuguese, Turkish, and French families. The onset is usually at 6 months of age, with hypotonia and motor developmental delay and normal intellectual development. An acute and dramatic deterioration in functional ability is seen after a febrile illness, with back-to-baseline functioning level after recovery. Weakness is usually diffuse, progressive, more proximal than distal, and affecting lower limbs more than upper and extensors more than flexors. The weakness improves with steroid therapy, and worsening of weakness occurs with steroid reductions. Muscle hypertrophy is seen in the posterior leg and, in some patients, the tongue. Spinal rigidity, joint contractures, and cardiomyopathy may occur [55, 56].

The serum CK is usually extremely high. Muscle biopsy shows dystrophic changes with muscle fiber necrosis, increase in endomysial connective tissue, macrophages infiltration around necrotic fibers and in the endomysium without eosinophils, and nearly absent glycosylated α-dystroglycan. Laminin-α2, laminin-β1, and laminin-γ1 are mildly reduced. Brain MRI is normal although vermis hypoplasia and polymicrogyria have been reported.

LGMD 2M is secondary to defective glycosylation of α-dystroglycan, collectively known as "dystroglycanopathies" (Figs. 57.8 and 57.9), secondary to mutations in the Fukutin gene on chromosome 9q31.2.

LGMD X-Linked

The X-linked LGMDs are summarized in Table 57.3. Brief descriptions of selected X-linked LGMDs are provided below.

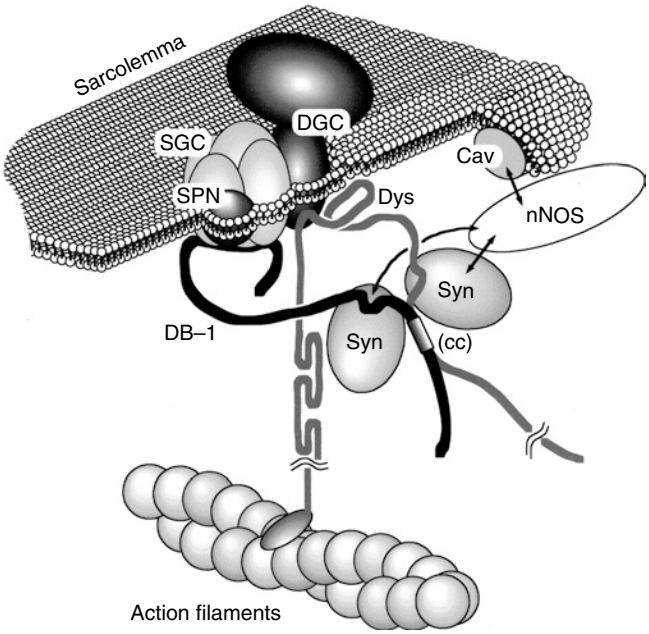

Fig. 57.8 Dystrophin and dystrophin-associated proteins. Basal lamina including laminin which binds to α-DG is removed from this scheme. Note that N-terminal dystrobrevin associates with sarcoglycan complex at protoplasmic sites. *Dys* dystrophin, *DGC* dystroglycan complex, *SGC* sarcoglycan complex, *SPN* sarcospan, *DBN* dystrobrevin, *SYN* syntrophin, *nNOS* neuronal nitric oxide synthase, *Cav* caveolin-3

Barth Syndrome (X-Linked Dilated Cardiomyopathy)

This syndrome is characterized by cardioskeletal myopathy and neutropenia [57]. The clinical course may be severe with lethal cardiac disease and recurrent infections during infancy and early childhood but relative improvement in later childhood. The initial presentation varies from congenital dilated cardiomyopathy to infantile congestive heart failure to isolated neutropenia without clinical evidence of heart disease. The myopathy is mild and nonprogressive. Early in the course, patients may have hypotonia. Later, weakness may be more prominent proximally than distally; Gowers' sign is usually present. The patient often maintains ambulation, and there has been no report of respiratory failure.

Lab evaluation demonstrates a normal CK, neutropenia, and increased level of 3-methylglutaconic acid. Increased urine levels of some branched-chain organic acids may be appreciated. Mitochondrial function is impaired with 3-methylglutaconic aciduria. The genetic loci map to Xq28. The gene, designated G4.5, is highly expressed in cardiac and skeletal muscle and encodes Tafazzin which is involved in phospholipids synthesis [58].

Emery–Dreifuss Muscular Dystrophy 1

Clinically, the patients have difficulty climbing stairs initially, and later symmetric humeroperoneal weakness evolves, involving biceps and triceps. Deltoid is usually spared. Early contractures are very common. Cardiac involvement is manifested by conduction disorders, syncope, sudden death, and bradycardia which is an indication for pacemaker placement in certain cases.

Serum CK is mildly to moderately elevated. Muscle biopsy shows myopathic changes, endomysial fibrosis, type 1 fiber atrophy, and breakdown of nuclear membrane. Immunostaining with antibodies to emerin shows no immunoreactivity. It is a recessive disorder linked to Xq28,

Table 57.3 The X-linked LGMDs

	Clinical phenotype			Gene information		
	Typical onset	Progression	CK	Allelism	Gene/loci	Protein
Duchenne muscular dystrophy	Early childhood	Slow to moderate	10 to 20 X	Becker muscular dystrophy	DYS	Dystrophin
Becker muscular dystrophy	Late childhood	Slow	10 to 15 X	Duchenne muscular dystrophy	DYS	Dystrophin
Barth syndrome	Infancy	Moderate	Normal	X-linked dilated cardiomyopathy	TAZ	Tafazzin
Emery–Dreifuss muscular dystrophy 1	Variable; teen age	Slow	2 to 10 X	X-linked sinus node dysfunction	EMD	Emerin
Emery–Dreifuss muscular dystrophy 6	Adult	Slow	2 to 10 X	Hyaline body myopathy, X-linked myopathy with postural muscle atrophy	FHL1	Four-and-a-half-LIM protein 1
Danon's disease	Early childhood	Moderate	4 to 35 X	X-linked vacuolar cardiomyopathy and myopathy	LAMP-2	Lysosome-associated membrane protein 2

affecting Emerin gene which encodes for Emerin protein, a membrane protein that interacts with lamins or chromatin. The exact function of the emerin protein still remains unknown.

Emery–Dreifuss Muscular Dystrophy 6

Emery–Dreifuss muscular dystrophy type 6 is characterized by weakness in the shoulder girdle and peroneal muscles, with a myopathic form of scapuloperoneal syndrome [59]. The age of onset was between 20 and 58 years of age, and clinically, patients have an early foot drop. Arms are affected proximally before the hand weakens distally, and scapular winging is present. Other features include weakness in neck extensors muscle, hearing loss, skeletal contractures, and cardiac disorders. Death occurs from respiratory or cardiac failure. Serum CK is 1.5–10 times normal. On muscle histopathology, hyaline body inclusions seen as eosinophilic bodies on H&E staining are localized at the central or subsarcolemmal areas, mostly in type 1 fibers. These inclusions are formed by desmin, four-and-a-half-LIM protein 1 (FHL1), and dystrophin.

FHL1 gene mutations are responsible for this dominant disorder and are localized to the X chromosome, Xq26.3, with 60–80 % penetrance and the succeeding generation of same sex being more affected [60]. Mutations include missense (Trp122Ser) and in-frame insertion. However, FHL1 protein mutations are involved in multiple diseases including X-linked myopathy with postural muscle atrophy, Emery–Dreifuss muscular dystrophy 6, and X-linked reducing body myopathy.

Danon's Disease

Danon's disease is characterized by weakness in scapuloperoneal distribution, hypertrophic cardiomyopathy, and mental retardation. The onset of the disease is between 5 and 25 years of age, with death occurring by the third decade. Serum CK is elevated three to eight times normal. Skeletal muscle biopsy shows no fibrosis or inflammation. Fiber size is normal. A slight increase in internal nuclei and few centrally located pale vacuoles may be appreciated. Immunohistochemistry demonstrates absence of lysosome-associated membrane protein-2 (LAMP-2).

Mutations in LAMP-2 gene (at chromosome Xq24) underlie Danon's disease. Women that are carriers of LAMP-2 have cardiomyopathy [61]. LAMP-2 is thought to protect the lysosomal membrane from proteolytic digestion and to act as a receptor for proteins imported into lysosomes.

Prognosis of LGMD

The LGMD syndromes cause progressive weakness, although the rates of progression vary considerably among the LGMD. Certain LGMD syndromes have cardiac involvement, and patients are prone to cardiac conduction-system deficits, which may lead to sudden death. Rarely, respiratory insufficiency may occur but usually in late stages of the diseases. In general, the later the disease onset, the better the prognosis.

Treatment of LGMD

The LGMDs cause progressive weakness. Physical therapy and occupational therapy should be provided to the patient to prevent formation of contractures and to maximize the use of the limbs. Serial electrocardiograms and echocardiograms may be helpful in monitoring the heart. Cardiological follow-up with placement of pacemaker/defibrillator may be necessary if abnormalities are appreciated. Although significant respiratory involvement in most LGMDs has not

been observed, pulmonary function tests may be helpful in identification of respiratory weakness. Whether noninvasive or invasive methods of ventilation are helpful in the clinical setting is not clear. Steroids have been helpful in maintaining muscle function, as in the case of Duchenne muscular dystrophy and fukutinopathy. Some patients complain of cramps in the muscles and symptomatic treatment may be provided with either baclofen or tizanidine. Genetic counseling may be helpful for the affected families and the patients.

Currently there is no specific treatment of LGMD. At least in a subset of patients with heart involvement, screening and early diagnosis may prevent premature cardiac death. Exon-skipping treatment strategies are being attempted in both Duchenne muscular dystrophy and dysferlinopathies.

LGMDs are a heterogeneous group of disorders. As the name suggests, the disease manifests as weakness in the shoulder girdle and the pelvic girdle muscles. Both dominant and recessive forms of LGMDs have been described, and the current classification system of LGMDs utilizes the notation type 1 and type 2, respectively. With the advancement of sequencing technologies, the list of LGMD will grow. Understanding of gene functions and mutation pathology will help shed insights into the disease process and possible therapy in the future.

Facioscapulohumeral Muscular Dystrophy

58

Rabi Tawil

Introduction

Facioscapulohumeral muscular dystrophy (FSHD) is an indolent inherited myopathy characterized by an initially restricted, distinctive regional distribution of muscle weakness. It is the third most common muscular dystrophy after myotonic dystrophy and Duchenne dystrophy with a prevalence of 1:20,000 [1, 2]. It is a dominantly inherited dystrophy but up to a third of the cases are sporadic resulting from de novo mutations. The spectrum of clinical severity is wide, from minimally symptomatic to wheelchair-bound individuals. There are as yet no effective treatments for FSHD. However, recent research has identified the likely causal genetic mechanism in FSHD opening the way for targeted treatment of this disorder.

Etiology and Pathogenesis

Since 1992, the causal genetic defect in >95 % of patients with FSHD was known and consists of deletion of an integral number of large repetitive DNA elements, each 3.3 kb in size, known as D4Z4 on chromosome 4q35 [3, 4]. Whereas healthy individuals have 11–100 D4Z4 repeats, most individuals with FSHD carry one array of 1–10 units. How this deletion results in FSHD remained unclear until recently. A series of observations over the past 15 years have lead to the discovery of a unifying mechanism for FSHD [5]. This mechanism postulates that FSHD results from a sequence of events leading to the aberrant expression of the *DUX4*, a gene contained within each D4Z4 repeat [6]. First, contraction of the number of D4Z4 repeats to between 1 and 10 repeats changes the chromatin structure from a closed (heterochromatic) to an open (euchromatic) configuration allowing gene expression [7, 8]. Each repeat, containing a copy of the *DUX4* gene sequence, starts transcribing the *DUX4* gene. The resultant mRNA, however, is unstable as the *DUX4* gene sequence within each repeat lacks a polyadenylation (polyA) signal which is essential in stabilizing mRNA (Fig. 58.1). Only the most distal *DUX4* copy can potentially produce a stable mRNA as it can splice on a polyA sequence just distal to the last repeat that is present in only one of two variants (A variant) of the 4q35 subtelomere. Consequently, a contraction of the repeats occurring on the appropriate A variant background allows the expression of stable *DUX4* mRNA and consequently DUX4 protein from the last D4Z4 unit [5, 9]. DUX4 is normally expressed only in germline cells. The consequences of its ectopic expression in muscle are not clear. In vitro expression of DUX4 was shown to cause apoptosis, increase susceptibility to oxidative stress, and interfere with myogenesis [10–12].

Whereas greater than 95 % of patients with FSHD present with the characteristic contraction in the D4Z4 repeat (FSHD1), less than 5 % of patients with a typical FSHD clinical phenotype show no contraction of the D4Z4 repeats (Fig. 58.1) [13]. Such patients, now known as FSHD2, have permissive chromatin changes at the D4Z4 repeat similar to that observed in patients with FSHD1 [14–16]. In addition, just as in FSHD1, FSHD2 requires that at least one 4q35 allele have a permissive A distal genetic variant. Thus, although FSHD1 and FSHD2 are distinct genetically, the ultimate causal gene abnormality, the aberrant reactivation of DUX4 expression, is likely to be the same for both conditions [17].

Clinical Presentation

Most patients with FSHD come to medical attention by the second decade of life. However, in a comprehensive survey of familial FSHD in Holland, Padberg found that as many as 30 % of affected individuals remain asymptomatic [2].

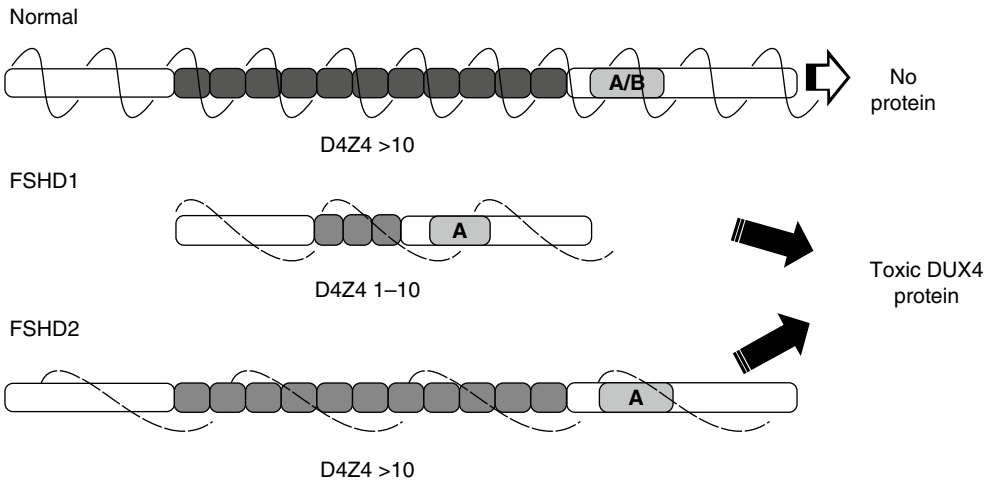

Fig. 58.1 Molecular mechanisms of FSHD. *Top:* normal 4q35 with greater than 10 D4Z4 repeats and nonpermissive chromatin structure. *Middle:* in FSHD1, there is a loss of a critical number of D4Z4 repeats leaving 1–10 repeats leading to chromatin relaxation and in the presence of the poly A containing **A** distal variant results in inappropriate expression of DUX4 protein in somatic cells. *Bottom:* in FSHD2, there is a primary relaxation of chromatin without loss of D4Z4 repeats and in the presence of distal **A** variant allows the inappropriate expression of DUX4 protein

The most common presenting symptom relates to weakness of shoulder fixators. Although FSHD is generally thought of as starting rostrally and having a descending course of progression, a surprising number of patients present with difficulty walking from foot drop. Examination, however, almost invariably, reveals coexisting scapular fixator and facial weakness to which the patient may not be aware of. This fact reflects the indolent nature of this disorder and consequent unconscious adaptation of these patients to their functional limitations. Often, the complaint is unilateral and the presenting history is one of the subacute deterioration suggesting an acquired disorder. This is especially true of patients presenting with unilateral scapular winging and misdiagnosed as long thoracic nerve injury with associated serratus anterior muscle weakness. In such patients, careful examination will reveal the existence of weakness of several periscapular muscles in addition to pectoral muscle weakness. In patients presenting with what appears to be an acquired acute or subacute weakness, careful questioning usually elicits a long-standing history of weakness elsewhere. Long-standing facial weakness is confirmed by a patient's inability to whistle, blow up a balloon, or drink through a straw and the observation by family members that the patient sleeps with their eyes slightly open. Indications of long-standing scapular weakness are difficulty climbing rope or doing push-ups and long-standing winged appearance of the scapulae.

Typical FSHD is defined by a descending sequence of progression with initial involvement starting in the facial and shoulder girdle muscles followed by variable involvement of the peroneal and hip-girdle musculature. Although the severity of weakness of a given muscle group generally reflects this progression, it is not invariably so. Thus, patients whose initial involvement was clearly in the shoulder and face may show moderate weakness in these muscles but more profound foot dorsiflexor or hip-girdle weakness. Indeed, proximal lower extremity involvement in FSHD is more common than previously thought. A prospective natural history study demonstrated that, when compared to age- and gender-matched normals, patients with FSHD frequently have notable weakness of knee extensors and flexors even in the early stages of the disease [18]. On examination of the face, the palpebral fissures are widened and facial expression is diminished. The lips are pouty with dimples often evident at the corners of the mouth. Bifacial weakness is confirmed with a transverse smile, inability to purse lips, or inability to bury eyelashes (Fig. 58.2). As with all muscle involvement in FSHD, facial weakness is often asymmetric. Extraocular, eyelid, and bulbar muscles are spared. Neck flexor muscles are relatively spared compared to the neck extensors. The characteristic shoulder appearance includes straight clavicles as well as forward sloping and rounding of the shoulders. The pectoral muscles are atrophied resulting in the presence of axillary creases (Fig. 58.3). The scapulae are laterally displaced and winging is evident either at rest or with attempted forward arm flexion or abduction (Fig. 58.2). Preferential wasting of the lower trapezius muscles results in a characteristic upward jutting of the scapulae on attempted arm forward flexion (Fig. 58.2). The biceps and triceps muscles are also involved with sparing of the deltoid muscles. Except for wrist extensors, the forearm and hand muscles are spared (Fig. 58.3). Weakness of abdominal muscles results in a protuberant abdomen and exaggeration of lumbar lordosis. Preferential weakness of lower abdominal muscles results in upward movement of umbilicus on attempted neck flexion (Beevor's sign), a sign specific for FSHD (Fig. 58.2) [19]. In the lower extremities, foot dorsiflexor weakness sparing the calf muscles is evident. Proximal lower extremity

Fig. 58.2 Monozygotic twins with FSHD. (**a**) Asymmetric weakness of orbicularis oris muscles on attempted whistling. (**b**) Wide-set, winged scapulae at rest (*right*) and marked winging on attempted arm forward flexion. (**c**) Marked rostral movement of the umbilicus (*left*) with neck flexion in a supine position (Beevor's sign) (Reprinted from Griggs et al. [47]. With permission from John Wiley & Sons, Inc.)

is usually spared early on although early proximal lower extremity involvement is more common than previously thought [18]. Muscle stretch reflexes are often reduced in FSHD and sensory examination is normal.

Extramuscular Manifestations

Largely asymptomatic hearing loss and retinal telangiectasias occur in association with FSHD [20, 21]. Screening of FSHD families with audiograms also shows mild high-frequency hearing loss in the majority of affected individuals [20]. Rarely, especially in severely affected infantile-onset FSHD, hearing loss can be severe enough to require the use of a hearing aid. In the vast majority of patients with FSHD, the retinal vascular abnormalities are asymptomatic with subtle vascular changes seen at the periphery of the retina on fluorescein angiography [21]. These vascular malformations rarely result in an exudative retinal detachment or Coats' syndrome with resultant visual loss [22–25].

Symptomatic cardiac involvement in FSHD is rare. Atrial, AV-nodal, and infranodal abnormalities on surface ECG are evident in greater than 60 % of patients [24]. In addition, 10 of 12 patients studied electrophysiologically had inducible

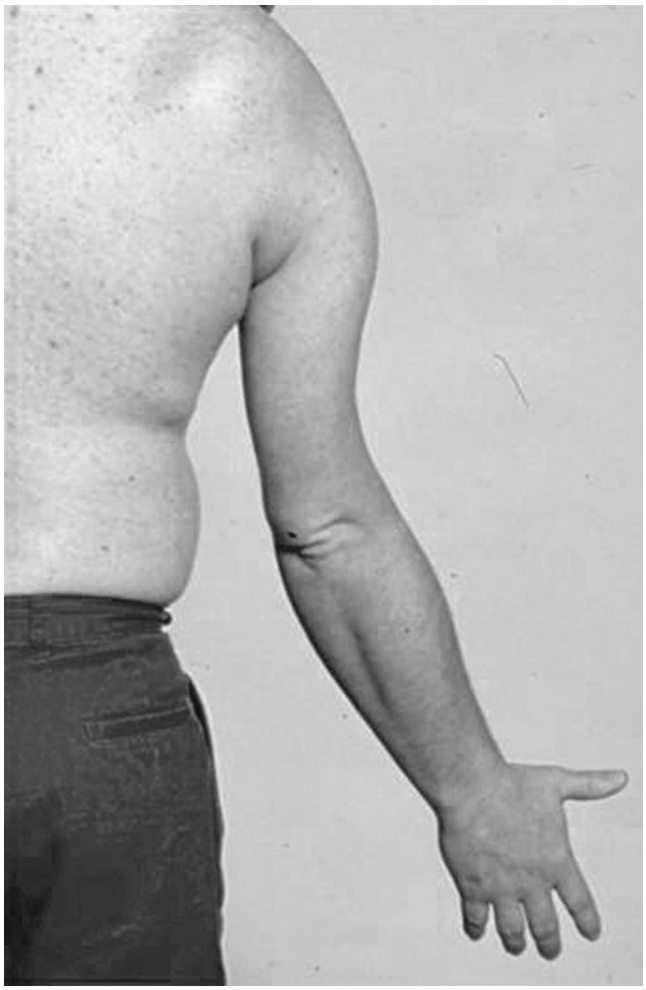

Fig. 58.3 Preservation of the forearm muscles with selective wasting of the biceps and triceps muscles giving the characteristic "Popeye" arm appearance. Prominent axillary crease resulting from pectoral muscle atrophy (Reprinted from Tawil and Griggs [48]. With permission from Butterworth-Heinemann)

atrial flutter or fibrillation [24]. In a large study of genetically confirmed cases of FSHD, 5 % were estimated to have cardiac involvement with conduction abnormalities and a predilection for supraventricular tachyarrhythmias [26].

Symptomatic restrictive respiratory insufficiency is rare in FSHD, with only 1 % of patients developing respiratory insufficiency that is severe enough to require intervention [27, 28]. Respiratory complications are typically seen in more severely affected individuals. Risk factors for respiratory insufficiency include the presence of severe pectus excavatum, significant limb-girdle weakness, kyphoscoliosis, and hyperlordosis and wheelchair-bound patients.

Central nervous system involvement does not, as a rule, occur in FSHD. However, a survey of Japanese patients with molecularly confirmed FSHD showed that, of 20 patients with severe, early onset FSHD, 8 were mentally retarded of whom 4 also suffered from seizures [29]. More recent case reports have extended this finding in other populations [29–31]. All these patients invariably have severe, often infantile-onset, FSHD with large deletions.

Table 58.1 Differential diagnosis

Limb-girdle dystrophy type 2A (calpainopathy)
Emery-Dreifuss syndrome
Polymyositis
Inclusion body myositis
Mitochondrial myopathy
Myofibrillar myopathies
Congenital centronuclear myopathy
Acid maltase deficiency

Differential Diagnosis

The differential diagnosis is fairly narrow when there is a confirmed autosomal dominant history as there are few dominantly inherited myopathies and most are easily distinguishable from FSHD based on clinical features. The differential diagnostic list is longer in sporadic cases as a number of myopathies can have some of the features of FSHD such as scapular winging and facial weakness. Table 58.1 includes conditions reported in the literature mimicking FSHD as well as conditions referred to our clinic initially misdiagnosed as FSHD. Most of these conditions can be differentiated from FSHD by careful attention to the pattern of clinical involvement, associated clinical features, the pattern of progression, and, in many, by their characteristic histopathological changes.

Evaluation and Diagnosis

Clinical Diagnosis

Individually patients with FSHD may differ greatly, but most fit in a clinically typical pattern of presentation. Table 58.2 includes previously published clinical inclusion and exclusion criteria [32]. Also included is a list of supportive features, characteristic of FSHD, that help bolster confidence in the clinical diagnosis. The presence of a dominantly inherited pattern is very helpful as it significantly narrows the differential diagnosis and allows confirmation of FSHD clinical features in other family members. Ancillary testing shows a serum CK level which can be normal but is most often mildly to moderately elevated (<10× upper limit of normal). Electromyographic findings in FSHD are nonspecific and help rule out the presence of a neurogenic condition. With the advent of specific and sensitive FSHD molecular diagnosis, muscle biopsy is no longer considered a routine procedure in the evaluation of a patient with suspected

Table 58.2 Clinical diagnostic criteria

Inclusion: Weakness of facial muscle, weakness of scapular stabilizers and ankle dorsiflexors
Exclusion: Autosomal recessive or x-linked inheritance, diffuse severe contractures, extraocular and bulbar weakness, sensory loss, neurogenic EMG, biopsy suggestive of alternative diagnosis, skin rash suggestive of dermatomyositis
Supportive features: Prominent asymmetry, descending sequence of involvement, sparing of deltoids, early involvement of abdominal muscles (Beevor's sign), selective involvement of lower trapezius, typical shoulder appearance, relative sparing of neck flexors, minimal if any contractures, high-frequency hearing loss, or retinal vasculopathy

FSHD. Muscle biopsy should be reserved to patients with suspected FSHD whose DNA testing is negative and where an alternative diagnosis is being considered.

Molecular Diagnosis

Molecular diagnosis of FSHD is currently limited to FSHD1 and is highly specific (95 %) and sensitive (>95 %) [33–35]. Molecular diagnosis is performed on DNA extracted from leukocytes, double digested with the restriction enzymes *Eco*RI and *Bln*1 followed by Southern blot or pulse field gel electropheresis and hybridization to probe p13E-11. The results measure the size of a DNA fragment that encompasses the repeats on 4q35. Normal individuals will have alleles between 50 and 300 kb in size. Individuals affected with FSHD have one allele containing a deletion of variable size resulting in a restriction fragment from 10 to 38 kb in size depending on how many residual repeats remain (i.e., the larger the deletion, the smaller the allele size). Interpretation of this test can be complicated by the presence of translocated 10q26 repeat elements on 4q35 [35]. In patients where the clinical presentation of FSHD is typical and genetic testing is done for confirmation, a simple determination of the presence of a contracted allele at 4q35 should suffice. However, if the clinical presentation is atypical, further testing is needed. The subtelomere of 4q35 distal to the repeats comes in two variants: 4qA or 4qB. As discussed above, only the 4qA variant is pathogenic. Thus, a false-positive test can result if the contraction occurs on a 4qB background. Most molecular diagnostic labs will test for the 4qA/B variants when requested.

Genetic confirmation of FSHD2 is currently not available in clinical diagnostic laboratories because of the complexity of the testing required. Prenatal diagnosis for FSHD1 is possible and offered by several diagnostic laboratories. Preimplantation genetic diagnosis (PGD) is more complicated and the outcome less certain. PGD for FSHD1 cannot be done directly on DNA from a single cell because FSHD genetic is not PCR based and requires more DNA than can be obtained from a single cell. Consequently, affected status is determined by linkage, an indirect method that is less certain and requires DNA from several family members to complete [32].

Management and Treatment

There are no effective treatments to arrest or reverse muscle weakness in FSHD. Nevertheless, supportive treatment and management of potential complications is important. A recent ENMC conference resulted in recommendations for the diagnosis and management of individuals with FSHD [32].

Individuals with FSHD often develop effective adaptive strategies to compensate for their disabilities without necessitating the use of assistive devices. Nevertheless, certain forms of bracing are often needed at various stages of the disease. Ankle-foot orthoses (AFO) are useful for foot drop early on but may become a hindrance to ambulation when quadriceps muscles become severely affected. When foot dorsiflexion weakness coexists with knee extension weakness, a lightweight, carbon fiber dynamic AFO is much more useful than a conventional posterior AFO. A frequent complaint among patients with FSHD is neck and shoulder pain as well as lower back pain. The shoulder and neck pain is due to traction on the musculoskeletal structures from the forward displacement of the shoulder. Some patients may even have associated symptoms and signs of traction on the brachial plexus. Various forms of shoulder bracing can be tried and may offer temporary relief but are usually too constrictive and uncomfortable to be worn for any length of time. Physical therapy and management of chronic pain are often needed for such patients.

Surgical scapular fixation is used successfully in FSHD patients to improve shoulder range of motion [36]. Before surgery is recommended, however, several factors should be considered. The first critical determination is how much gain in range of motion can be expected from scapular fixation. This can easily assessed at the bedside; by manually fixing the scapula to the chest wall, the patient can determine the degree of functional gain that can be expected. The other consideration is the functional state of the arm and shoulder muscles and the individual's rate of disease progression. Surgery is best done in patients with fairly preserved upper arm function and slowly progressive disease. Scapular fixation can also result in difficulty rolling the shoulders forward especially if done bilaterally. Scapular fixation is best done by shoulder surgeons experienced in the procedure. Several different surgical methods for scapular fixation are used but scapula-thoracic arthrodesis is the preferred method [36].

Respiratory insufficiency is infrequent in FSHD but clinicians should be vigilant to its occurrence in patients at risk. The risk factors include wheelchair-bound patients, presence of kyphoscoliosis, significant hip-girdle weakness,

and the presence of pectus excavatum [27]. Such patients should have yearly pulmonary function tests and should be regularly asked about symptoms of nighttime hypercapnea [32]. Measurement of forced vital capacity is also indicated in all FSHD patients prior to surgery.

In patients with infantile FSHD, special attention to hearing loss and retinal vascular abnormalities is critical as they are much more likely to be symptomatic than the rest of the FSHD population. Failure to detect significant hearing loss early in such patients may result in delayed language development. On the other hand, failure to detect and treat significant retinal vasculopathy could result in an exudative retinopathy and blindness (Coats' disease) [25]. In fact, given that an exudative retinopathy is potentially preventable in with laser treatment, it is recommended that all patients diagnosed with FSHD obtain a screening dilated ophthalmologic exam [32].

As in other neuromuscular diseases, about 25 % of women with FSHD experience worsening of their overall strength during pregnancy [37, 38]. Although no consistent adverse pregnancy outcome was noted, it is recommended that pregnant women with FSHD be followed by high-risk obstetricians [32]. Additionally, close monitoring of respiratory function is indicated, especially in more severely affected individuals and those with one or more of the risk factors listed above.

The utility of exercise in slowing progression or improving muscle function is a frequent concern and question of patients with different forms of muscular dystrophy. Short-term studies of moderate weights or resistance training have shown no adverse effects in FSHD [39]. Additionally, it was shown that regular aerobic exercise improves exercise performance in FSHD [40]. Based on these findings, interested patients should be referred to physical therapy to develop an exercise program emphasizing aerobic fitness that is individualized to a patient's particular physical limitations.

Therapeutic trials in FSHD to date have been limited to nonspecific interventions aimed at slowing disease progression, none of which proved effective. Pharmacologic interventions have included corticosteroids, beta agonists, diltiazem, and MYO-029, a myostatin inhibitor [39, 41–45]. Two small studies of a number of neuromuscular conditions, including FSHD, demonstrated improvement in overall strength following short-term supplementation with creatine monohydrate. There have been no subsequent confirmatory studies in FSHD. With the identification of the likely primary causal mechanism in FSHD, the inappropriate expression of the DUX4 gene, a more targeted approach to therapy in FSHD is now possible.

Prognosis

In general, the absence of significant bulbar, respiratory, and cardiac involvement predicts a normal life expectancy in FSHD. Nevertheless, 1 % of patients with respiratory insufficiency requiring intervention are likely to have a poorer prognosis and shorter life span. Progression is steady and slow but some patients report long periods of quiescence interrupted by relatively rapid deterioration in a particular muscle group [18]. About 20 % of patients above the age of 50 eventually become wheelchair bound [2].

One factor affecting prognosis is deletion size. There is no linear correlation between deletion size and severity; however, large deletions that result in 1–3 residual repeats, resulting contracted allele sizes of 10–15 kb, have earlier onset and more severe disease. Gender also plays a factor in prognosis. Female patients with FSHD, as a group, tend to do better than male patients [2, 46]. It is likely that other, unknown, genetic, epigenetic, or environmental factors also affect prognosis and could explain the marked intrafamilial variability that can be seen in FSHD.

Introduction

The myotonic dystrophies are muscular dystrophies that are clinically and genetically complex disorders and are distinct from both the non-myotonic muscular dystrophies and the non-dystrophic myotonias. Myotonic dystrophies directly involve almost all organ systems in the body [1–3]. Although the name "myotonic dystrophy" does not indicate the multisystem nature of these disorders, it is a historically well-established designation and aptly identifies two prominent features of these disorders, i.e., myotonia and muscular dystrophy. In addition to myotonic dystrophy type 1 (dystrophia myotonica 1, DM1) which was described more than 100 years ago, recent clinical studies and genetic mapping revealed a second rather distinct form, myotonic dystrophy type 2 (DM2) which was originally referred to as proximal myotonic myopathy (PROMM). Repeat expansions are the mutations underlying both types: DM1 is caused by CTG repeat expansion in the 3′ untranslated region of the *dystrophia myotonica protein kinase* (*DMPK*) gene in chromosome 19q13.3, where DM2 is due to CCTG expansion in intron 1 of the *zinc finger protein 9* (*ZNF9*) gene in chromosome 3q21.3 [2].

History

Myotonic Dystrophy Type 1 (Dystrophia Myotonica Type 1, DM1, Steinert's Disease)

Following Thomsen's seminal descriptions of familial myotonia congenita in 1876 [1], investigators began to notice differences in the disorders of affected families. In the early twentieth century, atypical families with myotonia were reported to not maintain the classic features of Thomsen's disease because their involved muscles ultimately became atrophic and weak. Following detailed descriptions by Steinert in 1909 [1], these families were eventually identified as having a distinct disorder that was referred to as Steinert's disease, myotonic dystrophy, or dystrophia myotonica. When involvement of the eye and heart was recognized, the multisystem nature of the disorder was appreciated, which further distinguished it from myotonia congenita.

The full description of the clinical features, inheritance, and epidemiology of myotonic dystrophy was accomplished during the twentieth century. Neurologists and medical geneticists identified non-Mendelian features of inheritance, including variable penetrance, anticipation, a maternal transmission bias for congenital forms, and preferential transmission of the pathogenic allele rather than the normal allele [4, 5]. Although the genetic locus of myotonic dystrophy was mapped to chromosome 19 in the late 1970s, the causative mutation was not identified until the recognition that trinucleotide repeats could expand to cause Fragile-X and bulbospinal muscular atrophy (Kennedy's syndrome). Following that lead, several laboratories reported the genetic cause of the most common form of myotonic dystrophy, i.e., DM1 in 1992 [6–10], identifying an expanded region of repeated cytosine, thymine, and guanine (CTG) residues in the 3′ untranslated region of the *DMPK* gene. This led to a genetic testing, and recognition of DM as the most common form of muscular dystrophy in adults. At the time of discovery, no clear pathogenesis could be deduced. However, there were

several hypotheses, including theories of decreased DMPK protein from an abnormal gene (haploinsufficiency) and interaction with nearby genes, such as the upstream *DMWD* gene, which is expressed in the brain and testes, or the downstream *SIX5* gene, which is associated with cataracts. The last and most important hypothesis, initially described in 1995, is the concept of RNA toxic gain of function [11, 12]. This theory was later supported by the discovery of a tetranucleotide repeat expansion in the DM2 gene in 2001 [13], which led to a better explanation and understanding of DM (see below).

Myotonic Dystrophy Type 2 (Dystrophia Myotonica Type 2, DM2)

In 1995, several reports identified families with dominantly inherited multisystem myotonic disorders that were genetically distinct from the classical form of myotonic dystrophy, i.e., DM1 [14–16]. Ricker et al. most thoroughly evaluated this new disorder [16] and clearly demonstrated that the genetic cause in these families was distinct from the known causes of myotonia congenita, paramyotonia, and DM1, indicating the existence of a novel genetic locus. The authors furthermore noted that the pattern of weakness of affected family members differed from DM1 and referred to the disorder as proximal myotonic myopathy (PROMM) to emphasize the proximal distribution of weakness which contrasts the characteristic distal weakness of DM1. In 1998 and 1999, Day and Ranum reported a large Minnesota kindred with a second form of myotonic dystrophy (DM2) in which affected members had a phenotype that closely mimicked the phenotype of DM1 [17, 18]. They localized the disease gene to a 10cM locus on chromosome 3q. Subsequently, Ricker reported that the gene for PROMM also mapped to the DM2 locus for many families [19].

The International Myotonic Dystrophy Consortium and Online Mendelian Inheritance in Man (OMIM) both recognize that DM2 and proximal myotonic myopathy refer to the same condition. Most families with PROMM have now been shown to have the characteristic tetranucleotide repeat expansion in *ZNF9* observed in individuals with DM2. Currently, the diseases are collectively referred to as the myotonic dystrophies, and each individual genetic disorder is referred to by the same name as the locus name (DM1 or DM2). The term PROMM is sometimes used to refer to the clinical phenotype if the causative mutation is unknown. However, the International Myotonic Dystrophy Consortium and others have suggested that any new identified multisystem myotonic dystrophy should be sequentially named as forms of myotonic dystrophy. A single family which was initially labeled as DM3 was subsequently shown to have familial inclusion body myositis, Paget disease, and frontotemporal dementia caused by mutations in *valosin-containing protein* (*VCP*) gene [20, 21].

Epidemiology

DM is recognized as being the most common form of muscular dystrophy in adults and may prove to be overall the most common form of muscular dystrophy when the multiple genetic causes of DM are all known. In Germany and in Minnesota, many families with DM2 have been identified, suggesting that the disease is not uncommon, at least in populations of northern European ancestry [17–19]. Before the identification of the distinct genetic mutations of DM1 and DM2, the combined prevalence of the myotonic dystrophies was estimated at 1 in 8,000 (12.5/100,000) with a wide difference among populations. There are now reports of high prevalence in northern Sweden, the Quebec province of Canada, and the Basque region of Spain. DM1 is most common in populations of European descent, is less common in Japan, is rare in India and the Middle East, and is absent in Africa except for a kindred form of DM1 in sub-Saharan region. DM2 is most common in Finland and northeast Europe but single kindreds of Afghan and Japanese origin have been identified [2]. A higher prevalence of DM2 is observed in individuals of German and Polish ancestry [22].

Classification of Myotonic Dystrophies

Patients with DM1 have diverse presentations which could be often classified into 3 subgroups: an adult-onset DM1 is the most common myotonic dystrophy, while childhood-onset and congenital forms are more severe but less prevalent [23] (Table 59.1). In contrast, DM2 has no known distinct subgroups including no evidence of congenital or childhood forms [2].

Congenital Myotonic Dystrophy Type 1

This is the most severe form of DM1 with a common but poorly understood maternal transmission. It may present prenatally by signs of polyhydramnios, reduced fetal movements, and other deformities detected on ultrasound examination. At birth, hypotonia, respiratory failure, and feeding difficulties are the common presenting features. Mental retardation becomes soon evident. Affected infants have bilateral facial weakness and a characteristic inverted V-shaped upper lip (also termed tented or fish-shaped) which renders sucking and feeding difficult [3, 24]. Despite the high mortality rate, some infants survive and are intubated and may achieve independent walking [2].

Table 59.1 Types of DM1

Phenotype	Clinical signs	CTG repeat size	Age of onset
Congenital	Hypotonia, respiratory failure, mental retardation, cardiorespiratory complications	Usually >1,000	Birth
Childhood onset	Mild mental retardation, early cardiac conduction abnormalities, facial weakness, subtle neuromuscular problems	50–1,000	1–10 years
Classical adult onset	Distal muscle weakness, foot drop, ptosis, axonal peripheral neuropathy, and neck/finger/wrist flexors are involved; handgrip myotonia, multisystem involvement (cataract, heart, etc.)	50–1,000	10–30 years
Mild late onset	Cataract, late moderate muscle atrophy, mild myotonia	50–100	20–70 years

Childhood-Onset Myotonic Dystrophy Type 1

This relatively uncommon form of DM1 usually presents with mental retardation; children have no or minimal limb weakness or myotonia. In many cases, the diagnosis is made when a parent, also usually the mother, is diagnosed with adult-onset DM1 [2].

Adult-Onset Myotonic Dystrophy Type 1

This is the most common form of the myotonic dystrophies. It is a multisystem disease and often presents with the classical triad of myotonia, muscle weakness, and cataracts. The multisystem nature of the disease may result in varied symptoms in affected family members. In moderately or severely affected individuals, DM1 is easily recognizable on clinical grounds [1, 23]. Patients commonly come to medical attention due to weakness, myotonia, or myalgias, though the multisystem nature of the disorder may trigger the initial symptoms due to ocular, endocrine, cardiac, reproductive, gut, or skin abnormalities.

Myotonic Dystrophy Type 2

DM2 has a variable mode of presentation, which includes proximal muscle weakness, myalgia with no weakness, asymptomatic hyperCKemia, or cataracts. Early cardiac death and respiratory failure have been reported but are less common than in DM1. Also, the majority of patients become symptomatic later in life, usually after the age of 40 years, and congenital and childhood-onset forms have not been described in DM2 (Table 59.2).

Clinical Features

Muscle

Muscle weakness is the most common presenting complaint in DM [1, 18, 23, 25, 26]. In DM1, symptoms become evident between the second and fourth decade of life and slowly progress with time (except for the congenital form). Patients with DM1 and DM2 commonly complain of muscle pain that is distinct from, but related to, the coexistence of myotonia. The pain is a deep ache that can be confused with rheumatologic disorders and incompletely responds to various treatments (steroids, nonsteroidal anti-inflammatory drugs, quinine, phenytoin, mexiletine). While muscle atrophy usually distinguishes DM from the non-dystrophic myotonias, minimally affected individuals with either DM1 or DM2 may have normal bulk; rare DM1 patients and occasional DM2 patients actually have muscle hypertrophy, as is seen in myotonia congenita.

Distribution of Weakness

DM1 patients have a very characteristic distribution of weakness, with ptosis, and weakness of eye and mouth closure, neck flexion, long finger flexors, and ankle dorsiflexors [1, 18, 23, 25, 26]. A careful observation of minimally affected DM1 subjects reveals weakness of forearm, thumb, and deep finger flexors prior to involvement of finger extensors, with preferential involvement of the lateral fingers. This distribution is similar to that seen in inclusion body myositis, but is distinct from the pattern seen in facioscapulohumeral dystrophy wherein extensors are involved prior to flexors. DM1 patients may develop weakness of hip and shoulder girdle muscles at some time during the course of their disease, with most having preserved strength proximally despite profound distal weakness; some have more equal involvement of proximal and distal muscles.

DM2 patients have this same distribution of weakness (see Table 59.2), though the degree of weakness is typically mild until late in the course of the disease. As in DM1, DM2 patients have ptosis, facial weakness, weakness and atrophy of sternocleidomastoid muscles, and weakness of thumb and lateral finger flexors early in the course of their disease. Unlike DM1, weakness in DM2 only rarely becomes marked, with the most marked weakness involving neck flexors, long finger flexors, and hip girdle musculature. The distal finger flexor involvement early in the course of disease was identified in studies of DM2 families, often in subjects who had not

Table 59.2 The common and distinguishing features of DM1 and DM2

Feature	DM1	DM2
General features		
Congenital form	Common with maternal inheritance	Not reported
Anticipation	Common	Rare
Life expectancy	Reduced	Normal
Disability due to muscle weakness	30–50 years	60–85 years
Muscle symptoms		
Myotonia	Common	Variable and may be absent
Ptosis	Present	Mild
Eye and mouth closure weakness	Prominent	Variable
Neck flexor weakness	Common	Variable
Distal muscle weakness	Evident	Mild
Proximal muscle weakness	Late	Common and early
Calf hypertrophy	Not present	May be present
Myalgia	Rare	Common
Systemic symptoms		
Cardiac conduction block	Common	Variable
Cataracts	More common	Less common
Dysphagia	Prominent, late	Rare, mild
Respiratory failure	Late	Rare
Testicular failure	Common	Occasional
Hyperglycemia	Common	Occasional
Male frontal balding	Common	Variable
Hyperhidrosis	Rare	Common
Excessive daytime somnolence	Common	Absent
Central nervous system abnormalities		
Mental retardation	Variable, severe in congenital form	Rare and mild
Brain MRI abnormalities	Common	Subtle
Pathological findings		
Muscle fiber internal nuclei and atrophy	Mostly type I fibers	Mostly type II fibers
Nuclear clumps	Late	Early
Ring fibers	Frequent	Less frequent
Genetics		
Chromosome	19q13.3	3q21.3
Mutation gene	*DMPK*	*ZNF9*
Location	3′ untranslated region	Intron 1
Mutation type	CTG expansion	CCTG expansion

DMPK, *dystrophia myotonica protein kinase*; *ZNF9*, *zinc finger 9*

sought medical attention for any recognized weakness. In contrast, most DM2 individuals who seek medical attention for muscle weakness typically are most concerned about proximal lower extremity weakness, but do usually complain of weakness in other muscle groups. Winged scapulae have been reported in both DM1 and DM2 patients [27].

Deep tendon reflexes in DM2 patients are usually normal or brisk, in contrast to DM1 in which DTRs are hypoactive or absent [28], except in the few cases associated with upper thoracic myelopathy due to disk herniation triggered by neck extensor weakness [29].

Facial Features

Patients with DM have characteristic facies, which is, in the eyes of experienced observers, pathognomonic. The face is typically long and has a hatchet-like shape due to temporomandibular wasting, with slack eyes, ptosis, flat smile, and balding. The head may tilt slightly backwards (to compensate for the ptosis) revealing the significant atrophy of the sternocleidomastoid muscles. However, this typical appearance is extremely variable between families and within the same family of patients with DM1 or DM2 (Figs. 59.1 and 59.2).

Myotonia

Myotonia is demonstrable in almost all patients with DM1. The predominant myotonic symptom in DM1 is grip myotonia, due to the effects of the disease on finger flexor and extensor muscles of the forearms (Fig. 59.3). Compared to myotonia congenita, the myotonia associated with DM1 is typically much milder, is more likely distal and less diffuse, and usually does not require specific symptomatic treatment. The myotonia can be relieved by repeated muscle activation ("warm-up" phenomenon) [2]. Patients commonly mention cold-induced exacerbation of the myotonia, but DM1 is not associated with the cold-induced contractures that are typical of paramyotonia [1, 18, 23, 25]. Myotonia is often absent in infancy and becomes evident later in childhood. Though myotonic discharges are easily elicitable during needle EMG in the vast majority of DM1 individuals, occasional subjects have fibrillation potentials with rare true runs of electrical myotonia. The myotonic runs typically last for several seconds, with frequencies ranging from 30 to 100 Hz. The molecular basis for myotonia remains unclear, though in DM1 it is associated with markedly increased muscle fiber expression of a calcium-activated potassium channel (the apamin receptor). The means by which this increased potassium current results in repetitive muscle fiber activation remains unclear, but local injection of apamin was reported to stop myotonia in DM1 [30–36].

Myotonia is less prominent and more variable in DM2 than in DM1, both clinically and electromyographically [16, 18, 23, 25, 26]. In DM2, myotonia is clinically evident in 75 % of patients and electrically in 90 % of patients [28]. Patients may have intermittent grip myotonia which may also improve with quinine or mexiletine. Percussion myotonia may be demonstrable in the tongue, extensor forearm, and thenar muscles of DM2 patients. Clinical myotonia may be also absent in many patients. Electrical myotonia is,

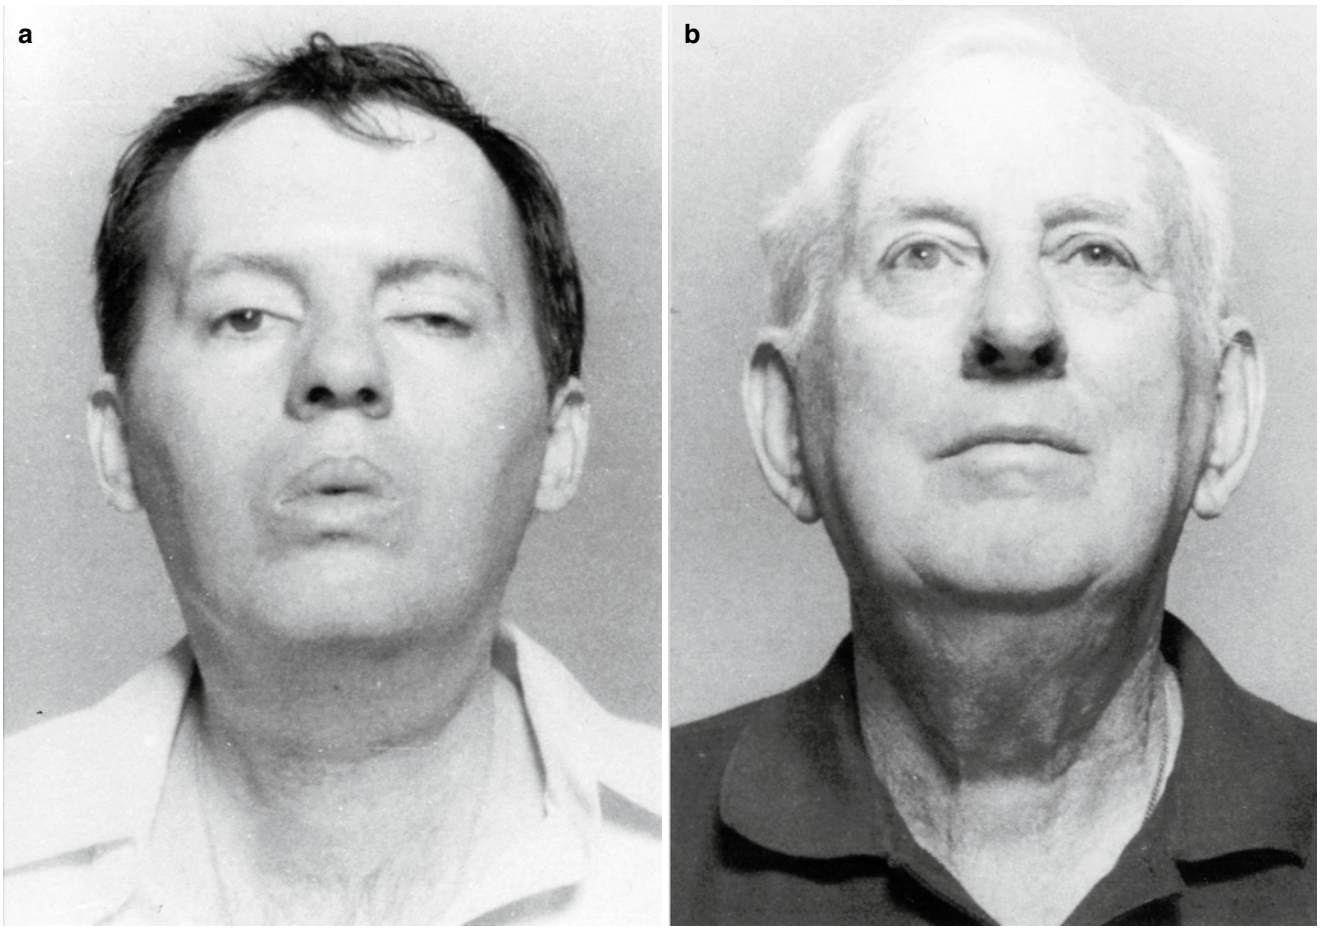

Fig. 59.1 Facial appearance in a 41-year-old son (**a**) and a 77-year-old father (**b**) with DM1. Note the ptosis, facial weakness, and masseter and temporalis wasting in the son and the minimal facial changes in the father (From Meola et al. [155]. With permission)

Fig. 59.2 Facial appearance in a 26-year-old daughter (**a**) and her 47-year-old mother (**b**) with DM2. Note the transverse smile, mild ptosis, and temporal wasting in the daughter. Contrast this family with the family in Fig. 59.1. The clinical features in both families suggest anticipation

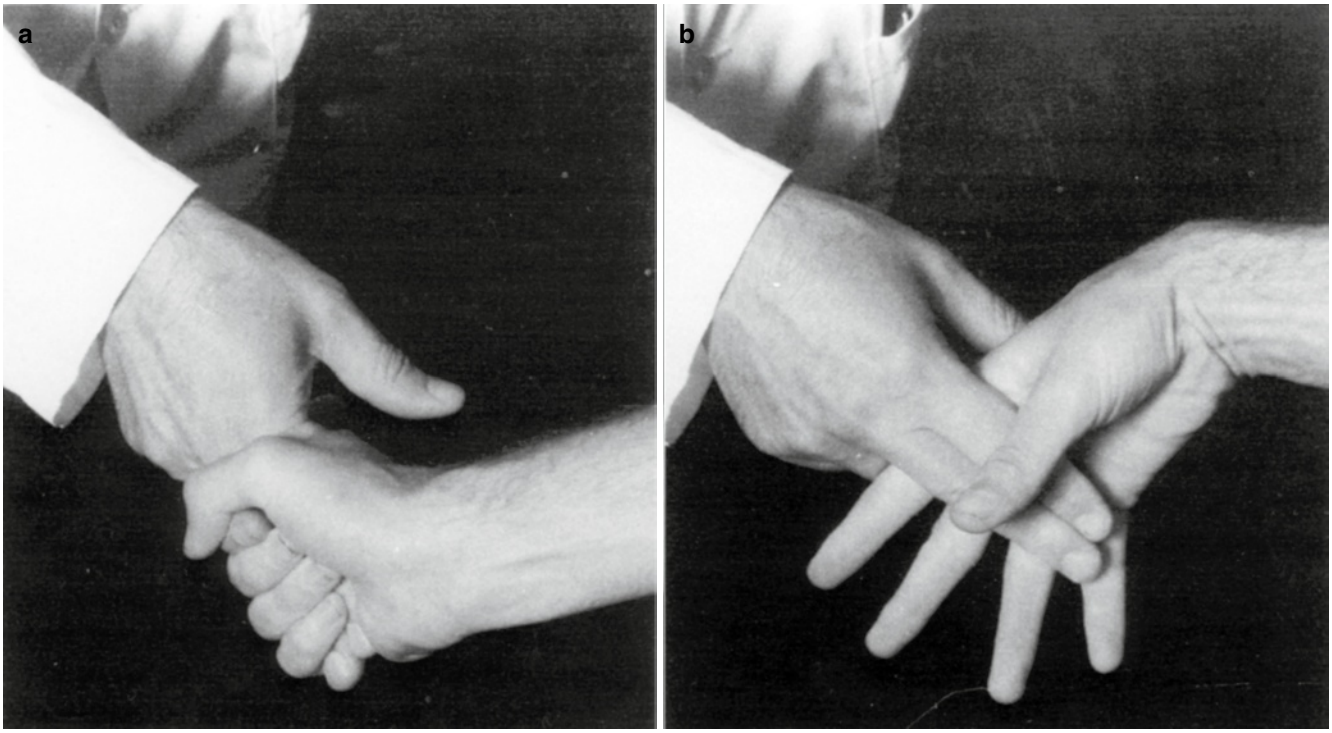

Fig. 59.3 Grip myotonia. Forceful grip (**a**), followed by delayed relaxation (**b**). Note that the thumb and fingers remain flexed at the metacarpophalangeal joints while the other joints are extended (**b**). This usually lasts about 5–10 s, but occasionally as long as a minute (From Meola et al. [155]. With permission)

however, a highly penetrant feature of DM2 patients, but often requires a detailed needle EMG examination which should include proximal and distal muscles as well as paraspinal muscles. Occasional patients with DM2 may have no evidence of electrical myotonia despite a thorough search [37, 38]. Sometimes, affected individuals have diffuse fibrillation potentials and occasional fasciculation potentials that obscure the myotonic runs, leading to misdiagnoses of diffuse neurogenic atrophy or motor neuron disease. Some have reported seeing occasional brief high-frequency (250–300 Hz) "pings" in DM2 and believe this finding might be specific to DM2 [16, 25, 26].

Eye

A reliable feature of the disease is the presence of iridescent posterior subcapsular ("Christmas tree") cataracts that are identifiable by slit lamp examination in almost all adults affected by DM1 or DM2. Many adults are completely asymptomatic despite the presence of such cataracts, while some DM1 and DM2 patients may require lens removal as early as the second decade of life to preserve visual acuity [1, 18]. "Christmas tree" cataracts are highly suggestive of DM, but whether they are truly pathognomonic of DM has been challenged [39]. In a prospective study, fewer than 2 % of normal individuals without a DM1 CTG expansion had characteristic cataracts. However, no other clinical or genetic assessment was apparently performed to see if these individuals had DM2. In addition to cataracts, DM1 has been associated with ptosis, slow saccades, and decreased intraocular pressure, with both central and peripheral mechanisms proposed for the eye movement abnormalities [40–42]. DM2 is occasionally associated with ptosis, but the other ocular features have not been described. Frank ophthalmoplegia is rare in DM1 and not observed in DM2.

Heart

The heart is commonly involved in DM1 which is associated with cardiac conduction defects and fatal arrhythmias [1, 18]. These cardiac defects are highly variable in DM2. Atrioventricular conduction defects are present in a high percentage of individuals with DM1, but are rare in DM2. Intraventricular conduction abnormalities occur in both disorders and may be more directly related to arrhythmias and sudden death, which also occur in both disorders [43–46] and do not correlate with disease severity or repeat length [47, 48]. Cardiomyopathy and heart failure are rare, but were reported in both DM1 and DM2 [49, 50]. Sudden death may occur in patients with DM1 as a consequence of myocardial

fibrosis and degeneration of the cardiac conduction system. Sudden death may result from asystole after atrioventricular block or from a ventricular tachyarrhythmia. Arrhythmias may occur including sinus node dysfunction; progressive heart block; atrial tachycardia, flutter, or fibrillation; and ventricular tachycardia or fibrillation. Atrial tachyarrhythmias predict sudden cardiac death [51]. Cardiac manifestations including severe cardiac arrhythmias may also be the first symptoms in young patients with DM1 [52]. Sudden cardiac death due to arrhythmogenic right ventricular cardiomyopathy attributed to cardiac DM1 has been also reported [53].

Cardiac involvement initially manifests as asymptomatic electrographic abnormalities, commonly prolongation of the PR interval and QRS duration. Therefore, it is recommended for patients to have annual EKG, and Holter monitoring and transesophageal echocardiogram every 2 years. Electrophysiological cardiac studies should be performed in patients who experience syncope, dizziness, or palpitations, or have documented arrhythmias or family history of sudden death or ventricular arrhythmias [54]. Cardiac pacemaker is recommended for patients with clinically significant cardiac conduction abnormality and implantable cardiac defibrillator in patients with cardiac tachyarrhythmia [51, 54].

Endocrine

Hyperinsulinemia, hyperglycemia, and insulin insensitivity are common features of both DM1 and DM2, with frank diabetes occurring occasionally in both disorders [1, 18]. Hypothyroidism is infrequent in both, but can be a remediable cause of worsening myopathy [55]. Hyperthyroidism was also reported in DM1 patients [56]. Testicular failure commonly results in hypotestosteronism and can also cause oligospermia in both DM1 and DM2, with serum testosterone levels commonly remaining in the low normal range despite the presence of markedly elevated follicle-stimulating hormone (FSH) levels [1, 18]. Adrenocortical regulation may also be affected in DM1, which could have secondary effects on multiple systems [57, 58] and on cytokine levels that further affect the function of many organ systems [59]. Serum levels of dehydroepiandrosterone are markedly reduced in DM 1 patients compared with age-matched healthy controls [60]. There are also reports of hyperparathyroidism due to pituitary adenoma, with multiple systemic effects that may result from the aberrant calcium regulation in DM1 patients [56, 61, 62].

Central Nervous System

DM1 results in personality changes, behavioral abnormalities, centrally mediated hypoventilation, mental retardation, dementia, and nonspecific cerebral white matter MRI T2 abnormalities [63–68], with seemingly early specific effects on memory [69].There is a growing evidence that cognitive impairment in the myotonic dystrophies is characterized by impairment in frontal lobe functions resulting in dysexecutive syndrome both in DM1 and DM2 which is not correlated to the degree of cortical atrophy or white matter hyperintense lesions on brain MRI but rather to a reduced cerebral perfusion in the frontal and temporal lobes by positron emission tomography (PET) scans. The cognitive impairment is usually frontal (attentional) and progressive, without extension to additional areas of cognition. The efficacy of a specific treatment, whose target is muscle strength improvement, may be underestimated by the coexistence of a dysexecutive syndrome [70]. Pathologically, neurons in the limbic system and/or brain stem of patients with DM1 and DM2 contain tau-associated neurofibrillary tangles, suggesting a common neuropathological process and a possible link with the central features of DM1 including apathy and sleepiness [3].

In addition to executive dysfunction, patients with DM1 and DM2 tend to have avoidant personality trait disorder [71]. Obsessive-compulsive personality and passive-aggressive personality features have also been reported in myotonic dystrophies [66]. In DM1, anxiety and depression are common and quality of life can be significantly impaired. Apathy in patients may be confused with depression [3].

Frontotemporal dementia has been reported in individuals with proximal muscle weakness at onset, clinical/electrical myotonia, and DM-type cataracts. The diagnosis was supported by brain single-photon emission computed tomography (SPECT) study that revealed marked frontotemporal hypoperfusion and by postmortem examination that showed frontotemporal spongiosis, neuronal loss, and rare neuronal and glial tau inclusions. There was cortical atrophy without white matter lesions on brain MRI [63–71].

Sleep and Respiratory System

Excessive daytime sleepiness (EDS) is a common complaint of DM1 patients, more particularly in those with higher degree of muscular impairment. In addition, DM1 patients sleep longer at night, and those with EDS more frequently reported hypnagogic hallucinations and feelings of weariness and pain in the legs upon morning awakening [72]. EDS in DM1 may be severe and may resemble the sleepiness of primary hypersomnias such as narcolepsy. Besides EDS, severe fatigue is present in up to 74 % of adult-onset DM1 patients [73]. Central and obstructive sleep apneas are yet other commonly reported sleep abnormalities in DM1. In addition, DM1 patients may exhibit sleep-onset rapid eye movement periods in the multiple sleep latency test such as those classically found in narcolepsy. Decreased hypocretin-1

levels in the cerebrospinal fluid of DM1 patients with EDS were recently observed, suggesting a dysfunction of the hypothalamic hypocretin system [72].

In DM2, EDS is usually absent, a clinical feature that helps differentiating it from DM1 (see Table 59.2). On the other hand, there is a decrease in the quality of sleep in patients with DM2, likely due to nocturnal awakenings caused by muscle pain and not explained by depression or other comorbidities. Pain management may improve sleep and quality of life in DM2 patients [73]. Fatigue is another commonly experienced symptom in DM2 and is not correlated with the use of beta blockers, thyroid dysfunction, or poor sleep quality.

In addition to EDS, respiratory involvement in patients with DM1 includes alveolar hypoventilation, which results from respiratory muscle weakness as well as dysfunction of the central control of respiration. Also, patients with DM1 are at higher risk of aspiration pneumonia due to weakness and myotonia of the pharyngeal and esophageal muscles. Acute postoperative respiratory failure is a reported complication in older patients with DM1 with advanced muscle weakness undergoing abdominal surgery. This was explained in part by the depressant effect in the respiratory system of certain anesthetic agents such as thiopentone, halothane, and suxamethonium [74]. In contrast to DM1, patients with DM2 have relative preservation of respiratory function which also reduces the risk of right heart failure which may occur in patients with DM1 [28].

Skin

In addition to early male balding [1, 18], hyperhidrosis is a unique complaint in patients with DM2, affecting the hands and trunk mostly [28]. Other dermatological manifestations include seborrheic dermatitis as well as pilomatrixomata and epitheliomas on the scalp which may be misdiagnosed as sebaceous cysts [3, 22, 75].

Immune System

In both DM1 and DM2, hypogammaglobulinemia is associated with low levels of IgG and IgM [1]. The frequency of autoimmune diseases and overall presence of autoantibodies (such as antinuclear antibody and rheumatoid factor) are increased in DM2 patients. This may be due to the effect of the DM2 mutation on the immune system through an RNA-mediated disease process or through a genetic linkage [76].

Gastrointestinal Tract

Gastrointestinal dysfunction is common in DM1 and is disabling in ¼ of the patients [2, 77]. Gastrointestinal complaints in DM1 range include dysphagia, diarrhea, constipation, and fecal incontinence. Dysphagia in DM1 may contribute to aspiration pneumonia. Reduced motility is common in DM1 patients and severe obstructive symptoms such as megacolon have been described. New evidence suggests that gastrointestinal problems are also common in DM2 patients [78]. Cholecystitis and gallbladder stones due to an increase tone of the gallbladder sphincter have been reported in DM1 patients with high postoperative complication after cholecystectomy [3].

Neoplasia

Patients with DM1 may have an increased risk of thyroid cancers and choroidal melanoma. An increased risk for malignancies of the testis, prostate, endometrium, ovary, colon, thymus, and brain has been also reported [75].

Other System Abnormalities

In addition to hormonal abnormalities mentioned above (testosterone, FSH, LH, thyroid studies), abnormal laboratory studies are very common in patients with DM1 and DM2. This includes low BUN and creatinine, low serum albumin, low calcium, and elevated cholesterol [79, 80]. Total white cell count, platelets, hemoglobin, and hematocrit are typically reduced in both patient populations. Total lymphocyte count and red cell mean corpuscular volume may be increased in DM1 patients. Liver dysfunction is frequently implicated as a cause for serum transaminase elevation in both disorders [81], with normal liver biopsies frequently and needlessly performed, since the source of the increased enzymes is often the skeletal muscle; minimal gamma-glutamyl transpeptidase (GGT) elevation may indicate some true, though apparently slight, hepatocellular injury [1, 16, 18, 26]. Mildly elevated GGT does not require specific liver investigation in these patients [82].

Genetic Mechanisms and Pathogenesis

Research into the genetics of myotonic dystrophy (DM) leads to advances in the areas of molecular pathogenesis and pathophysiology, both of which aid in understanding the clinical manifestations of this multisystem disease. In addition, this research will ultimately have implications for potential therapeutic options.

DM was initially described about 100 years ago. In the past 10 years, there have been a number of advances, particularly in the concept of genetics and molecular pathomechanisms. Here we describe the clinically relevant genetics of DM.

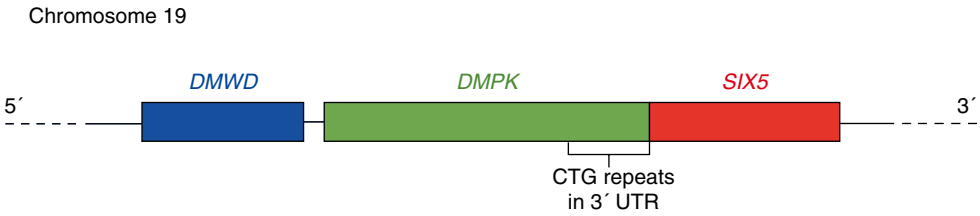

Fig. 59.4 The location of *DMWD*, *DMPK*, and *SIX5* genes on chromosome 19. Of note, diagram is not depicted in the actual ratio. UTR, untranslated region

Mutations

As compared to some other genetic diseases, the genetic mutations of DM1 and DM2 are not as complicated. Indeed, there is only one gene involved in each DM subtype, and the basic changes are trinucleotide and tetranucleotide repeat expansion in DM1 and DM2, respectively.

DM1 results from a CTG repeat (CUG in RNA) expansion in the *DMPK* gene, which is located in the 3′ untranslated region (UTR) of chromosome 19q13.3. This gene is immediately upstream to the promoter region of the *SIX5* gene (Fig. 59.4). In DM2, there is a CCTG (CCUG in RNA) repeat expansion in intron 1 of the *zinc finger 9* (*ZNF9*) gene on chromosome 3q21.3 (see Table 59.2). Both DM1 and DM2 have an autosomal dominant mode of inheritance. Most patients are heterozygous, but a minority is homozygous. Proximal myotonic myopathy (PROMM), which was described clinically before the discovery of DM2 gene, was found to have the same genetic mutation as DM2 [25]. Therefore, PROMM is, in fact, the same entity as DM2. There were case reports of possible myotonic dystrophy type 3 (DM3) when the patients had clinical phenotypes similar to DM, particularly DM2, but genetic testing for DM1 and DM2 was negative [22, 83, 84]. However, one family was proven later to be inclusion body myopathy with Paget disease of bone and frontotemporal dementia associated with *valosin-containing protein* (*VCP*) gene mutation [20, 21]. Diagnosis of DM3 needs to be cautious since two standard genetic techniques including standard PCR and Southern blot can detect only approximately 80 % of DM2 patients [85]. It is also possible that reported DM3 cases may in fact have DM2 or other undiagnosed neuromuscular diseases.

There are two important concepts in nucleotide repeat expansion disorders which deserves a detailed discussion. These are: (1) anticipation and (2) the relationship between the number of repeats and disease severity.

Anticipation

In 1918, DM1 was the first disorder in which anticipation was described [86]. Anticipation is an increase in the number of repeats when the gene is passed to future generations that lead to an earlier disease onset and an increase in disease severity. Instability of repeat sequences may be caused by slippage of replication machinery during DNA synthesis [87]. In normal circumstances, slippage can occur and mismatch repair processes will then take place. Mismatch repair defects, in addition to slippage during DNA synthesis, can lead to unstable repeat expansions.

Short repeat sequences, known as "simple tandem repeats (STR)," are found in normal individuals. When the number of repeats within one particular gene expands, usually to the upper limit of the normal range, the repeats become unstable and are referred to as "unstable repeat expansions (UREs)." UREs are prone to further expansion.

It is worth mentioning that in DM, the reported number of repeats refers to the number of repeats as measured in leukocytes. "Somatic instability" refers to the fact that different cell types have different numbers of repeats [88, 89]. For example, muscle and brain cells have a significantly greater number of repeats as compared to leukocytes, but leukocytes are the cells used most often in genetic studies of DM. In addition to somatic instability, age is another factor that affects the number of repeats [90–92].

Gender also plays an important role in DM and there is a maternal transmission bias in transmitting congenital DM. Congenital DM1 usually occurs in infants born to mothers with DM1 or repeat sequences in the premutation range of DM1. In congenital DM1, the number of repeats is typically greater than 1,000. The maternal transmission observed may be related to UREs during oogenesis [93]. It is also proposed that sperms with a high number of repeats may not survive [94]. Sex and "meiotic drive," a preferential transmission of a particular allele during meiosis at a given locus, is another proposed theory but this remains controversial and debating data is discussed elsewhere.

Disease Severity and the Number of Repeat Expansions

In general, the patients have earlier onset and greater severity of disease when the number of repeats is higher [95, 96]. However, there is no clear correlation between the number of repeats and disease severity; In other words, we can neither predict the exact number of repeats based on disease severity nor predict the severity of the disease from the number of repeats. We can only infer the possible range of repeats. It is very difficult to predict disease severity, especially when the number of repeats is high. However, as mentioned above, normal individuals have a low number of repeats. As the number of repeats approaches the premutation range, sequences are more unstable. When the number of repeats is in mutation

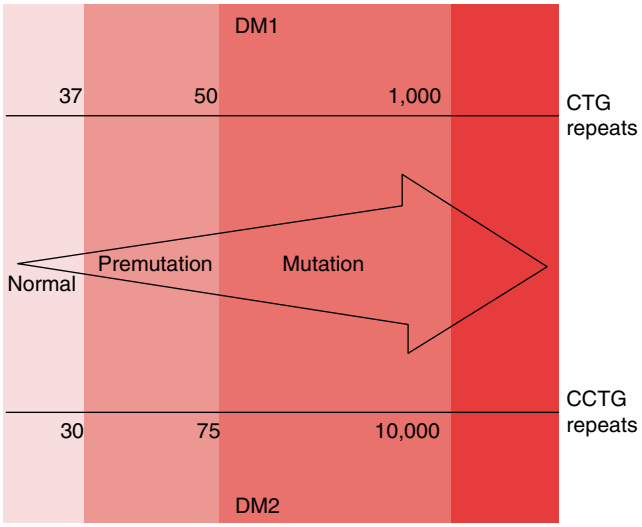

Fig. 59.5 Correlation between severity of diseases and the number of repeats in DM1 and DM2

range, the patient will have earlier onset and more severe disease if the number of repeats is higher. When the number of CTG repeats is greater than 1,000, the patient typically has congenital DM1 [97] (Fig. 59.5).

DM1 manifests clinically when the patient has a repeat number greater than 50. In the 50–100 range, patients will have a mild form of the disease, with such symptoms as skin abnormalities and frontal balding but without cognitive impairment. If the number of repeats is greater than 1,000, the patients often have severe clinical manifestations at birth or even in utero, i.e., congenital DM1 [96, 98].

Even though clinical phenotypes of DM1 and DM2 share some similar features, the number of repeats in the two diseases is different. Interestingly, in DM2, the number of repeats overall is much higher than in DM1 and can be in the 11,000 range (with an average around 5,000) despite milder clinical phenotype [85]. Although the nucleotide repeat expansion concept is similar between DM1 and DM2, there are several issues not yet fully explained. As opposed to DM1 and despite the high number of repeats, DM2 does not usually result in a congenital phenotype [99].

Molecular Pathogenesis

Knowing the genetic basis of DM1 and DM2 as nucleotide repeat expansion disorders provides the opportunity to explain the pathogenesis of these diseases. It is interesting why a mutation in one gene leads to multisystem disease, including myotonia, weakness, cataract, insulin resistance, and cognitive impairment.

We will use DM1 as a model herein. Prior to 2001, there were several proposed mechanisms, including haploinsufficiency, interaction between neighboring genes, and

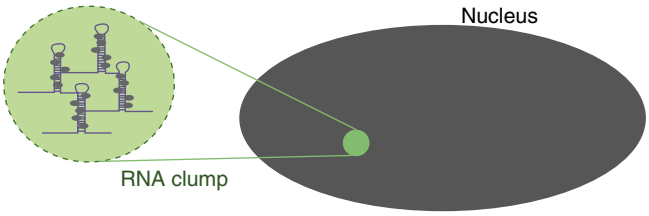

Fig. 59.6 RNA clump ("toxic RNA") within nucleus of myocyte demonstrated by fluorescence in situ hybridization (FISH) technique. This clump comprises pre-mRNA with hairpin loop formation and RNA-binding proteins sequestered in hairpin loops

RNA toxic gain of function. The discovery of CCTG repeat expansion in DM2 and several subsequent studies support the latter theory, which is believed to be the main and the most important mechanism at present.

RNA Toxic Gain of Function

This mechanism has been proposed since 1995 [11, 12]. With regard to genetic dogma, DNA is transcribed to pre-mRNA in nucleus, which then will have posttranscriptional modification and alternative splicing into mRNA. mRNA will then be translated into protein in the cytoplasm.

When pre-mRNA is transcribed from unstable repeat sequences in DNA, it forms multiple hairpin loops. Protein sequestration then occurs when RNA-binding proteins in the nucleus bind to these hairpin loops [100]. RNA then becomes "toxic." This mechanism is confirmed by demonstrating nuclear foci of RNA clumps, rather than dispersion throughout the nucleus, on fluorescence in situ hybridization (FISH) technique (Fig. 59.6). One of the important RNA-binding proteins is CUG-binding protein 1 (CUGBP1) (Fig. 59.7). This protein was thought to be sequestered in hairpin loops; hence the name "binding protein" was initially assigned. However, CUGBP1 failed to co-localize with the RNA clumps in the nucleus on FISH, possibly due to weak affinity for expanded CUG repeats. In fact, CUGBP1 level is increased within the cell [101–103]. The mechanism with regard to increased CUGBP1 level remains unclear. Also, importantly, protein kinase C, which has an increased activity in DM1, will phosphorylate CUGBP1 and lead to multisystem problems as mentioned below [104]. The trigger of protein kinase C activation also remains unclear. Although CUGBP1 has a role in DM1 pathogenesis, it has no role in DM2 [105]. A protein that co-localizes nuclear foci of toxic RNA clumps was found later. It is the muscleblind-like protein (MBNL) [102, 103, 106, 107]. This protein is a homolog of *Drosophila* muscleblind protein and can lead to muscle and eye problems, as the name implies [108]. There are three subtypes of MBNL, MBNL1, 2, and 3 [109]. All subtypes co-localize toxic RNA clumps within the nucleus. This is the second protein that is sequestered within hairpin loops and is also important in the toxic RNA pathomechanism [110, 111].

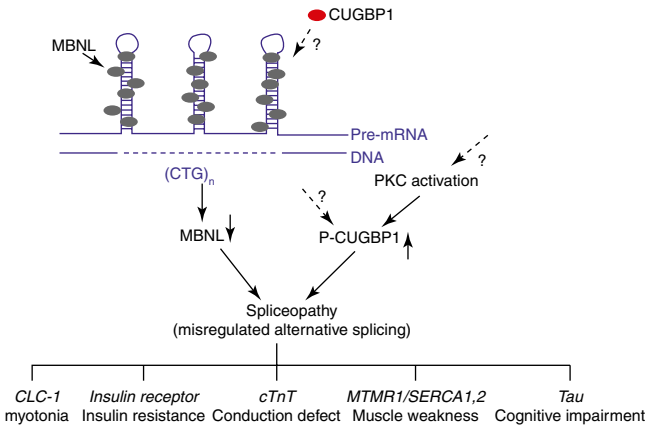

Fig. 59.7 RNA toxic gain-of-function pathomechanism. MBNL, muscleblind-like protein; P-CUGBP1, phosphorylated CUG-binding protein 1; $(CTG)_n$, CTG repeat expansion; PKC, protein kinase C; *CLC-1*, *chloride channel-1* gene; *cTnT*, cardiac troponin T gene; *MTMR1*, *myotubularin-related 1* gene; *SERCA1, 2*, *sarcoendoplasmic reticulum* Ca^{2+} *ATPase 1, 2* gene; ?, unclear mechanism. Of note, spliceopathy is a misregulated alternative splicing of mRNA products of these genes, not the genes

Unlike CUGBP1, MBNL level is decreased within the cell due to sequestration [112].

Increased phosphorylated CUGBP1 and decreased MBNL can explain multisystem phenotypes of DM1 by leading to misregulated alternative splicing of mRNA [113, 114]. This is also called "spliceopathy." Normally, alternative splicing of mRNA can produce different combinations of exons resulting in the synthesis of different proteins with different functions [115]. This spliceopathy may lead to misregulated alternative splicing of mRNA products including those from chloride channel gene leading to myotonia [116–118], from the insulin receptor gene leading to insulin sensitivity [119], from the *tau* gene leading to cognitive impairment [120, 121], from the cardiac troponin T gene leading to cardiac conduction defect [122, 123], and from *myotubularin-related 1* (*MTMR1*) and *sarcoendoplasmic reticulum* Ca^{2+} *ATPase 1, 2* (*SERCA1, 2*) genes leading to muscle weakness [123, 124].

This mechanism also applies in DM2. There is evidence of nuclear foci of CCUG repeats in DM2, similar to that seen in DM1. Co-localization of MBNL proteins and these nuclear foci is also found [112, 125]. These findings make this theory more convincing for shared pathogenesis between DM1 and DM2. However, data on DM2 is limited as compared to DM1 and needs to be further investigated.

Haploinsufficiency

This mechanism was proposed even prior to the RNA toxic gain-of-function mechanism. However, there is some compelling evidence that will be discussed below. It was previously thought that CTG repeat expansion in *DMPK* gene would cause reduced expression of one allele. However, this might not be true. Although the DMPK protein level is decreased in cytoplasm, pre-mRNA level from the *DMPK* gene is, in fact, not decreased in the nucleus [11]. Heterozygous *DMPK* knockout mice, which were comparable to heterozygous mutations in humans, did not show evidence of myopathy or multisystem phenotypes, whereas homozygous *DMPK* knockout mice had cardiac conduction defects and skeletal muscle abnormalities, but not typical DM1 histology [126, 127]. Not all systemic features can be explained by the *DMPK* knockout mouse model. In addition, haploinsuffiency of *SIX5* gene which is immediately downstream to *DMPK* gene has been proposed in DM1. *SIX5* knockout mice showed abnormal cardiac and muscle development [128]. Heterozygous *SIX5* knockout mice had QRS prolongation that was apparent only under general anesthesia [129]. Therefore, *SIX5* haploinsufficiency cannot explain all DM1 clinical features. In DM2, *ZNF9* knockout mice had abnormal forebrain development and craniofacial abnormalities, but did not show classic phenotypes of DM2 [130].

Gene Interaction

The promoter region of the *SIX5* gene is immediately downstream to the *DMPK* gene [131, 132] (see Fig. 59.4). The *SIX5* gene is related to eye and distal limb muscle development in the fruit fly and mouse, respectively. Cataracts and distal limb weakness are common features in DM1. Therefore, it was thought that there might be an interaction between the *DMPK* and *SIX5* genes. However, this theory cannot explain all systemic features [133]. In addition, despite the similarity of phenotypes between DM1 and DM2, DM2 cannot be explained by the interaction between these genes as they do not exist on chromosome 3.

Genotype-Phenotype Correlation

As mentioned previously, the number of repeats correlates with the onset and the severity of disease in both DM1 and DM2. However, phenotype cannot be accurately predicted based solely on the number of repeats. This is especially true when the number of repeats is beyond 600 in DM1. A CTG repeat count greater than 1,000 in the *DMPK* gene is associated with congenital DM1 [96, 98].

Diagnosis and Evaluation

In moderately or severely affected individuals, myotonic dystrophy is easily recognizable on clinical grounds [1, 23, 24]. Even in minimally affected individuals, the clinical phenotype is highly suggestive of the diagnosis. Patients commonly come to medical attention due to weakness, myotonia, or myalgias, though the multisystem nature of the disorder may result in initial presentations due to ocular, endocrine, cognitive, cardiac, reproductive, sleep, gut, or skin

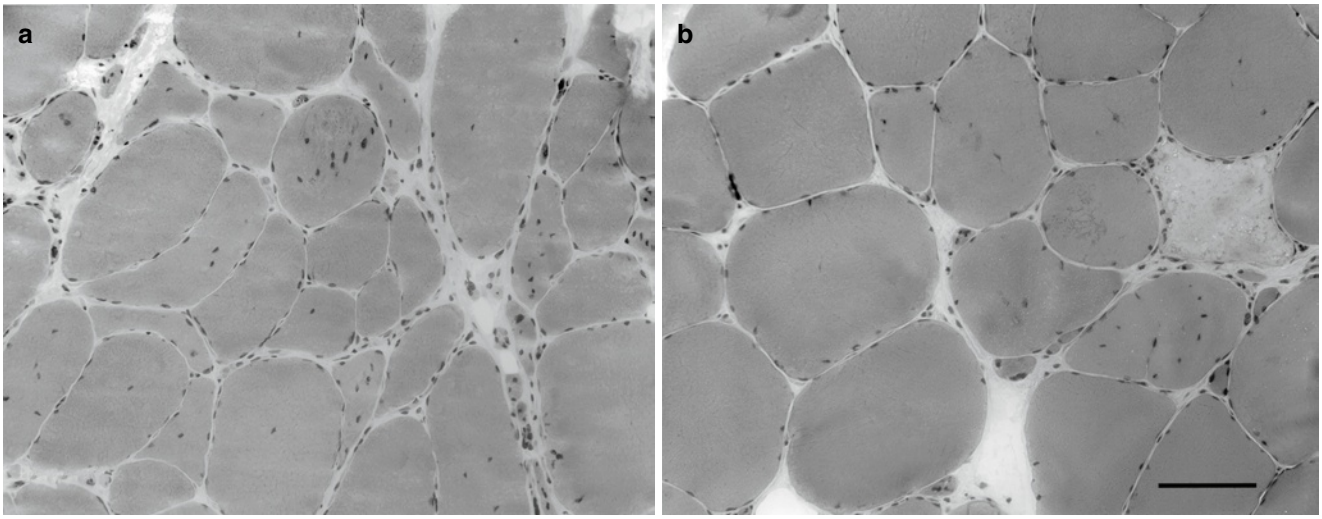

Fig. 59.8 Histology of DM1 and DM2. The figure shows hematoxylin- and eosin-stained sections of myotonic dystrophy type 1 (**a**) and myotonic dystrophy type 2 (**b**). In each section fiber size variation is greater than normal, with diameters ranging from 10 to more than 200 μm. There are many severely atrophic fibers. There is a marked increase in the number of fibers with centrally located nuclei. Fiber splitting is evident in both sections. A necrotic fiber is evident in the DM2 muscle. There is endomysial and perimysial fibrosis. Calibration 100 μm

abnormalities. The presence of typical facies, clinical and electrical myotonia, characteristic pattern of weakness, modestly elevated serum CK, the typical histological pattern on muscle biopsy (see below), iridescent posterior subcapsular cataracts, insulin insensitivity, hypogammaglobulinemia, male balding, and testicular failure, all inherited as a dominant disorder, provides a compelling clinical diagnosis of DM1 [18]. DM2 is slightly more difficult to diagnose clinically because of the variability of symptoms and lack of typical facial features and subtle myotonia. Genetic testing reliably identifies affected DM1 and DM2 patients, obviating invasive diagnostic testing in this disorder.

Muscle Biopsy

The histological features of muscle biopsies in DM1 and DM2 are distinct, though not pathognomonic (Fig. 59.8). Characteristic findings to both types include prominent central nuclear migration, muscle fiber atrophy, bags of myonuclei, and ring and split fibers. In DM1, type I muscle fibers are predominantly affected, while DM2 shows preferential involvement of type II muscle fibers. Fibrosis and adipose deposition does occur late and parallels disease severity [1, 18, 23]. Despite this, DM1 and DM2 specimens cannot be reliably differentiated histologically. The severely atrophic fibers seen in DM1 and DM2 are curiosities since they are typically seen in neurogenic atrophy, though definite features of muscle denervation or reinnervation have not been identified in either DM1 or DM2 [1, 18]. The fiber necrosis, fibrosis, and adipose deposition in DM1 and DM2 validate the categorization of the disease as a muscular dystrophy.

Genetic Testing

Genetic diagnosis remains the gold standard test for DM1 and DM2. It is not infrequent that the clinical manifestations, including characteristic facies, myotonia, cataracts, and apathy, provide a convincing evidence for the diagnosis of DM1. In DM1, polymerase chain reaction (PCR) is used as a first step. The principle is that PCR cannot detect very large repeats. It can detect only small repeats. In normal individuals, there should be two bands if the numbers of repeats in each allele on chromosome 19 are different. However, a single band can occur if numbers of repeats in each allele are equal or very close. In DM1 patients, there is also only one band, as the pathogenic allele which contains large repeats cannot be detected by PCR. Therefore, if there are two bands shown on PCR, the disease can be excluded. However, if there is only one band, this could be a normal individual with an equal number of repeats in two alleles or a DM1 patient. Further Southern blot testing is necessary to confirm the diagnosis [134, 135].

In DM2, similar techniques are used but a third test – the repeat-primed PCR-based assay – may also be required to increase the detection rate to 99 %. The first two tests may detect only 80 % of DM2 [22, 85, 136]. The threshold for genetic testing in DM2 should be low since myotonia and cataract may be absent and the clinical presentation may be late, mild, or predominantly myalgic in type. Also, findings that are fairly typical for DM2 on muscle biopsy are sometimes another indication for genetic testing [82].

Prenatal genetic diagnosis using chorionic villous sampling and amniocentesis can be done with some risks of miscarriage. In vitro fertilization is also used in preimplantation genetic diagnosis. Sperm and egg are fertilized in vitro and

the embryonic cell is then genetically tested and selected. A normal cell is selected and implanted into the uterus [137, 138].

Recommended Additional Tests

Once the diagnosis of DM1 or DM2 is made, several evaluations need to be obtained to assess and monitor systemic disorders. These include measurement of blood count, electrolytes, lipid panel, TSH, FSH, LH, testosterone, IgM/IgG levels, and 2-h glucose tolerance test. Patients should have an initial and an annual EKG [54]. Holter and echocardiography are recommended by others every 2 years [54]. Patients with syncope, dizziness, palpitation, documented arrhythmias, or family history of sudden death or ventricular arrhythmias should undergo cardiology consultation and undergo electrophysiological cardiac studies [54]. Annual ophthalmologic examination to detect cataract and choroid melanoma and annual thyroid examination to detect early thyroid cancer should be done [75]. Sleep studies should be considered for patients with suspected EDS.

Differential Diagnosis

Patients with severe or advanced form of DM1 are relatively easy to diagnose. In contrast, patients with mild DM1 or DM2 are more elusive and may be misdiagnosed for years. These mild disorders may be difficult sometimes to distinguish from the non-dystrophic myotonias including myotonia congenita. Other inherited and acquired disorders with electrical or clinical myotonia need to be included in the differential diagnoses (Table 59.3). DM2 may be mistaken for limb-girdle muscular dystrophies since they both exhibit proximal limb weakness and for inclusion body myositis because of the late onset. Congenital DM1 may be difficult to diagnose accurately due to the lack of myotonia during infancy and may be mistaken for congenital myopathy or muscular dystrophy.

Treatment and Management

There is currently no known curative therapy for DM1 or DM2. Appropriate clinical management of patients with DM includes symptomatic treatment of muscle pain and myotonia and prevention and management of complications and other organ involvements.

There is a strong recommendation (class I evidence) regarding the use of mexiletine as an antimyotonia treatment in patients with DM1. Mexiletine given at a dosage of 150–200 mg three times daily is well tolerated, safe, and effective in reducing grip myotonia with no associated serious adverse events or prolongation of PR, QTc intervals, or QRS duration [139]. Flecainide at a dose of 50–100 mg twice a day or propafenone at a dose of 150–300 mg twice a day may be considered as an alternative treatment of myotonia [82]. Quinine, phenytoin, and dihydroepiandrosterone are also of value in patients with DM1 or DM2, though drugs with effects on cardiac function or conduction need to be used cautiously due to the intrinsic effects of DM on the heart.

Excessive daytime sleepiness is significantly reduced with a single 20-mg daily dose of methylphenidate in patients with DM1 [140]. Hypothyroidism and gonadal failure are treated with hormonal replacement therapy [82]. Constipation is treated with dietary and pharmacologic adjustments like osmotic laxatives, along with supplementary fibers. The use of tramadol and other opiates should be avoided because of the potential negative side effects on gastrointestinal motility or precipitating megacolon [78].

Therapeutic implications of the genetic discoveries in DM1 and DM2 are still evolving. RNA toxic gain-of-function theory leads to several important therapeutic implications. For example, antisense oligonucleotides (ASOs) can be used to bind mRNA, thereby preventing hairpin loop formation and subsequent protein sequestration [141–147]. Reducing protein kinase C activity [148], increasing MBNL activity [149–152], or reducing CUGBP1 activity [105] can lead to a decrease in misregulated alternative splicing. There are also other targets of which the studies are under way.

Prognosis

Most patients with DM1 and DM2 remain ambulatory till later in life. DM1 and DM2 typically remain stable during childhood, but lead to progressive loss of function and motor

skills during adulthood. However, life expectancy in DM1 is significantly reduced due to the increased risk of fatal arrhythmias, ventilatory failure, neoplasia, and coronary artery disease [46, 153, 154]. In DM1, death can occur as early as the 2nd or 3rd decade [47]. DM2 has rarely been associated with fatal arrhythmias as early as the 3rd decade of life and is unlikely to cause severe ventilatory insufficiency even in later life.

Congenital DM1 is characterized by hypotonia, poor feeding, and respiratory compromise, with the potential for neonatal fatality due to ventilatory collapse. Myotonia may be absent in infancy, and most children have mild or moderate mental retardation.

Oculopharyngeal Muscular Dystrophy

60

Bernard Brais, Nicolas Chrestian, Nicolas Dupré,
Jean-Pierre Bouchard, and Guy Rouleau

Introduction

In 1915, Taylor from Boston, Massachusetts, reported the familial association of eyelid ptosis and dysphagia in a family of French-Canadian (FC) descent [1]. However, it was not until 1962 that oculopharyngeal muscular dystrophy (OPMD) was recognized as a distinct muscular dystrophy [2]. OPMD manifests primarily as an autosomal dominant disorder usually after the age of 50, with late-onset selective progressive ptosis and dysphagia. A recessive form has also been reported [3]. In 1980, Tomé and Fardeau identified by electron microscopy a specific histological marker, unique filamentous intranuclear inclusions, in the deltoid muscle of three unrelated OPMD patients [4, 5]. In 1998, the gene defect of OPMD was found to be a $(GCG)_n$ repeat expansion in the first exon of the polyadenylate-binding protein nuclear 1 (*PABPN1*) gene, known as PABP2 [6]. OPMD was thus the first disease to be caused by a short $(GCG)_n$ expansion coding for polyalanine residues.

OPMD has a worldwide distribution with patients described in, or originating from, 30 countries (Fig. 60.1). OPMD is particularly prevalent in the FC population (1:1,000) and in Bukhara Jews living in Israel (1:600) [7, 8]. Most North American cases of OPMD descend from three French sisters who arrived in Québec in 1648 [6, 9]. Numerous other historically distinct OPMD mutations have also been introduced or have appeared in North America in Louisiana Cajuns, Hispanic Americans from the Southwestern United States, Jews of Eastern European origin, Italians, Mennonites, and descendants of British immigrants [6, 10–14]. In France, a prior estimate of OPMD prevalence identified one case per 200,000 [15], but the identification of many new families over the past decade suggests that OPMD has at least twice this prevalence [16]. The Western European prevalence, based on the large number of families tested for the mutation since 1998, may also be in the range of 1:100,000–200,000. The predicted prevalence of the recessive form is about 1:10,000 in Québec, France, and Japan [6].

Etiology and Pathogenesis

Pathologically, the OPMD intranuclear inclusions (INI) consist of tubular filaments often arranged in palisades or tangles [4]. The filaments are 0.25 μm in length and have an 8.5 nm external diameter and a 3 nm internal diameter (Fig. 60.2). In deltoid muscles, 4–5 % of the nuclei seen in every ultrathin section contain these filaments [4]. Other nonspecific pathological findings in OPMD include rimmed vacuoles and small angulated muscle fibers [5]. One group reported that 8 % of nuclei in the more affected cricothyroid pharyngeal muscle bear INI compared to half that percentage in the deltoid muscle. In homozygous OPMD patients, twice as many muscle nuclei show INI than is usually observed in heterozygous patients [17–19]. Tubular filaments described in OPMD muscles are also found in inclusion body myositis [20, 21].

Using three large FC families, the dominant OPMD locus was mapped to chromosome 14q11.2-q13 [7]. Linkage to the same haplotype was documented for families of other ethnic backgrounds suggesting that dominant OPMD is a genetically

homogeneous condition [10, 13, 22, 23]. A positional cloning strategy led to the identification of short $(GCN)_{8–13}$ expansions in the *PABPN1* gene in all dominant OPMD patients (Table 60.1) [6]. The mutations consist of mitotically and meiotically stable insertions of GCN triplets in the first exon of the gene [24]. All GCN trinucleotide codons code for alanine. Thus, the normal allele is characterized by 10 GCN repeats $(GCN)_{10}$, and dominant mutations consist of the addition of 12–17 (GCN) repeats of the normal $(GCN)_{10}$ stretch (formerly referred to as the $[GCG]_6$ normal allele) [6]. In a study of 81 non-FC families originating from 17 countries, six different mutation sizes were found. The percentage of families sharing the mutations were 5 % $(GCN)_{12}$, 40 % $(GCN)_{13}$, 26 % $(GCN)_{14}$, 21 % $(GCN)_{15}$, 7 % $(GCN)_{16}$, and 1 % $(GCN)_{17}$ [6]. In FC, OPMD is caused by a founder $(GCN)_{13}$ mutation [6, 19]. Recessive inheritance characterized by homozygous $(GCN)_{11}$ has only been observed in few individuals [3, 6, 19, 25]. A gene dosage effect seems clearly to affect the phenotype as demonstrated in an observational study homozygous OPMD cases of four FC and three Bukhara Jews. They demonstrated an earlier age of onset (18 years earlier), more severe muscle involvement, and significantly reduced life span as well as cognitive decline [3, 19, 25].

PABPN1 is a nuclear protein of 306 amino acids which is involved in the polyadenylation of all messenger RNAs [26–30]. PABPN1 has four distinct domains: polyalanine, RNA binding, dimerization, and nuclear localization signaling. The biphasic polyadenylation process depends on poly(A) polymerase, cleavage and polyadenylation specificity factor (CPSF), and cleavage stimulation factor (CstF), while the rapid final elongation of the poly(A) tails is dependent on adjoining PABPN1to the polyadenylation complex [26]. PABPN1 is expressed in all tissues but more highly in skeletal muscle [6].

At the protein level, the OPMD mutations cause the lengthening of the predicted N-terminus polyalanine domain (see Table 60.1). A polyalanine nuclear toxicity gain of function is proposed as a pathogenic mechanism [6, 31, 32]. In this model, PABPN1 is suggested to carry a expanded polyalanine domain to the nucleus. This is reminiscent of carrier models proposed in CAG repeat diseases [33]. The polyalanine oligomers could form degradation-resistant macromolecules. Polyalanine oligomers are known to be resistant to protease digestion or chemical degradation such as KCL extraction [34, 35]. They form β-sheet structures in vitro [34, 36]. Furthermore, polyalanine oligomers containing more than eight alanines in a row form spontaneous fibrils [37]. It is proposed that beyond ten alanines, the normal number of alanines in PABPN1, polyalanine domains polymerize to form stable β-sheets that are insoluble and resistant to nuclear proteosomal degradation. The mutated PABPN1 is an integral part of the muscle OPMD inclusions [4, 35, 38]. The misfolded and resistant PABPN1 protein induces aggregation of ubiquitin-related proteins such as HSP-40, HSP-70, and ubiquitin itself, thus avoiding degradation by the intranuclear proteasome system [39]. Also, poly(A) RNA were found inside the misfolded protein, and mPABPN1 is known to interact with hnRNP proteins interfering with mRNA export from the nucleoplasm [35, 39]. Although PABPN1 is expressed ubiquitously, muscles are particularly involved in OPMD. This could be explained by mPABPN1 protein interference with co-transcription factor SKIP (SKI-interacting protein), preventing the expression of muscle-specific genes [39, 40]. When a significant part of the nucleus is occupied by the inclusions, normal nuclear function would be altered leading to cell death either by trapping of other proteins or of mRNA. The phenomenon would lead to gradual muscle cell death, thereby giving rise to the OPMD phenotype.

Clinical Presentation

The following diagnostic criteria for dominant OPMD have been proposed: (1) a positive family history of OPMD, (2) ptosis with at least one palpebral fissure at rest smaller than 8 mm (or previous corrective surgery), and (3) dysphagia with a swallowing time greater than 7 s when asked to drink 80 ml of ice-cold water [7]. The decade-specific penetrance for carriers of a dominant $(GCN)_{13}$ mutation are 1 % (<40), 6 % (40–49), 31 % (50–59), 63 % (60–69), and 99 % (>69) [41]. Therefore, dominant $(GCN)_{13}$ OPMD is fully penetrant past 70 years old. Other signs observed in affected individuals are proximal arm weakness (38 %), facial muscle weakness (43 %), limitation of upgaze (61 %), dysphonia (67 %), proximal leg weakness (71 %), and tongue weakness/atrophy (82 %) [42]. Some patients also develop mild to severe ophthalmoparesis, and of these, some complain of diplopia. Rarely, distal weakness occurs [43–45]. The recessive OPMD phenotype appears to be similar, though possibly milder with an older age of onset [46]. One recessive OPMD patient was also found to have coincidental hereditary neuropathy with liability to pressure palsies [47].

The severity of the dominant OPMD phenotype is variable [42]. Severe cases have onset of ptosis and dysphagia before age 45, followed prior to age 60 incapacitating

proximal leg weakness with ultimate wheelchair dependence. In the FC cohort, patients are identified as severe OPMD if symptomatic proximal leg weakness begins before age 60. These represent 5–10 % of patients. Twenty percent of the more severe patients inherit, beside a dominant mutation, a polymorphism in the other copy of the *PABPN1* gene, which causes the insertion of one extra (GCG) triplet (i.e., a $(GCG)_7$ mutation) [6]. This polymorphism has a 1–2 % prevalence in North America, Europe, and Japan. Severe cases tend to cluster in families, suggesting that other genetic factors modulate severity. However, patients with more severe phenotypes do not appear more likely to transmit their phenotype variability than patients affected with the classical form.

The molecular basis of autosomal recessive OPMD appears to be at least in some cases the double inheritance of the $(GCG)_7$ polymorphism [6]. Therefore, these patients may be underdiagnosed because of a milder phenotype and the absence of a clear family history. Recently, Semmler described the first two recessive $(GCG)_7$ OPMD cases in Europe that showed a more severe phenotype than the two cases reported previously in FC cases [19]. Thus, the $(GCG)_7$ allele is an example of a polymorphism which may act either as a modifier of a dominant phenotype or as a recessive mutation.

The most severe OPMD phenotype occurs in individuals homozygous for the dominant OPMD mutation [6, 18, 19]. A study of four FC and three Bukhara Jewish OPMD homozygotes identified an average age of onset of 18 years earlier than in $(GCN)_{13}$ heterozygotes. These patients have twice as many muscle nuclei containing intranuclear inclusions than heterozygotes (9.4 % vs. 4.9 %). Interestingly, in the same cohort, after a follow-up of many years, most homozygotes showed mental changes such as paranoid behavior or other psychiatric disorders, as well as subcortical dementia. They also demonstrated a reduce life span with death in their 50s. Thus a large burden of mutated PABPN1 could affect the central nervous system [25]. In addition, the more severe phenotypes observed in homozygotes and compound heterozygotes for a dominant and a recessive mutation suggest a gene dosage effect [6, 19, 31].

Differential Diagnosis

A diagnosis of dominant OPMD should be considered in the face of cardinal features of a slowly progressive late-onset ptosis accompanied with dysphagia, dysarthria, proximal limb weakness, and a family history. Other diagnoses that may be entertained include myotonic muscular dystrophy, myasthenia gravis, or mitochondrial myopathy with or without progressive external ophthalmoplegia. The presence of fluctuating symptoms suggests myasthenia gravis or congenital myasthenic syndrome. Lambert-Eaton myasthenic syndrome can be more difficult to differentiate because it presents with ptosis, dysphagia, and proximal limb weakness. In chronic progressive external ophthalmoplegia, ptosis and ophthalmoparesis predominate, while dysphagia is a late manifestation. Inflammatory myopathies and progressive bulbar palsy are usually excluded by the absence of ptosis. Late-onset isolated familial ptosis is distinguished from OPMD by the lack of dysphagia. Inclusion body myositis presents with typical features of late-onset proximal weakness (particularly involving the quadriceps) often with swallowing difficulties. Finally, proximal myopathic myopathy, some late-onset limb-girdle muscular dystrophies, and oculopharyngodistal myopathy are other diagnostic considerations [48–50]. Most of these disorders may be distinguished from OPMD on clinical grounds alone. If in doubt, repetitive nerve stimulation, serum acetylcholine receptor antibody, or voltage-gated P/Q-type Ca^{2+} antibody assessment may be performed to identify myasthenic syndromes. Needle electromyography may point towards an inflammatory muscle condition or myotonic muscular dystrophy. Mitochondrial disorders may require a muscle biopsy and genetic testing for confirmation. The clinical diagnosis of recessive OPMD may be more problematic. Late-onset ptosis and dysphagia without a clear family history should raise this diagnostic possibility and lead to genetic testing for OPMD [25].

Evaluation and Diagnosis

Until the identification of the OPMD *PABPN1* mutations, definitive diagnosis relied on the observation of OPMD INI on electron microscopic evaluation of muscle biopsy specimens [51]. Genetic testing has now replaced muscle biopsy [6]. Since autosomal dominant and recessive OPMD are allelic, the molecular diagnosis of both conditions is straightforward. A single polymerase chain reaction (PCR) is required to establish the carrier status of an individual [6]. The test, which is offered commercially and in numerous academic laboratories worldwide, has more than 99 % sensitivity and 100 % specificity. The major indications for DNA testing of symptomatic individuals are (1) confirmation of the diagnosis in a family where no individual has been tested previously, (2) a clinical picture presenting a diagnostic dilemma, (3) a patient with a severe early onset form, and (4) a patient with possible recessive OPMD. Testing of asymptomatic individuals in an OPMD family should not be offered routinely, since there is no known medical therapy to slow disease progression, and it is unclear that such individuals would benefit from testing. Therefore, presymptomatic testing should thus be performed with prior genetic counseling and psychological support.

Needle electromyography shows, as in other dystrophies, myopathic changes with small polyphasic motor unit

potentials [31]. Neuropathic changes on nerve conductions are not found in OPMD [31, 52–54]. Serum CK may be normal or mildly elevated [31]. Muscle MRI utilization is growing and may be useful to identify dystrophic muscle groups such as the adductor, the harmsting, soleus, and gastrocnemius. MRI has been used as a prognostic indicator [55, 56].

Management

There is no specific medical treatment for OPMD, but therapies exist to moderate symptoms. Surgical treatments are used to correct ptosis and improve swallowing in moderately to severely affected individuals. Resection of the levator palpebrae aponeurosis and frontal suspension of the eyelids are used to correct the ptosis [57]. Resection of aponeurosis is easily done but usually needs to be repeated once or twice [58]. Frontal suspension of the eyelids consists of using a thread of skeletal muscle fascia or special wires as a sling that is inserted in the tarsal plate of the upper eyelid and attached at its ends to the frontalis muscle, which is relatively preserved in OPMD [57]. Its major advantage is that it is a permanent solution. Surgery is recommended when ptosis interferes with vision or when cervical pain appears secondary to compensatory extension of the neck, since this position may also aggravate swallowing problems [59]. Contraindications to blepharoplasty are marked ophthalmoplegia, a dry-eye syndrome, or a poor orbicularis oculi function.

The first step in the treatment of dysphagia generally consists in the optimization of the swallowing process such as improved head positioning and food consistency. A high-protein diet is strongly recommended to avoid weight loss and starvation [40, 60, 61]. Surgical evaluation for symptomatic dysphagia is prompted by marked weight loss, choking (which may rarely be a cause of death), or recurrent pneumonia [62]. Cricopharyngeal myotomy will alleviate symptoms in most patients. In usual circumstances, this surgery requires an overnight hospitalization and a 1-week convalescence. Unfortunately, dysphagia will reappear slowly over years in many patients. Severe dysphonia and lower esophageal sphincter incompetence are contraindications to surgery [63]. Repetitive dilatations of the upper-esophageal sphincter with bougies are still at an investigational stage [64]. In patients with advanced manifestations, percutaneous gastrostomy should be considered [60].

Some experts recommend evaluation for obstructive sleep apnea syndrome since OPMD is a dystrophy particularly affecting the pharyngeal muscles [65]. Despite numerous searches for experimental therapies in animal and cell models of OPMD, no clinical trial have been launched because of unacceptable side effects of the candidate substances [66–69].

Prognosis

Except for homozygous cases [25], life expectancy is close to normal for most OPMD patients. However, quality of life is diminished. The impact of this disease depends on individual severity and the familial experience with the condition. OPMD severity is likely influenced by other genetic and environmental factors. Molecular diagnosis may in some patients confirm that the disease will progress to significantly affect mobility, such as when patients are compound heterozygotes for a dominant $(GCN)_{12–17}$ *PABPN1* mutation and a recessive $(GCG)_7$ mutation. The major clinical predictor of severity is the appearance of symptomatic proximal leg weakness before the age of 60. Though the definitive answer is still to come, the larger the size of the mutation likely also influences phenotypic severity. Early surgical treatment for ptosis and dysphagia is encouraged and appears to significantly improve quality of life. Local and general anesthesia seems safe in patients with OPMD [70]. The usual recommendation of a high-protein diet, as for all dystrophic patients, applies also in OPMD. Mild exercise is suggested mostly to maintain cardiovascular health. Since aspiration pneumonia is a frequent cause of death, patients should be advised to consult early if they develop productive cough accompanied by fever. Social withdrawal is one of the most devastating consequences of this condition, and its possibility should be discussed with patients. Patients are strongly encouraged not to avoid social gatherings simply because they are often accompanied by meals. Rather, patients should eat prior to or after these events. Lastly, the hope of finding a medical treatment that stops disease progression now that the mutations are known allows clinicians to present a more optimistic future to patients and their descendants.

Emery-Dreifuss Muscular Dystrophy

61

Luciano Merlini and Nadir Mario Maraldi

Etiology and Pathogenesis

EDMD can be inherited in an X-linked, autosomal dominant (AD), or autosomal recessive (AR) fashion and is caused by mutations in proteins of the nuclear membrane. Mutations in the *EMD* gene, which encodes emerin, a transmembrane protein found at the inner nuclear membrane, are responsible for the X-linked form (EDMD1) [1, 2]. Mutations of the *LMNA* gene, that encodes the intermediate filament protein lamins A and C, cause autosomal dominant [3] and recessive [4, 5] EDMD (EDMD2 and EDMD3, respectively). Mutations in additional genes encoding nuclear membrane proteins have been implicated in few families, such as *SYNE1* in EDMD4 [6], *SYNE2* in EDMD5 [6], *FHL1* in EDMD6 [7], and *TMEM43* in EDMD7 [8].

The finding that emerin and lamin A/C mutations cause similar disorders indicates that nuclear membrane components play a crucial role in skeletal and cardiac muscle function, and that *loss of integrity of the nuclear component is an underlying cause of the muscular dystrophy*. The nuclear envelope comprises the outer and inner nuclear membranes, separated by a lumen, and the nuclear lamina. The nuclear lamina, a meshwork of intermediate filaments (IF) called lamins, is localized between the inner nuclear membrane and chromatin. Lamins interact with several integral proteins of the inner nuclear membrane including, the lamina-associated proteins LAP1 and LAP2, emerin, the lamin B receptor (LBR), MAN1, small nesprin 1 isoforms, and SUNs. SUNs interact with large nesprin isoforms, integral proteins of the outer nuclear membrane, which also interact with actin, linking the nuclear lamina to the cytoskeleton. Emerin is a type II integral nuclear membrane protein that extends into the nucleoplasm from a hydrophobic C-terminal tail anchored to the inner nuclear membrane [9]. LAPs 1A and 1B specifically bind to both lamins A and C and lamin B1 [10]. LAP 2 has a key role in the initial events of nuclear envelope reassembly, and both LAP 2 and LAP 1 may be involved in attaching lamins to the nuclear envelope [10].

Pathogenesis

The use of integrated approaches that combine mouse models of nuclear envelopathies with cell-based and biochemical assays has been instrumental in beginning to determine the molecular mechanisms underlying how nuclear envelope proteins function in a variety of integral cellular processes, including chromatin dynamics, nuclear architecture, and transcription regulation.

The working hypotheses attempting to explain how mutations in ubiquitously expressed proteins of the inner nuclear membrane specifically affect cardiac muscle and certain skeletal muscles and tendons include and combine nuclear envelope fragility, signaling defects in response to mechanical stress and altered gene expression caused by a disorganized lamina [11, 12].

The "mechanical stress hypothesis" is based upon the fact that cells with lamins mutations present characteristic deformation of the nuclear profile and nuclear fragility upon stress, predicting that disease-causing mutations interfere with the atomic structure, assembly, and stability of lamins [13–16]. The nuclear fragility model may be particularly effective in tissues which undergo mechanically induced strain such as skeletal and cardiac muscles, vascular smooth muscles, or fibroblasts of some connective tissues. Many of the mutations causing the muscular laminopathies alter the lamin incorporation in the nuclear lamina [17], as well as the localization of emerin and nesprin-3 [18], which could result in

B. Katirji et al. (eds.), *Neuromuscular Disorders in Clinical Practice*,
DOI 10.1007/978-1-4614-6567-6_61, © Springer Science+Business Media New York 2014

increased levels of apoptosis following mechanically induced strain [19].

The "gene expression hypothesis" proposes that proper expression of lamins and associated integral proteins of the nuclear envelope inner membrane play an essential role in chromatin scaffolding and mutations in the nuclear membrane proteins will alter chromatin organization and gene expression [12, 20]. EDMD-linked lamin point mutation, when expressed in *C. elegans*, causes abnormal retention at the nuclear envelope of a gene array bearing muscle-specific promoter and an altered expression of a number of muscle-specific genes; moreover adult animals carrying the same mutation have perturbed body muscle ultrastructure and reduced muscle function [21]. Positioning of the nucleus is an active mechanism essential to the formation of functionally polarized cells, cell division, cell migration, and formation of multinucleated syncytia. Cytoskeleton-nuclear interactions are mediated by the LINC complex (*LI*nker of *N*ucleoskeleton and *C*ytoskeleton), which spans the nuclear envelope via nesprin proteins in the outer nuclear membrane and SUN proteins in the inner nuclear membrane [22]. Multiple LINC complexes assemble into transmembrane actin-associated nuclear (TAN) lines that attach nuclei to actin filaments during nuclear movements in migrating cells [23]. This mechanism is altered in EDMD4 patients carrying heterozygous mutations in *SYNE-1* and *SYNE-2* genes [6]. Because nesprins bind emerin, it has been suggested that disrupting the interaction with emerin could impair the coupling of the nucleus and the cytoskeleton, leading to the progression of EDMD4 [24]. This has been further confirmed by the demonstration that disruption of nesprin-1 causes an EDMD-like phenotype in mice and cardiomyopathy [12, 25].

A further mechanism by which accumulation of SUN1 could be pathogenic in laminopathies has been recently reported. In $Lmna^{-/-}$ mice, which represent the animal model of dominant EDMD, Sun1 over accumulation in the Golgi is cytotoxic and causes a reduction of cell viability of cultured cells. Accordingly, loss of the *Sun1* gene in $Lmna^{-/-}$ mice extensively rescues cellular, tissue, organ, and life-span abnormalities [26].

The "cell differentiation/proliferation hypothesis" proposes an impairment of tissue homeostasis and regeneration in patients. Some data suggest that abnormal control of cell differentiation or proliferation is responsible for the striated muscle abnormalities in EDMD. Expression of lamin A encoded by an *LMNA* mutant that causes autosomal dominant EDMD in cultured myoblasts inhibits differentiation into myotubes [27]. Similarly, myoblasts lacking or with reduced levels of A-type lamins or emerin exhibit impaired differentiation kinetics, reduced differentiation potential, and decreased levels of proteins important for muscle differentiation [28]. Regenerating muscles from emerin-deficient mice have abnormalities in cell-cycle parameters and delayed myogenic differentiation, which is associated with perturbations to transcriptional pathways, regulated by the retinoblastoma and *MyoD* genes [29]. Emerin has also been reported to regulate beta-catenin activity by restricting its accumulation in the nucleus, and the aberrant cellular localization of beta-catenin in emerin-deficient cells may lead to abnormalities in proliferation [30]. Hence, abnormalities in muscle satellite cell proliferation or differentiation may underlie the pathophysiology of skeletal muscle disease in EDMD by impairing the replacement of fibers.

Clinical Presentation

EDMD presents in one of three ways: muscle weakness (1) or contractures (2), which precede cardiac signs or, a less frequent but more dangerous cardiac onset (3) with sudden death [1, 31, 32].

Myopathy and Contractures

Onset is commonly in childhood with toe walking, frequent falls and difficulty running. At this early stage, muscle wasting may be difficult to notice or only present in calf muscles. A careful search for contractures may reveal early limitation of elbow extension, neck flexion, and ankle dorsiflexion. An earlier presentation with predominantly proximal weakness and mild equinovarus deformity has been reported in a 2 1/2-year-old boy with EDMD1 [33]. Initial manifestation in childhood with muscular weakness in the upper arms has also been noted [34]. The other usual presentation is with flexion contractures at the age of 4–6 years, with no significant muscle weakness [35].

Neck extension and elbow and ankle flexion contractures are present in all patients with muscle involvement. Progression of contractures is noticeable during the growth spurt leading to the typical phenotype (Figs. 61.1 and 61.2). In EDMD, contractures are in the direction of the weakest joint-moving muscle. This is in favor of a passive mechanism within the weakest muscle, i.e., loss of elasticity (substitution of elastic-contractile tissue by fat-connective tissue) with muscle shortening, limiting the movement of the joint in the opposite direction. The biceps is weaker than the triceps and shorten, causing flexion of the elbow and impeding its full extension; gastrocnemius is weaker than tibialis anterior and the shortened posterior leg muscles cause equinus deformity of the feet; wrist and finger extensors are weaker than flexors and shorten resulting in limitation of wrist and fingers flexion. Contractures of the neck extensors cause limitation of neck flexion and contractures of the weak lower

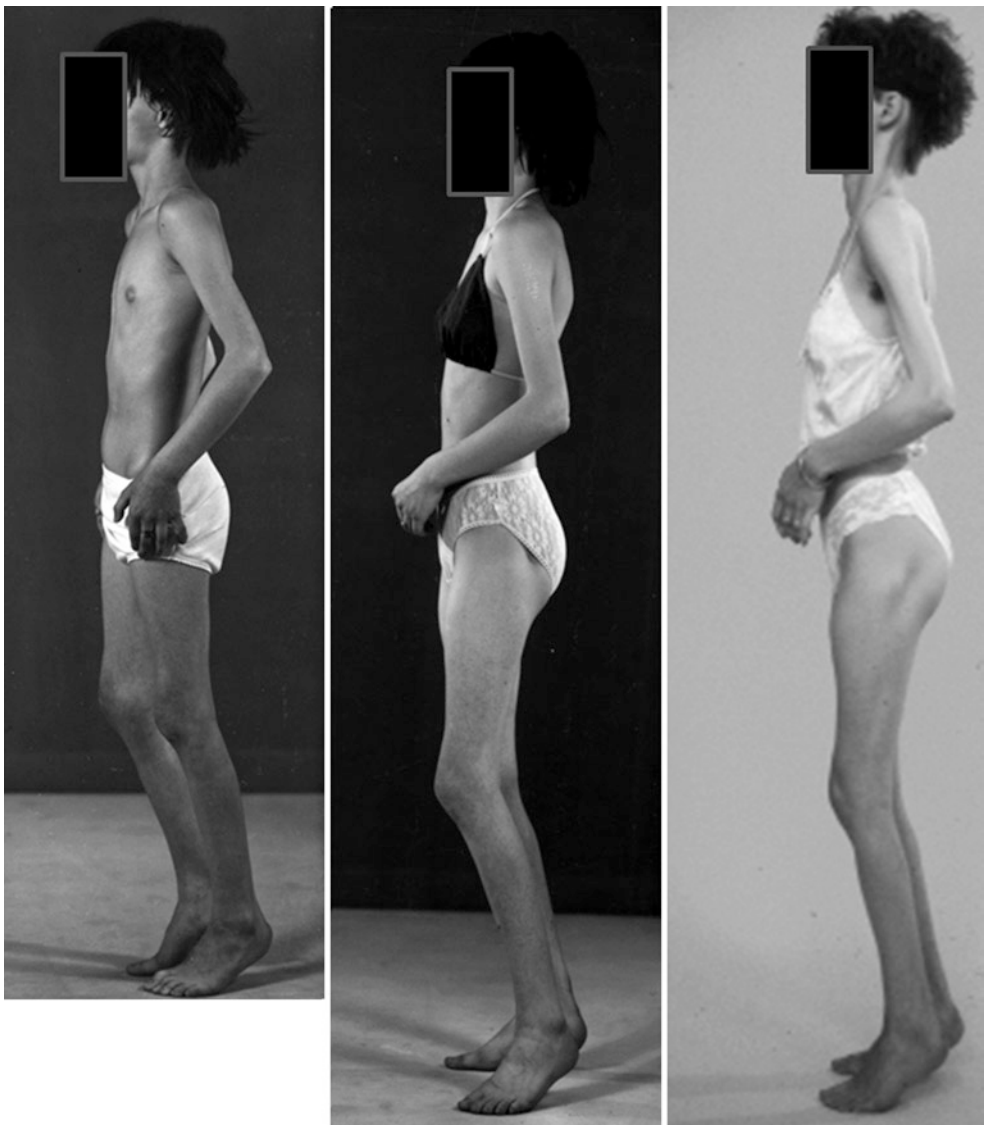

Fig. 61.1 Woman with EDMD2 shown at ages 10, 15, and 22. Spine, elbow, and ankle contractures were first noticed at the age of 8 years and were then increased in severity with time. Cardiac involvement was documented at age 10 years with conduction block and arrhythmia. Later on she developed dilatative cardiomyopathy, atrial fibrillation and flutter, and ventricular ectopic beats. Sudden death occurred at age 27

back muscles cause rigid spine. Knee flexion contractures are rarer [36]. In early adulthood, functional impairment is more dependent on the limited range of motion of the spine, elbows, and ankles than on muscle weakness. An exception is elbow flexion, which can be particularly weak, owing to the early and progressive degeneration of the biceps [32–34].

Muscle wasting is particularly evident in the posterior leg compartment and in the biceps brachii (Figs. 61.1 and 61.2) [32]. Some patients demonstrate a striking hypertrophy of the extensor digitorum brevis muscle despite prominent posterior leg muscle wasting [35, 37]. Clinical examination of muscle strength shows selective weakness of elbow flexion and finger extension compared to scapular and hip girdle strength, which are relatively spared. Strength of lower leg muscles may be difficult to test reliably owing to the fixed deformity of the ankle. Slight weakness of the intrinsic hand muscles is not exceptional [38, 39]. Slight symmetrical weakness of the orbicularis oris and oculi has been described [1, 36, 38]. Progression of weakness is very slow and patients rarely lose the ability to walk. It should be stressed that both in EDMD the severity of muscle involvement may be extremely variable, even within families [11, 12, 32, 40–42]. Occasionally patients exhibit a severe phenotype with inability to walk in adolescence [43, 44] or even earlier [38, 45]. Carriers of EDMD1 usually do not manifest musculoskeletal symptoms, but occasionally skewed inactivation may produce a typical phenotype in women [46].

Scoliosis is usually neither frequent nor severe in EDMD1 [1, 32, 47]. Mild scoliosis occurred in three patients but stabilized without treatment [47] and thoracic deformity was documented in eight of ten patients [48] but not the extent of the deformity. Occasionally marked hyperextension of the neck and thoracic lordoscoliosis may cause postural

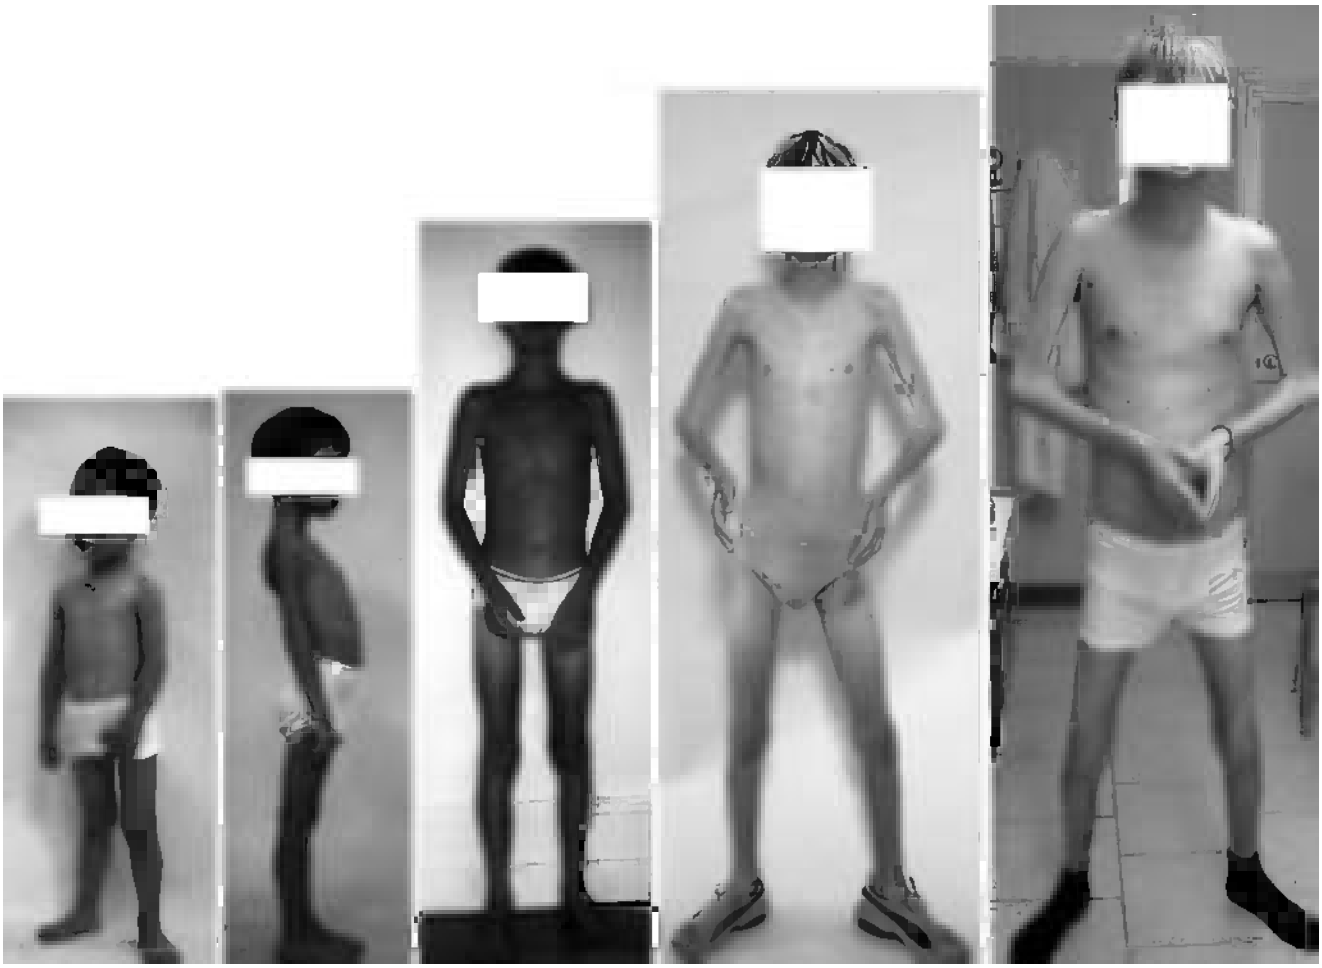

Fig. 61.2 A patient with EDMD2 shown at ages 3, 5, 8, 14, and 24. First steps at 13 months, he was never able to run. At age 3 years positive Gowers maneuver and CK three times normal. Lumbar hyperlordosis at age 8 years and limitation of neck flexion and elbow flexion. Rigid spine, increase in elbow flexion contracture, limitation of finger flexion, and lipodystrophy at age 14. He then developed dilatative cardiomyopathy and severe cardiac conduction defects. He had heart transplantation at age 20

imbalance and severe discomfort [49]. Borderline [39] or reduced [35, 48] intelligence is found in some patients.

Cardiac Manifestations

EDMD may manifest with cardiac symptoms consisting of arrhythmias causing syncope, cerebral emboli, or sudden death [50, 51]. Cardiac involvement invariably presents between the early second to fourth decades in EDMD1 and between the third to fourth decades in EDMD2. Two major types of cardiac involvement are recognized: atrial paralysis and dilated cardiomyopathy. Atrial paralysis is the hallmark of EDMD1, while both complications may be present in EDMD2. Permanent atrial paralysis is a rare condition and in 33 % of 109 of well-documented cases it was found to be associated with Emery-Dreifuss muscular dystrophy [52].

In six families with definite X-linked inheritance (EDMD1), 30 of 73 patients died suddenly between 25 and 59 years of age [32]. Among the 36 patients who underwent cardiac examination only 4 [1, 48] were normal, and all were under 16 years of age. Of the 32 patients with cardiac abnormalities [32], only four had minor subjective symptoms such as dizziness or syncopal episodes, while the remainder were symptom-free. Risk of sudden death is thus extremely high and unpredictable [32]. Women carriers of EDMD1 have a substantial cardiac risk which increases significantly with age [38, 48, 53, 54]. In one family with a novel deletion of the last three exons of the emerin gene, a carrier had a cardiomyopathy and very low emerin levels due to skewed X-inactivation [46]. Cardiac transplantation has successfully been performed in EDMD [55–58].

In autosomal dominant EDMD according to a meta-analysis involving 299 patients [59], cardiac dysrhythmias have an early onset (in 18 % before age 10 years) and occur in 92 % of patients after the age of 30 years. Cardiomyopathy with heart failure manifests later and is found in 10 % of patients by age 30 years and in 64 % after the age of 50.

Sudden death was the most frequently reported mode of death (46 %) in both the cardiac and the neuromuscular phenotype. Carriers of lamin A/C gene mutations often received a pacemaker (28 %). However, this intervention did not alter the rate of sudden death.

Both X-linked and autosomal dominant EDMD patients risk not only bradyarrhythmia (requiring pacemaker implant) but also atrial fibrillation/flutter, which often anticipates atrial standstill and can cause disabling embolic stroke at a relatively young age [55].

Cardiomyopathy in EDMD1 affects the atria with predominant right heart involvement. The reason for this is unknown but may relate to the smaller muscle mass of the right heart [60]. The normal myocardium is replaced by adipose and fibrous tissue resulting in loss of atrial contractility (atrial paralysis) and marked atrial dilatation [34, 35, 56, 61]. The conduction system, atrioventricular node or bundle of His, show no significant abnormalities [61]. In the later stages of the disease, the ventricles may become involved with fibrous replacement of the myocardium and, ultimately, ventricular failure occurs. Macroscopic and microscopic examination of the explanted heart in a patient with EDMD2 showed a dilated cardiomyopathy with hypertrophy and dilatation of the atria and ventricles, fiber size variability, and a predominately focal interstitial fibrosis [62].

EDMD1 vs. EDMD2

There is wide clinical variability in EDMD1. However, patients almost invariably have a combination of early musculoskeletal signs and late cardiac conduction disorders; isolated cardiac involvement is exceptional; walking is usually preserved. In EDMD2 there is significant intra and interfamilial variability. Individuals carrying a heterozygote mutation may be asymptomatic. De novo mutations are quite frequent, isolated cardiac involvement is not exceptional, ventricular fibrillation and dilated cardiomyopathy are more common, and there are some patients with loss of ambulation by 8–13 years.

Differential Diagnosis

Clinical overlap exists with rigid spine syndrome, mild congenital myopathies including Bethlem myopathy, and some muscular dystrophies. However, the presence of early flexion contractures at the elbows, ankles and neck, characteristic distribution of weakness, and cardiac involvement are helpful in differentiating among these disorders. Some patients with a clinical diagnosis of rigid spine syndrome [63] have been subsequently recognized to have EDMD1 [39] or EDMD2 [4]. Any muscle biopsy of a patient with elevation of CK up to ten times normal and possible muscular dystrophy should probably be tested for the presence of emerin.

Evaluation and Diagnosis

Patients are examined clinically for the distribution of muscular wasting and weakness, contractures, and cardiac involvement.

Laboratory Studies

In young patients creatine kinase (CK) may be elevated to ten times normal [31, 32, 64]. Detailed electromyography study of the limb and paraspinal muscles, including automated analysis of the interference pattern and single fiber electromyography, shows myopathic changes, but no definite neurogenic involvement of the muscles. Nerve conduction studies are normal [65].

Muscle Imaging

Muscle CT or MRI scans may complement the clinical evaluation (Fig. 61.3). They may reveal more extensive fatty muscle degeneration than suggested by clinical findings particularly in the posterior leg and paravertebral muscles [67]. Patients with EDMD1 and EDMD2 have an early involvement of the gastrocnemius particularly of the medial head, while the lateral head is relatively spared at the beginning [66, 68]. At the thigh level, vastii muscles, hamstrings, and abductors are all involved to varying degrees, while irrespective of the age and severity of the disease a clear sparing of the rectus femoris is evident [66].

Muscle biopsy commonly shows a myopathic picture with variation of fiber size, endomysial fibrosis, and type I fiber atrophy or predominance [32, 53]. Emerin is absent in nuclei in more than 95 % of EDMD1 patients; [69] residual or normal emerin is detectable in the rare missense or promoter mutations [70]. In contrast, the perinuclear localization of lamin A/C and emerin is preserved in patients with EDMD2 [37].

Nuclear changes ranging from marked condensation of chromatin to complete damage are noted in skeletal muscle and skin cultured cells at the ultrastructural level [71, 72], indicating anomalous nuclear lamina organization in the absence of emerin [72].

In younger patients with initial cardiac involvement, EKG shows low amplitude P waves with prolongation of the P-R interval. Subsequently conduction disturbance may progress to atrial fibrillation or flutter. The characteristic EKG pattern is that of a junctional escape rhythm at 40–50 beats/min

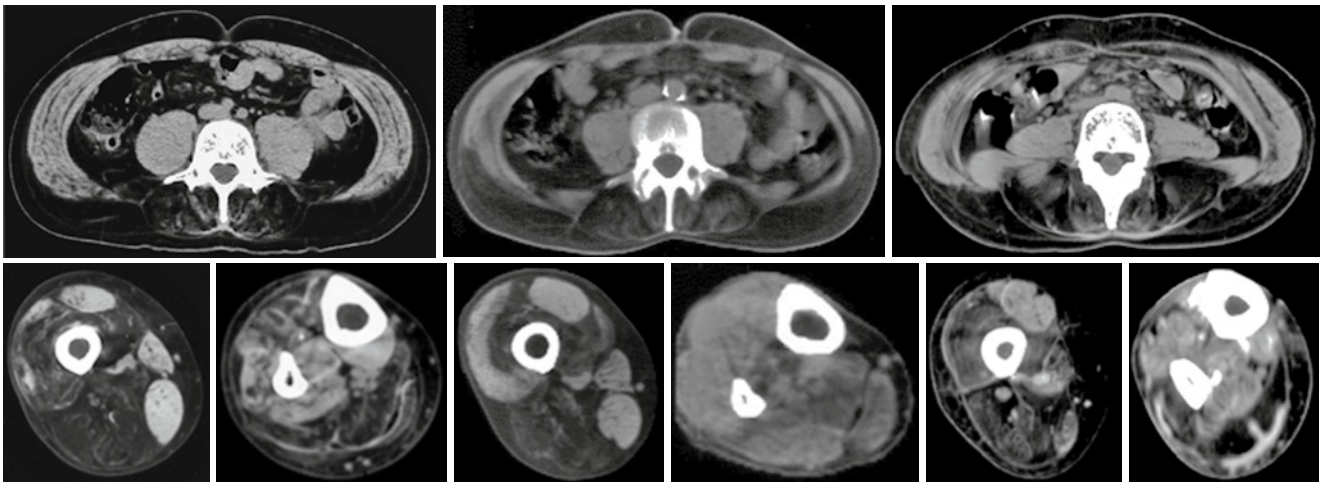

Fig. 61.3 *Left panel.* Muscle CT of a 55-year-old man with EDMD1 with a del 29 bp frameshift mutation in the emerin gene causing a codon 22>stop [2, 32]. Note complete hypodensity of the lumbar paravertebral muscles, early involvement of the abdominal muscles with patchy spots of low-density and normal psoas muscles (*top left*). The mid-thigh level (*bottom left*) shows complete substitution of muscle with low-density fat and connective tissue of the posterior compartment (adductors and hamstrings) and of the vastii, with preservation of rectus femoris [66], sartorius, and gracilis muscles. The mid-calf level shows marked hypodensity of the soleus and gastrocnemius and some involvement of the anterior compartment (tibialis anterior, extensor digitorum and peroneal muscles). *Middle panel.* Muscle CT of a 47-year-old man with EDMD2 caused by a R527P mutation of the LMNA gene [4]. Muscle CT shows a nearly identical pattern of selective involvement/preservation of muscles as in the patient with EDMD1. Note in particular the similar severe involvement of the lumbar paravertebral muscles (*top middle*), of the vastii and ischiocruralis with selective sparing of the rectus femoris. At the mid-calf there is a clear involvement of the sural and medial gastrocnemius muscle. *Right panel.* Muscle CT of a 38-year-old woman with EDMD2 with progressive muscle weakness and who lost the ability to walk unaided at age 36. Note the severe involvement of the lumbar paravertebral muscles (*top right*), of the vastii and ischiocruralis with selective sparing of the rectus femoris. At the mid-calf there is a severe involvement of the medial and lateral heads of the gastrocnemius muscle

without an obvious P wave because of the atrial standstill. The diagnosis is confirmed by lack of all electrical and mechanical activity of the atria and the inability to pace the atria. This last feature demonstrates that EDMD affects the atrial myocardium and is not confined to impulse formation or transmission [44].
